The writer having been connected with one of the metropolitan railways for many years, and coal being so very expensive in the south, was led to the consideration of economy in fuel and the production of steam at the lowest possible cost, the accomplishment of which appeared to be in the employment of coal to be used in a separate and distinct fire-box, but in connection with the coke fire-box of the locomotive engine; and this idea was strengthened by the observation of the working of coke ovens in the manufacturing of coke, where he often lamented to see the great amount of flame and combustible gases pass off into the flues and chimney without producing any useful effect; and when it is remembered that 1½ ton of good coking coal is required to produce one ton of coke, some estimate may be formed of the quantity of combustible gases that is thrown off.

Being anxious to secure the advantages which appeared to be got by the use of coal in connection with coke in the generation of steam, the writer considered the proper mode was to use coal and coke in separate furnaces, so arranged that the flame and combustible gases thrown off the coal fire would enter into and pass over that of the coke fire, and entering by short tubes into a combustion chamber, situated partly central between two sets of tubes in the cylindrical portion of the boiler, and where complete combustion would be effected.

A new engine on this principle has not yet been completed, but it has been applied in part to six engines with the ordinary boiler on the London and South-Western Railway, and the results of working have been found most satisfactory. One of them, the 'Britannia Engine,' with 15-inch cylinders, 21-inch stroke, and 7 feet driving-wheels, has been working since August 1853, and run 13,600 miles between Southampton and London, a distance of 78¾ miles, taking the regular running of passenger trains; the average consumption has been 17 lb. per mile, one-third of which was coal, but charged in weight as coke. An experimental trip was made with this engine by Mr. Edward Woods, in October last, with one of the passenger trains to Southampton, and back to London; and another experimental trip was made by Mr. W. P. Marshall, Secretary of the Institution, on the same engine with the 10·15 a.m mail train from London to Southampton, on the 17th January, returning with the 3 p.m train to London; the particulars of these experiments are appended, and the general results are as follows:—

*Experiments with the 'Britannia' Engine and Passenger Trains from London to Southampton and back.*

| | | Oct. 26, 1853. | Jan. 17, 1854. |
|---|---|---|---|
| Length of double trip with train | miles | 157½ | 157½ |
| Length of double trip with engine | miles | 161¼ | 161¼ |
| Down trip, average train | carriages | 12·8 | 11·2 |
| Down trip, average speed running | miles per hour | 31·4 | 28·3 |
| Down trip, number of stoppages | No | 8 | 8 |
| Up trip, average train | carriages | 18·5 | 19·3 |

| Greatest pressure during trips | lb. per mile | ... | 128 |
| Least pressure during trips (omitting last ten miles | lb. per mile | ... | 82 |
| Average pressure in up trip over 17 miles, rising 1 in 250, between Bishopstoke and Basingstoke | lb. per mile | ... | 122 |

The action of the coal and coke fire-boxes is as follows:—The coal fire-box A A, figs. 1 and 2, Plate XXIII., is attached to the back of the fire-box B B, of the ordinary locomotive engine, as shown in the plan, fig. 2, and placed partly below the foot-plate, the water-space of which is in connection with that of the coke fire-box by two branch pipes C C, at bottom and two at top. The flame and combustible gases thrown off the coal fire pass into the coke fire-box through tubes D D, inserted into the intervening water-space; and to promote the combustion of the gases, by giving more time for better admixture, a curved fire-tile bridge E, forming a sort of combustion-chamber, is placed within the coke fire-box, fronting the tubes leading from the coal fire-box, thereby checking the velocity of the flame in its passage over the surface of the coke fire. The coal fire-box and the coke fire-box are provided with separate ash-boxes and close-fitting dampers F, G, whereby the draught to each can be regulated with the greatest nicety, and independent of each other. The damper of the coke fire-box F, is generally kept nearly closed, and is only opened 1½ inch with trains of 20 to 24 carriages; but the damper of the coal fire-box G, is generally kept *quite* open, to admit the *full draught* of the blast, by which means, the coal fire being excited to the utmost, the gases and flame pass into the coke fire, and with them the air in a *heated* state; the high temperature of the coke fire is maintained, and more perfect combustion is the result. The combustion of the smoke is completely effected, the smoke being scarcely perceptible. An important practical advantage is gained from the circumstance of the ordinary coke fire-door being kept almost constantly closed, the door being opened only three times to put on coke during the whole trip of 78¾ miles, thus preventing the frequent rush of cold air cooling the fire-box and tubes, and causing a liability to leakage: in the present case, all the air entering at the coal fire-door, becomes highly heated before coming in contact with the main fire-box and tubes.

The next subject which attracted the author's attention was, the fact that all the water required for the supply of the engine when working was sent cold into the boiler, and to obviate this evil, attempts were made to warm the water in the tender by steam from the boiler *before* the engine started to work, but this was obtained at the *expense* of the fuel, and was only available as far as the first quantity of water in the tender would supply the engine. The next supply of water taken into the tender must be used cold, because the engine being *on the journey* could not afford to part with steam to heat the water, as in the first instance, before starting. The great evil of frequent loss of time in travelling was a consequence of the cold-water system of working, and so much was this felt, that when an engine was heavily loaded and taxed to her *utmost capability*, and having to ascend a long steep gradient, the extra steam to be generated to accomplish this task necessitated an extra supply of *cold* water to be pumped into the boiler, thus checking the generation of steam, reducing the pressure in the boiler, and crippling the engine. This evil being so great, the author attentively reviewed the whole action of the engine, with a view to improvement as well as economy; seeing that nearly the whole of the caloric which had cost so much was finally dismissed as useless at the chimney, it occurred to him that part of such caloric might be intercepted and communicated to the cold water used for supplying the boiler, a source of heat being thus available.

Various apparatus for this purpose have been contrived and put in operation, one of which is that attached to the 'Britannia' engine. It consists of an oblong rectangular chamber H H, placed in the smoke-box, and cast in one piece with the exhaust-pipe, and communicating to the upper part of the ordinary blast-pipe; this chamber is filled with a series of small tubes shown in section in fig. 3, fixed in tube-plates at each end, and communicating with inlet and outlet chambers in connection with the engine, pump, and boiler. A branch pipe I, from this rectangular chamber communicates with an outer condensing apparatus fixed in front of the chimney, consisting of three upright pipes K K L, standing on a cast-iron foundation, shown in plan in fig. 4, and connected at top by a hollow cap. Two of these pipes, K K, are provided with jets or injections supplied by the cold-water pump, which draws its supply direct from the tender. There is an overflow-pipe M, for conveying the water after it is heated to the hot-water pump, and an overflow-pipe N N, leading to the tender to convey any surplus water which may not be taken by the hot-water pump. The third upright pipe L, is provided with a disc or throttle-valve O, by which the exhaust steam from the lower chamber H H, can be admitted into the condenser. P P, is an air-pipe inserted in the centre of the orifice of the blast-pipe, with a funnel-shaped mouth at the lower end, to catch the air and assist the blast.

The action of the apparatus is as follows:—When the engine is working, the exhaust steam from the exhaust steam-pipe, before it reaches the orifice of the blast-pipe, fills the lower chamber, forming a steam bath around the small tubes (through which the water passes into the boiler), and flows upwards into the outer condenser, where it is condensed by the jets from the cold-water pump, and such water, together with that obtained from the condensed steam falling to the bottom of the condenser, is carried off by the overflow-pipe before named to the hot-water pump, which propels it through the small tubes in the lower chamber; and as the water passes slowly through these pipes on its way to the boiler, it absorbs heat from the constant supply of steam rushing to the condenser to be condensed, and enters the boiler at a very high degree of temperature, and causing little or no check to the generation of steam in the boiler, thereby maintaining the *full power* and energy of the engine. The average pressure in the experiment throughout the whole down trip was 105 lb., and 100 lb. in the up trip; the total fluctuation in pressure during the trip being very limited.

This is a desideratum of no small value, and is experienced especially in the working of the engine between Southampton and London, as there are many *long* and *sharp* gradients, particularly that between Bishopstoke and Basingstoke, the gradient averaging 1 in 250 for 17 miles; the Southampton, Portsmouth, Gosport, and Salisbury trains, being all joined at Basingstoke, and taken in one train to London, which generally contains from 20 to 26 carriages. The advantages of the improvements just described are particularly apparent whilst ascending this *long* gradient, as was shown in the experiment last referred to, in which a uniform pressure of 120 lb. per square inch was maintained up this incline of 17 miles 1 in 250, with a load of 21 carriages; in consequence a high rate of expansion could be employed throughout, the steam being cut off at 5 inches out of 21-inch stroke, or at less than one-fourth of the stroke during the whole time,—an important source of economy.

There are six engines, adapted for burning coal and coke upon this principle, working on the London and Southampton line (the 'Britannia' being one of them), whose united running amounts to 100,360 miles, and the average consumption of fuel, coal and coke together, has been 15·6 per mile, the 'Britannia' having run 13,600 miles with an average consumption of fuel of 17 lb. per mile. In conclusion, it may be remarked, that in no *one* instance have any of these engines failed in *any* part of the apparatus connected with these improvements; also the same remark applies to the fourteen other engines (although in daily use) which are furnished with the heating and condensing apparatus. Should any mishap occur, the engine-driver can cut off the communication from the heating apparatus in an instant, and supply the boiler and work the engine in the ordinary way, and without stopping the train.

## ON AN APPLICATION OF THE PROPERTIES OF THE WEDGE.*

### PROPOSED BY M. MINOTTO FOR IMPROVING THE METHODS OF TRANSMITTING MOTION IN MACHINERY.†

By H. Hennessy, M.R.I.A., Librarian to Queen's College, Cork

Among the most usual methods of transmitting motion from one part of a machine to another are trains of wheels, acting on each other either by friction alone, or more frequently by the contact of projecting teeth placed along their edges. The disadvantages of both of these methods have been so long recognised, that it would be almost superfluous to point them out; and any proposal which would be likely to remove such disadvantages must be regarded with considerable interest. In order to transmit force by a train of wheels, it is essential that their surfaces of contact should adhere with a force greater than that required to be transmitted. This adhesion will depend—1st, upon the nature of their materials; 2nd, the form of their surfaces of contact; and 3rd, the pressure at these surfaces. The second of these conditions is that to which the improvement proposed by M. Minotto refers. He proposed that the edges of every alternate wheel in a train of geering should be indented with a groove of trapezoidal section, the other wheels having each a corresponding truncated wedge-like projecting rim. The properties of the wedge immediately explain the object of such an arrangement. The power applied at the head of a wedge, or that side of it opposite the vertex, is to the resistances opposed by its lateral faces as the area of the head to the area of the faces; consequently, in an isosceles wedge with rectangular faces, if $i$, represent the angle at the vertex, $p$ the pressure at the head, P the pressure at one of its faces, we have

$$p = 2\,\mathrm{P}\sin. i; \text{ or } \mathrm{P} = \tfrac{1}{2}\,p \operatorname{cosec.} i.$$

Therefore, by diminishing the angle at the vertex we have a means for indefinitely augmenting the pressure exercised by the faces of the wedge. These results are evidently unaltered if the wedge is truncated; consequently, the adhesion at the surfaces of contact in such wheels as those described, may be made very great without augmenting the actual pressure between them, but simply by diminishing the inclinations of the surfaces of the truncated wedge in one, and of the groove in the other.

As the nature of the materials used in machinery must influence the adhesion at the surfaces of contact, some experimental illustrations of the resistance produced by the application of the wedge would be useful. From experiments made by M. Minotto on the motion of wedges of different angles and substances through grooves similarly varying in their angles and the substances of which they were made, he has drawn up a table of results, a few of which will serve to illustrate the point in question. A wedge of cast-iron with an angle of 30°, moving in a cast-iron groove with the pressure or weight 5, produced the resistance 3·75. A wedge of the same substance with an angle of 20°, and carrying the same weight, produced the resistance 5·06. Another wedge with an angle of 10°, and in all other respects similar to the last, produced the resistance 9·53. A wedge of brass, shaped as the last, and carrying the same weight, produced the resistance 10·60.

These experiments fully confirm the principle on which the wedge is to be applied in machinery. The nature of the new system of geering is best understood by comparing it with a system of friction wheels, such as are sometimes used for the transmission of motion. Let us suppose two such wheels in the same plane, touching at their convex edges. They are in contact only on a line equal to their common thickness, and would slide over each other without any resistance, if their surfaces were totally free from friction. In order that they should be capable of transmitting force, their surfaces must not only possess a certain degree of friction, but also must adhere with a normal pressure, the direction of which necessarily passes through their centres, thus throwing a considerable pressure upon their axes and gudgeons. This pressure is evidently diminished in a system of wedge and groove wheels, for the entire pressure at the surfaces of contact may be decomposed into two—one perpendicular to the axes, the other parallel to the axes. When the angle of the wedge is small, the former must be considerably less than the latter. Thus it appears that in the wedge system a part of the injurious pressure on the axes is not only removed but utilised. A series of experiments have been made by M. Minotto on the friction and adhesion at the edges of wedge and groove wheels of different dimensions and materials, a few of the principal results of which are appended in the following table. The pressures are given in kilogrammes, but the results are precisely the same if we suppose them changed to any other units of weight:—

| Conditions of Experiment. | Pressure of one wheel on the other. | Ratio of Friction at edges to the Pressure | Ratio of Adherence to the Pressure |
|---|---|---|---|
| *Angle of* 30°, *iron on iron*— | | | |
| Both wheels large ............ | 14·435 | 0·0237 | 0·440 |
| Small grooved wheel with large wedge wheel...... | 25·534 | 0·0300 | 0·501 |
| Ditto .................. | 47·514 | 0·220 | 0·596 |
| Small wedge wheel with large grooved wheel ... | 47·357 | 0·0255 | — |
| Ditto .................. | 96·257 | 0·0174 | — |
| *Angle of* 20°, *iron on iron*— | | | |
| Both wheels large ............ | 20·390 | 0·0140 | 0·720 |
| Both wheels small ............ | 40·000 | 0·0292 | 0·806 |
| Small wedge wheel with large grooved wheel ... | 34·290 | 0·0185 | 0·758 |

From these experiments it appears that the friction is greater

* From the 'Journal of Industrial Progress,' No. V.

† The views of M. Minotto were first published in Italian, at Turin, and attracted a great deal of attention last year on the Continent, having been examined or noticed in several scientific journals, and having been made the subject of a report to the Institute of France by M. Poncelet.

with small wheels than with large, and that it slightly diminishes in proportion to the increase of pressure. It deserves to be remarked, that in combination of two wheels, one large and the other small, the friction is less when the greater one is grooved and the small one wedged than in the opposite case. From a mean of all the experiments, the adhesion with an angle of 30° for the wedge is 0·529 of the pressure, and for an angle of 20°, 0·772.

Further experiments were made to ascertain the comparative friction of two plane surfaces and two surfaces shaped in the wedge form, the results of which confirm those previously made, and the ratio of the frictions of the two kinds of surfaces underwent scarcely any change by varying the charge or pressure—a result which does not seem to have been noticed by M. Minotto himself.

To compare the friction produced by the proposed method of geering with that of ordinary toothed wheels, M. Minotto has used the expression:—

$$f\,R\,\pi\left(\frac{1}{m}+\frac{1}{m'}\right),$$

$f$ being the coefficient of friction for the substance composing the teeth; R the force exercised by the wheels on each other; $\pi$ the ratio of the diameter to the circumference; $m$ and $m'$ the number of teeth in each wheel respectively. He gives an example of two wheels of cast-iron, one of ten, the other of twenty teeth, transmitting an effort say of 300 lb.; here $f = 0{\cdot}152$, and consequently the friction of the teeth is 21·45 lb. Two wheels on the wedge system, having to transmit the same force, would undergo an amount of friction measured by 9·081 lb., or less than half the friction with the system of teeth. Calculation would partly suggest the advantages of making the angle of the wedge small, not only to augment adhesion, but also to diminish the pressure and consequent friction on the axles.

Although this new system of geering possesses great simplicity and many other important advantages, it has to contend with some practical difficulties. It is essential that the edges of the wheels should be continually pressed against each other—a condition which becomes less and less possible as they wear away—and some contrivances are required to compensate for the gradual diminution of pressure. It is proposed that the gudgeons of one of the wheels should be made moveable, and capable of being screwed towards the axle of the other, or to have the grooved wheel consist of two discs, separated by a third capable of more or less compression, so that the two others could be brought together by screws as often as the wearing of the groove would require. The inventor also proposes in such cases as present a great likelihood of wear on the faces of wedge and groove, from the nature of the resistances to overcome—high velocity of motion and smallness of angle—that this effect could be obviated by indenting the edges of the wheels with two or more grooves and corresponding wedge-shaped projections. He concludes that the most suitable material for such wheels is cast-iron, next wrought-iron, or one wheel of brass and the other of cast-iron. He acknowledges that the system appears at present inapplicable to bevel wheels for the transmission of motion obliquely.

Wheels on the wedge-and-groove principle have undoubtedly the advantage of being easily constructed, of being free from jars and shocks, by which so much *vis viva* is lost in ordinary arrangements, and of being capable of easy engagement or disengagement during rapid motion. But yet much of the simplicity of the system is lost by the necessity of contrivances, such as have been mentioned, for the preservation of continuous pressure between the wheels at their edges. One important application will immediately suggest itself, as it did to us long before seeing the remarks of M. Minotto, or the confirmatory observations of M. Poncelet in his report to the Institute of France—namely, the haulage of railway trains up steep gradients. It is evident that this could be easily effected if the locomotive were provided with a wedged driving-wheel, placed centrally, which could run in a grooved rail extending the whole length of the gradient. This application would have the advantage of not requiring any contrivance for pressing the wedge into the groove, as the weight of the locomotive would do so most effectively, even for large angles of the wedge. Similar rails laid down near stations would furnish a method for stopping the train probably superior to the break now in use. Another important application is that of directly transmitting a rotatory motion to the great axles of screw steam-ships, the screws of which should revolve with considerable rapidity in order to produce a sufficient reaction on the exterior fluid. Quick motion might also be given to the driving-wheels of locomotives, without a rapid motion of the pistons, by the intermedium of some wheels on this system between the cranks and driving-wheels. The smoothness and equability of motion which ought to accompany all the movements of properly constructed wheels on the wedge system, suggest to us the importance of its application to clocks and chronometers, and to such astronomical and physical instruments as have hitherto been moved by the aid of toothed wheels or rack work. For such applications the angle of the wedge should be small, and every precaution taken to insure such an amount of adherence as would prevent any possibility of slipping. The facility of turning such wheels is so great, and so much is to be reasonably expected from their use, that we hope practical engineers and millwrights will soon bring the system to a final and complete test of its merits.

## ON THE STRENGTH OF LOCOMOTIVE BOILERS, AND THE CAUSES WHICH LEAD TO EXPLOSION.*

By William Fairbairn, F.R.S.

A difference of opinion having arisen between a gentleman high in authority and Mr. Fairbairn, concerning the causes of an accident which took place through the explosion of a locomotive engine at Manchester, on the eastern division of the London and North-Western Railway, a series of experiments was instituted by Mr. Fairbairn, not for the purpose of confuting the arguments of others or confirming his own, but to determine the real causes of the explosion, and to register the observed facts for our future guidance in guarding against such fearful catastrophes.

After a careful examination of the boiler a few hours subsequent to the explosion, one side of the fire-box was found completely severed from the body of the boiler, the interior copper box forced inwards upon the furnace; and with the exception of the cylindrical shell which covers the tubes, the whole of the engine was a complete wreck.

Mr. Ramsbottom, the Locomotive Superintendent, in his Report to the Directors, states that "the engine in question was made by Messrs. Sharp, Roberts and Co. in the year 1840, has been worked at a pressure of 60 lb. per square inch, and has run in all a distance of 104,723 miles, a great part of which has been either entirely without load, or nearly so. As the cylinders are only 13 inch diameter, it has been for some time too light to work any of our trains; and has therefore been chiefly employed since 1849 in piloting the trains through Standedge tunnel, along with another engine of the same size, which is now at work.

"The fire-box was originally $\frac{7}{16}$-inch thick, and is now a little over $\frac{6}{16}$-inch; and from its excellent condition, might well be supposed (as indeed it was by Mr. Sharp, of the firm of Sharp Brothers and Co., who inspected it a few days after the accident) to have been recently put in new. It is perfectly free from flaw or patch, and would certainly have run at least 100,000 miles. The same may also be said with respect to the outer shell, which is nearly of the original thickness. The engine had been in the repairing shop the three months previous to the accident; and the iron fire-box stays, about which so much has been said, were tested by the hammer in the usual way, and were considered, both by the workmen and the foreman, Wheatley, to be all sound. When originally made, they were $\frac{11}{16}$ths in diameter, and were equal to a strain of at least ten times the force they had to sustain. With the exception of one stay, which was on the top row, the one most reduced from oxidation was half-inch diameter; and supposing the hold on the copper box to have been good, it was capable of resisting a strain of rather more than $6\frac{1}{2}$ times the working pressure, equal, say, to 390 lb. per square inch. The only point therefore which could admit of doubt as to the safety of the boiler, was with respect to the hold which the stays might have in the copper box; but it appears, from experiments since made, and which have been repeated by Mr. Fairbairn, that from the force required to pull some of the old stays out of a copper plate similar to the fire-box, into which they had been screwed by the *old threads only*, and *not riveted*, the boiler could not have

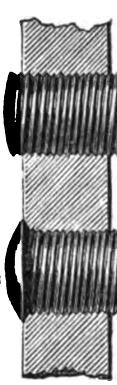
* Extracted, by permission, from the forthcoming Volume of the 'Transactions' of the British Association for the Advancement of Science.

burst under a pressure of less than 300 lb. per square inch. One of the old stays, which had had the thread partially damaged from being ripped out of the copper box by the explosion, was screwed by hand into a copper plate, by the old thread, to a depth equal to the thickness of the fire-box plate, but not riveted, and it required a dead weight of 8204 lb. to pull it out; and as each stay has to support a surface of 5 inches × 5⅜ inches, say 27 square inches only, it follows that a pressure of 8204 ÷ 27 = 303·85 lb. per square inch would have been required to strip it. Another stay, which had not been stripped by the explosion, but which was screwed out of the old box, was similarly treated, and required a force of 9·184 lb. to strip it, equal to 340 lb. per square inch."

Since the experiments here referred to were made, Mr. Fairbairn has repeated them with great care; and taking into account the tensile strength of the stays—in their corroded state—of the side of the fire-box, which to appearance was the first to give way, shows that a force of 380 lb. upon the square inch would be required to effect rupture; and the results of the experiments on the resistance of stays screwed into the copper fire-box fully confirm those already made by Mr. Ramsbottom. Assuming therefore that the ends of the screws were riveted, and sound in other respects, we may reasonably conclude that a strain not less than 450 to 500 lb. upon the square inch would be required to strip the screws, or tear the stays themselves asunder. These facts are founded upon the experiment of the resisting powers of the iron stay screwed into a portion of the copper cut out of the ruptured fire-box, and another experiment of a similar stay first screwed and then riveted, as shown in the annexed engraving.

The stay marked A, ¾-inch in diameter, in the first experiment required a force of 18,260 lb. = 8·1 tons to strip the screw, and draw it out of the copper; and the stay B, of exactly the same dimensions, but riveted over the end, required a force of 24,140 lb. = 10·7 tons before it was dislodged. Taking therefore the mean of those experiments, including those of Mr. Ramsbottom, and we arrive at the results given above,—namely, a resisting power of 785 lb. on the square inch, to burst or produce fracture in the stays and side of the fire-box.

A



B

Fig. 1.

In locomotive engines of more recent construction, where the stays are thicker and formed into squares of 4 to 4½ inches, the resisting powers wlll probably be increased to 850 or 900 lb. on the square inch, that is, seven or eight times the working pressure.

On a careful examination of the fire-box and every other part of the boiler, it was found that the stays and copper were perfect, and that they were able to sustain a pressure much exceeding 207 lb. upon the square inch, as given in the following table.

In these experiments, the top of the fire-box sank a little, owing to the breakage of a bolt of one of the cross-bars; but the fire-box stays were quite perfect, and to every appearance would have sustained nearly double that pressure. If the fire-box stays had been new and the top well-stayed, it is more than probable that a force from 800 to 900 lb. on the square inch would have been required to cause rupture.

As much stress has been laid upon the weakness of the stays which unites the flat surface of the boiler to the sides of the fire-box, the following experiments clearly indicate that the fire-box stays are not the weakest parts of a locomotive boiler, and that we have more to fear from the top of the furnace, which under severe pressure is almost invariably the first to give way. Great care should therefore be observed in the construction of this part, as the cross-beams should not only be strong, but the bolts by which the crown of the fire-box is suspended should also be of equal strength, in order that no discrepancy should exist, and that all the parts shauld be proportioned to a resisting force of at least 500 lb. on the square inch.

Finding the knowledge with regard to the power of resistance of locomotive boilers to strain exceedingly imperfect, Mr. Fairbairn availed himself of the present opportunity, to determine by actual experiment the laws on which these powers are founded; and for this purpose the Directors of the London and North-Western Railway Company placed in his hands an engine of the same age, constructed by the same makers, and in every respect a fac-simile of that which exploded. This engine was subjected to hydraulic pressure as follows:—

*Experiment made May 4th, 1853, to determine the Resisting Powers of the Fire-box and Exterior Shell of No. 2 Engine on the Eastern Division of the London and North-Western Railway.*

In this experiment, the boiler was furnished with a valve, 1 inch area, and a lever of suitable dimensions. This lever, 15 : 1, gave as the weight upon the valve 35 lb. and having suspended the scale, which indicated with the lever 50 lb., the following results were obtained:—

TABLE I.

| Number of pounds on scale. | Weights per sq. inch upon the valve. | Number of pounds on scale. | Weights per sq. inch upon the valve. |
|---|---|---|---|
| Lever ... | ... 35·0 [1] | 5½ ... | ... 132·5 |
| Scale ... | ... 50·0 | 6 ... | ... 140·0 [2] |
| ½ ... | ... 57·5 | 6½ ... | ... 147·5 |
| 1 ... | ... 65·0 | 7 ... | ... 155·0 |
| 1½ ... | ... 72·5 | 7½ ... | ... 162·5 |
| 2 ... | ... 80·0 | 8 ... | ... 170·0 [4] |
| 2½ ... | ... 87·5 | 8½ ... | ... 177·5 |
| 3 ... | ... 95·0 | 9 ... | ... 185·0 |
| 3½ ... | ... 102·5 | 9½ ... | ... 192·5 |
| 4 ... | ... 110·0 [3] | 10 ... | ... 200·5 |
| 4½ ... | ... 117·5 | 10½ ... | ... 207·5 [5] |
| 5 ... | ... 125·5 | | |

[1] This engine was the same age, and had run about the same number of miles as the exploded engine. The fire-box was considerably sunk or bulged, and the rivets as well as the stays much weakened. The engine had been at work since 1840.

[2] With this pressure a leakage was observed at some of the joints.

[3] Leakage increased.

[4] Leakage still increasing.

[5] With this pressure one of the bolts of the cross-bar over the fire-box broke, which caused the experiment to be discontinued, as the leakage was greater than the force-pump could supply.

From the above, it is evident that the boiler which led to these experiments could not have burst under a pressure of less than 300 to 350 lb. upon the square inch, as the failure of a single bolt in one of the cross-bearers above the fire-box, under a pressure of 207 lb. on the square inch, was not the measure of its strength, but one of those accidental circumstances which is calculated to weaken, but not absolutely destroy its ultimate powers of resistance. This conclusion was arrived at from the fact of finding the upper part of the fire-box in every respect perfect. After the removal of the pressure of 207 lb. on the square inch, and comparing these experiments with the appearance of the crown of the ruptured fire-box, Mr. Fairbairn is confirmed in the opinion that steam of high elastic force must have been present to cause the disastrous explosion which eventually occurred.

Again referring to the Report, Mr. Ramsbottom states,—"That it has been objected that the steam could not have been raised from 60 lb. per square inch, the pressure at which the safety-valve was blowing off before being screwed down, to the pressure stated by Mr. Fairbairn, in twenty-five minutes; but although I do not go all the way with Mr. Fairbairn as to the strength of the boiler, I find, from experiments made upon a boiler of somewhat similar dimensions, and placed as nearly as possible under the same circumstances, that the steam was raised from 30 lb. per square inch to 80 lb. as shown by Bourdon's steam-gauge according to the following scale, namely,—

| | h | m | s | | |
|---|---|---|---|---|---|
| Safety-valve screwed down | 3 | 1 | 20 | = | 30 lb. per square inch. |
| ... ... ... | 3 | 2 | 30 | = | 35 ... ... ... |
| ... ... ... | 3 | 3 | 45 | = | 40 ... ... ... |
| ... ... ... | 3 | 5 | 00 | = | 45 ... ... ... |
| ... ... ... | 3 | 6 | 15 | = | 50 ... ... ... |
| ... ... ... | 3 | 7 | 20 | = | 55 ... ... ... |
| ... ... ... | 3 | 8 | 30 | = | 60 ... ... ... |
| ... ... ... | 3 | 9 | 30 | = | 65 ... ... ... |
| ... ... ... | 3 | 10 | 30 | = | 70 ... ... ... |
| ... ... ... | 3 | 11 | 30 | = | 75 ... ... ... |
| ... ... ... | 3 | 12 | 20 | = | 80 ... ... ..." |

These experiments, although perfectly satisfactory as regards the time required to raise the steam (under ordinary circumstances of the engine, standing with the fire lighted, and the usual quantity of coke in the furnace) from 30 up to 80 lb. on the square inch—it was nevertheless considered desirable to repeat them through a still higher scale of pressure and temperature, and to ascertain, not only the exact time, but the ratio of increase, and the corresponding temperature of the steam in the boiler as the pressure progressively increased. For these objects, two delicately constructed thermometers were prepared by Dalgetti, and having adjusted Bourdon's pressure-gauge by a corresponding column of mercury, and an engine having been placed at Mr. Fairbairn's disposal, the following results were obtained:—

*Experiment made May 7th*, 1853, *to determine the rate of Increased Pressure, Temperature of Steam, &c. in a Locomotive Engine with the Safety-valve screwed down and the Fire under the Boiler.*

TABLE II.

| Time. | Pressure. | Temperature, No. 1 gauge. | Temperature, No. 2 gauge. | Mean Temperature. |
|---|---|---|---|---|

| 3·04 | 101·15 | 331 | 331 | 331·00 |
| 3·05 | 108·75 | 335½ | 335¾ | 335·62 |
| 3·06 | 111·75 | — | — | —[1] |

[1] This experiment was lost, the thermometers not indicating a higher temperature.

Let us now endeavour from this table to discover the law expressing the relation between the time and pressure, or between the time and temperature.* The observations being made at intervals of one minute of time, and the furnace being maintained at the same intensity, it may be presumed that the quantity of heat communicated to the water was uniform, or that there were equal quantities of absolute heat communicated to the boiler in equal times. The column of pressures gives the successive augmentations of pressure at equal intervals, and the column of temperature gives the corresponding augmentations of heat as indicated by the thermometer. The column of pressures shows that the increments of pressure, in equal intervals of time, increase with the temperature; thus at or near 260° the average increment of pressure is at the rate of 3·1 lb. per minute; at or near 282°, it is 5·4 lb. per minute; at or near 326°, it is 7·1 lb. per minute. Mr. Ramsbottom's table of experiments indicates a similar result; thus at or near 268° the average increment of pressure is at the rate of 4 lb., whereas at or near 304° it is at the rate of 5 lb. per minute. The law, therefore, expressing the relation of time and pressure does not appear to admit of assuming a simple form. But the case is different with respect to the law expressing the relation of time and temperature. Thus if $T$ = temperature in degrees, and $t$ = the time in minutes at which this temperature is observed, estimated from the commencement of the experiments, then

$$T = a \times t + b \quad \text{.........................(1)}$$

will give the relation between $T$ and $t$ with great precision where $a$ and $b$ are constants, whose values, derived from these experiments, are $a = 4{\cdot}44$ and $b = -486$.

For example, let $t = 166$, then $T = 4{\cdot}44 \times 166 - 486 = 251°$, which exactly corresponds with the tabular value. Again, let $t = 180$, then $T = 4{\cdot}44 \times 180 - 486 = 313°{\cdot}2$; in this case the tabular value is 313°. Again, let $t = 185$, then $T = 4{\cdot}44 \times 185 - 486 = 335°{\cdot}4$; in this case the tabular value is 335°·6. From this formula we find

$$t = \frac{T + 486}{4{\cdot}44} \quad \text{.........................(2)}$$

If $t$ = the number of minutes which elapse between the temperatures $T$ and $T'$, then we find from 29 (1),

$$T' - T = 4{\cdot}44\, t' ; \quad \text{.........................(3)}$$

* The mathematical analysis of this question was supplied by Mr. Tate.

which shows that *the temperature increases with the time*; and presuming that the heat of the furnace remained constant, this formula also shows that *equal increments of absolute heat produce equal increments of sensible temperature as indicated by the thermometer.*

To determine the time, estimated from a given pressure, at which the boiler would burst,—

1st. Let the given pressure be that of the atmosphere, and let the boiler be able to sustain 240 lb. pressure per square inch. From an experimental table of pressures and temperatures, we find 240 lb. pressure to correspond to 403° temperature, and 15 lb. pressure to 212° temperature; hence we have by formula (3),

$$t' - = \frac{403 - 212}{4{\cdot}44} = 43 \text{ minutes},$$

which is the time in which the boiler would burst, estimated from the time at which the water begins to boil.

2nd. Let the given pressure be 60 lb. per square inch, and the boiler-pressure 240 lb. per square inch, then

$$t' = \frac{403 - 296}{4{\cdot}44} = 24{\cdot}1 \text{ minutes}.$$

3rd. Let the given pressure be 60 lb. per square inch, and the boiler-pressure 300 lb., then

$$t' = \frac{422 - 296}{4{\cdot}44} = 28 \text{ minutes},$$

which is nearly the time in which the boiler experimented upon would burst.

These facts appear to be sufficiently conclusive to enable us to judge of the dangers to which people expose themselves under circumstances where the necessary precautions are not taken for allowing the steam thus generated with the fire under the boiler to escape. The great majority of accidents of this kind have arisen during the time the engines are standing, probably with the safety-valve fastened and a brisk fire under the boiler. How very often do we find this to be the case in tracing the causes of these melancholy and unfortunate occurrences!

The statements contained in the earlier part of this paper regarding the strength of the stays of the fire-box would have been incomplete if we had not put those parts of a locomotive boiler, comprised in the flat surfaces or sides of a fire-box, to the test of experiment. This was done with more than ordinary care; and in order to attain conclusive results, two thin boxes, each 22 inches square and 3 inches deep, were constructed; the one corresponding in every respect to the sides of the fire-box, distance of the stays, &c., the same as those which composed the exploded boiler; and the other formed of the same thickness of plates, but different in the mode of staying, which, in place of being in squares of 5 inches asunder, as those contained in the boiler which burst, were inserted in squares of 4 inches asunder. The first contained sixteen squares of 25 inches area, representing the exploded boiler, or old construction; and the other, twenty-five square of 16 inches area, representing the new construction.

To the flat boxes thus constructed, the same lever, valve, and weight were attached as used in the previous experiments; and having applied the pumps of a hydraulic press, the following results were obtained:—

TABLE III.—*Experiment 1st.*—To determine the ultimate Strength of the Flat Surfaces of Locomotive Boilers when divided into squares of 25 inches area.

| No. of Experiment. | Pressure in lbs. per sq. inch. | Swelling of the sides, in inches. | No. of Experiment. | Pressure in lbs. per sq. inch. | Swelling of the sides, in inches. |
|---|---|---|---|---|---|
| 1[1] | 245 | + | 11 | 545 | ·05 |
| 2 | 275 | + | 12 | 575 | ·05 |
| 3 | 305 | + | 13 | 605 | ·06 |
| 4 | 335 | + | 14 | 635 | ·06 |
| 5 | 365 | + | 15 | 665 | ·06 |
| 6 | 395 | + | 16 | 695 | ·07 |
| 7 | 425 | + | 17 | 725 | ·07 |
| 8 | 455 | ·03 | 18 | 755 | ·07 |
| 9 | 485 | ·03 | 19 | 785 | ·08 |
| 10 | 515 | ·04 | 20 | 815 | —[2] |

[1] The box representing a portion of the flat surface of the side of the fire-box of a locomotive boiler was composed of a copper plate, on one side ½-inch thick, and an iron plate on the other ⅜-inch thick, being the same in every respect as the boiler which exploded.

[2] Burst by drawing the head of one of the stays through the copper, which from its ductility offered less resistance to pressure in that part where the stay was inserted.

The above experiments are at once conclusive as to the superior strength of the flat surfaces of a locomotive fire-box, as compared with the top, or even the cylindrical part of the boiler; but taking the next experiment, where the stays are closer together, or where the areas of the spaces are only 16 instead of 25 square inches, we have an enormous resisting power; a force much greater than anything that can possibly be attained, however good the construction, in any other part of the boiler.

TABLE IV.—*Experiment 2nd.*—To determine the ultimate Strength of the Flat Surfaces of Locomotive Boilers when divided into squares of 16 inches area.

| No. of Experiment. | Pressure in lbs. per sq. inch. | Swelling of the sides, in inches. | No. of Experiment. | Pressure in lbs. per sq. inch. | Swelling of the sides, in inches. |

| 19 | 785 | ·08 | 43 | 1595 | ·14 |
| 20 | 815 | ·08 | 44 | 1535 | ·16 |
| 21 | 845 | ·08 | 45 | 1565 | ·22 |
| 22 | 875 | ·08 | 46 | 1595 | ·34 |
| 23 | 905 | ·08 | 47 | 1625 | —[3] |
| 24 | 935 | ·08 | | | |

[1] The flat box on which these experiments were made has the same thickness of plates as that experimented upon in the preceding table, viz., one side of copper ½-inch thick, and the other of iron ⅜-inch thick. The only difference between the two is the distance of the stays, the first being in squares of 25 inches area, and the other in squares of 16 inches area.

[2] From 995 to 1295 lb., the swelling or bulge on the side was inappreciable.

[3] Failed by one of the stays drawing through the iron plate after sustaining the pressure upwards of 1½ minute.

In the above experiments, it will be observed that the weakest part of the box was not in the copper, but in the iron plates, which gave way by stripping or tearing asunder the threads or screws in part of the iron plate at the end of the stay.

The mathematical theory would lead us to expect that the strength of the plates would be *inversely as the surfaces between the stays*; but a comparison of the results of these experiments shows that the strength decreases in a higher ratio than the increase of space between the stays. Thus according to the mathematical theory, we should have—

$$\text{Ult. strength 2nd plate per sq. in.} = \text{strength 1st plate} \times \tfrac{25}{16} = 815 \times \tfrac{25}{16} = 1273 \text{ lb.}$$

Now this plate sustained 1625 lb. per square inch, showing an excess of about one-fourth above that indicated by the law. This is in excess of the force required to strip the screw of a stay $\frac{11}{16}$-inch in diameter, such as those which formed the support of the flat surfaces in the exploded boiler.

It will be found that a close analogy exists throughout the whole experiments, as respects the strengths of the stays when screwed into the plates, whether of copper or iron; and that the riveting of the ends of the stays adds to their retaining powers an increased strength of nearly 14 per cent. to that which the simple screw affords. The difference between a fire-box stay when only screwed into the plate and when riveted at the ends is therefore in the ratio of 100 : 76, nearly the same as shown by experiment in the Appendix.

It is desirable, therefore, that we should ascertain the strain exerted on each stay or bolt of the fire-box. Let A, B, C, D, E, F, represent the ends of the bolt or stays; $O_1, O_2, O_3, O_4$, the centres of the squares formed by the bolts. Suppose a pressure to be applied at each of the points $O_1, O_2, O_3, O_4$, equal to the whole pressure on each of the squares, then the central bolt A, will sustain one-fourth of the pressure applied at $O_1$, also one-fourth of the pressure applied at $O_2$, and so on; so that the whole pressure on A, will be equal to the pressure applied to one of the square surfaces. Hence we have—

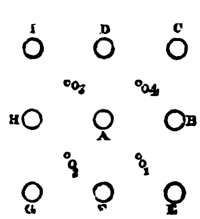

FIG. 2.

$$\text{Strain on the stay of Table III.} = \frac{815 \times 25}{2240} = 9 \text{ tons.}$$

$$\text{Strain on the stay of Table IV.} = \frac{1625 \times 16}{2240} = 11\tfrac{1}{2} \text{ tons nearly.}$$

The stay in the latter case was $\frac{11}{16}$-inch in diameter; hence the strain upon one square of section would be about 13 tons, which is considerably within the limits of rupture of wrought-iron under a tensile force.

In the experiments here referred to, it must be borne in mind that they were made on plates and stays at a temperature not exceeding 50° of Fah.; and the question naturally occurs, as to what would be the difference of strength under the influence of a greatly increased temperature in the water surrounding the fire-box, and that of the incandescent fuel acting upon the opposite surface of the plates.

This is a question not easily answered, as we have no experimental facts sufficiently accurate to refer to; and the difference of temperature of the furnace on one side, as compared with that of the water on the other, increases the difficulty, and renders any investigation exceedingly unsatisfactory. Judging, however, from practical experience and observation, Mr. Fairbairn is inclined to think that the strengths of the metals are not much deteriorated. His experiments on the effects of temperature on cast-iron do not indicate much loss of strength up to a temperature of 600°. Assuming therefore that copper and wrought-iron plates follow the same law, and taking into account the rapid conducting powers of the former, we may reasonably conclude that the resisting powers of the plates and stays of locomotive boilers are not seriously affected by the increased temperature to which they are subject in a regular course of working. This part of the subject is, however, entitled to future consideration; and it may be hoped that some of our able and intelligent superintendents will institute further inquiries into a question which involves considerations of some importance to the public, as well as to the advancement of our knowledge in practical science.

## APPENDIX.

In order to test with accuracy the tensile power of the different descriptions of stays used in locomotive boilers, and to effect a comparison between those screwed into the plates and those both screwed and riveted, it was deemed expedient to repeat Mr. Ramsbottom's experiments on a larger scale; and by extending the tests to copper stays as well as iron ones, it was considered that no doubt could exist as to the ultimate strength of those simply screwed, the tensile powers of the stays themselves, and the relative difference between those and the finished stays when screwed and riveted on both sides of the fire-box. The large lever and requisite apparatus being at hand, the experiments proceeded as follows:—

*Experiments to determine the Ultimate Strength of Iron and Copper Stays generally used in uniting the flat surfaces of Locomotive Boilers.*

*Experiment* I.—Iron stay ¾-inch diameter, screwed into a copper plate ⅜-inch thick (as fig. 3).

| No. of Experiment. | Weight in lbs. | No. of Experiment. | Weight in lbs. |
|---|---|---|---|
| 1 | 9,860 | 4 | 14,900 |
| 2 | 11,540 | 5 | 16,580 |
| 3 | 13,220 | 6 | 18,260[1] |

[1] With the last weight, 18,260 lb. = 8·1 tons, the threads in the copper plate were drawn out or stripped after sustaining the weight a few seconds.

*Experiment* II.—Iron stay ¾-inch diameter, screwed and riveted into a copper plate ⅜-inch thick (as fig. 4)

| No. of Experiment. | Weight in lbs. | No. of Experiment. | Weight in lbs. |
|---|---|---|---|
| 1 | 9,860 | 6 | 18,260 |
| 2 | 11,540 | 7 | 19,940 |
| 3 | 13,220 | 8 | 21,620 |
| 4 | 14,900 | 9 | 23,300 |
| 5 | 16,580 | 10 | 24,140[1] |

[1] When the last weight, 24,140 lb. = 10·7 tons, was laid on, the head of the rivet was torn off: and the stay, along with the threads in the copper, was drawn through the plate.

*Experiment* III.—Iron stay ⅞-inch diameter, screwed and riveted into an iron plate ⅜-inch thick (as fig. 4).

| No. of Experiment. | Weight in lbs. | No. of Experiment. | Weight in lbs. |
|---|---|---|---|
| 1 | 9,860 | 6 | 23,300 |
| 2 | 13,220 | 7 | 25,980 |
| 3 | 16,580 | 8 | 26,660 |
| 4 | 19,140 | 9 | 27,940 |
| 5 | 20,780 | 10 | 28,760 [1] |

[1] With the last weight, 28,760 lb. = 12·5 tons, the stay was torn asunder through the middle, both screw and plate remaining perfect.

*Experiment* IV.—Copper stay ⅞-inch diameter, screwed and riveted into a copper plate ⅜-inch thick (as fig. 4).

| No. of Experiment. | Weight in lbs. | No. of Experiment. | Weight in lbs. |
|---|---|---|---|
| 1 | 9,860 | 4 | 14,900 [2] |
| 2 | 11,540 [1] | 5 | 16,265 [3] |
| 3 | 13,220 | | |

[1] With 11·540 lb. the body of the stay was slightly elongated.
[2] Elongation considerably increased with 14,900 lb.
[3] Broke with 16,265 lb. = 7·2 tons, after sustaining the load upwards of three minutes. The ultmate elongation was 0·56 inch in a length of 3 inches.

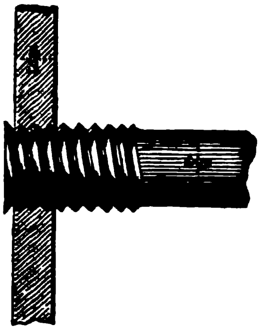

Fig. 3.

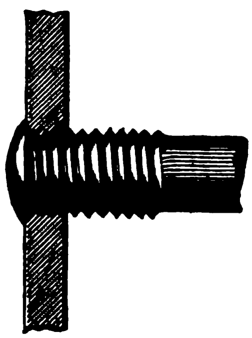

Fig. 4.

It will be observed, on comparing the results obtained from the above experiments, that iron plates and iron stays are considerably stronger than those made of copper. It may not be advisable to have the interior fire-box made of iron, on account of its inferior conducting powers and its probable durability; but so far as regards strength, it is infinitely superior to that of copper, as may be seen by the following

*Summary of Results.*

| No. of Experiment. | Breaking weight in tons. | Resistance per sq. inch in tons. | Ratio, Exp. III., the iron stay and iron plate taken as 1000. | |
|---|---|---|---|---|
| III. | 12·5 | 27·7 | 1000 : 1000 | Iron and iron. |
| I. | 8·1 | 18·8 | 1000 : 648 | Iron and copper screwed only. |
| II. | 10·7 | 23·6 | 1000 : 856 | Iron and copper screwed and riveted. |
| IV. | 7·2 | 16·1 | 1000 : 576 | Copper and copper screwed and riveted. |

On the above data, it will be found that the iron stay and copper plate (not riveted) have little more than one-half the strength of those where both are of iron; that iron stays screwed and riveted into iron plates are to iron stays screwed and riveted into copper plates as 1000 : 856; and that copper stays screwed and riveted into copper plates of the same dimensions, have only about one-half the strength of those where both the stays and plates are of iron. These are facts in connection with the construction of locomotive, marine, and other description of boilers having flat surfaces, which may safely be relied upon, and that more particularly when exposed to severe strain, or the elastic force of high-pressure steam.

*Royal Institute of British Architects.*—At the annual general meeting of the Institute, held on the 1st of May, the following officers were elected for the ensuing year:—President: Earl de Grey. Vice-Presidents: Messrs. T. H. Wyatt, B. Ferrey, and F. C. Penrose. Honorary Secretaries: Messrs. J. J. Scoles and C. Nelson. Ditto for Foreign Correspondence: Mr. T. L. Donaldson. Members of Council: Messrs. H. Ashton, J. Bell, M.P.; J. H. Good, jun., R. C. Hussey, G. Mair, E. Christian, H. Clutton, J. H. Hakewill, G. O. Leicester, and P. C. Hardwick. Auditors: Messrs. T. H. Lewis, fellow; and W. A. Buckley, associate.

## DRAINAGE OF THE DISTRICTS NORTH OF THE THAMES.

We last month gave the joint report of Messrs. Bazalgette and Haywood, and that of Sir William Cubitt, on the proposed plan for the drainage of the districts lying north of the Thames. The report of Sir Robert Stephenson, on the same subject, which is given below, has been subsequently received by the Metropolitan Commissioners of Sewers, and was read at a special meeting held on the 16th ult:—

Gentlemen—Absence from England prevented my uniting with Sir William Cubitt in drawing up his remarks, dated February 25, 1854, on the joint Report of Messrs. Bazalgette and Haywood, on a proposed system of intercepting drains throughout that portion of the metropolis lying on the north side of the river Thames. I therefore now take leave to lay before you a few observations on that Report, and before doing so may premise that it is not my intention to revert to those points touched upon by Sir William Cubitt, as I entirely concur in the opinion he has given respecting the general merits of the plan and the estimated cost of carrying it out. My observations will rather have reference to the general principle of intercepting sewers upon which the design is based, and to one or two of the localities where it has been deemed advisable to depart from this system to meet special conditions.

With respect, then, to the application of the principle of intercepting sewers to very large towns, and more especially to the metropolis, where it has become imperative to lessen, as far as practicable, the nuisance of discharging the sewage directly into that part of the Thames upon which the metropolis is situate, I believe there is considerable unanimity of opinion among engineers who have been called upon to direct their attention to the subject. When I was a member of your body it fell to my lot to examine upwards of 150 suggestions for improving the drainage of London, among which were many from professional men of experience, and by far the majority of these, when a comprehensive study of the subject had been made, agreed on adopting a series of intercepting sewers, as the only method affording a simple and efficient system of drainage, and at the same time freeing the Thames through London of pollution.

The plan which was afterwards submitted by Mr. Frank Forster to the Commissioners may be regarded as embodying most of the useful views which such of the plans contained as were based upon the principle of interception by main lines of sewer, carried to a point on the river so far down as to prevent the reaction of the tidal waters bringing the feculent matter back among the inhabitants of the metropolis.

The design now produced by Mr Bazalgette and Mr. Haywood may be regarded as the extension of Mr. Forster's views, adapted to the new features which every suburb of London is yearly presenting. They have also made some judicious modifications suggested by time and further information, one of the most important of which is the removal of the lowest intercepting drain from the shore of the river, as such a position, although chosen for the purpose of making the system of interception complete, would have been carried out with the utmost difficulty, in consequence of the loose nature of the soil, and at a cost incapable of any certain calculation beforehand.

The construction of this low-level intercepting sewer does not, however, press for immediate attention, for it is clear, that of the three intercepting sewers comprehended in Messrs. Bazalgette and Haywood's plan, the construction of the upper and middle levels should be proceeded with first. Their completion alone will greatly relieve the Thames of impurities by lessening the direct discharge, will render the construction of the lowest level less difficult and less costly. Indeed, it is not improbable, that by the diversion of so large a portion of the sewage matter from the river as would be under the control of the middle and upper lines of interception, the formation of the lowest would become comparatively much less important, and might be postponed for some length of time, and so relieve the demand upon those who supply the funds.

The two upper lines of interception would in fact leave less offensive matter to be discharged into the sewers than has taken place in any time within living recollection. It is the only mode of procedure which seems adapted eventually to remove, and at once to mitigate, many of the chief difficulties and annoyances attaching themselves to this complicated question.

In this design, the system of interception is applied to the whole of the metropolis on the north side of the river, excepting a portion which is designated the western district, comprising an area of about eighteen square miles, commencing a little to the east of Brompton and Chelsea, and extending westward as far as Brentford. The level of all this district is so low, that it is impossible to obtain any other natural means of drainage than into the river, as at present. To obviate this objection, it is proposed to treat the western district by a different method, which appears to me well calculated to overcome the obstacles arising out of this circumstance, namely, to direct the whole of the sewage to one point on the shore of the river near the entrance into Kensington Canal, and there take means for separating the liquid and solid portion of the sewage before the former is discharged into the river. Experiments on a large scale with this process are now being made, and with such result that its ultimate success may be fairly deemed probable.

I agrée therefore with the recommendations made in this Report as to the method to be applied to the western district, in consequence of its extremely low level.

With the general lines of direction which have been selected for interception I also concur; but, in anticipation of the success of the method for extracting solid manure from the sewage, and its becoming remunerative, it is suggested, "that considerations may arise seriously affecting the scheme proposed," and a question is raised, "whether it would not then be advisable, on the score of economy, to modify the designs presented for the middle and low-level sewers, and to abandon the chief portion of the line between the river Lea and Barking Creek." In this I do not go to the full extent with Messrs. Bazalgette and Haywood, for, although the process for the manufacture of manure may prove successful, I do not think this probably would tend to, still less would justify, the delay of the construction of the middle-level works. These seem to me to be absolutely necessary to rectify the present defective system of drainage, whatever shape the manure question may eventually take. I have already stated that the middle-level is calculated, when properly dealt with, to ameliorate the evils so much complained of in so marked a manner, that the execution of the lower level may perhaps safely be postponed for a time; but I can foresee no degree of improvement in the manufacture of manure in prospect that would tend to any material alteration in its construction, or position, or cost. It strikes at the root of many of the existing evils in the most direct manner, while it comprehends within its scope and influence so large and important a district that I think no minor obstacle ought to stand in the way of its execution, The extension to Barking might, I think, be dispensed with, as suggested.

If in extending and perfecting the drainage of London, the chief objects be the improvement of the general sanitary condition of the inhabitants, and the purification of the Thames from noisome matter, I cannot help repeating that I regard the middle intercepting sewer as one of the most important features of the scheme on which I am now reporting, and, indeed, without it either object, and the last especially, could only be very partially attained, for no arrangement in the extraction of the solid matter from the sewage, that I can conceive, would prevent the frequent discharge of the usual amount of noxious filth into the river.

This can only, I believe, be avoided by the intercepting system being fully carried out, and no part of the proposed plan is more effective than the middle interception, and none can be so ill spared or postponed.

I am induced to express this opinion somewhat decidedly, because, having had my attention called to several methods that have been proposed for the extraction of manure from sewage, I have been led to the conclusion, that, instead of multiplying such establishments within the precincts of towns, as some contemplate, a complete system of interception, with the concentration of the manure process on a few points, is that which is best calculated to attain success.

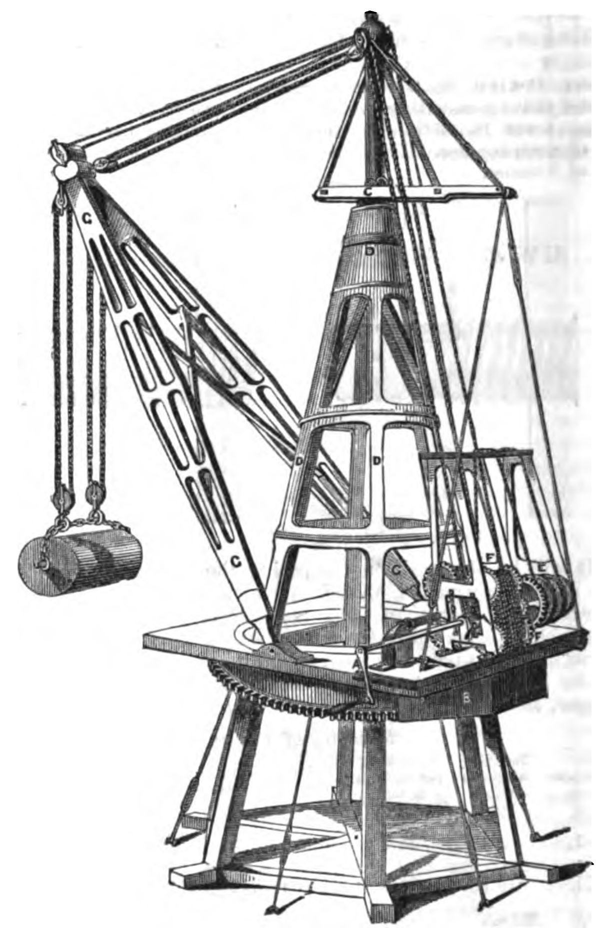
With reference to the dimensions of the proposed sewers, I have not been able to go into the details of the calculations, but having examined the tabular statements attached to the Engineers' Report, and having received explanations from them respecting the directions of the flow in the various sewers intended to take place, I have every confidence in the correctness of their conclusions.

I have only further to add, that I regard the design of Messrs. Bazalgette and Haywood as comprehending, in a very practical shape, all the essentially useful suggestions which have from time to time been made by engineers respecting the drainage of the metropolis; and I have no doubt whatever, that if the Commissioners be put in a position to carry it out, it will be found effective. I am, &c.,

*24, Gt. George-street, Westminster,* ROBERT STEPHENSON.
*May 15th*, 1854.

## PATENT IMPROVED DERRICK.*

JOHN B. HOLMES, U.S., *Patentee*, February, 1854.



THE main part of this derrick consists of an upright frame *d*, placed on a revolving platform B, on which is fixed a boom *g*, with two arms, the jointed heels of which are secured in the platform between the central upright frame and the horizontal capstans. On the top of the frame is a revolving cap *c*, with the mast secured on it. *f*, are double capstans; and *e*, are reels for taking up the the slack of the ropes; *a*, is the crank for working the whole machinery. This derrick can be worked by hand, horse, or steam power. A pinion gears into the large wheel of platform B, and moves it round as desired; it can be thrown out of gear when required. The boom *g*, can be elevated along with the weight to be raised, or it can be held stationary when the weight is being lifted, or it can be raised and the weight held at any position—neither raised nor lowered. One capstan is for working the boom *g*, and the other for working the lifting block and tackle. The boom is suspended from the top of the revolving cap, the latter being held down by tension rods on the other side. The platform B, is held down by a collar, which is sustained by the vertical under tension-rods. As the platform B, is thus constructed and arranged in connection with the revolving cap *c*, a very light mast can be employed, and the use of guys, connected with anchors (in the usual way), is obviated.

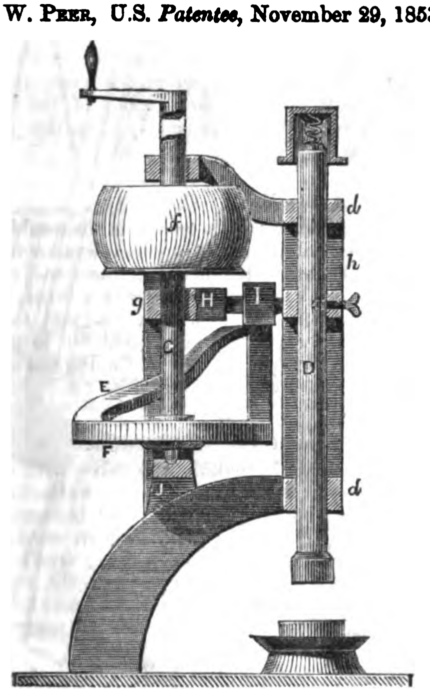
There are two falls for hoisting, shown on the end of the boom;

* From the 'Scientific American.'

both ropes are wound up at the same time on the capstan, and all the slack is carried over small pulleys, and wound up on one reel *e*; the other reel takes up the slack of the boom ropes. It will be observed that there are four ropes passing from the cap; the one at each side for working the falls that lift the weight, and the two inside ones for working the jointed boom *g*. The weight can be brought in and out on a level, or hoisted above or below a level, with the platform. The cap and boom can be carried round the circle together, and by placing the working machinery, capstans, &c., opposite to the weight to be hoisted, they form a counterbalance to that weight on the platform. Two coils of rope will be observed on the two horizontal capstans, which worked by the main shaft of *a*, are capable of being thrown in and out of gear with that shaft, to work either capstan and reel, singly or altogether, as required. They are also geared for a fast or slow motion, for light and heavy hoisting. It will be observed that by elevating the boom, the circle described by the hoisting lever can either be increased or diminished—a very important arrangement.

## TRIP HAMMER.

J. W. Peer, U.S. *Patentee*, November 29, 1853.



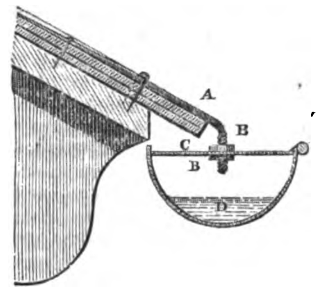
The nature of this invention consists in raising and lowering the hammer by means of a screw-cam arranged upon a circular plate, secured fast on a revolving shaft, and connected to the helve of the hammer by means of a horizontal lifting-arm, which has one of its ends attached fast to the hammer by set-screws, and its other end sliding freely up and down over the vertical cam-shaft as the hammer rises and falls, the said arm carrying a small friction-roller, which, as the cam-shaft revolves, turns freely and plays upon the top of the screw-cam, and prevents friction from the weight of the hammer upon the cam, as it is gradually raised by the cam. This invention further consists in arranging the screw-cam upon an adjustable frame, so that it may be adjusted to any position desired, and the length of the blow to be given to the hammer regulated so that if a full or half blow be required they may be secured

The annexed engraving represents an elevation, partly in section, of this machine. D, is the hammer moving up and down in guides *d*, *d*; E, the screw-cam secured to the plate F, and extending more than half round it. The plate F, is secured to a revolving shaft G, the lower end of which rests on a table J, which can be raised or lowered by means of two set-screws one of them in front and the other in rear of the shaft G; *f*, is the driving-pulley. The shaft G, is connected to the hammer D, by means of the arm H, with its two collars *g*, and *h*; the collar *g*, slides freely over the shaft G; and the collar *h*, is fastened to the hammer; I, is the friction-roller.

## SUSPENDING EAVES' TROUGHS.

Chauncey D. Woodruff, *Patentee.*

The annexed engraving represents a transverse section of an improved method of suspending and fastening eaves-troughs. A, is an iron rod, fitted with screw and nuts B, at its lower end, and secured to the rafters by staples and nails. D, is a cross-bar soldered to the eaves-trough, of sufficient strength to keep the trough in shape and sustain its weight. The screw and nuts on the rod A, allow of the trough being elevated and lowered as required.

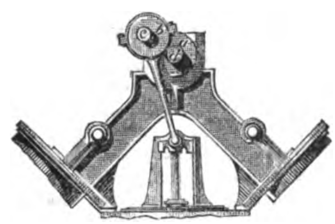


This invention gets rid of the unsightly straps and rails which at present disfigure the cornices of buildings.

## AIR-PUMPS OF STEAM-ENGINES.

Douglas Hebson, *Patentee*, April 13, 1853.

This invention consists in causing the main driving-crank of this engine to be made so as to form an eccentric, from which motion is conveyed to work the air-pump by connecting the eccentric band or hoop to the air-pump rod. The annexed engraving represents a front elevation of the driving-crank and

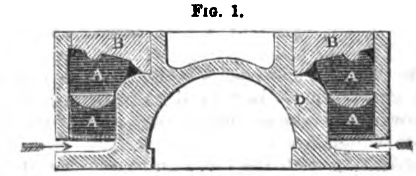


crank-pin, with inverted eccentric on the same for working the air-pump. *a a*, is the centre portion or boss of the main driving-crank; *b b*, the eccentric for working the pumps; *c*, the crank-pin, to which motion is given by the engine; *d*, the crank-shaft. The eccentric *b b*, may be made solid or in one piece, either with the crank or crank-pin or in a separate piece, properly secured to the crank-pin. Or, instead of the above arrangement, the crank itself may be made to work as an eccentric, whilst the eccentric strap conveys motion to the air-pump.

## STEAM SLIDE-VALVES.

E. T. Rees, *Patentee*, February 8, 1854.

Fig. 1.



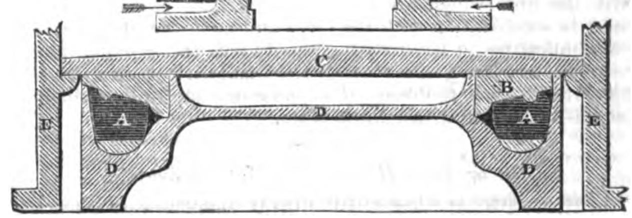


Fig. 2.

Fig. 1 of the above engravings represents a transverse section, and fig. 2 a longitudinal section of this improved slide-valve for steam-engines. A, A, are portions of vulcanised india-rubber, let into a mortice or channel in the valve-casting, and covered by a metallic cover B; C, is the back plate of the valve-casing; D, the valve; and E, the steam-chest. By the elasticity of the india-rubber, and the pressure of steam which is admitted at the sides of the valve, the plate is kept steam-tight against the steam-chest cover or plate, secured in the steam-chest.

## RECENT AMERICAN PATENTS.

[Reported in the Journal of the Franklin Institute.]

*Rotary Engines.* E. Barrows.

*Claims.*—1. The revolving steam-wheel, having projecting rims or flanges, revolving within the interior of a stationary cylinder, in which are two or more fixed abutments or stops, which fit steam-tight, so as to close and divide the annular space between the cylinder and wheel, into two or more steam-chambers; the said steam-wheel having four or more pistons whose operation is controlled by a stationary curved groove or way in each cylinder-head, so as to be alternately acted upon by the steam in the cylinder, and down within the wheel, so as to pass and clear the abutments or stops; 2. The six way-cocks or steam-heads, having each a steam-passage leading to its plug-seat, two steam-passages leading from the plug-seat to opposite chambers of the cylinder, two exhaust-passages leading from opposite chambers of the cylinder back to the plug-seat, and one leading from the plug-seat to the exhaust-pipe, their cock-plugs being provided with suitable openings and passages to make communication to or from the steam and exhaust pipes to either division of the cylinder, or to close both; 3. The mode of uniting the face and side packing-pieces of the pistons and abutments, so as to make them steam-tight at their corners by dovetailing them. The patentee further claims making the steam cylinder within and a part of the piston-wheel, the stationary rim forming the outer side of said cylinder, so that three sides of the said cylinder shall revolve with the pistons.

*Ruling Paper.* J. and W. McAdams.

*Claims.*—1. A machine for ruling paper, in which both the horizontal and vertical lines of the sheet are ruled in passing once through the machine, by any arrangement of devices which carries the sheet, after one set of lines is ruled, in a direction at right angles to its first course, to another set of pens, which rule the sheet across the lines first made; 2. Changing the direction of the movement of the sheet after passing from the first set of pens, by means of the travelling-band and revolving-drums; 3. Lifting the pens so as to leave a heading to the sheet, by means of the roller with its moveable tongue and cam projection, acted upon by the edge of the paper and the motion of the feed-roll, so as to lift an adjustable arm connected to the pen-holder; 4. Forming grooves in the feed-rolls so that the pens may rest over these grooves, and not upon the rolls between the passage of the different sheets; 5. Guiding the sheet straight to the second set of pens, after the direction of its movement is changed, by means of the converging bands, which carry the edge of the sheet against a proper guide, or against the side framework of the machine; 6. Forming the last roll which carries the sheet after it is ruled to the receiver of a polygonal or angular shape, so that its revolution may give a vibratory motion to the sheet.

*Making Nuts.* J. Reese.

*Claims.*—1. The use of the trough of cold water, in combination with the rotating die-box, for the purpose of cooling each die or mould after it has discharged its nut, and preventing the water from coming in contact with other parts of the machine, or with the nuts which are made in it; 2. The use of the guide-head, in combination with the lever and guide, for the purpose of communicating to the rotating mould-box the peculiar motion required, consisting of a succession of sudden yet steady quarter revolutions, each followed by a pause or rest, during which the mould-box is held firmly in its place.

*Bit or Drill Holders.* D. H. Chamberlain.

*Claim.*—There is a hand-drill already constructed so as to have its drill-shaft supported in a stock, and rotated by means of two bevilled gears, one of them being fastened on the top of the drill, while the other was affixed on a separate shaft, disposed at right angles with the drill-shaft, and having the crank applied so as to enable a person to rotate it, and thereby put the drill-shaft in rotation. In the said drill-stock, the crank of it is made to rotate in a plane parallel to the axis of the drill-shaft; the consequence is, that during a rotation of the crank there is an uneven pressure exerted on the drill, the said pressure being increased at one moment and diminished at another, and in the direction of the axis of the drill. A steady pressure on the drill, longitudinally as well as laterally, is desirable, particularly when a small drill is used, as without it the drill is not only liable to be broken or injured, but to be made to deviate in its desired course in passing through anything. The complication of the construction of the bevilled gear bit-stock, and the disadvantages incident to it while in use, render it an instrument of little value and utility. The inventor lays no claim to the above arrangement, nor the method of making the tool-stock and the bell-crank in one piece of metal, so that their rotations may be equal and simultaneous; but what he does claim is, the arrangement of the bell-crank separate from and so as to play or rotate within the tool shaft stock, the said bell-crank having a spur gear to work into a pinion fixed into the end of the tool-shaft, and to impart to said tool-shaft an accelerated motion.

*Tool Holders.* D. H. Chamberlain.

The inventor does not claim a split or jaw socket having a screw and screw-nut applied to it for the closing its jaws upon the shank of an awl or tool inserted between them; but the method of arranging, constructing, and applying together the jaws and confining screws, the same consisting in making the jaws separate from the screw-shank on which the screw is cut; and not only providing the screw-nut with a closing concavity or socket, but the screw-shank with a closing socket for the jaws to rest in, the whole being so that when the screw-nut is screwed down upon the jaws, the combined action of the jaws and the screw-nut shall operate to simultaneously close the jaws at their upper and lower ends.

*Lime Kilns.* C. D. Page.

*Claim.*—The form of the stack or cupola, in combination with the arrangement of flues from the fire-chambers for the introduction of the products of combustion at the lower end, to insure the burning of the central part of the charge. Also, cooling the calcined lime preparatory to drawing it out and exposing it to the atmosphere by causing a current of cold air to pass through the saddle, or its equivalent, placed at the bottom of the stack, and on to which the calcined lime descends.

*Valve Cocks.* J. Griffiths.

This invention consists in making the valve with a cylindrical stem, passing through a hollow stem, which is attached rigidly to or forms part of the body of the cock, and is furnished outside with a screw, to which is fitted a nut, which carries a yoke, in which the valve-stem is capable of turning freely, but not of moving longitudinally. By turning the nut the valve is raised and lowered from and to its seat in a right line, the valve being always kept in such position that it will fall truly into its seat and close tightly.

*Claim.*—The combination of the hollow fixed stem, the solid stem, and the yoked nut.

*Fire and Burglar Proof Safes.* F. C. Goffin.

This invention consists in filling the space between the two casings of a safe or vault door with glass or slag, when in a vitrified state, for the purpose of rendering the safe or door fireproof, and also proof against the efforts of burglars, glass being a poor conductor of heat, and so hard as to effectually prevent the operation of boring or drilling through the sides of the safe or door.

*Turning Lathes.* E. Bancroft and W. Sellers.

*Claim.*—The method of varying the motions of the mandril, and screws or leader, by means of the two series of wheels, each series consisting of wheels of different diameters, and all the wheels of one series being connected and turning together, and imparting motion to all the wheels of the second series, with different degrees of velocity, when this is combined with the method of locking any one of the wheels of the second series with the shaft of the screw or leader, by having the wheels on separate sleeve-arbors, fitted to turn on each other, and adapted to receive a locking pin or bolt, fitted to holes in a plate attached to the shaft of the screw. Also, the manner of supporting and sustaining the screw or leader by combining therewith a trough, having the outer end of the said screw or leader without a journal.

*Fire-Arms.* T. Cook.

*Claims.*—1. Cutting slots in the tubes of the magazine, and with each tube a spring connected with a ring moving on the outside, for feeding up the spring and maintaining the compressed position given at the time of charging the tubes with ammunition, whereby such charge can be forced into the conveyor by power independent of gravity, whether the feed-ring be combined with a screw exteriorly placed, or within the interior of the cluster of tubes, or whether the same effect be produced by any manner analogous; 2. Combining the tube-magazine with the conveyor, in such manner that it will be revolved so as to bring each tube of the series successively opposite to the hole through which the charge is fed to the conveyor, whenever and so often as a charge has been transferred to the barrel; 3. The follower in combination with the cavity of the conveyor, and the lever for ejecting the charge into the barrel; 4. The cam-groove in combination with the finger-levers, and the cap-case to regulate the feed.

---

*Ploughs.* J. S. Neall.

This invention consists in fixing the mould-boards of either single or double ploughs on hinges, so as to be capable of being adjusted to any required width of furrow or crop to be cultivated, in so attaching the beam to the body of the plough by means of screw-bolts that the point of the beam can be raised or lowered at pleasure with great precision, so as to cut any required depth of furrow, in the manner of giving a nice lateral adjustment to the end of the beam by means of a set screw, so as to regulate the angle of the plough with the line of draught, in such way as to give land to the plough or take it from it, and also in the mode of raising or lowering the points of draught of the plough, without altering the position of the beam.

*Claim.*—The hinges, constructed in such a way that the edge of the front part of the mould-board may lap over the edge of the back part or wing of the mould-board, to prevent clogging.

---

*Dies for Making Seamless Metal Tubes.* T. D. Jackson.

*Claim.*—A die for drawing seamless metal tubes, constructed with an eye, whose periphery is formed of a series of narrow friction-rolls, which produces a substantially equable extension of every part of the circumference of the tube being drawn.

---

*Snow-Ploughs for Railroads.* A. Hall and S. Sturtevant.

*Claim.*—So shaping, proportioning, and placing the notched shares of the snow-ploughs that they will extend down within the inner sides of the rails nearly to the cross-ties, without coming in contact with the chairs, for the purpose of removing snow and ice from the immediate vicinity of the inner sides of the rails, and, by means of their mould-boards, discharging the same at a proper distance outside of the rails.

---

*Controlling the Pressure of Steam.* H. S. Williams.

*Claims.*—1. Opening the water-cock of the steam-boiler for the purpose of letting on water for reducing the temperature and pressure of the steam, and thereby preventing explosions, by means of a plunger and slotted arm, and operated, when the supply should be let on, by the pressure of the escape steam of the safety-valve, and by means of a spring attached to the boiler and slotted arm, when the supply is being shut off; 2. Starting the steam-pump or "doctor" running, in case it should not be in operation when the pressure of the steam in the boiler rises above the given point, by means of the escape steam from the safety-valve, when admitted to the steam-chest of the pump through a branch pipe of that carrying the plunger, the said branch pipe being provided with a valve, which prevents the steam from the doctor passing into the boiler when the pump is running, but allows of the steam being admitted to the steam-chest when the pump is not running.

---

*Fusible Discs in Steam-Boilers.* W. Burnett and J. Absterdam.

The nature of this invention consists in inserting in a steam-boiler, at a point below the proper water-line, and above all the heating surfaces, a pipe, which, at a suitable distance from the said boiler, is stopped up by a plate of fusible metal or other fusible compound, it being so arranged, that by freely exposing the said pipe to the atmosphere, the water contained therein shall have its temperature so far reduced by radiation as to preserve in a solid state a fusible metal that will be easily melted by the temperature of the steam in the boiler when the water-level shall have fallen so low as to admit steam into the pipe.

*Claim.*—Placing in a pipe which is connected with a steam-boiler a fusible plug or disc, the said plug or disc being so far removed from the boiler, but so connected with the water therein, that when the water is sufficiently high, the plug or disc will be in contact or so surrounded with water cooler than that in the boiler as to prevent it from being fused; but when the water in the boiler shall fall below a proper height, the steam will enter and come in contact with the plug, or so surround it as to cause it to melt.

---

*Corrugating Metal Plates.* R. Montgomery.

This invention consists in passing a plate a number of times through a pair of grooved rolls and a stationary crimping die, by which the folds of the beam are gradually brought to the proper depth without endangering the rupture of the metal, which is unavoidable when the corrugation of folds of any considerable depth is effected by rollers alone.

*Claim.*—The method of forming corrugated metal beams by passing a plate of metal of the proper size through a series of grooves between rolls, and through a series of crimping dies.

---

*Quartz Crushers.* S. W. Bullock.

*Claim.*—The application of gear-wheels, solely for the purpose of causing the crushing-wheels to turn on their axis faster (or make more revolutions) than they otherwise would in rolling around in the trough, the point of contact (or pitch-line) of said gear-wheels being on a line drawn from their common centre to a point upon the crushing-wheels within its outer diameter or periphery, thereby giving the periphery a slip or sliding motion upon the quartz.

---

*Railroad Chair Machines.* M. M. Gray.

This invention consists in the manner of causing a series of punches, knives, and dies, and a former and its base, to operate upon a heated plate of malleable iron, so as to pierce, cut, and compress the same into the form of a railway-chair.

*Claim.*—Operating the sliding former or mandril upon the base or pedestal to keep it firm and cool, and cutting, curling, and swedging the plates of metal to be formed into the chairs while in a stationary position, and at a proper heat, on the top on the top of this sliding former, instantly to produce the chairs uniform in shape, and cheaply, of low-priced or red short iron, without fracture.

---

*Making Bed-Pins.* W. McBride.

*Claim.*—Attaching to a common turning-lathe, a sliding cutter-stock, and providing stock with two peculiarly-shaped cutters, one stationary and the other moveable, the stationary cutter being of such shape that it forms a tapering part of the pin, while the moveable cutter is of a proper shape and construction to form a round head on the pin, and simultaneous therewith cut off the pin from the block, ready for being discharged. Also, making all the pins of a set of a uniform length, by employing a spring plug or gauge, and by the same means effecting their discharge after being turned, headed, and cut off.

---

*Zinc White Furnaces.* J. Renton.

*Claims.*—1. The combination of any number of ore tubes and tubes or spaces, placed side by side, and communicating with each other through openings in their sides, the ore tubes being exposed to a degree of heat sufficient to evaporate the oxides or other substances contained therein, and make them pass through the openings into the tubes or spaces, the said tubes or spaces being protected from the heat by the ore tubes, and serving either to collect and condense the oxides or other vapours, or to convey them to any other suitable receptacles; 2. The hood or trunk, furnished with suitable openings for the admission of air, and placed over the air-tubes and tubes or spaces, for the purpose of receiving, leading off, and cooling the oxides or other vapours escaping from the ores.

## SEWERAGE AND DRAINAGE OF DEVONPORT.*

THE borough of Devonport is the most westerly of the three contiguous towns of Plymouth, Stonehouse, and Devonport, and is bounded by the dockyards and Morice-town, and separated from Stonehouse by Stonehouse-pool and Mill-lake. On the south-west of Devonport and Morice-town, there is a great breadth of mud exposed at low water of each tide in Millbank-lake, St. John's-lake, St. Germans, and Weston Mill-lake, which is greatly obnoxious to the surrounding neighbourhood.

The high land from Mount Edgcumbe, northward and westward, protect the towns from the north-west gales, and Staddon-heights from the south-east gales, the Sound being open to the south. The damp and warm atmosphere produced by its situation favours decomposition in Devonport, which readily taints the air, and renders the most scrupulous cleanliness and extra care in the immediate removal of all refuse matter more than ordinarily imperative.

The "three towns" are built on limestone, clay-slate, and dunstone (a semi-crystalline rock, which protrudes between the clay-slate and limestone, or intercepts them in dykes). The limestone is extensively used for building purposes, as are also the slate and dunstone. The average annual fall of rain in the district is about 35 inches; the average temperature about 2° higher than prevails on the coast of Sussex and Hampshire; 3½° higher than that of London, and 5° or 6° above that of Northumberland. Sewers have been made from time to time in detached portions to the extent of 16¾ miles, but they have been laid down without any plan, or reference to the natural facilities of the locality. Of these 16¾ miles of sewers, 29,747 lineal feet were constructed by the Commissioners of Devonport, and 58,565 lineal feet by the manor authorities and private persons. The Commissioners' sewers vary in size from 1 ft. 3 in. internal diameter, to 4 feet high by 2 ft. 5 in. wide; the other sewers vary from 2 feet by 1 ft. 4 in. to 4 feet by 2 feet. These sewers have at present three outlets within the lines of fortifications—viz., Mutton-cove, the Chamber in the dockyard, and at North-corner. The sewage of Morice-town and a portion of Upper Stoke, outside the lines, is collected into one sewer at the north end of Tamar-street, and is ultimately discharged into Hamoaze. These outlets are much complained of, as the sewage is discharged from them over the shore above low water, so as to cause offensive nuisances.

Mr. Joseph May, surgeon, and member of the Board of Commissioners, states, that "the sewers were most imperfectly constructed. Streets constantly required to be taken up to remove stoppages and cleanse foul sewers and drains from deposit. Night-soil percolated through the open stonework and into the subsoil on either side, presenting rather the appearance of cesspits than drains. The contents of privies are washed out into open gutters, and allowed to traverse the adjoining district, because underground drains do not exist. The surface and subsoil in many parts of the town is now reeking with foul night-soil. Houses in many parts of the town are not only undrained but overcrowded. Fever is common, and cholera has prevailed." It would appear from the above statement that the existing sewers have been more pernicious than beneficial to the town; however, active measures are now in progress to remedy these evils. Devonport is at present most imperfectly supplied with impure water by a company acting under the powers of a local act passed in 1793. "The works consist of a considerable drainage area, 4467 acres, a portion of which is upwards of 1300 feet above the level of the sea; the mountains around rising to 1800 and 2000 feet above the sea; the district is exposed to south-west winds, which are moist. The company takes the waters of three rivers near their source, West Dart, Cowsic, and Black-brook. The subsoil of the gathering-ground is for the most part decomposed granite, in part covered with peat. Water from the West Dart and Cowsic is beautifully bright and pure; that from Black-brook is discoloured, and in wet weather is turbid: this water flows from a morass of several square miles, which acts as a sponge in very dry weather; on this account the Devonport works can withstand a drought better than the Plymouth works. There are several natural agents which cause the company trouble: in summer evaporation carries off much water, and at all times the subsoil absorbs a great quantity, and in winter frost and snow impede the flow. It is not uncommon for the leat to be buried 20 feet deep beneath snow; on such occasions it occupies many days before the engineer can open the channel. The company, some time ago, wished to construct a large storage reservoir near the town to avoid these contingencies; there had been local difficulties sufficient to prevent their doing so. The total consumption of water from the works, so far as can be ascertained by measurement, is found to be 1½ million gallons of water per day: 800,000 gallons are used by the inhabitants of Devonport, Stoke, and Morice-town; about 351,000 gallons by the government establishments; and the residue by the inhabitants of East Stonehouse. There are about 3,500 tenants; on an average, each house, it is found, uses or wastes about 225 gallons of water each day. The average annual rental for each house supplied is 19*s.* a year; some of the houses are charged 16*s.* a year water rent: the supply is intermittent."

The West Dart river is brought into the Cowsic round a lofty mountain, then the Cowsic is brought into the Black-brook, forming the Devonport leat, which travels round Royal and passes underground for the space of 2000 feet by tunnel, which was under a ridge that separated the catchment-basin of the Plymouth Waterworks from the catchment-basin of those of Devonport. The length of the leat is thirty-five miles, and the elevation of the sources no less than 1300 feet above the level of the sea. The leat is flat until it passes the tunnel, when it passes at Stanlake-bridge, the river Meavy—the main supply of the Plymouth leat. 300 feet of fall is got rid of by a cascade at Stanlake, from which point fall is lost until the leat arrives at Roborough-down, where the leat is flat, and passes underground; then a pretty regular fall ensues, and the leat stands at 600 feet elevation above zero at Jump, six miles from Plymouth, and where any necessary head of water can be obtained. The leat next runs on to Knackerskowle, 388 feet above zero, or 370 feet above high-water mark. The next point is Mill-house, the extreme verge of the borough of Devonport, and at an elevation of 164 feet; the leat then passes round the Mill to the Lines, where it used to discharge itself into the old reservoir in Devonport, 135 feet above the sea. In 1795, the leat was cut, and the water distributed to the inhabitants through hollow trunks of trees; afterwards, one of the Rennies introduced stoneware pipes, which proved total failures, the material not sustaining the pressure, and the joints giving way. In 1820, the company established the present reservoir at Stoke-Damerel, containing 2,000,000 gallons, and supplied by a pipe brought from Brooklands, in the line of the turnpike-road. After taking what the company supposed to be good engineering opinions, a 9-inch pipe, having the immense natural fall, was laid, which proved totally inadequate for supplying the reservoir, not delivering above one third or fourth part of the water from the leat. This reservoir-pipe, and other improvements, cost 16,000*l.* or 17,000*l.* However, the Stoke reservoir enables the company to command the whole of the district of Stoke and the higher parts of Devonport.

The great bulk of Devonport is supplied from an underground reservoir, situated within the Lines, and consisting of three chambers 72 feet long, 13 feet wide, and 9 feet deep; the depth of water was 8 feet. The water is not filtered into these covered chambers, which contain about 157,000 gallons.

The second reservoir, at Outlands, Mile-house, 168 feet above the sea, supplies the Royal Naval Hospital, part of Stonehouse, the Marine Barracks, and the Long-room point. The next point at which water was taken up is at the back of Morice-town, for the supply of part of Morice-town and the Gasworks, and then at Navy-row are small tanks for the supply of the remaining portion of Morice-town,—a most defective method of supplying water to the inhabitants, the water being drawn direct from the leat. Finally, the leat-water is delivered into the Granby covered reservoir, which supplies the government barracks, dockyard, Gun-wharf, Lines, and the whole of the lower portion of the town of Devonport, making altogether three distinct distributing apparatus, worked on the intermitting system. The minimum supply of water in summer time which the leat could obtain was 1000 gallons a minute; in wet seasons it rose to 2800 gallons a minute. The rain-fall on Dartmoor is about 56 inches per annum.

In consequence of the uncertain supply derived from these sources, evaporation in summer, and frosts in winter, when it is no uncommon thing for the leat to be buried 20 feet deep in snow, the company has been anxious to provide an extensive store reservoir in the immediate vicinity of Devonport; but owing to indifference on the part of the manor authorities, and legal dis-

* Extracted from the Report of Mr. Robert Rawlinson to the General Board of Health.

abilities in the way of transferring the freehold of the land selected by them at Brooklands, together with other insuperable difficulties incident to a neighbouring mining company, they have been obliged to abandon the project. The company is now in treaty for another site, sufficiently large to construct a reservoir of five or six acres in extent, so as to provide the town against the consequences of frost and drought. It is also intended to lay down 12-inch pipes by the side of the present 9-inch main from Knackerskowle into Devonport, so as to supply the whole of the consumers constantly and at high pressure.

The situation of the proposed distributing reservoir was to be near the north-east boundary of the parish, and the top water to be about 130 feet above low-water mark on the dockyard gauge. Its clear contents are to be in round numbers 18,700,000 imperial gallons; the total reserve with existing reservoirs would then equal 21,000,000 gallons, calculated to serve the inhabitants and government for thirty-one days. These calculations emanate from Mr. Bampton, and do not appear at all satisfactory to the committee of the Town Council, who produce in evidence against them, the suggestions of Mr. Bampton himself, with respect to the improvements in Plymouth, in which he says, "about eight acres of land would be required for settling reservoirs; this is just the quantity necessary for the single new reservoir at Devonport. The storage reservoirs at Meavy should be capable of affording an auxiliary supply of 1,000,000 to 1,500,000 gallons during four months of the year, to meet the exigencies of dry seasons. Each acre immersed 16 feet on the average, would contain 4,000,000 gallons, or forty-five acres would contain 180,000,000, being adequate to 1,500,000 gallons auxiliary for 120 days. With banks, roads, &c., the quantity required for this storage reservoir would not be less than sixty acres."

In the Report of Mr. Rawlinson to the Board of Health, he says that, "the district in which Devonport is situated affords natural means for one of the best and most complete water supplies; granite mountains, elevation, a great breadth of available land sufficiently near, a moist atmosphere, and an excessive rain fall. Works to bring in water were completed in the time of Queen Elizabeth, and up to this day they remain in a rude, unfinished, and most improper state. Water is taken from open streams after surface contamination: it is conducted to the towns by means of open channels, '*leats*,' contouring hill-sides; passing through farm-yards, cultivated lands, and receiving surface washings, without filtration, from these, as also from adjoining roads. Water, so collected, is distributed for use intermittently, through cast-iron mains and lead service pipes. Filling and emptying the mains produces rust. The open leat admits mud and other contaminating material; light and air produce vegetation and animalculæ, so that at no time is the water fit for drinking. The intermittent mode of supply compels the poor to receive their water in tubs, pots, pans, and other open vessels, which expose it to all the gaseous contaminations of crowded dwellings. The price charged for water so supplied being more than is necessary to collect the springs at their source, and preserve the water pure until it is delivered within each room at high pressure, and by constant service.

"In these remarks it is not intended to cast undue censure upon the existing water company, but rather the more forcibly to draw attention to the subject. Devonport has increased rapidly in population; huge works have been established by Government, and it has become imperative that some improved form of water supply should be established for a population so large and so important. There are many reasons why a public water supply should be in the hands of a popular body. Water is required without stint for washing footwalks, channels, lanes, courts, alleys, backlets, &c.; as also for watering streets and roads, for public baths, and for public wash-houses. A company may sell in bulk for these purposes, and profitably, even at comparatively low charges, if the works have been properly devised and are economically managed. An excessive charge diminishes consumption, fosters discontent, and sooner or later begets successful rivalry. The present company must either sell their works at their value as assessed by a jury, or they must entirely alter their mode of collection, storage, and supply, and reduce their charges. The springs should be taken at their source, the water should be conducted in closed earthenware or cast-iron aqueduct conduits into covered service reservoirs, from which it should be delivered free from contamination by means of proper house services within each house and tenement. Nothing short of this will be satisfactory."

With these remarks we quite agree, and at the same time deplore that the office of supplying the inhabitants of the towns of Plymouth, Devonport, and Morice-town, together with the neighbouring districts, should be entrusted to so many independent and antagonistic bodies of officials and divided jurisdictions, instead of a combined plan being entered into by all, for their common benefit. At present, the arrangements in all these places are most imperfect and unsatisfactory. In the town of Devonport, the annual rate of mortality to 1000 persons is 27; the cholera, in 1849, made fearful havoc amongst the lower class, whose dwellings are densely overcrowded and entirely devoid of drainage. The density of population to houses in Devonport is double that of the average of all England, and the mortality is about 7 in each 1000 over the same average.

The Report sets forth—"That a new and complete system of drainage, a full and pure water supply, and efficient street cleansing, are required; that one local board of management should be established for all municipal and sanitary purposes; that the existing water supply is impure and irregular, and the company's charges unequal and excessive; that the sewerage and drainage is limited in extent and defective in practice, without any systematised plan of procedure; that the present system of cleansing streets and removing house refuse is imperfect;" and recommends the establishment of public baths and washhouses, and proper receptacles for the dead; and also recommends that the mayor, aldermen, and burgesses of Devonport be nominated as the local board of health for the district.

## PERMANENT WAY.

JOHN PYM, *Patentee*, March 29, 1853.

THIS invention consists in constructing sleepers (which are transverse sleepers) of earthenware, slate, stone, or other suitable materials; and of whatever material they may be made, they are formed hollow, instead of solid as heretofore. In order to prevent what is termed sopping, the patentee perforates the bottom or sides, to allow the water to enter the interior chamber thereof, and to run off at either end. To fix the chairs upon the sleepers, where not desirable or practicable to adopt the methods now in use, the sole of the chair is formed sufficiently long to overlap the sides or edges of the sleeper; and the ends of the sole are secured by passing a bolt from side to side, through the sleeper, and fastening the same by a nut, pin, or rivet.

To prevent the jarring of the chair and sleeper, wood, felt, or other suitable material is placed between the chair and the sleeper.

*Claim.*—1. The construction of hollow perforated sleepers, as hereinbefore described; 2. The construction of sleepers of slate and earthenware; 3. The construction of chairs, and mode of fastening the same, as hereinbefore described.

## STEAM-ENGINES.

NATHANIEL CLAYTON and JOSEPH SHUTTLEWORTH, *Patentees.*

THIS improvement consists in placing the working cylinder or cylinders of portable or locomotive steam-engines in a steam-chamber or jacket within the smoke-box, whereby condensation of steam within the cylinder, and radiation of heat therefrom, is effectually prevented.

The form of the steam-chamber or jacket, its position within the smoke-box, and the communication between the steam-chamber and the boiler, may be so disposed and varied as to suit the particular construction of the engine, and the purpose for which it is used,—the best arrangements of which will occur to any intelligent workman. The patentees remark, that they are aware that the working cylinders of steam-engines have been heretofore surrounded by a steam chamber or jacket, and also that the working cylinders of locomotive and portable steam-engines have been sometimes placed within the smoke-box; but they have found considerable advantage to arise from surrounding the working cylinder with a steam-chamber, such steam-chamber being placed within the smoke-box of the engine.

*Claim.*—The combination of surrounding the working cylinder or cylinders of portable and locomotive steam-engines with a steam chamber or jacket, placed within the smoke-box of the engine.

## REVIEWS.

*Lectures on Architecture and Painting, delivered at Edinburgh in November* 1853. By JOHN RUSKIN. London: Smith, Elder, and Co. 1854. pp. 239.

WE are very glad to see this book; we strongly recommend our architectural readers to buy it, for it is a cheap one, and not a very big one, and it will enable them to understand what Mr. Ruskin is, though they are none the more likely to understand what he says or means. We are very thankful to Mr. Ruskin for publishing this book, as it can be read or looked through, while his more ponderous tomes frightened away many a sober reader, who therefore took Mr. Ruskin's reputation by hearsay and on trust from his admirers. This little volume is the quintessence of Ruskinism; it contains in a concise form the doctrines of the great master on the subject of art as exemplified in Architecture, Turnerism, and pre-Raphaelitism; and as it is printed *permissu superiorum*, its authenticity cannot be gainsaid. The papal authority of Ruskinism has issued this bull, and the faithful must acknowledge its infallibility until the said authority again changes the infallible decrees.

This is no inferior work of the great master; it boasts all the vigour of his mind, and is marked with his distinguishing characteristics, and if at other times his effusions have been of greater length, they have never been more authoritative or more precise in their terms. We say that this book shows what Mr. Ruskin is, and the portrait so daguerreotyped is not a flattering one. Whether we look at Mr. Ruskin's conclusions, or the means by which he proposes to arrive at them, the impression is equally unsatisfactory. The unprejudiced reader will wonder how such a man can have been so bepraised and held up as an authority, before which artists and the public were to bow in reverence.

It is in the spirit of cliqueism that we must seek the solution of the riddle. As a University man he received the support of many members of the press on his first appearance as an author, and he has since been bepuffed and belauded by the confraternity of Puseyites in its various sects. In this band of misguided and wrong-minded men, Mr. Ruskin is one of many who, like Newman, Pusey, and others, have united genius with debasing superstition and mystic cant. Then, too, he made his debut cunningly on a subject where, though the *modus operandi* was the canonical one, the end was not recognisable neo-catholic. Mr. Ruskin's homilies on Turner, nevertheless, had all the marks of its parentage,—they were dogmatical and intolerant; they were mystified and mysterious. Even in this day, without fear of exclusion from the fold of neo-catholicism, he can revert to Turnerism, and bring it within the limits of his orthodox works. The public, who would have shrunk back from openly-avowed Puseyism, listened on a subject of art; they admired his eloquence, his subtlety, his fervour, as they would those of a Jesuit preacher. Profiting by this reception, Mr. Ruskin, having got the ear of the public, has proceeded until he is a recognised missionary of neo-catholicism.

Just as the Jesuits of the Roman Catholics adopt various disguises and resort to various schemes, to get access to the population whom they propose to corrupt, so do the Jesuits of Anglo Catholicism. Diverse in means, sometimes conflicting in opinion, their end—that of enslaving the minds of a free people—is the same. One writer advocates the sports of the middle ages, and would lead the flock to the confessional through the cricket-ground, albeit his love of art and nature is not so great as that of some of his brethren.

> "Let *arts* and learning, trade and commerce die,
> But give us still our old nobility."

Some, earnest in points of architectural æsthetics, attach themselves to symbolism, and catch the ears of the unwary country parson, who straightway gives himself up to the vesica piscis, to sedilia, monstrances, and candles lighted or unlighted. Young ladies of pious aspirations, who are content to marry curates and make love to vicars, are led to embroider altar-cloths instead of slippers, and to decorate the church instead of the boudoir. The lover of song is awakened to the horrors of the nasal twang of charity children, and lends himself to the Gregorian chant, little thinking that his part in the play is subservient to that of Pope Gregory himself, whose Hildebrandine pretensions are the real aims of his art-loving leaders. If a man has a love of masonry, they claim him for the freemasons of the church, and persuade him he is restoring an institution of the middle ages which in the middle ages was unknown. The painter is appealed to; the love of mysticism, which in inferior minds stands in the stead of genius, or is the alloy of it, is fostered, and Hunt, Millais, Rossetti, and other like disciples are enlisted. Thus the forms of the middle ages are restored,—and be it not supposed that the spirit is wanting. Pope Gregory the Great will never die while sect or priest exists, and the haughty and overbearing monkery of the middle ages will always find fitting copyists in narrow-minded pedagogues and over-weening parsons. Thus is got together an army of co-operating bodies, neither confederates nor allies, moved by their own special objects, but made to unite in the promotion of one great end, which they are ignorant or heedless that they are fulfilling.

There is one marked characteristic and distinction in all this movement. With all the zeal for the revival of the middle ages in their entirety, there is no desire to revive forms of most national freedom and individual independence, which are the most truly interesting features of the middle ages, which are the germs of our free institutions, and many ancient types of which could worthily be imitated or restored. How little of the spirit of a Dante, a Chaucer, or a Wickliffe enters into the proceedings of the mediævalists; how little do we see of the freshness of genius, of the halestrong vigour of thought, of the noble expansion of mind. What they seek to restore is the slavery of mind from the cradle, the debasement of thought, and its confinement within fetters of which priests indeed bear the keys, but which are never used to unlock. The inculcation of a mind-debasing mysticism is pernicious enough, but to subject the human reason to that ecclesiastical tribunal which for so many ages has warred with free thought, more strongly marks the insidious enterprise for evil. The fate of architecture under such an influence can be only that of the other arts;—the genius of its professors must be unshackled in order to have free scope. Degrading restrictions are however laid down to trammel the aspirant; to one style of architecture his exertions must be confined, and the precedents of the ancients and the dictations of the priest are to be his strict guides. The canons of taste are to be abandoned for the mystical relations of magical numbers and colours and forms, trine and septenary, legends and symbols and types. Against such influences it becomes every well-wisher of architecture to protest, as they can only operate to the retrogradation of art.

In the middle ages, there were holy and salutary influences, there were free and noble inspirations, which ennobled the artist. In the contest of mind against priestly thraldom and superstition, which ultimately resulted in the liberation of a large part of Europe, the poet and the artist were found enrolled on the side of independence, and they were co-operators with the priest in consequence of the latter conceding to the claims and merits of the artist. Had the artist been, as Mr. Ruskin and his fellow-disciples believe and wish, the slave and tool of the priest, we should never have witnessed those noble works which it is supposed the call of the priest can now reproduce.

As a missionary of the neo-catholic system for the enslavement of the human mind, Mr. Ruskin made his appearance in Edinburgh—an enterprise daring in its conception, and craftily carried out. Edinburgh is a place where the morbid horror of popery overcomes the inherent love of the beautiful, engendered among a poetical people by constant association with the most romantic scenery, and earnest sympathy with the works of nature. Mr. Ruskin begins by praising the modern Athenians and modern Athens beyond even the degree of Scotch laudation, and that distribution of mutual and reciprocal praise in which the lowlanders proverbially indulge. On the strength of this glorification, Mr. Ruskin proceeded to pour into the fascinated ears of his auditory the choicest dogmas which distinguish his system; but fortunately he has gone further, and having printed his lucubrations, he has given his dupes the opportunity of scanning at leisure those passages which in their delivery too readily met with acquiescence and acceptance.

Earnest in the propagation of false doctrines, he possesses the zealous spirit which distinguishes many such missionaries, and which gives his style an air of earnestness, impressiveness, and (so far) of originality, as to claim by sympathy the ready concurrence of the unreflecting. By appealing boldly to the prejudices of his auditors, he gains a hearing for crotchets of his own, which pass muster on the credit of their introduction. Mr. Ruskin is necessarily less a reasoner than an advocate,—less a logician than a sophist,—less anxious for truth than for the propagation of a sect and a faith. Many of his assertions are simple concessions to his listeners, and his own system is one of paradoxes and of mystical formulæ. Thus is brought together a mass of contradictions, such as a masked Jesuit can alone parallel. The pre-Raphaelite appeals to John Knox to court his audience, and to the bible because the bible is the superstitious shibboleth of the northern Athenians. An appeal to John Knox the iconoclast comes passing strange from such lips, and the bible appealed to as a standard of thought among the bold spirits of the north affords the Puseyites and mediævalists only a convenient story whereon to string a series of subjects. For a sample we give the following example:—

"Whatever has been advanced in the course of this evening, has rested on the assumption that all architecture was to be of brick and stone; and may meet with some hesitation in its acceptance, on account of the probable use of iron, glass, and such other materials in our future edifices. I cannot now enter into any statement of the possible uses of iron or glass, but I will give you one reason, which I think will weigh strongly with most here, why it is not likely that they will ever become important elements in architectural effect. I know that I am speaking to a company of philosophers, but you are not philosophers of the kind who suppose that the Bible is a superannuated book; neither are you of those who think the Bible is dishonoured by being referred to for judgment in small matters. The very divinity of the book seems to me, on the contrary, to justify us in referring *every* thing to it, with respect to which any conclusion can be gathered from its pages. Assuming then that the Bible is neither superannuated now, nor ever likely to be so, it will follow that the illustrations which the Bible employs are likely to be *clear and intelligible illustrations* to the end of time. I do not mean that every thing spoken of in the Bible histories must continue to endure for all time, but that the things which the Bible uses for illustration of eternal truths are likely to remain eternally intelligible illustrations. Now, I find that iron architecture is indeed spoken of in the Bible. You know how it is said to Jeremiah, 'Behold, I have made thee this day a defenced city, and an iron pillar, and brazen walls, against the whole land.' But I do not find that iron building is ever alluded to as likely to become *familiar* to the minds of men; but, on the contrary, that an architecture of carved stone is continually employed as a source of most important illustrations. A simple instance must occur to all of you at once. The force of the image of the Corner Stone, as used throughout Scripture, would completely be lost, if the Christian and civilised world were ever extensively to employ any other material than earth and rock in their domestic buildings. I firmly believe that they never will; but that as the laws of beauty are more perfectly established, we shall be content still to build as our forefathers built, and still to receive the same great lessons which such building is calculated to convey; of which one is indeed never to be forgotten. Among the questions respecting towers which were laid before you to-night, one has been omitted: 'What man is there of you intending to build a tower, that sitteth not down first and counteth the cost, whether he have sufficient to finish it?' I have pressed upon you, this evening, the building of domestic towers. You may think it right to dismiss the subject at once from your thoughts; but let us not do so, without considering, each of us, how far *that* tower has been built, and how truly its cost has been counted."

From the false position on which Mr. Ruskin first entered, he never escapes, had he even the desire to do so. Empty description and paradoxical assertion form the staple of each discourse. To examine such a work seriously, or to contrast its prepositions, would be an utter waste of labour, and a grievous affliction on the patience of our readers. If there are any Ruskinists among architects, it would be fruitless to attempt to change their convictions; but as architects are men of sense, they need but little to enable them to appreciate the exertions of Mr. Ruskin. With them, Mr. Ruskin is not an authority on matters of art or of taste, nor is he likely to become so, and they will listen to his dicta with more impatience than attention.

After a great deal of parade about what Mr. Ruskin has done and was to do for architecture, and about the new style he was to invent, it turns out that his grand system is, to introduce the mediæval styles in all their completeness; a doctrine which it needed no new expositor to lay before the architectural world, as it was propounded by Mr. Pugin,—so that Ruskinism turns out to be only a new name for Puginism, with the difference that Mr. Pugin was a practical man.

It is very dangerous to quote from Mr. Ruskin what seems to be right, for there is so much error mixed up, that it is scarcely possible to get at anything straightforward. As to give examples of choice *morceaux* of Ruskinism is a waste of print and paper, we hardly know whether we are justified in stating that the following piece of tomfoolery is an exemplification of Mr. Ruskin's theory of style:—

"You must all, of course, have observed that the principal distinctions between existing styles of architecture depend on their methods of roofing any space, as a window or door for instance, or a space between pillars; that is to say, that the character of Greek architecture, and of all that is derived from it, depends on its roofing a space with a single stone laid from side to side; the character of Roman architecture, and of all derived from it, depends on its roofing spaces with round arches; and the character of Gothic architecture depends on its roofing spaces with pointed arches, or gables. I need not, of course, in any way follow out for you the mode in which the Greek system of architecture is derived from the horizontal lintel; but I ought perhaps to explain, that by Roman architecture I do not mean that spurious condition of temple form which was nothing more than a luscious imitation of the Greek; but I mean that architecture in which the Roman spirit truly manifested itself, the magnificent vaultings of the aqueduct and the bath, and the colossal heaping of the rough stones in the arches of the amphitheatre; an architecture full of expression of gigantic power and strength of will, and from which are directly derived all our most impressive early buildings, called, as you know, by various antiquaries, Saxon, Norman, or Romanesque. Now the first point I wish to insist upon is, that the Greek system, considered merely as a piece of construction, is weak and barbarous compared with the two others. For instance, in the case of a large window or door, if you have at your disposal a single large and long stone you may indeed roof it in the Greek manner, as you have done here, with comparative security; but it is always expensive to obtain and to raise to their place stones of this large size, and in many places nearly impossible to obtain them at all: and if you have not such stones, and still insist upon roofing the space in the Greek way, that is to say, upon having a square window, you must do it by a miserably feeble adjustment of bricks. You are well aware, of course, that this latter is the usual way in which such windows are now built in England; you are fortunate enough here in the north to be able to obtain single stones, and this circumstance alone gives a considerable degree of grandeur to your buildings. But in all cases, and however built, you cannot but see in a moment that this cross bar is weak and imperfect. It may be strong enough for all immediate intents and purposes, but it is not so strong as it might be: however well the house is built, it will still not stand so long as if it had been better constructed; and there is hardly a day passes but you may see some rent or flaw in bad buildings of this kind."

As the book before us is strictly a reprint from Mr. Ruskin's lectures, and has engravings from the original illustrations to which frequent references are made, it is further difficult to find passages conveniently adapted for quotation, were we even disposed to take advantage of the opportunity. We are nevertheless tempted by the following:—

"I have hitherto appealed only to your national pride, or to your common sense; but surely I should treat a Scottish audience with indignity if I appealed not finally to something higher than either of them,—to their religious principles.

"You know how often it is difficult to be wisely charitable, to do good without multiplying the sources of evil. You know that to give alms is nothing unless you give thought also; and that therefore it is written, not 'blessed is he that *feedeth* the poor,' but, 'blessed is he that *considereth* the poor.' And you know that a little thought and a little kindness are often worth more than a great deal of money.

"Now this charity of thought is not merely to be exercised towards the poor; it is to be exercised towards all men. There is assuredly no action of our social life, however unimportant, which, by kindly thought may not be made to have a beneficial influence upon others; and it is impossible to spend the smallest sum of money, for any not absolutely necessary purpose, without a grave responsibility attaching to the manner of spending it. The object we ourselves covet may, indeed, be desirable and harmless, so far as we are concerned, but the providing us with it may, perhaps, be a very prejudicial occupation to some one else. And then it becomes instantly a moral question, whether we are to indulge ourselves or not. Whatever we wish to buy, we ought first to consider not only if the thing be fit for us, but if the manufacture of it be a wholesome and happy one; and if, on the whole, the sum we are going to spend will do as much good spent in this way as it would if spent in any other way. It may be said that we have not time to consider all this before we make a purchase. But no time could be spent in a more important duty; and God never imposes a duty without giving the time to do it. Let us, however, only acknowledge the principle;—once make up your mind to allow the consideration of the *effect* of your purchases to regulate the *kind* of your purchase, and you will soon easily find grounds enough to decide upon. The plea of ignorance will never take away our responsibilities. It is written, 'If thou sayest, Behold we knew it not; doth not he that ponderth the heart consider it? and he that keepeth thy soul, doth not he know it?'

"I could press this on you at length, but I hasten to apply the principle to the subject of art. I will do so broadly at first, and then come to architecture. Enormous sums are spent annually by this country in what is called patronage of art, but in what is for the most part merely buying what strikes our fancies. True and judicious patronage there is indeed; many a work of art is bought by those who do not care for its possession, to assist the struggling artist, or relieve the unsuccessful one. But for the most part, I fear we are too much in the habit of buying simply what we like best, wholly irrespective of any good to be done, either to the artist or to the schools of the country. Now let us remember, that every farthing we spend on objects of art has influence over men's minds and spirits, far more than over their bodies. By the purchase of every print which hangs on your walls, of every cup out of which you drink, and every table off which you eat your bread, you are educating a mass of men in one way or another. You are either employing them healthily or unwholesomely; you are making them lead happy or unhappy lives; you are leading them to look at nature and to love her—to think, to feel, to enjoy,—or you are blinding them to nature, and keeping them bound, like beasts of burden, in mechanical and monotonous employments. We shall be all asked one day, why we did not think more of this.

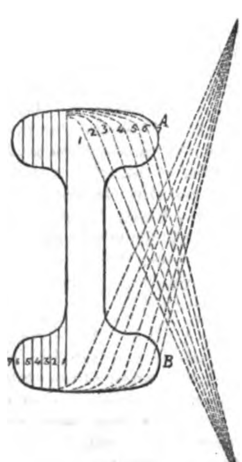
"Well but, you will say, how can we decide what we ought to buy, but by our likings? You would not have us buy what we don't like? No, but I would have you thoroughly sure that there *is* an absolute right and wrong in all art, and try to find out the right and like that; and, secondly, sometimes to sacrifice a careless preference or fancy, to what you know is for the good of your fellow-creatures. For instance, when you spend a guinea upon an engraving, what have you done? You have paid a man for a certain number of hours to sit at a dirty table, in a dirty room, inhaling the fumes of nitric acid, stooping over a steel plate on which, by the help of a magnifying glass, he is, one by by one labouriously cutting out certain notches and scratches, of which the effect is to be the copy of another man's work. You cannot suppose you have done a very charitable thing in this! On the other hand, whenever you buy a small watercolour drawing, you have employed a man happily and healthily, working in a clean room (if he likes), or more probably still, out in the pure country and fresh air, thinking about something, and learning something every moment; not straining his eyesight, nor breaking his back, but working in ease and happiness. Therefore if you *can* like a modest watercolour better than an elaborate engraving, do. There may indeed be engravings which are worth the suffering it costs to produce them; but at all events, engravings of public dinners and laying of foundation stones, and such things, might be dispensed with. The engraving ought to be a first-rate picture of a first-rate subject to be worth buying."

## PERMANENT WAY.

JOHN SHAE PERRING, *Patentee*, August 1, 1853.

THIS invention relates to an improved form of that part of the permanent way of railways called points or switches, and consists in so forming the rails which constitute such apparatus, that they can be turned over and used on either side—that is to say, the two moving or tongue rails are cut or otherwise formed to a pattern which will admit of their being adapted either side up, so that when the one surface is worn out, the other may be brought upward for the carriages to run upon, and in like manner the fixed rails are constructed which constitute the other portions of switches.

The annexed engraving represents an end elevation of one of the switches, *a b* explaining the sections thereof at various points. Upon the figure are marked the several numbers, 1, 2, 3, 4, 5, 6, 7, which indicate the sectional shape of the rail at various points; such sections gradually increase in breadth as the wheels of the carriage lose their bearing upon the fixed rail, that at 7 being of the full breadth. The upper part A, and the lower part B, are of the same form, so that when the one is worn out, it may be turned upside down, and moved to the other side, as from *a* to *b*, which latter being also in like manner shifted, so as to occupy the place of *a*, two new surfaces will be obtained as bearings for the train. The fixed rails *c*, of the switch are formed in the same manner, so that they may be reversed when desired, and present the proper relative shapes to the moveable parts *a*, *b*.



## PREVENTING COLLISIONS ON RAILWAYS.

W. GOSLING, Woolwich, *Inventor*.

THIS apparatus consists of a pendulum attached to the under side of a locomotive tender, which, coming in contact with a stop when turned up on a sleeper, causes it to raise a lever which is placed by the side of the tender. Connecting-rods are attached to this lever, which raise the break, turn off the steam, and ring a bell to apprise the driver of danger. Attached to the driver's bell are wires, which pass under each of the carriages, and by a peculiarly constructed crank the bell can be rung whether the train is travelling on a level or descending an incline, so that the guard or any passenger can immediately give warning to the driver in the event of danger. A lever is also provided on the engine, which is made to act upon every carriage-wheel, so that the train would not pass over more than fifty yards after the breaks are applied; consequently any collision would be prevented.

## TEMPERING, GRINDING, AND POLISHING STEEL, AND OTHER METALS.

JAMES CHESTERMAN, *Patentee*, November 1, 1853.

THIS invention consists—First, in the process of hardening and tempering strips or plates of thin steel, such as saw-blades, &c. The coil of steel is wound into a circular cast-iron case, in the side of which is an aperture through which one end of the coil protrudes. The case is then closed in by a cast metal lid, and placed in the furnace, where it remains until red-hot. It is then removed, and the strip of steel is drawn out through the aperture in the case, and passed between a pair of cold steel, metal, or stone dies or plates, by which it is hardened and flattened. Means are provided for keeping the dies or plates cool. Smaller and thicker lengths of steel are placed in the furnace until red-hot, and then subjected to pressure between two dies or plates, mounted in the manner of a press; the effect of which treatment is to harden the steel and prevent it from warping or buckling. The press is cooled by the application of cold water to it. These shorter lengths are tempered in the ordinary manner, but the thin strips of steel are removed, after passing from the dies, to a stretching table, where one end is secured between screw-clamps, or otherwise, and the other end is clipped between another pair of screw clamps attached to a leather strap, which is fastened to a drum or roller furnished with a lever, weighted so as to produce a gentle strain on the steel. Oil or grease is then applied to the steel, and blazed off by the heat of a portable furnace or gas-light, or other source, which imparts a fine spring temper to the steel, and flattens it at the same time. The steel, after passing from the hardening-dies, may be drawn through a fixed gas-furnace, thus rendering the two operations of hardening and tempering continuous.

Secondly, in the process of grinding both sides of a flat article, or the entire periphery of a circular or similar shaped articles. Upon a central tube or axis is attached a cylindrical grindstone, which is made plain or indented with semicircular or other grooves, according to the shape of the article to be ground. A second similar grindstone is mounted over the first. Rotary motion is imparted to these rollers, and the article to be ground is passed through them in a direction contrary to that of the rollers. When the articles to be ground are flat, the sides of one of the rollers are provided with collars or flanges formed of grindstone, and of larger diameter than the roller, which effects the grinding of the edges as well as the sides of the article when requisite. These rollers are capable of adjustment to the varying thickness of different articles. When one side only of a steel or metal article is required to be ground, a plain wooden roller is substituted for one of the grindstones. Combined with this arrangement are guide-rollers for cross-grinding.

Thirdly, the inventor employs in the operations of glazing, buffing and brushing blades of steel and other metal articles, two similar rollers formed of soft wood, with emery on the surface, or buff leather or bristles, or partly of buff and partly of bristles.

By these improvements, men engaged in grinding will be enabled to stand to their work at a much greater distance from the stones than at present, and in front of the stones instead of leaning over them; they will thereby be less liable to the injurious effects of the stone grit, and more removed from danger in the event of a stone flying to pieces.

## ARCHITECTURE IN THE ROYAL ACADEMY EXHIBITION.

The fine art collections are now in full glory, and first and foremost the "Royal Academy of Painting, Sculpture, and Architecture." We propose conducting the reader, to the best of our ability, through the comparatively small portion of the exhibition devoted to the latter subject, but, before starting, it will be well to get a notion from the catalogue of what we are likely to see,—and what we shall not. This latter clause we may safely add, remembering the experience of past years, and perceiving that the usual complement is this year maintained; and it revives in us the annual wonder at the patience and ingenuity so largely taxed to cram 1531 works of art within the given space. What a pity 'tis that *quantity* is still so much the desideratum, and that in the item of their being hung, though "excessive breadth in frames may prevent pictures obtaining the situation they otherwise merit," a lucking-fitting frame stands a better chance than a good picture of less happy dimensions.

To say nothing of the endless monotony and manifest absurdities which this system occasions, nor of its detracting influence on the subject it professedly seeks to promote: not to allude to the disheartening effect on many a one who chuckled at his good fortune in being admitted an exhibitor, till he descried his favoured effort in some spot over which his familiar eye had repeatedly wandered without its detection, and then, in the depth of chagrin, as heartily wished his work as safely *out* as he had been overjoyed to learn it was *in*:—not to dwell on these matters, if it were only for the sake of the plodding, gazing public who go and pay their shilling, anticipating a feast on the good things before them; and so, beginning with right goodwill at the "Cheetahs" of No. 1, follow on seriatim till a bewildering surfeit comes over them, and they make a hasty exit, with but chromatropic ideas of the pictures they have beheld, but with sensibly stiff necks, aching heads, and strained optics;—we wish it were otherwise. How can the public taste thus be expected to improve, or a relish be created for that art of which they have, generally speaking, but little notion? The necessity for a separate architectural exhibition is every day more apparent. We do not desire to run counter to the Academy; but it is evident that its numbers and predilections so vastly preponderate in one channel, that the other sister-arts (as they are called) are now shamelessly slighted, and must seek to secure some footing of their own. The exclusively architectural exhibitions which have been held, though under many and manifest disadvantages, have shown the disposition both on the part of the profession and of the public to foster such a scheme, and we hear that there is a possibility of the greatest obstacle to its establishment—the want of a permanent gallery—being overcome. At any rate there is to be a meeting of the subscribers and friends on the 7th of this month (June), at the rooms of the Institute of British Architects, in connection with the subject. An annual collection of purely architectural drawings—not showy or tricky ones got up for the purpose—would be instructive, interesting, and easily available, and would especially serve to indicate the current tone of feeling among all parties around.

But to return to our subject. We regret to find that not one of the Architect-Academicians has this year contributed a single production. This argues something bad, even if we infer that they are at length satisfied with honorary distinctions, and content to resign the more active duties to their juniors or less fortunate compeers. Even the worthy Professor himself, whose delightful architectural groupings are familiar to all, has this time given place to another distinguished individual who is not so frequently an exhibitor. The absence of other first architects is much to be regretted. This is an age of architectural transition; the public taste is in the act of formation; and those who ought to form it seem to shrink too much from the *désagrémens* attending the task. Art, it is universally admitted, has a high educational influence upon the mind; and architecture, perhaps, a larger influence than her sister arts, since it is more universally present in the social and religious life of the people. The architect, then, is a public teacher, and when he is invited to come and preach sound principles to the great assembly of art-disciples who come here year by year for instruction, he is surely neglecting a duty when he leaves it to the inferior members of his profession to disseminate meagre or false teaching, without let or antidote.

The architectural drawings are placed in the same room as usual, which once bore a corresponding title; this has been of late exchanged for the more chilly one of "North Room," since canvas paintings are now permitted to overhang and overwhelm our poor paper drawings. However, we are allowed, this year, *three* sides of the apartment instead of *two*.

The most elaborate drawing on the walls is the one to which we have referred, by Mr. Tite, and it appropriately faces the spectator on entering the room. It is (1172) a composition of the works of Inigo Jones, including his full design for the Whitehall palace; views of old St. Paul's, as altered by him; also old Somerset House, Covent-garden and Church, Stoke, Ambresbury, Drumlanrig, Burley on the Hill, Castle Ashby, the Water-gate (London), parts of Greenwich Hospital, St. John's College, Wilton, the Queen's house at Greenwich, Heriot's Hospital, Coleshill, and other houses; and in the distance his mill and Llanwrst Bridge. These form, as will be imagined, a magnificent group, and contain a mine of valuable study. No. 1121 is also an important drawing, and more attractive at first sight than that just named. In it Mr. J. D. Harding has lavished his well-known skill in landscape delineation, to set off the new Crystal Palace and grounds, showing the fountains that are to perform such wonders, and also the restored antediluvian creatures (which look like giants according to the apparent scale of the picture), in and about the lake. Nos. 1168 and 1234 give us more ideas of the fairy scenes to be enacted at Sydenham under the magic wand (or hand) of Sir Joseph Paxton. While speaking of this place, we may mention, that Mr. G. H. Stokes has a view (1152) of the Sheffield Court as it is to appear when complete and fitted up. The Pompeian restorations of Mr. E. Falkener (1173, 1174, 1175,) are beyond all praise for care and delicacy of treatment, and the coloured decorations introduced, "for the general character of which there is abundant authority," are gorgeously rich, yet without gaudiness. The secret of this result we, in England, have yet to learn. Near Mr. Falkener's drawings is one by Mr. M. D. Wyatt (1162) of the Pompeian house now being erected in the Crystal Palace, in which the coloured enrichments form a principal feature. These, which are here cleverly shown, have been in the original "executed under the superintendence of Signor Abbate, of Naples, from tracings made upon the walls of the principal buildings in Pompeii;" so that we may rely on the fidelity of the translation.

There are a great many views of public buildings in course of erection, and of designs for others, a few of which we must notice. No. 1228 is the "Town Hall at Leeds" about to be erected from the designs of Mr. Brodrick. It shows an ample use of columns engaged and detached, both in the building itself, and in the tower which it is now proposed to add. "The Public Rooms and Corn Exchange, Kidderminster, by Messrs. Bidlake and Lovatt," form the subject of (1144). This is a very good Italian composition, and shown to advantage by excellent colouring. The preceding number (1143) is attached to a view of a design submitted in competition for the "Music Hall and Assembly Rooms, Newcastle," and which obtained the first premium of 100 guineas. It is the interior which is shown; it has a dull heavy appearance; partly, it may be, owing to the way the drawing is tinted;—decorative enrichment in colour is not indicated, but it would certainly be needed. There is considerable boldness and better effect in an "Interior, by Mr. E. B. Lamb, of the Exchange and News-room in the proposed Town Hall, Preston" (1135), in which arches in various directions, springing from columns, are judiciously introduced; the room is partially lighted by glazed panels in the ceiling. In (1188) we have an exterior view of another "Town Hall at Wakefield, about to be erected from the plans of G. T. Robinson." This design somewhat lacks identity of character, the front being spread out by long wings which do not explain their purpose; and it is otherwise deficient, especially in sculpture, which the breaks in the attic story decidedly require. There is considerable merit in the "Houses now being built in Ashley Place, Victoria-street, Westminster," and Mr. Ashton's drawing of them (1111) scarcely does them justice. It is a pity the heights of the different floors are so nearly equal, but we know the awkwardness in such cases, as well as the difficulty of combining the whole symmetrically. Had the top story been made less important, and a bolder cornice been used, we venture to think the façade would have been improved. The great feature in the plan (and it shows externally) is the large open staircases, screened from the street by arcades, &c., in continuation of the main line of the front, "on the Scotch principle," as it is expressed in the catalogue. In (1131) "Chambers erecting in New

Cannon-street, J. Belcher," this equality of division in the stories is again detrimental to the design. Another important contribution to our metropolitan street architecture is shown in (1171) "New Warehouses of Messrs. J. and R. Morley, Wood-street, Cheapside, built under the superintendence of Mr. J. Wallew." This is a very fine range of building, reminding one of the similar stately establishments in Manchester. Not far from the last mentioned is the "Australasian Bank, now being erected in Threadneedle-street," of which (1164) is a delineation, by Mr. P. C. Hardwick. This will also be an acceptable addition to our public buildings; but the outline of the plan, and some general features in the design, struck us having been previously carried out in the neighbouring "Sun Fire Office." We do not like the broken entablature against the sky-line, more particularly as there is no attic or other relief above the cornice. Mr. Armstrong's "Public Building, Newcastle-upon-Tyne" (1237) is good; the light and shade which the recessed centre (behind an arch and screened by columns in a line with the main front) secures, is by a simple and very effective scheme. The identical notion is repeated in (1138), by the same author, in a design for the Burslem Town Hall, and which gained a premium. (1224) is another competition design for the Newcastle buildings, by Messrs. Lawford and Heneker, and it obtained the first premium of 100 guineas. We presume this exterior is the companion to (1143), before noticed. There is nothing striking in the general elevation; but could not the subdivisions in the lower story be improved? At present they make what should appear, as well as be, substantial, look liny and weak. Professor Donaldson shows (1206) a scheme for exposing to public view, the sarcophagi of Nelson and Wellington, under the centre of the dome of St. Paul's, by means of a circular opening in the pavement so as to throw open part of the crypt. He styles his drawing—"An Architect's Dream." The idea was suggested, doubtless, by the similar treatment of Napoleon's tomb at the Invalides.

We find in (1137) one of the Gold Medal designs lately submitted to the Royal Academy, by Mr. J. T. Christopher. The subject, "a College, Military Academy, and Asylum for Veterans, in honour of the late Duke of Wellington," is treated on a very extensive scale, and of course with a profusion of enrichments. It forms a very pleasing composition, and the author has done well in following as his models in some parts of the design such men as Wren, Inigo Jones, and Vanbrugh. (1169) is placed too obscurely to be seen critically. It is a "Design for a Metropolitan Horse and Carriage Bazaar, by Mr. R. Suter," a good straightforward elevation, unpretendingly tinted in India-ink. There is no attempt at ornament except two or three bits of appropriate sculpture. (1196) and (1197) are designs for a college (probably in the same competition) by E. M. Barry, and by H. Field. The former is of red brick with white dressings, and on the whole exceedingly good. The centre part, in particular, has been carefully studied, and the turret rising from the roof above is unusually well designed. The other design is more homely and ordinary. (1229) "Cotton Factory Weaving Sheds, R. Rawlinson," has an air of appropriateness and character which looks well; and the same may be said of Mr. Tinkler's "Erris Fishing Settlement, County Mayo, Ireland" (1230). We cannot fall in with Luke Limner's suggestions for the glazing of the "Semicircular end windows of St. George's Hall, Liverpool." The author's name prepared us for something original,—in this case, we think, unsuccessfully; even if we grant, as he intimates has been his aim, that the jointing of the several portions should be mystified as much as possible; since the pattern on the glass is a series of delicate lines more elegantly flowing than geometrically arranged, and so wanting in concentration and evident meaning. In another part of the room (1235) is a "Cartoon, illustrating the true principles of Stained Glass," J. H. Powell, very differently conceived. This is mediævally treated, and, of course, conventionally in some degree. The incident (the offering up of Isaac) is fully told, the drawing good, and, bearing in mind the different uses of stained glass, we are disposed to think the way of handling the materials here shown is altogether the best. (1158) and (1232) are designs for Venetian Palaces—at least so-called;—we suppose because a kind of Venetian window is repeated in every space; otherwise there is an entire absence of the genuine character. (1186) "Design for a Canopied Tomb, G. Goldie," is boldly drawn and tinted, and in the ideas has some praiseworthy originality. As much cannot be said of the design for Congregational Church and Schools (1201), by E. C. Robins; nor for a similar building "now erecting," we are truly ashamed to find, "at Craven Hill, Hyde Park, from designs by A. Trimen (1179). In both these, as well as (1245), by J. James, there is a miserable attempt to mask a sprawling roof of one span by a triply-divided end or front wall; and in the Craven Hill case, the shape of flying buttresses, as if from nave over aisles, is taken advantage of (the wall of course filling them up in reality), while the ridge acts as partial coping to the said roof:—such a perpetration and outrage of principle, we have not seen for a long time. Unhappily (or perhaps by a sly humour, *in terrorem*, if we can suppose the hanging committee to be waggish), the drawing is hung immediately opposite the door! It is refreshing to pass on to (1182), by T. W. Goodman, which, though "In Nubibus," and likely to remain there, is really, setting aside a few extravagancies, a clever conception, and, as we overheard the remark, a decided "inflation!" Possibly this latter word may be applicable also to Mr. Betts's "Design for a Church Exterior" (1242), which we are not skilful enough to criticise.

Mr. F. P. Cockerell has three excellent drawings; the largest (1205) is called "Thanksgiving in St. Paul's after the Victory over the Spanish Fleet, 1718," but is in reality a nearly-west external view. From a glance at the surrounding buildings, we learn that Messrs. Cook's great warehouse was in progress of erection at the time; and the scaffolding here shown was only the other day removed! This beats the one man and boy at the Nelson Column, that *Punch* talks about.

There is a tolerable sprinkling of sketches from abroad, by Messrs. G. P. Boyce, V. P. Sells, H. Jenkins, De Fleury, Druce, and others. Mr. W. Deane has made a very clever view of the "Interior of a Church at Capri, Bay of Naples" (1112),—Mr. Macquoid has two from Spain, viz., "The Doors of Toledo Cathedral" (1193), hung so high that the details, which seem curious, cannot be examined;—and (1218), "The Court of the Lions, Alhambra," very beautifully shown. The architecture is, of course, peculiar; the basins of the fountains have considerable elegance in outline. There are two views of Antwerp Cathedral; one by S. Read (1195), and the other by J. Chase (1220)—both very good; in the former especially, the Cathedral is perfectly detailed. Mr. L. J. Wood exhibits two charming little oil pictures of the Palais de Justice, Rouen (1240); and the Hotel de Ville, Ghent (1244). In (1194), we see a most elaborate elevation of Giotto's "Campanile de Florence" (F. Oliver), which, nevertheless, gives little idea of the real effect.—(We do not say this depreciatingly of the drawing.) "In 1332," as writes Lord Lindsay, "Giotto was chosen to erect it, on the ground, avowedly, of the universality of his talents;" and "the republic passed a decree that the Campanile should be built so as to exceed in magnificence, height, and excellence of workmanship, whatever in that kind had been achieved by the Greeks and the Romans in the time of their utmost power and greatness."

The few old English buildings that have been depicted it will suffice to enumerate:—Lichfield Cathedral, (1125); and York, (1191); Eltham Palace, (1184); Wooton Church, Gloucestershire, (1118); and the North Doorway of Stone Church, Kent, (1217); Tintern Abbey, (1119 and 1222); and Water-Gate Row, Chester, (1126).

We shall call attention to a few other drawings exhibited, of works in progress. We find (1165), Sir Joseph Paxton's "Entrance Court, Mentmore, Bucks, for the Baron M. A. Rothschild," which forms so striking an object in the landscape beyond Tring, on the North-Western Railway. The design is highly enriched Elizabethan of the "John Thorpe" school, and bears also unmistakeable sympathy with Wollaton Hall, near Nottingham. There is a touch of the severe in the exterior of what appears to be the sculpture gallery. "An Artist's Residence, near Windsor, E. G. Pennington" (1104), is, as it should be, picturesque; and the same may be said of (1107), a Mansion at Haverfordwest, by Coe and Goodwin, who also exhibit a view of another Mansion at Bridgenorth (1151), very elaborate, and revelling in Jacobean oddities. Mr. Andrews, whose former beautiful drawings of Somerleyton will be remembered, has a pretty view of the Winter-Garden there, designed by J. Thomas (1163). The architecture seems brought into too violent contact with the slender metal work and glass, and there seems an unsuitableness in the four-columned portico, besides its being heavy;—the glazed domes are well-managed, and very good-looking. "Somerleyton Village" (1120), a series of picturesque cottages and church, the whole designed, we believe, by Mr. Thomas, is the result of that generous liberality for which Mr. Peto is so distinguished. (1106), "Ince Blundell Hall, Lancashire, with the Intended Additions and Alterations, by J. J. Scoles," is a good Italian pile. Gelly Dêg, Carmarthenshire, by W. W. Jenkins (1122), is plain Italian of a very suburban character. Mr. P. C. Hardwick sends (1133), View of the Abbots-Sompting, Surrey, and (1180), Gardener's Cottage at Laverstoke House, both exhibiting considerable piquancy and good taste in design and in the materials chosen, with a strong feeling for the "continental." (1140), "Mansion near Erith, by J. Brooks," is every way the reverse. It has altogether a very poverty-stricken look, with unmeaning features, attenuated mouldings, and pimping battlements. (1203), "Mansion at Harrow, F. Barnes," is not much better. The alterations at Hooton Hall, Cheshire, by Mr. J. K. Colling (1225), are very excellent and judicious. We have only to refer our readers to the engraving in the present Number in corroboration of the opinion. In (1160), Tromer Lodge, Down, Kent, by J. Tarring, the most is made of a very commonplace affair. The tower is the best feature: it rises from the ground, having a circular turret at one corner, which corbels out into a square at the cornice level, and is carried up above the general parapet, finishing in a lead roof.

The "View of Almshouses about to be Erected at Tunbridge Wells" (1204), is better than the ordinary kind of building; the group is effective, and has many good points, showing attention to what are often deemed minor matters, and therefore unimportant, but which, in truth, are often the making or marring of a design. This holds good also with (1150), Mr. Talbot Bury's Almshouses at Lamborne, Berks, which has moreover a thoroughly quaint look; and we must commend the practice which we observe here, and on one or two other drawings, of giving little vignette sketches and plans in further elucidation of a subject.

There are one or two good designs for schools, particularly (1155), one for Cheltenham, by G. F. Bodley. Every detail in this evinces considerable taste and study, and there is an ingenious diversity in the several windows and chimneys. Effect is also gained by varied materials. Mr. Ferrey exhibits but one small drawing, which is of this class;—"Buildings of Brick, for Educational Purposes, in Ireland" (1238). They appear plain, and rather poor in design.

We recognise Mr. Hardwick again in (1161), "The Clergy Orphan School, Canterbury," an important building, which has the merit of, to a great degree, explaining externally the real arrangement. Still, we can scarcely call it a good architectural composition. The large four-light windows, both in the main and dormer gables, coming immediately on the head of puny single-lights, are too crushing, and the succession of these little lancets, which almost touch, and are continued along the whole front and wing of the building close under the eaves, is productive of a marked yet not happy effect. We understand they are to light a series of dormitories; but could not these have been differently planned?

The two drawings of cemeteries and cemetery chapels do not commend themselves to our good opinion. "The Lambeth Burial Ground at Tooting," by Wehnert and Ashdown (1209), is in the worst possible taste in every respect. "The Cemetery Chapels now erecting at Hanwell, by Mr. T. Allom" (1170), cannot be redeemed even by the pictorial talent of the artist.

"The Clock-Tower for the Market-Square, Geelong," designed by James Edmeston, jun. (1239), will attract attention from the novelty of the subject. We have ascertained the following particulars as to its construction. The materials are cast-iron, with terra-cotta and encaustic tiles introduced in the panels. These latter fill in the surfaces between the constructive skeleton, and also serve for varying the colours. None of the tiles are to be glazed. Wrought-iron is wholly avoided, so that there will be no necessity for galvanising, and it is so contrived that the whole will fit and hang together by means simply of sockets, dovetails, &c. The experience and skill of Messrs. Sylvester and Co., have greatly assisted in the practical working out of the design.

The show of churches this year is neither very great nor very good. The most important of these is, unquestionably, (1192), a "South-East View of St. George's Church, Doncaster, as now being rebuilt by Mr. G. G. Scott." This is a drawing which should certainly have been hung on the sight-line, were it only for the amount of beautiful detail it contains; as a picture, it has an unfinished look, and in the situation where it is placed is not so attractive as its merits deserve. Then we have Mr. P. C. Hardwick's "New Church at Deptford" (1134); an exceedingly good design, of "Decorated" character. The tower and spire are well proportioned, and have evidently been well studied. In the belfry-stage, the management of the two lights, having one label carried gable-fashion over both (which allows of a niche in the space thus inclosed), is very good. St. Mary's, Newark, may have suggested the idea. There is something odd about the base of the tower buttresses, which, just above the plinth, jut out sharply and without apparent reason. We observe the like in the other church which the same gentleman exhibits (1176), "Elstree, Herts, as Rebuilt" by him,—a plain, sensible-looking structure. Mr. Norton contributes several drawing;—(1187, 1189), Interior and Exterior of St. Andrew's Church, Somersetshire;" a very good design, only a little too laboured. In the nave-piers and font (which is very tasteful), marble shafts are introduced. (1246), a large church, "Erecting at Bedminster, Bristol," is by the same architect; and so is (1145), a nicely-coloured interior, taken across the building, of the Collegiate Church of Westbury-on-Trym, Gloucestershire, showing the restorations just completed. This seems a very creditable edifice, only that the array of poppyheads on the seats might have been dispensed with. They are uncommon in that part of England, nor do we ever like their appearance. Once more, in (1149), Mr. Norton exhibits a beautiful drawing of a simple Village Church,—Abertily, in the diocese of Llandaff; showing also the surrounding buildings, which include a double group of schools. The whole on a highly picturesque and favourable site.

Mr. E. W. Pugin's (1124) View of St. Mary's and St. Peter's Cathedral Churches, Shrewsbury, is very lofty and long drawn out: it has quite a foreign aspect. The smaller parts are indistinguishable, as, like several other drawings we have mentioned, it is hung too much above the eye. There is a nice Lychgate and Railing lately erected at Horsham, by Mr. Truefitt (1154), in that gentleman's usual taste. (1105) is Woolpit Church, Suffolk, showing the new tower and spire being erected from the designs of Mr. Phipson, of Ipswich. We confess to not liking this design at all. What authority has the architect for a stone spire in a locality where spires are rare in the extreme, and those old ones that do exist (and we fancy we remember such a one at Woolpit) are but little leaden ones a few feet high? The one he proposes to erect is excessively commonplace; and so are his alterations in the tower itself.

In 1177, 1181, and 1210, Mr. Raffles Brown exhibits views of the new church about to be erected at Old Brentford. This is altogether a very fair design, a little *outré* perhaps in such matters as very pointed windows with very short jambs, with very sloping buttresses, and a very slender spire. The doorway to the tower, which is well planned by filling in between the buttresses and forming a curtain wall, is as much too large as the clock-face just over is ridiculously small. We observe there is a double aisle on one side. (1159), Decorations of St. John's Church, Hawarden, Flintshire, R. P. Phillan, show a profusion of colour. . The large columns, which are painted like the "barber's pole," are perhaps the best. The wall diaper is objectionable, since the lozenges are coloured so as to appear sunk prismatically, instead of being surface work only. The pulpit is quite unworthy of the rest of the fittings, especially of the prayer desk, which, with its gigantic angels on each side, holding long tapers so high as to ensure a "dim" if not "religious" light below, is one of the most extravagant notions that can be conceived. Mr. Christian's "Interior of St. Luke's, Marylebone," (1227) is, as usual, cold and correct. The Decalogue &c., take the place of an east window, there being only a small circular one in the gable above, and this is treated spherically inside, to harmonise with the outline of the roof.

We have now gone carefully over our task, jotting down such notes as suggested themselves, and which in a more connected form we have laid before our readers. It remains only to take leave for the present, hoping that another year may bring about a change for the better, both in the character of our Architectural Exhibition, and the mode of its appreciation at the Royal Academy.

---

The Directors of the West of England and South Wales District Banking Company, on the 19th of last month, decided on accepting for their new building at Bristol, the designs prepared jointly by Mr. W. B. Gingell, of Bristol, and Mr. T. R. Lysaght, of London, which is to be carried out under their superintendence. The premium of 50*l*. was awarded to Mr. E. M. Barry, of London; the premium of 30*l*. to Mr. J. Gibson, of London; and the premium of 20*l*. to Messrs. Gabriel and Hirst, of Bristol, for their designs. Upwards of fifty individuals submitted plans for competition.

## INSTITUTION OF CIVIL ENGINEERS.

*April* 25.—JAMES SIMPSON, Esq., President, in the Chair.

THE discussion being resumed on Mr. D. K. Clark's "Description of the Deep-Sea Fishing Steamer, *Enterprise*, with Ruthven's Propeller:" in allusion to the former experiments, it was shown that the power required for the propulsion of the *Enterprise*, at 9½ miles per hour, was 35 indicated horse-power, as estimated by Bourne's formula for resistance, founded on the results obtained by the *Rattler;* this power was nearly what was stated in the paper, (40-horse power,) with which also the stated consumption of fuel was in accordance.

It was argued, with respect to the supposed loss of power in communicating to the water the velocity of the vessel, that, inasmuch as the action of the propeller was in principle the same as if the intercepted water was raised to the height due to the velocity imparted to it, the velocity was only lent to the water, and ready, in virtue of that head, to be refunded when required; and that the necessary engine-power was equal to that which could raise the quantity of water required for propulsion, from the level of the sea to the height due to the velocity of efflux. On these principles, it was calculated from the data contained in the paper, that in the management of the water, exclusive of all frictional resistance, the ratio of power to effect was,

| | | | |
|---|---|---|---|
| The power used | = | 12·28 | horse-power |
| Ditto wasted . | = | 3·94 | ditto |
| Total . . | | 16·22 | ditto |

and it was concluded that there was much to be said in favour of Ruthven's mode of propulsion. The statements as to the former experiments were reiterated, viz., that the power required to communicate velocity to the water passed through the propeller, was not afterwards utilised. For, that assuming a ball to be suspended over the vessel, at a height due to the velocity of the vessel, and moving at the same rate, it was urged, that to raise the ball to that height, and to communicate to it the velocity, would obviously require just double the power necessary to raise it. Assuming the ball to be detached, it would descend vertically, as regarded the vessel, and would act upon it precisely as it would if both the ball and the vessel were at rest; as a consequence, therefore, it would only act with the effect due to the height from which it fell.

As another illustration, it was assumed that the deck of a vessel was level with the surface of the surrounding medium, and that a given portion of fluid was transferred from the medium to the level of the deck; then a certain amount of power would be expended in changing the condition of the water and imparting to it the velocity of the vessel; but as this water would only be at the level of the surrounding medium, it would not flow out again, and the power that had been absorbed would not be again utilised.

It was contended, that the inference from the experiments quoted, viz., that the pressure was double the hydraulic height due to the velocity, was incorrect; for the pressure was measured upon the reduced section of the "vena contracta," which was only five-eighths of the area of the real aperture, upon which area, as had been shown the unbalanced pressure should be estimated, and it was contended that the contrary inference led to inconsistent and anomalous results. But in no respect did these experiments apply to the case of water passing through a tube or pipe beyond the "vena contracta," as the area of unbalanced pressure would then be immediately reduced.

Referring to the experiment quoted in the paper, and assuming the possibility of the reaction pressure being equal to double the height due to the velocity, viz., 23 feet per second, *i. e.*, = $8\frac{6}{10}$ feet; then double that would = $17\frac{2}{10}$ feet + $\frac{9}{10}$ foot (the height of the issue above the sea) would give a total height of $18\frac{1}{10}$ feet; this × 25 feet (the quantity of water per second) and × into 60 (seconds per minute) and ÷ 528 feet (the quantity of water raised one foot high per minute, per horse-power) gave 51-horse power; then adding to that, the loss from the friction of the water in the passages, as stated in the paper, together with the friction of the engine itself, it would appear that the power applied must have been = 80-horse power instead of 40-horse power as stated, and thus showing that the experiment and the inference could not be reconciled.

Again, it was argued, that the useful effect was expressible, simply by the difference of the power consumed, in giving to the water the speed of the vessel and the power in expelling it; that, in the admission and in the expulsion of the water, reacting pressures, measured by twice the head due to the velocities of admission and expulsion, were exerted longitudinally upon the vessel, the difference of these reacting pressures expressing the useful effect. Putting V for the speed of the boat, and V′ for the effluent velocity of the water, with respect to the nozzles from which it issued; then the power expended being taken as unity, the useful effect was found to be represented by

$$2\,V\,\frac{V'-V}{V'^2}$$

which showed, that when the forward speed of the vessel and the effluent speed of the water were equal, there was no useful effect; and that the maximum useful effect was obtained when the effluent speed of the water was twice the speed of the vessel, and when the useful effect was just one-half of the power expended, exclusive of the friction resistance. Whereas, with the paddle or the screw, there did not appear theoretically, any limit to the ratio of the efficiency,—it might be equal to the power, —and in practice it was limited only by the extent of surface which it was convenient to give to the paddle-board or to the screw. Still, the amount of power obtained by the jet was less affected by deviations from the most useful velocity than in the case of the paddle or the screw; and there might be found to be practical advantages which would render the plan of the jet very advantageous in numerous cases.

With respect to the unbalanced pressure of reaction, by the flow of water through the side of a vessel at rest, it was argued that all attempts to explain the subject by reference to hydrostatic principles were fallacious, and that experiment alone could determine the results. Whitelaw, in his account of the reaction water-mill, had shown, by experiment, that the reaction was measured by the weight of a column of water of twice the head when the orifices were at rest.

A recent experiment on the reaction pressure was also described. A cylinder was fitted with a jet pipe in the side, at the bottom, of the form of the "vena contracta." It was suspended from a considerable height, so as to hang freely, and was filled with water, which was kept up to a constant level; when the water was permitted to flow out freely, an unbalanced pressure of one and a half the hydrostatic pressure under that head, was indicated on a balance, applied against the opposite side, as measured on the small section of the "vena contracta."

With respect to the formula, showing that the maximum useful effect was only-half the power expended, it was considered, that the conditions of the formula did not meet the case of a propeller, for it was assumed that the engine-power was available only for expelling the water, and that the mass of the vessel necessarily discharged the duty of taking up the water. Now, the facts were stated to be, that the machine not only discharged the water, but it also previously drew it into the vessel by exhaustion; and it was contended, that, under these circumstances, the maximum effect was obtained when the speed of the vessel was equal to that of the effluent water, and amounted to 100 per cent. of the engine-power, minus friction resistances.

In fine, though much difference of opinion was expressed as to the mode of action and the economy of Ruthven's propeller, it was agreed that in numerous situations the new propeller might be found to possess practical advantages over the paddle and the screw; and that the subject demanded further inquiry and investigation, theoretically and experimentally.

*May* 2.—The paper read, which was "*On Water-Meters,*" by Mr. David Chadwick (Salford), commenced by showing the long-experienced want of a good system of ascertaining the quantity of water delivered by water companies to private houses, public establishments or manufactories, direct from the pipes, without the intervention of cisterns, and under the varying pressures of high and low service, or under the circumstances of intermittent or constant supply. After alluding to the statement in the Reports of the Juries for the Exhibition of 1851 (Class V.), "that no instrument had hitherto been so far perfected, as to satisfy the conditions of a good meter;" the paper gave a list of the patented water-meters from 1824 to 1853, and then proceeded to explain succinctly the several systems hitherto employed under the several classifications of,—

1st. The Diaphragm principle.

2nd. The Water-wheel—the Turbine—the Spiral Fan—the Drum—and their various modifications.

3rd. The Piston and Cylinder.

Of the first-class, the machine of Mr. Parkinson appeared to have been most approved; but it was deficient in sensibility, was accompanied by a noise from the tumbling lever and weight, and was very liable to derangement from wear and tear.

The second class was the most numerous; and among the machines described were those of Mr. Taylor, Mr. Siemens, Messrs. Siemens and Adamson, and Captain Ericsson; which were considered the best. All these acted upon the principle of registering, by the pressure of the water against the vanes of a circular drum, or of a spiral screw, or of a fan. In practice they were all found to permit small quantities of water to pass continuously through the meter without registration, in consequence of a certain amount of force being required to overcome the resistance offered by those parts of the meter in connection with the counting apparatus, before motion could be given to it. An attempt had been made by Mr. Taylor to remedy this defect, by using a gutta-percha drum of the same specific gravity as water; but though the meter thus arranged measured correctly under full pressure, it varied much when either the inlet or the outlet pipe was partially closed. Mr. Siemen's inventions were well spoken of for their ingenuity, but the defect above mentioned equally applied to them. Captain Ericsson's rotary fluid meter was shown to bear a close resemblance to that of Mr. Taylor, and to be liable to the same objections. The reciprocating fluid meter, also by Captain Ericsson, was shown to have been used to some extent in the United States, and to be more effective in its action. Messrs. Donkin and Co's meter, on the principle of the disc engine, possessed a certain degree of merit, but it had not hitherto been rendered practically efficient.

The machines in ordinary use being generally defective, the want was in some degree supplied by the instrument introduced by Messrs. Hanson and Chadwick, of Salford, which was described by us last month in a paper read at the Society of Arts.

In the discussion many water meters were mentioned, and among them the various measuring machines introduced by Mr. Siemens were described, and it was shown that although a single screw suspended in a current of water might allow a considerable quantity of fluid to pass unmeasured, at low velocities, that defect had been counteracted by the addition of a second screw working in the opposite direction, and by a general equilibration of the working parts. That meters of this description had been found to measure water with great accuracy, at all speeds above one per cent. of the maximum speed; but had failed after working during a period of from six to fifteen months, in consequence of the inevitable abrasion of the spindles working under water. To obviate this serious difficulty, which applied equally to piston or to diaphragm meters, the more simple contrivance of a form analogous to that of a Barker's mill was adopted. The water entered the rotating disc of this meter through a contracted funnel, and spreading outward issued through tangential apertures into the surrounding casing. Inasmuch as the outlets would act to some extent in the manner of jets, this drum would revolve proportionately faster at high velocities, to counteract which upright blades were attached to the same revolving portion, giving a resistance in the water increasing as the square of the velocity. A uniform ratio within the limits of two per cent. was thus practically obtained. The only step or bearing of this meter was effectually protected from the water by forming a closed oil chamber at the bottom of the disc, into which there entered an upright stud with a steel point, abutting against a steel plate at the bottom of the chamber. In like manner the reducing wheels of the counter were enclosed in a sealed oil chamber. Out of three hundred meters on this plan, which had been in constant operation, under the most varied circumstances and pressures for about twelve months, not one had failed in the working parts. It was contended, that as the machine had ample power to overcome extraneous resistances, and as the friction had been reduced to a minimum, variations in that friction would not affect the measurement to any sensible degree. The advantages of this meter were its compactness, cheapness, and general applicability, either to waterworks purposes, or to measure the water pumped into steam boilers.

*May* 9.—The paper read was *"A Description of the Sliding Caisson at her Majesty's Dockyard, Keyham, Devon."* By W. Fairbairn, M. Inst. C.E.

The substitution of caissons for the ordinary lock-gates, and their employment for closing the wide entrances of docks, was first suggested in this country by Sir Samuel Bentham; since his time they appear to have been somewhat extensively used, although the objections of occupying a considerable time in having the water pumped out of them, and it being necessary to float them entirely away from the opening, before a vessel could pass, rendered them applicable only for special localities. The great width of opening required for the passage of ships of war, induced a rather general use of such caissons in the Royal Dockyards; and at the new dockyard at Keyham, where it was considered desirable to have the best accommodation for the newest class of large ships, the great breadth of the mouth and the depth of the basin, induced the trial of a new form and arrangement of caisson, which should be of such capacity and dimensions as to resist the pressure of the water, effectually close the entrance, and still be so easy of manipulation, as to admit vessels of war passing into the dock at any state of the tide.

The Keyham Docks were described as extending along the eastern shore of the Hamoaze, immediately below Morris Town; their construction was commenced in 1844, and they consisted principally of two capacious basins, with several entrances or locks from the sea; one of these it was thought desirable to construct in such a manner as to have the power of using it, when necessary, for a dry dock; its dimensions were 260 feet long, 80 feet wide, and 43 feet deep; the inner end, next the dock, was closed by a caisson of the ordinary form, and at the outer end, next the channel, the new caisson was tried. It was designed by Mr. W. Scamp, of the Admiralty, and was constructed by Mr. W. Fairbairn, by whom a description was transmitted to the Institution.

The form of the caisson was that of a rectangular vessel, 82 ft. 6 in. long at the top, 78 ft. 6 in. long at the bottom, 42 ft. high, and 13 ft. 6 in. wide; it was built of wrought-iron plates, varying in thickness from ⅞-inch at the bottom, to ⅜-inch at the top, well supported throughout by an inside framework of angle-iron and gusset-pieces, and by two decks of iron and one of timber for the interior arrangements, but which at the same time imparted great strength to the structure. The plates were connected by "butt-joints," with covering plates attached by double and quadruple rows of rivets, and at the bottom and ends were clothed with oak timber which bedded upon the cill, and against the jambs when the caisson was in its place. The internal arrangements of the caisson were such, that when it was required to withdraw it from across the opening of the lock, by merely opening a valve a sufficient quantity of water escaped from the upper chambers to allow the body to rise a few inches from the bottom cill, when instead of, as in the ordinary system turning it round and floating it away, it was drawn back by chains transversely into a channel or opening in the masonry, at right angles with the lock, leaving an opening of the clear span; and after the passage of the ship, it was drawn across again, and by opening another valve, as much water entered as settled it securely on its bed or cill. This operation was stated to have occupied only eighteen minutes for the passage of a line-of-battle ship, ten minutes for opening and eight minutes for closing. The total weight of the caisson was shown to be 290 tons; it contained 33 tons of iron ballast, and had an internal capacity for 323 tons of water. The mechanical arrangements were minutely described, and the general result appeared to have been very successful; and from the tabular statement of the deflection of the caisson, under the pressure of various depths of water, the structure appeared amply strong for resisting either the dead pressure, or the concussions of the waves which frequently beat heavily against the entrance of the docks.

*May* 16.—The Paper read was *"On the Fatigue, and consequent Fracture of Metals."* By F. Braithwaite, M. Inst. C.E.

Many accidenst, the causes of which have been pronounced "mysterious," having professionally engaged the author's attention, he had carefully examined the circumstances of each, and the condition of the fractured metal in all cases, and at length arrived at the conclusion that almost all the accidents might be ascribed to a progressive deteriorating action, which might be termed the "Fatigue" of metals.

Metal in a state of rest, although sustaining a heavy pressure or strain, as in a beam or girder, and exhibiting only the deflection due to the superposed weight, would continue to bear that pressure, without fracture, so long as its rest was not disturbed, and the same strain was not too frequently repeated; but if either of these cases occurred, a certain disturbance of the particles took place, the metal was deteriorated, and that portion subject to the reiterated strain was so far destroyed that it ultimately broke down. This might also arise from sudden concussions, when the metal was under a certain strain, and those concussions might be caused by the girder being suddenly unloaded.

Several examples were given of accidents of the kind that had been alluded to; for instance, that of a vat in a London brewery, carried on cast-iron girders, by which it had been supported for some years; but suddenly, without any apparent cause, they broke, and killed and wounded some workmen. In this case, it was shown that the girders were not originally sufficiently strong for the load, and therefore the intermittent load of the vat, which was sometimes full and at other times only partially so, and then empty, caused a constantly recurring deflection, and a subsequent corresponding effort to regain its natural position, by which the composition of the metal was disturbed, and fracture ensued.

Other examples of the same nature were given; and it was shown, that the repeated buckling of the tube-plate of a locomotive, arising from the action of the pistons, had a tendency to cause fracture mechanically; and also that the side-strains and vibrations to which the suspension-rods of the ash-pans of locomotives were subjected, had produced very serious results, which it sufficed to point out forcibly to guard against the recurrence of.

The author contended, that presuming adequate dimensions to have been given to girders, and the stipulated weight not to have been exceeded, the chances of accident were remote, but that any repeated deflection, either at intervals, or continued for so long as to induce a permanent depression, must be productive of danger, which could only be averted by altering or replacing the parts deficient in strength, and maintaining a rigid supervision, whether of beams when loaded, or of parts of machinery, or of railway stock after working. By such means, accidents would be prevented, and a greater degree of confidence be established in structures in which metal was employed.

*May* 23.—The paper *"On the Casualties of Tunnelling, with examples,'* by W. M. Peniston, M. Inst. C.E., was in reality a relation of the difficulties encountered in the formation of some tunnel headings through chalk and greensand, under a head of water at Holywell, on the line of the Wilts and Somerset Railway. The materials had been collected from the author's diary of the proceedings, and it had been his intention to give many more details, as practical examples for the younger members of the profession, but with access to the excellent work on 'Tunnelling,' by Mr. Simms, it was feared that the communication might be deemed too prolix. It was intended that No. 1 Tunnel should have been constructed in the usual manner, by sinking shafts, and connecting them by a bottom heading running through between open cuttings at the north and south ends; there were, however, indications from the borings of the ground being unfavourable, the body of the tunnel being in chalk full of faults, whilst the cuttings at both ends were in greensand, and copious springs showed themselves along the line of operations, which were conducted through strata generally dislocated, and not to be depended upon. In sinking the shafts, the water brought away with it such quantities of sand as to create cavities around and produce serious failures in the timbering, which required to be renewed and replaced several times. Numerous contrivances were essayed for overcoming the difficulties—gullets were cut at lower levels, in hopes of their drawing off the water, but the tenacity of the soil and the numerous faults precluded any chance of their being useful; nothing but incessant pumping could therefore be relied upon; but the consequence of this was that the framing of the shaft sunk bodily, until it was retained by a hanging kerbs and rod from the surface; then, in spite of close sheathing planks, a lateral settlement occurred, and amidst a recurrence of these accidents the shaft was carried down until the sand and water rose so rapidly in the bottom, that it was necessary to close it by a timber platform through which the water rose to a certain level, whence it was pumped. Similar difficulties were encountered in the other shafts, enhanced in the one case by the frequent recurrence of boulders of sandstone, which occasioned much loss of time and inconvenience in extracting them, and left large cavities behind the sheathing. The quantity of water also increased so much that the briefest delay in pumping obliged the men to leave the headings.

At length, it being observed that the dip of the sand-rock which was the water-bearing stratum, was in such a direction as to induce the inference that it might be used to convey the water away by having it tapped at a lower level, the attempt was made, and was attended with success. In the subsequent extension of the open cuttings, the numerous vertical faults were shown to have been, in a great degree, the cause of the slips in the shafts.

In consequence of observations on the saturated strata, it was determined to try the effect of a syphon, which was accordingly laid down; it was formed of cast-iron pipes six inches diameter, the short leg dipping into a hole at the bottom of one of the shafts, whilst the long leg extended through the crown heading and terminated in a cistern in the north cutting. By means of a hand-pump at the upper bend, the air was exhausted, and the action was so perfect as to drain the blocks of sand and enable the headings to be completed.

Accounts were given of numerous ingenious contrivances resorted to for overcoming difficulties, and also of the effects of the drainage upon the springs and wells in the neighbourhood. The various machines and devices employed were described in connection with all the tunnels; in fact, the paper was, as it professed to be, a detail of the casualties of tunnelling under circumstances of considerable difficulty, and it was well illustrated by a series of diagrams showing the works in all stages of their progress.

It was announced that the next meeting for the reading of papers would be held on November 14th, until which time the meeting was adjourned.

## THE ARCHITECTURAL INSTITUTE OF SCOTLAND.

The above Institute has resolved to hold an Architectural Exhibition in Glasgow, in December next, which, in addition to views, models, plans, and details of buildings, will embrace specimens of the various works of art and manufactures connected with architecture; such as carpets, furniture, tapestry, paintings, paperhangings, and all painted, carved, and sculptured decorations; painted, stained, and embossed glass; metallic castings, wrought-iron, &c.; marbles, mosaics, fountains, and vases; ornaments in porcelain, silver, cast and cut glass, &c.

We hope that the energetic efforts of this new Institute will be responded to by all interested in the dissemination of a correct taste in the arts of design amongst both manufacturers and the public in general.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated December 15, 1853.*

2911. A. B. Callier, Paris — Improvements in the manufacture of umbrellas and parasols

*Dated January 25, 1854.*

187. J. Petrie, jun., Rochdale, Lancaster—Improvements in apparatus for drying wool after it has undergone the process of washing or scouring

*Dated February 10.*

322. W. Dray, Swan-lane—Improvements in the construction of portable farm and other buildings; part of which improvements are applicable to the construction of cart and wagon bodies and other structures

*Dated March 1.*

499. J. B. Gottung, Hawley-place, Kentish-town—Embroidering on leather for harness and other purposes. (A communication)

*Dated March 4.*

527. C. de Bergue, Dowgate-hill—Improvements in apparatus for bearing and buffing purposes

*Dated March 6.*

533. D. Barr, Sudbrook-park, Richmond—Improved combined hair brush and comb

*Dated March 8.*

549. J. C. Edington, Leicester-square—Working machinery for propelling vessels and firing guns

*Dated March 11.*

588. J. C. Hall, Monkwearmouth, Durham—Improved windlass
594. J. J. Aston, Middle Temple—Improvements in the construction of envelopes

*Dated March 15.*

616. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in heating apparatus. (A communication)

*Dated March 20.*

655. E. Esnouf, C. Mauger, jun., and G. W. Lewis, Jersey—Improvements in portable dwellings and vehicles for travellers or emigrants

*Dated March 24.*

695. J. Jeyes, Northampton—Manufacture of pulp from twitch or couch grass

*Dated March 28.*

712. J. Woodward, Acton-street—Apparatus for stopping shot and other holes in ships and vessels
714. A. Hodgkinson, Springfield Bleach Works, Belfast—Improvements in bleaching linen fabrics
716. H. Francis, West Strand—Improvements in machinery for crushing, grinding, washing, and amalgamating quartz, and other matters containing gold or silver
718. F. Chambon and A. Meyniac, Chaylard, France—Improvements in bleaching or scouring silk
720. E. Rowland and J. Rowland, Manchester—Improvements in the manufacture of certain metallic springs

*Dated March 29.*

722. C. Barlow, Chancery-lane—Improvements in the permanent way of railways. (A communication)

*Dated March 31.*

738. J. M. G. Coste, Passy, near Paris—Revivifying animal charcoal that has already been used, and obtaining by a peculiar process prussiate of potass or soda from it
739. A. D. Brown, Glasgow—Improvements in beds, couches, and other articles of furniture
740. H. Homewood and J. Gregory, Mount-street, Lambeth—Improved fire-escape
741. A. A. Reginald Hely, Cannon-row, Westminster—Improvements applicable in exhibiting artistical, natural, or other objects, on a large scale
742. W. E. Newton, Chancery-lane—Improved manufacture of carpet. (A communication)
743. A. V. Newton, Chancery-lane—Improved mode of manufacturing carpets

*Dated April 1.*

745. F. S. Thomas, Cornhill, and Hook's-villa, Fulham—Improvements in locomotive engines
747. Sir R. J. Clifton, Clifton-hall, Nottingham—Improved percussion-shell
749. A. E. L. Bellford, Castle-street, Holborn—New and useful fabric for boot and shoe soles, machine banding, and other purposes. (A communication)
751. W. Johnson, Lincoln's-inn-fields—Improvements in the treatment or reduction of metallic ores and salts. (A communication)
753. W. Smith, Witney, Oxford—Improved mop
755. W. Kestall, Burnham, Berks—Improvement in fixing or cementing glass to metal

*Dated April 3.*

757. T. Scott, Brighton—Improvements in machinery for propelling
758. J. Forsyth, Caldbeck, Cumberland—Improvements in machinery for preparing and spinning wool and other fibrous substances
759. P. A. F. Bobœuf, Castle-street, Holborn—Application of electricity and fixed or moveable ærostation to military strategy and pyrotechny
760. W. Ashdown, Piccadilly—Improvements in gas-stoves
761. R. E. Hodges, Southampton-row, Russell-square—Improvements in connecting wheels, drums, cylinders, and pulleys with their naves, axes, and the parts thereof one to the other
762. W. Gossage, Widnes, Lancaster—Improvements in the manufacture of certain kinds of soap
763. G. Devincenzi, Grosvenor-street—Improvements in producing ornamental and figured surfaces, and surfaces for printing from, also the hardening or preparing of certain objects to be employed in the process
764. C. Walker, Bury, Lancaster—Improvements in steam-engines, and in apparatus applicable to safety-valves for steam-boilers

*Dated April 4.*

765. J. Gurney, Bradford, York—Improvement in machinery or apparatus for spinning wool and other fibrous materials
766. J. Higgin, Manchester—Improvements in the mode or method of separating metals from each other when in conjunction, and in obtaining useful products therefrom
767. J. Swarbrick, Baxenden, Lancaster—Improvements in steam-boilers
768. J. Bentley, Liverpool—Improvements in breech-loading fire-arms
769. H. Seebohm, Bradford, York—Improvements in preparing and combing wool, goats' hair, alpaca, cotton, and other fibrous material
770. G. S. Parkinson, Westbourne-park-road—Improvements in railway-breaks
771. B. Samuelson, Banbury, Oxford—Improvements in machinery for cutting turnips and other vegetable substances
772. R. Brisco, Low Mill-house, St. Bees, and P. S. Horsman, St. John Beckermet, Cumberland—Improvements in heckling machinery
773. H. Y. D. Scott, Queen's-terrace, Woolwich—Improved mode of manufacturing cement
774. A. V. Newton, Chancery-lane — Improved machinery for raising and forcing fluids. (A communication)
775. F. G. B. Capouillet, Brussels—Improved apparatus for generating heat by the combustion of bituminous or resinous substances. (A communication)
776. J. E. McConnell, Wolverton, Buckingham—Improvements in wheels, axle-boxes, and breaks for railway carriages
777. J. H. Glassford, Glasgow — Improvements in lithographic and zincographic printing

*Dated April 5.*

778. H. Blatter, Paris—Improved mode of constructing thermometers
779. W. Gilpin, Moorgate-street—Improvements in electrical communication
780. G. Ross, Falcon-square—Improved mode of preventing the alteration of bank-bills from one denomination to another. (A communication)
781. W. E. Newton, Chancery-lane—Improved apparatus for printing piece goods or fabrics. (A communication)
783. C. Bekaert, Paris—Improvements in machinery for doubling, twisting, and winding flax, silk, cotton, hemp, wool, and other fibrous substances. (A communication)
784. J. Harlow, Birmingham—Improvements in the manufacture of metal bedsteads
785. S. Smith, Hanover-terrace, Bristol—Improvements in vessels and apparatus used for raising sunken vessels and other bodies in the water, and for lowering materials for structural purposes in water
786. G. F. Wilson and J. M. Whiting, Rhode Island, U. S.—Improvements in the manufacture of wood screws
787. W. R. Gillard, Kirby-street—Improved method of colouring and ornamenting leather, vellum, book-edges, paper, and other like substances employed in bookbinding

*Dated April 6.*

788. J. Weston, Norwood—Improvements in transmitting and applying motive power for propelling railway-trains, ships' boats, barges, and such like vessels, and for other useful and mechanical purposes
789. J. Smith, St. Leonard's-on-Sea, Sussex—Improvements in the construction of railways
790. W. G. Craig, Newport, Monmouthshire—Improved mode of making communications between the commander and the engineer or the helmsman, or other person on ship-board

91. C. de Bergue, Dowgate-hill—Apparatus for acting on water and other liquid, so as to force, displace, or propel the same, or a body floating thereon
792. J. Nash, Thames-parade, Pimlico—Manufacture and refining of sugar
793. S. O'Regan, Liverpool — Improvements in engine-boiler furnaces and other furnaces
794. A. E. L. Bellford, Castle-street, Holborn—Improvements in sewing-machines. (A communication)
795. J. E. Boyd, Lewisham—Improvements in the construction of ships' anchors
796. E. Dupont, Boulogne-sur-Mer, France—Improvements in the manufacture of certain cements
797. J. Yule, Port Dundas-road, Glasgow—Improvements in the machinery for raising minerals from mines
798. J. Chance, Davies-street, Berkeley-square—Improvement in the manufacture of ribs of umbrellas and parasols, and of busks and substitutes for bones of stays and dresses
799. A. V. Newton, Chancery-lane—Improvements in the construction of hot-air engines. (A communication)
800. J. Bernard, Club-chambers, Regent-street — Improved mode of stitching, or uniting and ornamenting various materials, and in machinery or apparatus for the said purpose
801. J. Worrall, jun., Salford, Lancaster—Improvements in the method of bleaching fustians and other textile fabrics, and in the machinery or apparatus connected therewith
802. J. H. Johnson, Lincoln's-inn-fields—Revolving, blowing, and ventilating water-extractor for drying cloth. (A communication from T. F. King, New York)
803. W. Richards, Barcelona, Spain—Improvements in wet gas-meters

*Dated April 7.*

804. T. Williams, Manchester, and S. Ainley and M. Mills, Oldham—Improvements in machinery or apparatus for spinning cotton, wool, flax, or other fibrous materials
805. A. Tylor, Warwick-lane—Improvements in moderator-lamps. (A communication)
806. H. Moss, Mansfield-street, Cavendish-square—Auriferous quartz washing, pulverising, crushing, separating, and amalgamating machine
807. F. R. A. Glover, Bury-street, Westminster — Improvements in two-wheeled carriages
808. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in the preparation of photographic paper. (A communication)
809. L. F. Saugrin, Paris—Improvements in the construction of stereoscopes
810. R. Harling, Clerkenwell—Mechanical arrangements for multiplying power
811. J. Jopling, Bishopwearmouth, Durham—Improvements in preserving the tuyere used for blowing in forge and other furnaces from the action of the fire
812. W. H. Bentley, Bedford—Improvements in irrigators or machines for watering grass and other lands, roads, floors, flowers, plants, shrubs, and trees, and applicable for all purposes for which ordinary watering-pots are employed; parts of which improvements are also applicable to pumps for raising and forcing liquids
813. T. Wood, Ramford-street, Oxford-street, Manchester—Improvements in centrifugal machines
814. J. Rankin, Liverpool—Improvements in machinery for cleaning corn and seed
815. H. B. Condy, Battersea—Improvements in concentrating beer, ale, cyder, wine, and vinegar
816. J. E. Wilson, Great George-street, Westminster—Improvements in the construction of iron girders
817. J. R. Johnson, Stanbrook-cottage, Hammersmith—Improvements in the manufacture of type and other raised surfaces for printing
818. J. H. Johnson, Lincoln's-inn-fields—Alkaline steam-washing apparatus. (A communication from T. F. King, New York)
819. W. Rigby, Manchester—Improvements in machinery or apparatus for engraving metallic cylinders or rollers, employed for printing calico and other surfaces
820. W. Naylor, Norwich—Improvements in locomotive engines
821. W. Naylor, Norwich—Improvements in power-hammers
822. W. E. Newton, Chancery-lane—Improvements in producing stereoscopic pictures, and in the apparatus for exhibiting such or similar pictures. (A communication)
823. T. Whitehead, Leeds—Improvements in machinery for preparing, combing, drawing, and spinning wool, flax, cotton, silk, and other fibrous substances
824. J. Corlett, Luimbres, France—Improved machinery for preparing or scutching flax and other fibrous materials requiring such an operation. (A communication from B. Delatre, Setques, France)
825. A. V. Newton, Chancery-lane—Improvements applicable to the manufacture of weavers' harness. (A communication)

*Dated April 8.*

826. T. Bromley, Liverpool—Improvements in the manufacture of soap
829. W. Worby, Ipswich—Improvements in machinery or apparatus for separating grain from straws, broken-off ears, husks, and other refuse, after being thrashed
830. W. Williams, Park-cottage, Ebbw Vale, and T. E. Williams, Abersychan Ironworks, near Pontypool, Monmouth—Improvements in reverberatory furnaces
831. C. B. Clough, Tyddyn Mold, Flint—Improvements in the manufacture of coffins
832. W. C. Most, Strand—Machine for crushing, pulverising, and amalgamating
833. G. Savage, Stoke-Bruen, Northampton—Improvements in the manufacture of bricks and roofing tiles
834. H. Gilbee, South-street, Finsbury—Improvements in the construction of axle-boxes and axle-bearings. (A communication)

*Dated April 10.*

836. W. Wood, Monkhill-house, Pontefract, York—Improvements in treating animal matters and refuse
837. W. Wood, Monkhill-house, Pontefract, York—Improvements in apparatus employed in the manufacture of cut pile fabrics
838. A. S. Bolton and F. S. Bolton, Birmingham—Improvement or improvements in the construction of steam-boilers
839. A. S. Bolton and F. S Bolton, Birmingham—New or improved method of manufacturing certain kinds of metallic tubes
840. F. L. Bauwens, Pimlico—Improvements in distilling fatty bodies, and in stills or apparatus for such distillation
841. W. L. Baker, Hargreave, Northampton—Improvements in clock, tower, turret, and other like bells

*Dated April 11.*

842. R. A. Brooman, Fleet-street—Improvements in the manufacture of hats. (A communication)
843. Z. Round, Dudley, Worcester—Improvement or improvements in bricks to be used in certain parts of buildings
844. W. E. Brooks, Queen-street—Improvements in valves for atmospheric railway tubes
845. M. Lavender, Princes-road, Bermondsey—Improvements in apparatus for stirring and acting on matters subjected to heat in retorts
847. C. A. Noedl, Upper St. Martin's-lane—Portable vapour-bath
848. J Mitchell, Dunning's-alley, Bishopsgate-street—Improvements in machinery for pulverising, grinding, amalgamating, and washing ores
849. J. J. Peile, Whitehaven, Cumberland—Improved construction of lifting-jack
851. U. Scott, Camden-town—Improvements in the adaptation of elastic material to boots and shoes, and shoes for horses and other animals
852. J. Miller, jun,, and M. Burke, Liverpool—Improvements in machinery for transmitting motive power
853. T. Carr, Liverpool—Improvements in steering apparatus
854. B. Fothergill and W. Weild, Manchester—Improvements in machinery for combing cotton, wool, flax, silk, and other fibrous materials
855. W. H. James, Camberwell—Improvements in marine and other structures

*Dated April 12.*

856. L. Cruger, Washington, U. S.—New and improved mode of attaching propellers to ships and vessels of all classes. (A communication)
857. E. Briggs, Castleton Mills, near Rochdale, Lancaster—Improvements in machinery and apparatus for finishing yarn and thread
858. R. Whiteside, Egremont, Birkenhead—Improvements in treating or purifying wheat and other grain
859. W. Coltman, High-street, Leicester—Improvement in knitting-frames
860. J. Piper, Shoreditch—Improvements in apparatus for affixing adhesive stamps and labels
861. S. Colt, Spring-gardens—Improved machinery for cutting or shaping metals. (Partly a communication)
862. G. Letts, Northampton—Improved mole-trap

*Dated April 13.*

863. S. B. Parker, Deptford—Improved apparatus for consuming smoke
864. E. W. Hansen, Saxe Gotha—Electro-magnetic engraving machine
865. G. Elliot, St. Helen's, Lancaster—Improvements in the manufacture of carbonate of soda
866. A. H. Cox, Ship-street, Brighton—Improvements in coating pills and boluses
867. J. Greenwood, Irwell Springs, near Bacup, and R. Smith, Bacup—Improvements in sizeing, stiffening, and finishing textile materials or fabrics
868. G. Devincenzi, Grosvenor-street—Method or methods of producing engraved, figured, and typographic surfaces for printing and embossing from, and for ornaments; also certain machinery employed therein

*Dated April 15.*

869. J. Griffiths, Moorgate-street—Improved portable measuring instrument
871. H. Meyer, Manchester—Improvements in looms for weaving
872. J. Croisy, Paris—Improvements in machinery for manufacturing bolts, rivets, screw-blanks, railway-pins, and other similar articles
873. T. Lawes, City-road—Improvements in protectors for the head. (A communication)
875. A. Chaplin, Glasgow—Improvements in the application of cast-iron to building purposes
876. P. A. Lecomte de Fontainemoreau—Improvements in priming fire-arms. (A communication).
877. F. Barnett, Caroline-street, Bedford-square — Illuminated furniture, &c., for interior and exterior decoration
878. A. E. L. Bellford, Castle-street, Holborn—Improvements in the manufacture of steel and wrought-iron directly from the ore. (A communication)
879. G. L. F. Tiret, Paris—Improved canvas for embroidering

*Dated April 17.*

880. G. Heyes, Aspull, near Wigan, Lancaster—Improvements in the method of arranging and constructing the gearing or driving-apparatus of machinery, to prevent accidents, and save time and expense in arranging the same
881. T. Hawkins, Northfleet, Kent—Apparatus for creating an upward draught or current of air in chimneys; which apparatus is also applicable to the purposes of ventilation
882. W. Wilkinson, Nottingham—Improvements in the method of and machinery for manufacturing ropes and cords
883. W. H. Bentley, Bedford—Improvements in cannons, guns, and other fire-arms, and in projectiles for the same.
884. B. Fullwood, Bermondsey—Improvements in the manufacture of cement
885. J. A. Smith, Edinburgh—Improvements in the manufacture of explosive projectiles
886. D. Tannahill, Glasgow—Improvements in lithographic and zincographic printing

*Dated April 18.*

887. C. C. Davis, Bath—Improvements in portable blow-pipe apparatus
888. S. Healey, Over Darwen, near Blackburn, Lancaster—Improvements in apparatus applicable to steam-boilers for preventing explosions and saving fuel
889. C. Meason, Warrington, Lancaster—Improvements in supplying fuel and water to locomotive engines, or to the tenders of locomotive engines
890. J. Bernard, Club-chambers, Regent-street—Improvements in the manufacture of boots and shoes, and in the machinery or apparatus connected therewith
891. J. Bernard, Club-chambers, Regent-street—Improvements in stitching, and in machinery and apparatus connected therewith
893. C. Watt, Gloucester-gardens, Gloucester-place, Kentish-town—Improvements in bleaching hemp, flax, and other fibrous substances
894. H. H. Gibbs, Bishopsgate-street—Improvements in the manufacture of nitrate of soda. (A communication from P. Gamboni)
895. J. Frearson, Smethwick—Improvements in steam-engines
896. W. Denton, Addingham, York—Improvements in combing wool and other fibres
897. J. F. F. Challeton, Brughat, France—Machinery for purifying and condensing peat, and also for conveying it

*Dated April 19.*

898. J. D. Pfeiffer, Paris—Improvements in bookbinding
899. M. Poole, Avenue-road, Regent's-park—Improvements in drying and weighing fibrous and other substances. (A communication)
900. J. Kirkham, Tonbridge-place—Improved means of consuming smoke in furnaces
901. J. C. Haddan, Chelsea—Improvements in adhesive stamps and labels
902. J. Jeyes, Northampton—Improvements in the manufacture of pulp suitable for paper-making.
903. J. Briggs, Derby—Means of communicating intelligence from one part of a railway train to another
904. H. Clarke, Lincoln—Improvements in cannons, guns and other fire-arms
905. R. A. Brooman, Fleet-street—Improvements in separating substances of different specific gravities, and in machinery employed therein. (A communication)

*Dated April 20.*

906. T. Vickers, Manchester—Improvements in the manufacture of manure
907. E. Hunt, Walcot-square Kennington-road—Improvements in treating minerals for the extraction of their valuable metals
908. R. Richardson, Great George-street, Westminster—Improved method of joining or securing the joints of pipes
909. J. Pym, Bangor, Carnarvon—Improvements in the manufacture of pipes for the transmission of water and other fluids
910. H. Brown, Halifax, York — Improvements in combing wool, hair, cotton, and other fibrous materials
911. J. M. Reed, Northumberland-street, Strand—Improvements in the treatment of amalgams
912. G. Jones, Sedgley, Stafford—Improvements in landing apparatus to be used in working mines
913. W. Johnson, Lincoln's-inn-fields—Improvements in machinery or apparatus for making bricks or tiles. (A communication from M. A. Julienne, Paris)
914. W. Johnson, Lincoln's-inn-fields—Improved apparatus for discovering the leakage or escape of gas. (A communication from E. A. Maccaud, Paris)

*Dated April 21.*

915. T. Wood and S. H. Heginbotham, Culcheth, Lancaster—Improvements in metallic pistons for steam-engines and pumps
916. F. B. Anderson, Gravesend—Improvements in spectacles and eye-glasses
917. R. J. Crickmer and F. W. Crickmer, Bermondsey—Improvements in cannons and field-pieces
918. C. Cammell, Sheffield—Improvements in the permanent way of railways
919. R. H. Collyer, Norfolk-street, Strand—Improved machinery for crushing or triturating hard substances
920. W. Harcourt and J. Harcourt, Birmingham—Improvements in chamber or flat-bottomed candlesticks
921. S. Minshull and C. Austin, Birmingham—Improvements in securing and fastening the lids of boxes or cases used for packing manufactured or other goods
922. W. B. Stephens, Mark-lane—Improvements in lamps. (A communication)
923. A. Blavier, Chemin-de-fer de l'Ouest, Boulevard Mont Parnasse, Paris—Improvements in locomotive engines

*Dated April 22.*

924. H. B. Barlow, Manchester—Improvements in manufacturing metal nuts, and in machinery for stamping, forging, and punching the same. (A communication)
925. P. J. F. Mouchell, Paris—Improvements in melting, and in treating the ores and metals
926. J. Harlow, Moseley, Worcester—Improvements in the manufacture of paper, pasteboard, and millboard
927. T. F. Finch, Lidbury-street, Worcester—Improvements in the manufacture of buttons
928. J. Gill, Marsala, Two Sicilies—Improvements in apparatus for the distillation of spirituous liquors
929. R. Galloway, Lambeth—Improvements in the construction of furnaces
930. W. Goodchap, Walbrook-house, Walbrook—Improvements in obtaining power by carbonic acid gas. (A communication from H. Greenfield, New Orleans)
931. J. Warren, Old Broad-street—Improvements in the construction of railways

*Dated April 24.*

932. C. E. Blank, Trump-street—Improvements in winding or reeling yarn into hanks. (A communication)
933. D. Buddo, St. Andrew, Fifeshire—Magnetic weather-gauge, to give warning of the approach of gales and storms, &c.
934. C. Hart, Wantage, Berkshire—Improvement in the mode of applying power to combined threshing and dressing machines
935. M. Poole, Avenue-road, Regent's-park—Improvements in washing garments and fabrics. (A communication)
936. J. Wilson, Croydon—Improvements in the construction of portable houses and other buildings
937. W. E. Newton, Chancery-lane—Improved machinery for casting type. (A communication)
938. J. Combe, Belfast—Improvements in machinery for heckling flax and other fibrous substances
939. W. E. Newton, Chancery-lane—Application of a new or improved material or substance to the construction of certain parts of machinery. (A communication)
940. T. W. Dodds, Rotherham, York—Improvements in furnaces and fireplaces for effecting a more perfect combustion of fuel and prevention of smoke
941. J. Davidson, Edinburgh—Improvements in breakwaters
942. W. Blackwood, Arthurlie, Renfrew—Improvements in the treatment and finishing of threads or yarns

*Dated April 25.*

943. R. F. Sturges, Birmingham—Improvement or improvements in joining metals
944. F. L. H. Danchell, Acton—Improvements in obtaining and applying motive power
945. F. A. T. de Beauregard, Paris—Improvements in the manufacture of inks, and in the preparation of papers for receiving the same
946. W. Collier, Weston, Chester—Improvements in evaporating-pans for concentrating solutions of certain acids, alkalies, and salts
947. R. Ellis, and J. W. Martin, St. James's, Westminster—Improvements in the mode of drying or desiccating by the agency of atmospheric air
948. J. Aitken, Douglas, Lanark—Improvements in sawing machinery
949. J. Lawson and S. Dear, Leeds—Improvements in looms for weaving
950. J. Goucher, Worksop, Nottingham—Improvements in propelling ships and other vessels

*Dated April 27.*

951. C. Person, Paris—Improvements in coating with zinc by galvanisation
952. E. Crossland, Rochdale, and T. Boardman, Westhoughton, Lancaster—Improvements in weaving, and in machinery for manufacturing cut pile and other fabrics
953. T. G. Owen, Shrubland-road, Dalston—Improved construction of portable filter
954. W. Gravatt, Park-street, Westminster—Improvement in propelling ships and other vessels
955. J. H. Johnson, Lincoln's-inn-fields—Improvements in revolving fire-arms. (A communication).
956. J. H. Johnson, Lincoln's-inn-fields—Improvements in polishing and flattening metal plates. (A communication from H. Beaud, Paris)
957. Sir G. R. Farmer, Bideford, Devon—Improvements in safety-valves for steam-boilers
958. H. Clarke, Lincoln—Improvements in fire-arms and ordnance
959. R. Green, Sydney-street, Brompton—Improvements in propelling vessels
960. J. Barling, High-street, Maidstone—Improvements in treating the hop-bine, and rendering it applicable to the manufacture of paper and other articles.
961. F. Woodbridge, Green's-terrace, Lower-road, Rotherhithe—Improvements in furnaces

*Dated April 28.*

962. A. W. Gibson, Edinburgh—Improvements in mills for the manufacture of barley and rice
963. W. L. Tizard, Aldgate—Apparatus for roasting and calcining ores and minerals, and separating metals therefrom, which apparatus is in whole or in part applicable to the drying and roasting of malt and other vegetable substances
964. J. Evans, Abbots Langley, Hertford—New manufacture of paper
965. J. Heywood, Ratcliffe-bridge, Lancaster—Improvements in machinery or apparatus for printing yarns

*Dated April 29.*

966. A. M. Dix, Salford, Lancaster—Improvements in apparatus for regulating or governing the supply or pressure of gas as it is conducted from the main to the burners
967. B. Dixon, Birmingham—Improvement or improvements in the joints of measuring-rules
968. J. P. Varlet, Paris—Improvements in obstructing the holes produced by accidents or projectiles in the hulls of ships and boats

*Dated May 1.*

970. J. Porter, Salford, Lancaster, and R. Howson, Manchester—Improvements in forge-hammers
971. E. Briggs and W. Souter, Rochdale, Lancaster—Improvements in treating and preparing silk, and in machinery connected therewith
974. W. Macfarlane, Glasgow—Improvements in waterclosets, lavatories, dust-bins, and public and domestic conveniences.
975. J. Fenton, Low Moor, Bradford, York—Improvements in safety-valves
976. J. Hamilton, New York—Improvements in machinery for crushing quartz and other substances
977. W. R. Palmer, New York—Improvements in the construction of spike threshing-machines, whereby all liability to, and danger of, accident in their use is removed and prevented, and by which the grain is cleansed from chaff, smut, &c., at the same it is being threshed
978. J. Clarke, Leicester—Improvements in knitting machinery

*Dated May 2.*

981. J. Mayer, Burslem, Stafford, and J. D. Kind, Birmingham—Improvement or improvements in attaching door-plates, letters, and figures made of glass, porcelain, earthenware, or other vitreous or semi-vitreous substance to doors and such other surfaces as the same may be required to be attached to
982. A. Truman, Swansea, Glamorgan—Improvements in the manufacture of sulphuric acid when roasting copper ores, and also when burning sulphur or iron pyrites
983. R. Waller, Leeds—Improvements in valves applicable to steam-engines and other purposes, and in apparatus connected with the same
984. W. E. Newton, Chancery-lane—Improvements in moulding, preparing, and finishing articles and fabrics made of compounds of caoutchouc, gutta-percha, and other substances. (A communication)
985. C. Minasi, Brecknock-place, Camden-town—Improvements in apparatus for hatching eggs, and for raising or rearing the young when first produced
987. G. Die, Paris—Improvements in the manufacture of tracing-cloths and tracing-paper
988. D. Plisson, Paris—Improvements in chemical condensing apparatus
989. L. Gluckman, Sackville-street, Dublin—Improvements in effecting electric communications in railway trains and vessels
990. B. Bishop and J. Dyer, Birmingham—Improvements in the manufacture of stop-butts and other hinges

*Dated May 3.*

991. T. Main, Glasgow—Improvements in steam-engines
992. J. H. Johnson, Lincoln's-inn-fields—Improvements in lathes for turning wood and other materials. (A communication from A. Warth, New York)
993. W. W. Richards, Birmingham—Improvement or improvements in loading certain kinds of fire-arms
994. A. E. L. Bellford, Castle-street, Holborn—Improvements in grinding-mills. (A communication)
995. E. H. Rascol, Catherine-street, Strand—Improved connection for driving straps, bands, or belts. (A communication from Mdlle. M. Convents, Nancy, France)
996. M. Poole, Avenue-road, Regent's-park—Improvements in paving or covering the surfaces of roads, streets, or ways. (A communication)
997. W. H. Knapp, Cross-street, Islington—Improvements in the manufacture of hats and bonnets

*Dated May 4.*

999. E. Barlow, Bolton-le-Moors, Lancaster, W. Johnson, Farnworth, Lancaster, and W. Slater and P. Knowles, Bolton-le-Moors, Lancaster—Improvements in machinery for preparing and spinning cotton and other fibrous materials
1001. J. Nasmyth, Patricroft, near Manchester—Improvement in the process of puddling iron

*Dated May 5.*

1003. H. Stewart, Baker-street, Bedford-square—Pocket-protector and pocket
1005. F. C. Hills, Deptford—Improvements in the means of preventing or consuming smoke in furnaces
1007. A. G. A. Martin and C. Lefol, Paris—Improvements in the manufacture of iron wheels
1009. J. Wonfor, Bridge-street, Blackfriars — Improvements in the manufacture of manure
1011. V. Wanostrocht, Great Tower-street — Improvements in the construction of cannon, and in projectiles to be used therewith. (A communication)

*Dated May 6.*

1012. T. W. Gibson, Thomas-street, Stamford-street—New beverage, intended to be called "Gibson's pinerium, or aerated sarsparilla"
1013. E. J. M. Archdeacon, Walworth—Improved book-mark or index
1014. B. J. La Mothe, New York—Improvements in the construction of buildings
1015. J. G. Jennings, Great Charlotte-street, Blackfriars—Improvements in the manufacture of earthenware pipes for drains and sewers
1016. B. J. La Mothe, New York—Improvements in the construction of railroad cars
1017. J. G. Jennings, Great Charlotte-street, Blackfriars—Improvements in apparatus for regulating and supplying water for waterclosets and other purposes
1018. H. G. Drewe, Paddington—Improvements in obtaining metal from ores
1019. R. Waller, Leeds—Improvements in engines and apparatus, and means of obtaining motive power from liquids, vapours, gases, or air; parts of which invention may be applied also to ordinary steam or other engines
1021. C. Cammell, Sheffield—Improvements in buffer, draw, and bearing springs for railway carriages, and in the mode of or apparatus for making the same
1023. J. H. Higginbotham, Ashby-de-la-Zouch, Leicester—Improvements in the valves and apparatus connected with waterclosets; certain portions of which are applicable as cocks or valves for other purposes

*Dated May 8.*

1025. J. Jefferis, Grove, Southwark—Improvements in packing for pistons, piston-rods pumps, joints of pipes, and other like purposes
1027. H. M. Naylor, Birmingham—New or improved instrument for cutting various articles of food
1029. G. B. Goodman, Salisbury-place, New-road—Improvements in apparatus for holding together letters, music, and other loose sheets. (A communication)
1031. T. Lemielle, Bruxelles, Belgium—Improved apparatus applicable to the ventilation of mines, buildings, and other places

*Dated May 9.*

1033. W. B. Adams, Adam-street, Adelphi—Improvements in rails for railways, and modes of connecting and fixing them
1035. C. Liddell, Abingdon-street, Westminster—Improvements in moving boats on canals and rivers
1037. A. V. Newton, Chancery-lane—Improvements in the manufacture of artificial stone for building and other purposes. (A communication)

*Dated May 10.*

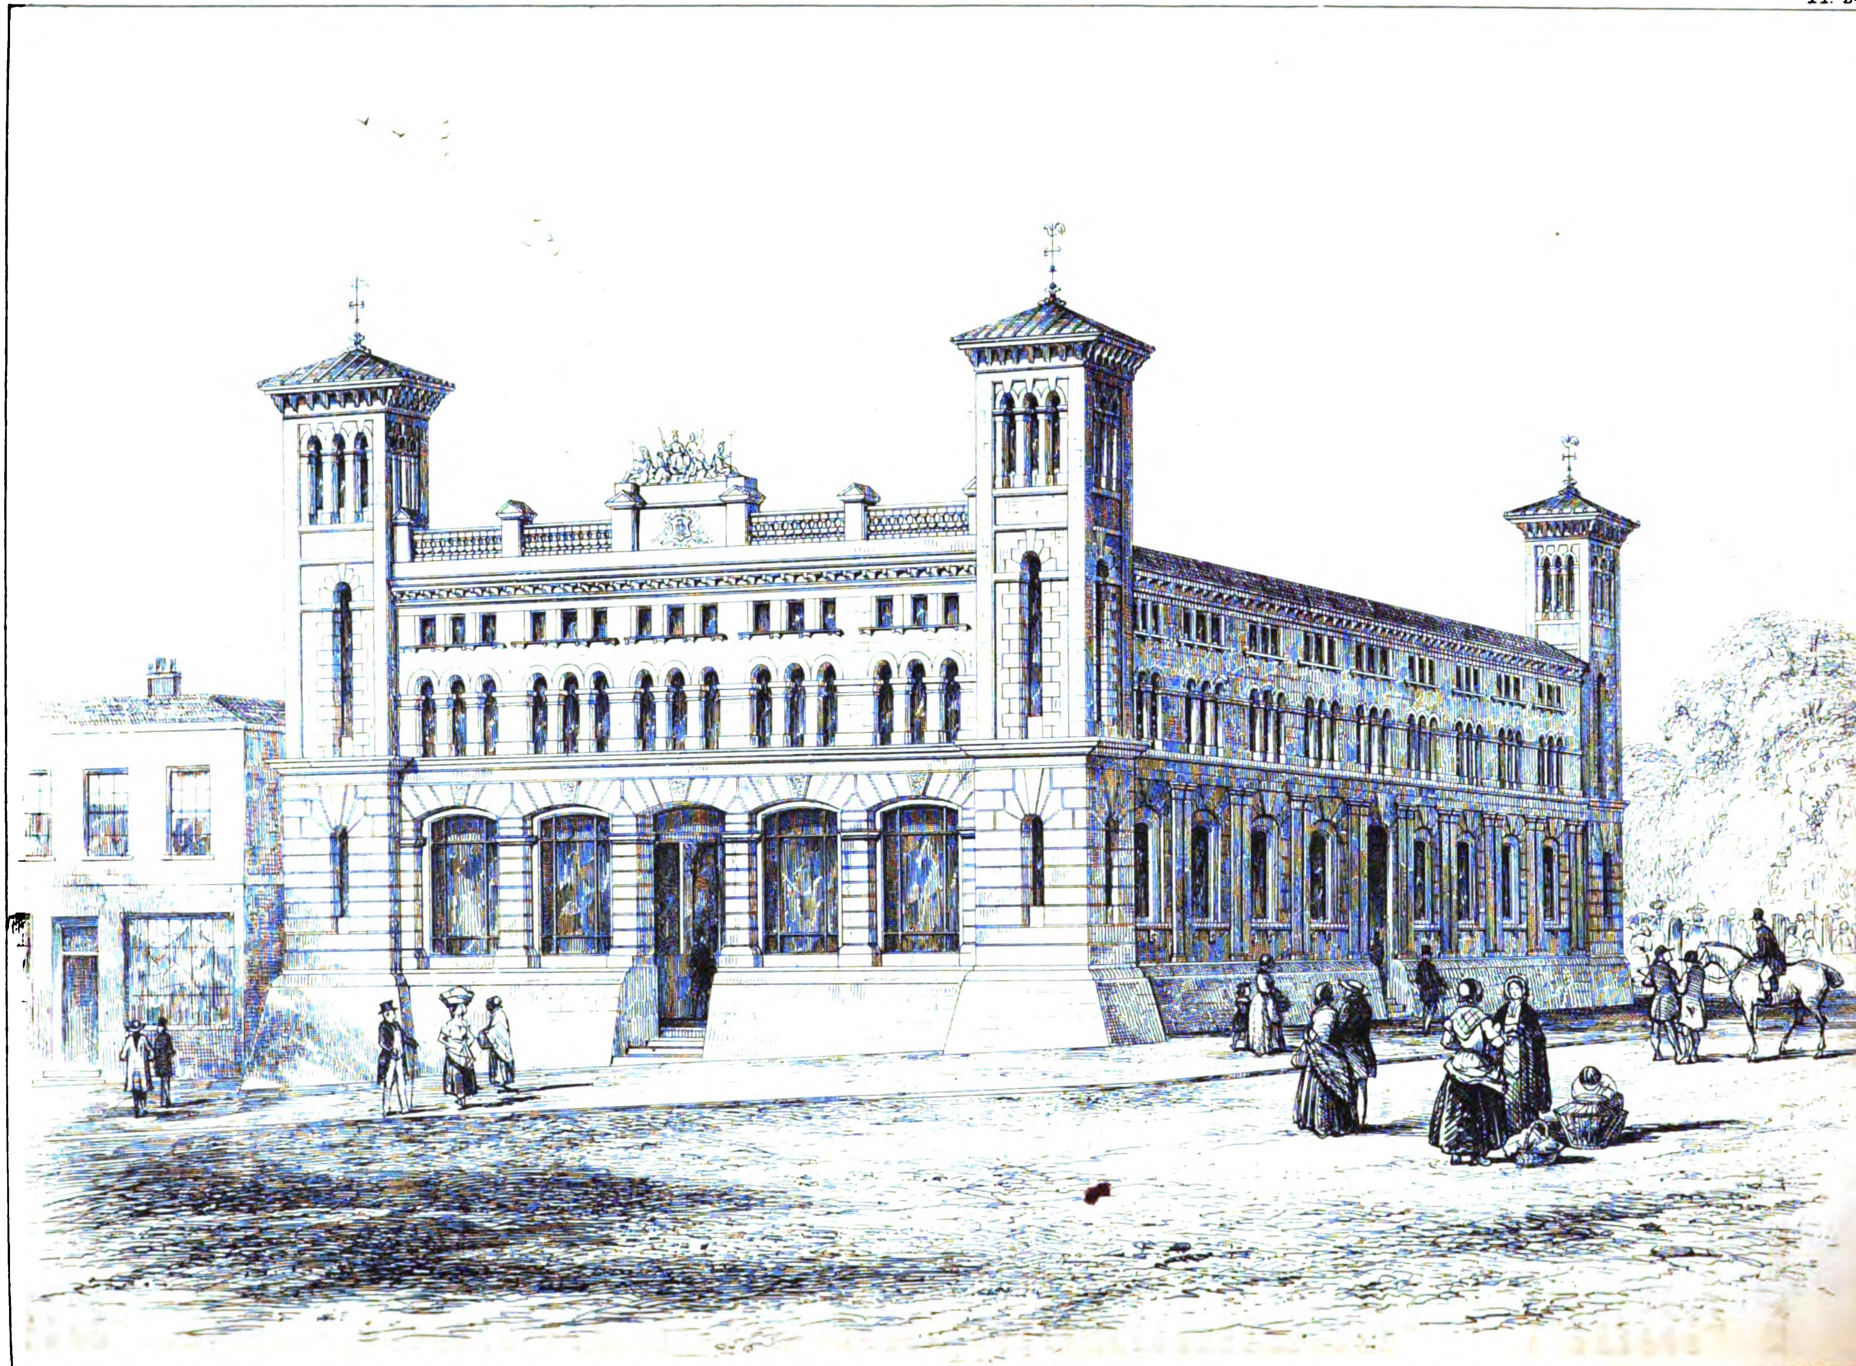
1039. W. C. Fuller, Bucklersbury, Cheapside—Improvements in the adaptation of india-rubber springs
1043. W. Williams, Dublin—Improved propeller
1045. J. Lawson, Glasgow—Improvements in drawing ships out of water. (A communication)

---

## PATENTS APPLIED FOR WITH COMPLETE SPECIFICATION.

870. W. Ridgway, Hanley, Stafford—Improvements in the construction of ovens and kilns.—April 15
1086. F. East, Warminster, Wilts—Taking photographic views and portraits in the open air by means of vertible machinery attached to a cubical box, by which the changes are seen, and the light and the time of exposure regulated

Pl. 24.



NEW MARKET BUILDINGS, NORWICH

## NEW FISH AND POULTRY MARKETS, NORWICH.

(*With an Engraving, Plate* XXIV.)

The general plan is rectangular. The external buildings will be occupied by shops and residences for parties connected with the markets, while the interior area will be arranged similarly to the markets at Birkenhead; the whole being roofed in by a semicircular iron and glazed roof. A gallery will probably be formed round the interior. White brick, with Caen or Bath stone dressings, will be used in the erection.

A description in detail of these Markets will be given in our next number.

## THE CRYSTAL PALACE, SYDENHAM.

### ARCHITECTURE OF THE SEVERAL COURTS.

Much as has been said and written in reference to the marvellous building just reared at Sydenham, there are few persons but will confess, on its actual survey, that, even in its present state, the half has not been told. The prototype to a great extent, and no small portion of the materials, it is true, have previously existed in Hyde Park; but the general proportions, features, and internal arrangements, have been so vastly modified that the eye at once approvingly detects the difference. The experiment of the one case has resulted in a near approach to perfection in the other. In place of the rectangular forms so monotonously repeated in the former work, the outline is here most agreeably varied by the addition of two transepts, which picturesquely break the sky line; and, with their accessories, greatly help the perspective lines of the building, as well as the play of light and shade. Let us add, too, that in these, as well as the main roof, the *arch* form has been adopted, profiting by the only redeeming feature (in point of design) which the Great Exhibition structure presented; one, by-the-bye, not included in the original scheme, but suggested by an architect during the progress of erection.

It is a cause for national pride, to be able to point to a great fact like the Crystal Palace as the result of private enterprise appealed to in the interests of civilisation, and to reflect that the project has won the favour of royalty, the sympathy of general opinion, and hearty co-operation among all classes of distinguished men. And as the chairman of directors gracefully added on the inaugurative occasion, "the liberality of foreign governments opened every museum, and afforded facilities never before known, for acquiring a complete series of the finest works of ancient and modern art. The educational object embraces a complete historical illustration of the arts of sculpture and architecture, from the earliest works of Egypt and Assyria, down to modern times, comprising casts of every celebrated statue in the world, and restorations of some of its most remarkable monuments." It is this latter department in which we, as architects, are most interested, and to this will our further remarks be directed as we journey through the several courts, to examine a few of these *re*-creations, and also the modern creations in which they are enshrined.

Fain would we linger awhile on the threshold, to gaze over the parterres at our feet, so beautifully diversified by wood and water,—fain would we creep down to the lakes to try and comprehend those fearful-looking monsters that find place on their margins;—our fingers itch to record some of the curious statistics of the building itself; its vast dimensions, all based on the multiple of the datum 8,—its ingenious construction,—its brilliant colouring,—and the admirable adaptation of the whole to its purposes;—but we must forbear, and enter at once upon our task.

The Architectural and Industrial Courts are ranged on each side of the nave, and occupy its whole length, except where interrupted by the transepts: the space along the centre of the building and great transept being devoted to a promenade, which is terminated at each of the extreme transepts by a large fountain. For the sake of convenience our route shall be in the order in which the courts are placed in the building, beginning on the west side of the nave, at the south end, where we find

*The Pompeian Court.*—This is a complete reproduction of a Pompeian house, carefully—nay, exquisitely—detailed from a variety of authorities. The prevalent arrangement of these plans is a very curious one. From the entrance doorway there is a narrow *prothyrum*, or passage (on each side of which is a room devoted to the doorkeeper and slaves), by which we are conducted into the large area, or *atrium*, the part of the building common to all visitors. The central portion of this is open to the sky, and in the pavement is a basin (*impluvium*), of a size corresponding with the aperture, to receive the rain which falls from above. To conduct this, the roof converges from each wall of the area, and is carried by elegant brackets. Round the court are arranged the *cubicula*, or bed chambers (little, dark apartments), and the *alæ*, or wings, where business was transacted. Proceeding onwards, we come to the more private part of the house, in the centre of which is the *tablinum*, answering to our modern drawing-room, and on each side is a passage, the whole communicating with a spacious *peristyle*, and apartments belonging exclusively to the master of the house or his special guests. The exterior of this house is very simple in design, and gives little notion of the gorgeous fancy displayed internally. Here the utmost delicacy of tone in the decorations is preserved, the arabesques being painted almost uniformly on a dark ground on the lower part of the walls, above which the usual ground is, like the atrium, quite light, or even white. The columns of the peristyle must not be overlooked. The order is a kind of Ionic, the lower part of the shaft plain, and coloured deep red, the remainder fluted, and white; the whole standing on a shallow plinth, coloured green. Mr. Digby Wyatt and Mr. Falkener's excellent drawings in the Royal Academy illustrate our subject; and to the investigations of these gentlemen, as well as Messrs. Cockerell, Gell, Mazois, Donaldson, Hayes, and Zahn, we are indebted for all the practical conclusions displayed in this interesting building. Retracing our steps into the nave, we next enter

*The Sheffield Court*, exchanging the marble and tesseræ for iron and glass. This court, like many others in the building, is as yet quite unfinished, and, consequently, it is only possible to form an approximate idea of the intended effect; and this must be our apology in such cases, if the design be misunderstood, or if future experiments shall have suggested alterations. The architect of this court (Mr. G. H. Stokes), exhibits an interior view of it in the Royal Academy. Externally the design is effective, without adhering to any particular rule. It occupies the full height, up to the constructive girders of the gallery, of the building, and is divided into two ranges, the lower being large square compartments, entirely filled in with plate looking-glass; and the upper subdivided by a series of open arches of Moorish character, resting on slender iron columns. This story is profusely enriched by gilding, relieved by blue, red, and chocolate. The detail of these ornaments has been well studied. Between the two stories is a long horizontal strip or series of panels, painted a deep blue, which connects the parts and tells very well in the general composition. A word of commendation is due, too, to the design of the little open metal brackets in the angles of the doorways. We have said that this elevation reaches up to the girders, which are (as in the old building) deep and open, strengthened by diagonals between the flanges. This construction is now being masked, above the arcade just mentioned, by glass panels corresponding with those at the bottom,—but, as we submit, to the detriment of the general appearance. It looks flat and heavy, compared with the *open* ironwork, which might have been slightly decorated, so as to be in keeping with the light ironwork just below. Adjoining this court is

*The Birmingham Court*, designed by Mr. Tite. There is no novelty in the architecture, the detail of which is decidedly poor, especially inside. The nave façade consists chiefly of a cast-iron screen, in the spirit of those so much in vogue during the 17th century: this is both well conceived and executed. In the centre is the entrance to the court, between pilasters of enamelled slate (!) having heavy bronze Corinthian capitals, and shallow, liny bases, which rest on an ornamental cast-iron dado filled in with slate panels. This slate is a perfect deception: how far such deceptions are allowable, we stop not here to consider. The framework of the interior is quite tame, nor do the decorations by Mr. Sang please us so much as many we have seen from his hand. The upper part of the wall surface above the—cases of goods, we presume, for the work is incomplete—is divided into panels of a light ground, on which are paintings, in encaustic, of alternately vases of flowers and picture groups. The architrave above is plain, and, with the cornice, far too shallow. The frieze is filled in with scroll ornamentation on a very dark ground, giving it a coarse look. We are sorry our great manufacturing town should be so unworthily represented.

*The Stationery Court* presents at least a *contrast* to the one we have just left, but outside is not very prepossessing. Instead of the open screen of the Birmingham Court, there is one flat surface, dull in colour, and disguising the material, which turns out to be wood. In the stately entrances, however, though architectural rules are little attended to, a species of Cinquecento ornamentation is used with good effect. The tone of the colour is rich and agreeable, while narrow crimson diaper-panels introduced between the pilasters add richness to the composition, as does also the coloured glass of the windows above. The inside decoration is excellent, and worthy of its designer, Mr. Crace. There is a kind of lean-to (that is to say, lean-*from*) roof, in the way we have described over the Pompeian atrium, but not so well managed. Its covering appears to have no thickness, while the supporting brackets are needlessly heavy.

We now cross over the main transept, continuing on the same side of the nave, to the Architectural Restorations, and Fine Art collections, which form an invaluable series. On entering the first of these—

*The Egyptian Court*, an indescribable feeling takes possession of the beholder. We approach it from the nave by an avenue of lions (cast from the immense granite ones in the British Museum), and see before us the outer walls and columns of a temple, against which are eight gigantic statues of Rameses the Great. Turning to the left is a colonnade of early date and simple character; whence we pass into a dark tomb, also with columns, the date supposed to be about 1660 B.C. The original is cut in the *solid* chain of rocks, bordering on the Nile. Following on, we come to the other side of the colonnade before noted, encountering a forest of massive shafts, so closely planted that one can scarce thread between them, and covered with mysterious hieroglyphics, papyri, palm and lotus leaves, birds, and human figures, blended, banded, and entwined in the most odd-looking combinations. But we look through this outward medium to its, to us, hidden purpose, when hieroglyphics were the only written language, and these on the most conventional system, when historical events were handed down by bas-reliefs and sculptured representations, and the whole scheme of art, awful as it was, yielded to the austerities of a stern hierarchical religion. Yet, says Mr. Bonomi in his instructively-interpreting hand-book to this court, "the vast scale of the monuments of Egypt, compared with the space at our command, absolutely prevented any attempt at the reproduction of a single monument, or even a portion of one, of the *real* size. The monuments forming the 'Egyptian Court' must therefore be regarded *as models on a considerably reduced scale*."

Well may we retire in wonder, musing with the poet—

"———— How strange the story
Of Thebes' streets three thousand years ago;
When the Memnonium was in all its glory,
And Time had not begun to overthrow
Those ancient piles, and monuments stupendous,
Of which the very ruins are tremendous!"

*The Greek Court.*—From Egypt to Greece the transition is easy and natural. The fundamental principles of the one may be readily traced in the other,—but improved, added to, and perfected. The Greek Courts are placed, according to the chronological position of Greece in history, between those of Egypt and Rome; and the mode of junction, so abrupt and uncompromising, might give occasion for remark were we disposed to carp at trifles. Suffice it to say, that while to each department has been allotted a certain space, that space has not been found too great, and so if one group rather ungraciously elbows its neighbour, it is a fault of necessity and not of choice. The arrangement of the Greek area is very simple. It is screened off from the nave by a plain wall, pierced by three openings conducting to the interior. These openings are flush in the thickness of the wall, and consist in each case of distyle columns *in antis*. The order throughout is Doric, of the proportions in the temple of Jupiter at Nemea, which is less massive than some other examples. Instead of the triglyphs and metopes so usual in this style, the frieze of the façade is decorated with wreaths, alternating with the names of the ancient Greek cities renowned for their connection with the fine arts. There is an appropriate inscription on the architrave over each entrance.

The central entrance opens into the principal court. This is square, and being flanked by porticoes, resembles the ancient *agora* ('αγορα), or place of public assembly, answering to the Roman forum or market place. Here the same architectural features are preserved as in the front, also the frieze (of a rich blue colour) is enriched by wreaths, &c. in the like manner. There is an extraordinary degree of chaste purity in every detail and ornament; it can scarcely be surpassed. This court and the side porticoes communicate with a large gallery, principally for bas-reliefs, which fills up the remainder of the allotted space. Down the centre of this is a series of square antæ, giving the visitor another specimen of Greek architecture. The coffered ceilings, too, will not be unobserved. With a well-earned commendation of the very beautiful model of the west front of the Parthenon, nearly one-fourth the size of the actual structure, in which the minute architectural refinements discovered, chiefly by Mr. Penrose, have been accurately reproduced under his direction, our architectural notice must close. We cannot, however, but cast an admiring glance on the surpassingly lovely collection of sculpture around, in which nature, a faithful adherence to nature alone, reigns supreme. It is stated that this collection "is to be regarded as one in comparative infancy;" yet, however inexhausted may be the sources, or tempting the subjects, we would suggest that the additions be not so numerous as to disturb the sympathetic repose which now pervades this charming spot; where the gazer may feast in rapture on the choicest monuments of art, examine their individual beauties, and find new delights at every turn. Regaining our place in the nave, we discover

*The Roman Court* immediately contiguous, presenting, as a front, a portion of lower story of the Coliseum at Rome, about two-thirds the size of the original. In this elevation we find the great distinguishing mark of Roman architecture, the semicircular arch. This feature, as a decoration to buildings, has until very lately been considered peculiar to the Romans, nevertheless it was long known to the Egyptians, and consequently to the Greeks, but not used by them for any external purposes. This portion of the Coliseum is of the Tuscan order, whose columns are therefore here introduced. There is an appearance of heaviness in this screen, not a little owing to the plainness of its parts, and the unrelieved dulness of the material (an imitation of dark marble). The internal apartments are enriched with polychromy; and rare marbles, porphyry, and malachite, are also copied. The ceilings have been painted and decorated in accordance with remaining examples at Rome, such as Raffaelle, Giulio Romano, and Giovanni da Udine delighted to pourtray. Though the architectural restoration of this court is correct, and so far interesting, neither the type selected nor the raw contrast in the colouring is what we should ourselves have preferred. Among the numerous Roman casts, we discover, oddly enough (320), the Athenian Monument of Lysicrates!

*The Alhambra Court*, which comes next to view, presents an entirely new phase of art, betokening a high degree of civilisation, yet flowing in to us a comparatively unknown channel. A verbal description of this gorgeous work could convey but a notion of the reality; so peculiar is its design, its detail, and its every ornament. Mr. Owen Jones has a world-wide fame in connection with his illustrations of Spanish art, and with his curious explorations of the Alhambra, on which the adaptations before us are in great measure founded. The part here produced is the celebrated Court of Lions, the Tribunal of Justice, and the Hall of the Abencerrages. This Saracenic or Moorish architecture, doubtless sprang from the Byzantine, the common parent of all subsequent styles, and the legitimate successor to the Roman. The Alhambra may be characterised as "externally a solid structure of plain, simple masonry; while the inside was literally covered, from end to end, with rich arabesque work in coloured stucco, and adorned with mosaic pavements, marble fountains, and sweet-smelling flowers." Statues alone were excluded by the Mahometan law, based on religous scruples. The surface decorations here restored, all in flat relief, are truly wonderful, both as regards the intricacy of the design and its ever-varying contours. They afford of themselves an endless opportunity for study, alike of outline and combined colouring. In the small cast room will be found many more of these ingenious devices. Our pen would fail in the attempt to describe what must be *seen* to be really understood, and we therefore relinquish the attempt. Mr. Jones's hand-book is an invaluable companion to the visitor, and prefaced by a valuable essay on general art.

Emerging from the Alhambra Court, the scene is totally changed; and what a change! from ultra-delicacy to comparative barbarism,—from fairy land to the abode of giants; for know, O! reader, that we stand face to face with the two grim Egyptian

Colossi. These huge figures, even in their sitting posture, rise to a height of nearly 70 feet, and are just snugly throned under the arched roof of the transept. Close to these is the entrance to the

*Assyrian Court*, constructed by Mr. Fergusson, with the aid of Mr. Layard, out of data furnished by the exhumations at Nineveh. These gentlemen, it is well known, have applied themselves unweariedly to the task of illustrating a system of art of which no specimen has hitherto been produced in Europe, and which, indeed, until the last few years, lay unknown even in the country where its remains have been unexpectedly brought to light. As now laid bare to us, Assyrian architecture displays, in its main characteristics, enormously thick mud-brick walls, covered with painted bas-reliefs; and roofs supported internally by light yet elegant wooden columns, ornamented with volutes and the graceful honeysuckle ornament which was afterwards introduced through Ionia into Greece. We notice, too, in this reproduction a highly-enriched semicircular arch (from Khorsabad); dwarf columns, with strange, double-bull capitals; those curious emblems, the winged bulls, with their *three* front legs; and hosts of other sculptures and inscriptions in which the arrow-headed character is everywhere predominant. As this architecture, however, like the Egyptian, is to us of but historic interest, we shall not detain the reader by dry enumerations of detail, but lead him over the nave to the remaining courts, beginning with

*The Byzantine*.—The treatment of this court, and that of the Mediæval, Renaissance, and Italian, which follow in succession, differs considerably from those which we have just left. In the Egyptian, Greek, and other courts already described, the forms or characteristics of some one distinctive structure have, to a greater or less extent, been given; but those into which we are about to penetrate are not architectural restorations, but rather so many collections of ornamental details, exhibiting the chief transitions of art between the 6th and 16th centuries. Our reference to these specimens will be confined to glancing at a few of the most valuable or interesting of each class.

The arcade which screens the Byzantine Court from the nave, is taken from the cloisters of St. Mary in Capitolo, an ancient church at Cologne, supposed to date about the eighth century. In this may be traced most of the elements of the style in question; its bold, deeply-recessed arches, often, as in this case, subdivided; its stunted columns with their peculiar caps; its massive pilasters and flatly-moulded cornices, all clothed in a goodly array of colours, mosaics, and variegated marbles. The capitals in the present instance deserve particular attention from their beautifully-composed detail.

The central arcade is a compartment of the cloisters of St. John Lateran, at Rome (13th century), a fine example of the later Romanesque style. The detail of the twisted columns (whatever may be said as to the form itself) is exquisite, being richly executed in real porphyry, serpentine, and glass mosaic, to show correctly the brilliant effect of the ancient "Opus Grecanicum." Mr. Digby Wyatt's beautiful delineations in his book on mosaic decoration will occur to mind. Among the objects which court our gaze against the walls is the magnificent doorway from Mayence Cathedral, and others from Shobden and Kilpeck churches in our own country. In both the latter, painting has been restored, and every part of the surface covered,—it is to be presumed on sufficient authority. We observe the same in most of the other restorations, both internal and external; but, if we must own to the fact as an ancient practice, it is one to which we confess ourselves as yet not altogether reconciled. We prefer the natural colour of the material in what are called the "Elgin marbles" of the British Museum, to Mr. Owen Jones's restoration of their painting on the casts in the Greek Court. The imitation of flesh tints is peculiarly distasteful in these, as well as on the figures in the Byzantine doorways. May we quote a remark by Dr. Waagen, the distinguished German critic, on the subject? He is speaking of part of the pedimental sculpture of the Parthenon, compared with its plaster cast, and he observes: "I never perhaps found so great a difference between a plaster cast and the actual sculpture as in these 'Elgin marbles.' The Pentelic marble, of which they are formed, has a warm, yellowish tone, and a very fine, and at the same time a clear grain, which has imparted to these sculptures a peculiar solidity and animation. The block, for instance, of which the famous horse's head consists, has absolutely a bony appearance; it gives the impression of being the petrified original horse that issued from the hand of the god." How a coating of colour would have destroyed all this sharpness, and dispersed the illusion! The *extent* to which painted decoration was anciently carried is yet undecided.

Before quitting the Byzantines, let us draw attention, among other things, to the "Prior's Doorway" at Ely; the fountain from Heisterbach, on the Rhine; the inlaid Florentine pavements; and the interesting early monuments on the floor. In

*The Mediæval Courts*, architecture and sculpture have taken a progressive step, and a collection of objects, renowned for their beauty, their variety, and their availableness for study, has been secured, which time would fail us to chronicle. There is one circumstance which this superabundance of materials seems to have forced upon its arrangers which is much to be regretted. We mean the composition (nosegay fashion) of certain groups, made up from different sources. Thus, in the large buttresses within the English court, the weatherings are gabled and niched after a recognised type; but, striding on these gables, are clustered corbels from *Wells*, which, in their turn, form rather clumsy pedestals for statues from another place; and these, again, are surmounted by *modern* canopies (as we presume). A Lincoln gabled doorway is finished with a Cambridgeshire church cross; and little figures have crept, cuckoo-like, into nests which it was never designed they should fill. Thus anachronisms are more or less committed, and distinctive localisms cancelled; and while the experienced eye detects the innovation and is pained, those who come to be instructed go away under a false impression. We have already touched on the subject of polychromatic decoration, which is here freely administered.

Adjoining the "English Mediæval court," are two smaller ones, devoted respectively to "German," and to "French and Italian" sculpture. Next in order comes

*The Renaissance Court*, which presents towards the nave an open arcade of nine bays, uncomfortably crowded with *petite* ornaments. It is modelled from the Hotel Bourgtheroulde example at Rouen (dating about 1520, or later); the open arches are of a nearly elliptic form, called *Burgundian*, the whole showing a lavish amount of richness, and a struggling with the influence of late Gothic art. What may be called by admirers of the style, the light prettiness of this screen, with its delicate gilding, is greatly marred by the heavy sculptural frieze from Pistoia (Tuscany), introduced above, which completely overwhelms it.

The harmony of colour in the interior of this court is pleasing, since a gradation of tints has been preserved. The wall surface is a quiet diaper pattern, succeeded by more positive colour, chiefly blue, toned down by occasional panels of other hues; the whole crowned by a well-moulded cornice, and an unbroken attic story. Arabesques and medallions on a white ground are introduced by way of enrichment. Within the inclosure is a well-selected series of castings, including the glorious, the matchless gates, by Ghiberti, to the Baptistery at Florence. The rest we must pass by unnoticed; but perhaps it may be the place here to refer to Mr. Digby Wyatt's screen at the south end of the nave, prepared to exhibit casts of the regal statues executed by Mr. John Thomas at the New Houses of Parliament. This screen is not, to our mind, altogether satisfactory. The square piers seem too massive for the slender arcading between, and they interfere with the continuity and due importance of the figures; the cornice and its surmounting sculpture are poor, and the narrow central feature in the design excessively paltry and frittered. We say this in deference to its talented designer, Mr. M. D. Wyatt, who, in the "Renaissance" hand-book (p. 14), comes out as champion of the style against those who have termed it "pestilent," and who may be better acquainted with its proper mode of treatment than we can profess to be.

*The Elizabethan Vestibule* is small, and its architecture little more than three repetitions of three arches from the exterior of Holland House (coloured, of course). The four doorways within are also all alike. Above the arcade cornice is a large fleur-de-lis cresting, which in the original, if we mistake not, forms the termination. Here, however, its disproportion is more evident, from its being filled in solid between the ornament, to support the last compartments of the Pistoia frieze, which we mentioned as overtopping the Renaissance façade.

This court contains several interesting monuments,—the Scotch Queen Mary, and the English Elizabeth, with the Stratford-on-Avon Shakspeare looking down upon her,—and the elegant tomb of the Countess of Richmond, by Torregiano, the Florentine artist who designed that of Henry VII., which also finds a place near.

*The Italian Court*, in its architecture, is borrowed from the Farnese Palace at Rome, which was the joint work of Sangallo and Michael Angelo. Here, again, colour is introduced of an agreeable tone. The internal area is ingeniously broken on plan, so as to make a central open quadrangle, and two side passages which are treated as interiors. The style of decoration is familiar to all who have met with Gruner's splendid work on the art as practised in Italy. Behind these areas is a long gallery, the flat ceiling of which (imitated from the library at Venice) is unusually tasteful. Copies from the productions of Raffaelle, M. Angelo, Bernini, Sansovino, and others, form an interesting assemblage for study.

*The Italian Vestibule*, as it is termed, is, like the "Elizabethan," but a small space, yet containing several gems of art. Like, too, the court just mentioned, its architecture consists of repetitions of three arches of an arcade, with their appropriate entablature. The model chosen is the Casa Taverna, at Milan, and a beautiful specimen it is, though very simple. The archivolt and spandrils are particularly worthy of attention, from the effectiveness of the overlaid ornament. Triglyphs are indicated on the frieze, but *painted* instead of being in relief.

Before we pass over the central transept to examine the remaining courts, we cast our eye on the sculptured memorials of great men of every age scattered about and around. Among them are not a few who won a distinguished name as architects; to wit, Brunelleschi, Michael Angelo, Palladio, Inigo Jones, and others.

Resuming our track, we approach, close to the large transept, the French and Italian sculpture; and next to this the French or Foreign court, designed by Sir Joseph Paxton. The style he has selected is Late Gothic, almost Flamboyant, if we take some of the features as samples. It is constructed of wood, emblazoned with colour, and with panels of silvered plate-glass. Internally, the detail is tame, and somewhat wiry. A series of arches, forming recesses, runs round each of the sides, inclosed in square compartments. The spandrils are enriched with perforated tracery; from the moulded cornice springs a small cove, by way of partial ceiling, as in some of the other courts, and there are decorations of shields, emblazoned with the arms of various nations, and legendary scrolls, setting forth the names of the principal seats of manufacture. Next comes

*The Mixed Fabrics' Court.*—This presents some novelty in its plan, being divided into two parts, one covered by a ceiling, to receive the more delicate fabrics likely to suffer from exposure, &c.; and the other uncovered, and destined for raw produce, and that less susceptible of injury. The ceiling of the covered portion is elaborately painted. There is considerable invention in the general design, which may be called of Cinquecento character; not that we like the broken pediments and vulgar panels which this style favours, and which may here be seen; still the architect (Professor Semper) has produced an agreeable variety.

*The Printed Fabrics' Court* is a very good one. It shows towards the nave a centre arch, flanked by projecting columns, with the entablature broken round them, and surmounted by vases. Beside these are niches for statues, above which are panel paintings, illustrating on one screen printing and weaving, and on the opposite spinning and dyeing. The columns are of dove-coloured scagliola, having very chaste white Corinthian capitals, touched out in gold; in the spandrel of the entrance arch is introduced a monogram of the architects, Messrs. Banks and Barry. The wings are composed of three Byzantine arches on each side, springing from slender doubled iron columns, and over the whole a well-proportioned entablature is continued, with a modillion cornice. The walls are adorned with medallions of eminent men in this branch of manufacture, and the frieze with bas-reliefs representing the raw material, and its several processes.

*The Musical Instrument Court* is the last we have to visit It is one in which inventive fancy has been altogether unrestricted. The four angles are strengthened by engaged columns, in which organ-pipes supply the place of flutes,—a misapplication by no means to be tolerated. Close to these are chamfered corners, with veritable Gothic stoppings. There are symbols of every possible kind in connection with the practice of the "divine art," and internally medallions of the most celebrated English and foreign composers, and a frieze prettily enriched with figures of boys playing on various instruments. The opening stanza to Collins's 'Ode to the Passions' forms an appropriate external inscription.

We are now arrived again at our starting-point, having completed the circuit of the building. If our notes have appeared occasionally desultory, let it be remembered how much it has been necessary to condense to bring them within readable limits; and, now that our readers have the opportunity, as they have doubtless the inclination, let them repair to Sydenham, and, at their leisure, fill up the outline, thus slightly sketched, with pleasure and profit to themselves.

## THE CRYSTAL PALACE AND ITS INFLUENCE ON THE ARTS.

We look with the deeper interest on the Sydenham Palace, because we long since anticipated the permanent influence of the Great Exhibition building on architecture. We have pointed out that the successful application, on a gigantic scale, of a new combination in construction would lead to a new class of edifices, and ultimately to a new style. The buildings at Dublin, New York, and Paris, are as yet only partial exemplifications, nor is the Sydenham structure to our minds anything more than a rudimentary step in the chain of progress. It is vast, undoubtedly, in its proportions—it is as yet unexampled; but, we are inclined to believe, far behind what is yet to be achieved in this department. The building is an extension and expansion of that in Hyde Park, but it can scarcely in reference to its architectural properties be regarded as a new example; it belongs to the first type, rather than to another original type; neither has it developed distinctive properties of style, such as we believe the material employed is capable of displaying. We do not say this to disparage the Sydenham Palace, for it is one of the most remarkable monuments the world has yet seen,—but we say it hypothetically, in reference to the artistic resources of which the subject is capable.

So far from speaking in the former sense, we look upon the Crystal Palace as an example essential for the architect to study, if he would properly appreciate the present position of his art, or its future direction. We have there displayed a vastness of proportion and capacity such as is seldom seen in modern structures, and most certainly unexampled for its rapidity and entirety of execution. The Louvre, or the New Houses of Parliament, wanting the latter qualities, cannot be brought into comparison. Then, too, the material presents peculiar artistic properties—its transparency, its reflective surface, are distinctive characteristics. If in other structures solidity is urged as a merit, here the very lightness is an advantage, producing its own proper effect, and affording a special resource to the designer. The application of glass and iron admits of adaptation for institutions particularly suitable to our climate and habits. Instead of the contemplative recreations of the porch, or the quiet of the siesta, or the warmth of the winter stove, our habits are essentially active and peripatetic: we like to move about at all seasons—to walk, to talk, to see, to be seen. Public meetings, religious anniversaries, races, parks, zoological gardens, flower shows, public gardens, and fairs, are eagerly sought for as occasions for meeting; but the winter presents few opportunities for such réunions. The theatre, the concert room, the ball room, and the casino do not afford such occasions for large assemblages; and the only winter garden attempted is on too small a scale. Marble halls, or prolonged galleries, well warmed, afford no adequate winter promenade.

Had the winter garden of the Royal Botanic Gardens in the Regent's Park been carried out on the contemplated scale, it would have had an acre of walks and plantations, and would have given a very good example of a place of winter resort. In its restricted dimensions, it is of too narrow application, although it sufficiently illustrates what may be done. The glass structures, with the use of warm-water heating, will give professional men a scope for what we may term winter architecture. There is no more inconvenience in going to Sydenham from the station than in going to the opera, and as the building admits effectively of artificial illumination, it may become a place of resort in the winter both at day and night, and may be applied to purposes as yet little contemplated. There we may have winter and spring flower-shows, when particular classes of flowers are in their prime; there may be held cattle and poultry shows, with more convenience and on a far larger scale than has yet been effected. Promenade concerts may be held under cover, and rival the fashionable assemblages of the summer. Thus, resources may become available to the managers which will contribute regular and permanent branches of revenue.

What may be done at Sydenham may be done by the architect in other places, and we may gain exhibition structures for other towns and districts. At Sydenham it is little likely that any extensive modification of the building will take place; but it is in the competition for other structures, and in the rivalry among architects, that the occasion will be found for producing new effects, and developing the properties of the style. Liverpool, Manchester, or Birmingham, may invite competitors to endow it with an industrial palace, and a great rival to Sydenham may arise. Other applications for special purposes will be made in the metropolis—indeed Sir Charles Fox has already proposed such. Perhaps the situation first suggested on the esplanade of Battersea Park may yet be occupied with a crystal edifice.

The situation of Sydenham is a happy one, and the gigantic proportions of the edifice are conspicuously seen, situated as it is on the southern range, and it would be difficult to find a better position in London of the like kind. A site on the northern range would have a southern aspect, but there no such space remains available. There are likewise many of our large towns in which such a situation cannot be obtained. The proposition made long since in this *Journal* for a crystal palace on the terrace of Battersea-park, pointed out the artistic effect produceable from the elevation of such a building on the river side casting its shadows and its reflected lights on the gleaming waters. A structure of this class, with a southern aspect on a river frontage, would have a most picturesque effect. There are likewise situations on level ground, amidst trees or park-like scenery, where glass edifices may be artistically placed, so that the capability of this material for various sites constitutes one of its advantages. The adaptation of the structure to such diversified positions will lead to modifications in design, which will effectually lead to some new or definite style. The old styles cannot be so closely followed in this material as to admit of strict application, and therefore the change of material must, we think, necessarily lead to extensive modifications of style, if not indeed to the absolute extent of a new style. The very adaptation, as in this example for instance, of old forms, leads to such alterations and changes, to such departures from precedent, and such new creations, that it is already equivalent in architectural value to the origination of a style. A mediæval cathedral is scarcely more distinctive than a crystal palace; they are each works of a special class, having differences so great that we are fully justified in placing them in comparison with those which result from characteristics of style.

The material employed, arranged to a greater or less extent in sheets, produces a uniformity and entirety of arrangement, such as do not necessarily attach to stone. It admits perhaps of less variation of form, and is less plastic, although the metal or timber framings and supports allow of every diversity and luxuriance of shape. The glass surface gives a mass and entirety of effect which must very much influence any style adopted, because although marble or stone may produce a surface equally uniform, this is not an essential property, for they may be as richly carved as Henry VII. Chapel, and be altogether without repose. It is possible, however, that at a future time, by the use of coloured glass, polychromatic effects, both exterior and interior, may be obtained correlative to those of ordinary polychromatic decorations, though very different in their form, for these are opaque, the others transparent. The painted windows of churches can give only a partial idea of what would be the resultant effect of an extensive crystal palace largely varied with coloured plates. It is evident the same richness of colouring and of transmitted light which is obtained in scattered cathedral windows, is available in suitable situations, but it will be further seen that masses of coloured light may be thrown in to a degree far beyond what has been effected by the most gorgeous east, west, or transept window. The crystal palace, as we now know it, bears the same proportion to the mature decorated structure, that a whitewashed modern columniated building does to the Parthenon in all its glory and vivacity of colour.

There is a scope for the management of light and colour, which Titian, Rubens, and Rembrandt would envy. These, worked on an easel, in their great decorations, Michael Angelo, Raffaelle, Giulo Romano, or Rubens thought himself happy to have the share of a chapel or a hall; but the artist of a crystal palace may have a thousand feet in length of a transparent medium on which to exercise his genius. There, too, he will have living colours, brightened by the sun's beams, pouring columns of the richest colour through the interior. The scenic effect of coloured light is a most valuable resource to the designer of spectacle, who is obliged to avail himself of artificial illumination; but in the proposition referred to, the great luminary of nature will be brought in to aid the effect.

When examining the Great Exhibition, we took the opportunity of pointing out how little the properties of transparent colouring, of coloured lights, of moving lights and substances, and of glass, had been studied by the artist, though capable of producing the greatest effects. We believe they have been neglected partly because colour has been altogether and wrongly neglected by the architect till of late, and partly from another erroneous theory, that such applications were artifices for the decorator rather than for the artist. The controversy as to coloured statuary in the Crystal Palace has resulted rather in the temporary victory of the purists, but the Crystal Palace itself is laying the foundation for their certain defeat. By its successful realisation, all their theories of the sublime and beautiful are set at naught. Here is a monument of the most flimsy instead of the most solid materials; much of its picturesque effect on the eye is owing to the play of light on its surface, and one great feature in the completion of the design is the establishment of giant fountains, spouting columns of glittering water in front of the gleaming walls. The mason and the bricklayer, the chosen servants of those who aspire to endless durability, are set aside, and workmen either neglected by or almost unknown to the builder, are those who have reared the structure. In the evidence of mind, in design, in the realisation of beauty, fame has been sought, instead of in marble and in stone, in brick and cement. Nevertheless, the fleeting gleam of the many-coloured rays of an oriel window, is as truly an offspring of art, and one as lasting as any portion of the edifice. It shows the mind of the designer as well, and is truly appreciated by the spectator, for whom, and not for the critic or the archæologist, does the artist labour.

The subtle and delicate properties of form are truly worthy of occupying the mind of the artist, but there is no æsthetic reason why they should exclusively demand his allegiance. In later times, the architect and the sculptor have limited themselves to the speciality of form apart from other properties—and yet on no valid ground, not even on the ground of precedent. It cannot now be denied, that in all other ages than the last two or three centuries, architects and sculptors have dealt largely with colour as well as with form, and have not thereby felt themselves degraded. Painters vary in their appreciation and application of the properties of form, yet no one thinks the worse of Michael Angelo or Raffaelle because he painted as well as drew cartoons. There is not one argument, indeed, for the exclusion of colour from architecture and sculpture which does not equally apply to painting. There is an enjoyment derivable from the properties of colour apart from form, which, in its abstractedness, is as pure as that derivable from the properties of form. The restriction of the practice of art to the latter has nevertheless no better basis than a vague, mystical notion, which seizes the more readily on some minds in proportion to its want of consistency and definedness. If purity of form is enhanced by being enjoyed alone, and by being exhibited isolatedly, then an outline cartoon must be the height of pure art; and it may be submitted to the purists whether the play of light and shade, which, both in architecture and sculpture, contribute so highly to effect, do not, like colour, impair the pure enjoyment of abstracted form.

The more catholic the appreciation of the beauties of nature and of the resources of art, the higher aimed will be the exertions of the artist, and it is equally honourable to him to work with slight materials or with small material. How anomalous is that law which would restrict an artist to marble and stone, and those only of one colour, and who require that his structures shall be of the greatest proportions and of the most durable materials, and yet will assign the honours of immortality to the designer of an altar-piece—nay, even of a cabinet picture. After all, there are more painters known to the world than there are sculptors,—perhaps as many sculptors as there are architects whose names are in the mouths of the many. What is the object of ambition in architecture? To produce a monument, which shall take years, perhaps centuries, to heap together the material, and yet perhaps remain incomplete. Under these circumstances, few are so happy as Wren or Barry, and raise a great edifice from the ground. Most great monuments have had several architects; a succession of them, and the distinctive designer becomes lost. Who was the architect of St. Peter's? who of this building, who of that? The cognoscente must give an answer in set form, the public know it not. Hence, too, the ambition of the architect is early cramped; he may design palaces and cathedrals as he likes, but it is a rare lot if it be his to execute one. In fact, he has to limit his ambition, and esteem himself happy if he be intrusted with the execution of a small structure. The new style of construction, however, admits of large proportions and rapid execution; it gives a man the opportunity of showing his artistic power and of acquiring distinction, and it must thereby react on the future of art in a most favourable manner.

Many of the large structures we have had of late have been those which have had the least pretensions to art—warehouses, factories, and railway-stations, though their plainness or ugliness is not a necessary or inherent property. The crystal palace must however be of a decorative character, and avail itself of the resources of art, and it gives a favourable opportunity to the artist. Architecture has the advantage over all other arts that it can deal with vast proportions and almost illimitable form, and the greatest colossus of the sculptor or founder, and the greatest fresco of the painter, bear no comparison in size with the creations of the architect. Hence, the new field of display will necessarily promote a greater breadth of treatment, a quality more necessary to the architect than to any other artist. It is not indispensable to the painter, and the sculptor has scarcely scope for its display. By giving the architect better opportunities for the realisation of his ideas, we shall give him a stimulus to exertion and the means of practice, without which chamber studies will do little towards making an architect. One or two men in their day may now hope for adequate commissions, but hereafter the occasion for exertion will be more frequent, and genius will have a fairer field against favoritism.

The new Palace at Sydenham will likewise, it seems to us, further benefit the architect by giving him an educated public. We shall say nothing now about other branches of study, but we shall limit ourselves to architecture, though the Crystal Palace is the grandest educational institute the world has yet seen. There is no college which could have been opened, no free library brought together, there is no intellectual power in twenty libraries of five hundred thousand volumes each, which will do as much as this Crystal Palace. It is that very library which the public want,—one which the eye can embrace in the integrity of the subject, and with which even the British Museum can bear no comparison, though it brings together originals where the Crystal Palace relies upon models and casts. It is because the Crystal Palace does so, that it is a better public teacher. The British Museum, with its original types, is invaluable to the man of learning and the teacher, and, in intrinsic price, is far beyond Sydenham; but the latter possesses the essentials for popular instruction in art. Even if lecturers were attached to the British Museum, as they ought to be, it cannot compete with the Crystal Palace, with or without lecturers. Inasmuch as an infant school is better adapted for a babe than the University of Oxford, so is the adaptation of the Crystal Palace to the popular wants greater. Compare the Nineveh or the Egyptian collection in the two palaces, and it is evident that the public will learn more and more readily at Sydenham than in Bloomsbury. The necessities of a museum are against it. It must avoid restorations, it must avoid imitations, it must avoid theories possibly erroneous; but the public want a complete idea, even if erroneous, they cannot suspend their judgment, they cannot abstract thought; the subject must be laid before them in something like connection, even if the connection be made up by hypothesis. The British Museum, again, cultivates archæologists and professional men; the Crystal Palace teaches a public, and a public is what we have long wanted for architecture. If we had a public as decided in their views upon architecture as they are upon other subjects, the deputation of the Institute would not obscurely go to petition for the fragment of a corner in St. Paul's Churchyard—which it is doubtful if they will get—but it would boldly demand and obtain what was required.

All that the public can learn of architecture in London, or even in England, amounts to very little. They can neither see mediæval buildings in their integrity nor genuine imitations of Athens; it is as much as they can do to get a notion of the Italian styles. Everybody cannot travel or purchase expensive books, and therefore, so far as catholic appreciation of art in architecture is concerned, it has been hitherto limited, but now we have at Sydenham a great school of architectural study. We care not whether the architect can learn enough there about Pompeii or Thebes, but of this we are sure, that any man, woman, or child, can obtain a definite notion of various styles and modifications of art, such as will, without reference to accurate or minute information, produce a beneficial impression. Scholars may dispute whether the tablinum or impluvium be according to the best authorities, and whether the restoration should be in this form or in that; but the public have been hitherto contented with far less than they now have, while, as they acquire instruction, they will find in the careful selection of well-authenticated subjects at Sydenham the materials for a further study, which will often be specially applied by the artisan and designer in his own pursuits. The interest of the public in architecture will be increased, they will find there is much to admire, and they will be found ready to appreciate.

## WATER SUPPLY AND SEWERAGE OF SWANSEA.

By Robert Rawlinson, C.E.

[*Abstract of a Report to the Local Board of Health, Swansea.*]

In establishing works of water supply, it is of primary importance to obtain the best source. The water should be the purest to be found in the district. The area from which it is to be drawn should be large, and free from works the tendency of which would be to taint the supply. If there are springs, they should be collected at the respective sources, and be conducted by means of earthenware pipes into covered fountain reservoirs. That source is the best which not only enables an engineer to secure such conditions, but which will enable him to supply the quantity required, or likely to be required, at such an elevation as will give high pressure, without pumping, and volume without flood-water storing. Any moderate cost of additional distance in length of aqueduct main may safely be incurred to secure works which will yield such a supply.

The Clydach district is the only place within reach of Swansea where the advantages enumerated can be secured. The minimum volume of water in the river is several millions of gallons per day. The district, as is proved by the analysis of the water, is free from mineral impurities; the land, from its slope, mountain character, and isolation, is not likely to be more highly cultivated or more densely inhabited, and there is elevation sufficient to give any required level above the town, with high land the whole distance, round which a comparatively cheap earthenware pipe conduit may be laid to service reservoirs above the town. Another advantage, and the greatest, consists in the district abounding with springs of singular purity, most of which are at elevations to render their waters available. Fully one-half the water required by the town may be, as it were, created; that is, by collecting the springs, and by preventing evaporation and waste, water will be obtained which at present is lost on the mountain side, never reaching the river or the mills.

The existing works do not supply the higher parts of the district, neither can they, in my opinion, ever be made available for this purpose; they may however admit of some improvement. The area of land above the old and new reservoirs is too limited and the springs and streams too small, to yield a full supply of water for a large and rapidly-increasing town. The water is also comparatively hard; and, as stored in open reservoirs, must be impure. At the time of my visit there were numerous tadpoles; at all times there will be conferva and animalculæ. The reservoir is at an elevation too low, and the volume of water too small. Engine power would raise the water to a sufficient elevation, but I do not consider there is area or water at command, to warrant such an outlay; or, indeed, any costly permanent extension.

In order to render the waters of the Clydach available, it would be necessary that the springs should be collected at the respective source, and be conducted through earthenware pipes into a fountain reservoir, which must be covered. The line of aqueduct main will contour the land as far as possible. Valleys, or water-courses may be crossed by light aqueducts, continuing any given gradient; or cast-iron syphon pipes may be adopted. Small covered service reservoirs may be constructed at the most convenient points where a supply is required, for populations situate on the line of the main; and one or more service reservoirs will be required for the town, at such elevation as will command every house within the borough. From these service reservoirs the mains, sub-mains, and branches will proceed into the town, and conduct the water into each street and every house, preserving it pure and cool, as collected from the springs.

The distance from the Clydach to Swansea is about seven miles; that is, an aqueduct main winding round or contouring the high land will be about seven miles in length. An earthenware pipe may be laid complete, capable of conveying one and a half million gallons of water in 24 hours, at a cost not exceeding ten shillings per lineal yard. This would make the cost of such a main about six thousand pounds. The necessary works on the Clydach for collecting springs, &c., need not cost more than four thousand pounds, making in the whole, for collecting the water and conveying it to Swansea, 10,000*l.*

Service reservoirs, service mains, sub-mains, and branches, within the town, will not cost more than fifteen shillings per head, making, for a population of 30,000 a sum of 22,500*l.* Add for land compensation, engineering, incidental expenses, and other contingencies, 10,000*l.* and the estimate will be as under:—

| | |
|---|---|
| Works on the Clydach | £4,000 |
| Aqueduct Main to Swansea | 6,000 |
| Plant within the Town, Service Reservoirs, Pipes, &c. | 22,500 |
| Compensation, land, engineering, and incidental expenses and contingencies | 10,000 |
| Total | £42,500 |

Mr. Scott estimates that the cost of water works (for an increased population of 55,000) would be as under:—

| | |
|---|---|
| Works on the Western District | £91,000 |
| Works on the Cwmgelly District | £55,000 |

The works, as projected for the Clydach district, will serve for a population of one hundred thousand, and may, at any time, be increased to serve a population of half a million, without the loss of one pound of the money expended on the projected works.

With regard to the sewerage of Swansea it appears that, with the exception of that portion within tidal influence, there will not be any work to execute either difficult, peculiar, or costly. Brick outlet sewers will be required in the low and level parts of the town; but in the higher parts, and along streets of steeper gradients, earthenware pipes may be adopted with advantage and economy. The necessary works for a population of 30,000, were estimated by Mr. Rawlinson to cost 25,000*l.*

## DRAINAGE AND WATER SUPPLY OF FALMOUTH.

By Robert Rawlinson, C.E.

[*Abstract of a Report to the General Board of Health.*]

The town of Falmouth stands upon a dry formation (clay slate); there is scarcely a square yard of low or level land. The means of atmospheric ventilation are good; and yet fever is said to be ever, more or less, present, and cholera has prevailed to as great an extent as on sites low, flat, and excessively damp. The same remarks apply with equal force to Plymouth, Dover, Tynemouth, Newcastle-upon-Tyne, Gateshead, and Sunderland. Cholera is true to no condition but filth. It breaks out in a dirty swamp at the level of the sea, and it rages at elevations hundreds of feet above this level; if the conditions exist, namely, populations living amidst their own filth. A town may be at the sea margin, as Falmouth, Dover and Plymouth; or inland, and at an elevation of 500 feet, as Bilston and Wolverhampton, in all of which places there has been cholera.

The district, included by the town of Falmouth and the parishes of Budock and Falwick, contains 1555 houses and 10,079 inhabitants.

The surfaces of streets, yards, and courts may be very clean, as in Paris, but the atmosphere may be very foul from decomposing refuse in cesspool and sewer beneath the pavements; and even where sewers and drains of transmission are in use, and where surface cleansing is also attended to, but where rooms are overcrowded, there may be an excessive mortality. The atmosphere is as effectually poisoned by overcrowding as by refuse retained in any form above described. The end to be attained by sanitary works or regulations is to secure pure air.

The gross estimated rental of the town is 7530*l.* 4*s.*, and the rateable value thereof is 6275*l.* 3*s.* 4*d.* More than one quarter part of the poor-rate (rateable value) is assessed on the owners of tenements, under the Small Tenements Act.

The harbour of Falmouth is a splendid sheet of water, presenting an area of some ten square miles, protected by high lands, so as to be a safe haven for shipping. Average spring tides rise 18 feet, neap tides about 7 feet. Heavy gales occasionally bring the water in two or three feet above the ordinary level of the tide.

The town of Falmouth extends about 2000 yards north-west and south-east along the south-western shore of the harbour; it is built on the side of a hill, there being scarcely any portion level. Nearly the whole of the houses bounding the harbour stand upon walls, which are washed by the tides; the line of wall and the fronts to the harbour being most irregular in line. In breadth, the town is about half-a-mile; it has outgrown the municipal borough limits, and extends into the parishes of Falmouth and Budock.

The streets are steep, narrow, and crooked; but crookedness and narrowness are common to most of the old towns in Cornwall. The buildings rise, terrace over terrace, abruptly from the water to an elevation of more than 100 feet. The municipal borough has been much over-built, and is now extremely crowded. Sites for houses and yards have been excavated in the rock; and as there is no proper drainage, the refuse from the upper inhabitants flows down to the annoyance and serious injury of those below. Many houses have been erected so that a privy cannot be constructed; and, as there is no effective drainage, the parties cannot put up a water-closet. In some cases one privy serves for many houses, and those who have no privies use a tub, which is emptied at intervals. The corporation and guardians have effected many improvements since 1848, but finding the most active measures ineffective, they have now applied for the powers of the Public Health Act to enable them efficiently to sewer and drain the town.

There may be perfect drainage, at a moderate cost, and there is a public supply of water which only requires filtering. The average annual rain-fall is about 36 inches. The advantages of comparatively soft and pure water, combined with site and climate, are seldom found. All places on the chalk or oolites have the great drawback to health—hard water. A railway now in course of formation will place the town within ten hours of London.

The town stands on *killas* (the local name for clay slate), granite forms the surface inland, rising at Carn Menelis to 820 feet above the sea. The shores of Falmouth harbour, which are principally mica slate and clay slate, rise some 200 and 300 feet above the sea. Dykes, veins, and "lodes" traverse the unstratified and stratified rocks; alluvium,—sand, gravel, marl, and clay,—covering portions of the surface in the valleys. Granite and slate, thinly covered by vegetation, or exposed, forming the higher land.

The present drainage is confined nearly to surface drains, there being no proper sewers; these drains are mostly built of rubble with slate bottoms, and empty themselves into the sea. The length of highway or streets, within the corporate district, is 2022 yards, of which about 300 or 400 yards only are provided with even surface drains.

Mr. Rawlinson recommends that each street and road should have its appropriate sewer, and each court, house, and yard its proper drain. Open cesspools should be abolished, and water-closets or common soil-pans should be substituted for the privies now in use. Any accumulation of refuse in large, exposed, or covered middens should be prevented by a regular removal of all such refuse at short intervals. That the rates be expended in opening out courts and confined places, in widening narrow streets, in rounding protruding corners, or in erecting covered markets, and costly public buildings. That all fluid and semi-fluid refuse, liable to decomposition, be at once removed from the site; cesspools abolished; sewers and drains through which such refuse will flow should be substituted; streets paved, and all lanes, passages, yards and courts, flagged, or otherwise finished so as to admit of sweeping or washing; ashes, and other solid refuse being removed at short intervals.

The sources of the supply of water to the Falmouth district are certain springs and streams at Kegilliack and part of the College river. The reservoir is situated at an elevation of 178 feet above high-water mark of spring tides, and calculated to contain 179,200 cubic feet of water; from this reservoir a 9-inch main is carried to the market strand, a distance of two miles, from whence the water is disseminated throughout the town. The cost of the works amounted to upwards of 12,000*l*. The water, as at present supplied, is dull and turbid, requiring filtration, and at times is tainted by the rusting of the pipes, by reason of the want of a quick and constant draught. These evils the company will find it advantageous to remedy immediately. The gasworks and slaughter-houses are also nuisances demanding the powers of a local act to remove. A new cemetery has been formed at Hangman-hill, about a mile from the borough, which it is hoped will abolish the dangerous practice of intramural interment in Falmouth.

It is proposed to erect public baths and wash-houses in Falmouth, and to extend the boundary of the borough so as to include Budock, Pendennis Castle, Flushing, and Little Falmouth; a portion of the harbour is also included, but it is not intended to interfere with the jurisdiction of the port. This boundary, as proposed for the purposes of the Public Health Act, contains only a portion of the area of the proposed extension of the municipal borough.

## STONEWARE DRAIN-PIPES WITH WEDGEULAR JOINTS.

— Roverr, *Patentee*, October 31, 1853.

Fig. 1.

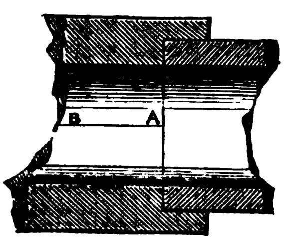


Fig. 2.

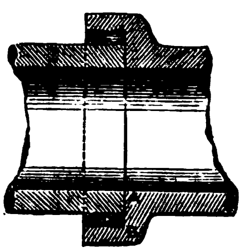

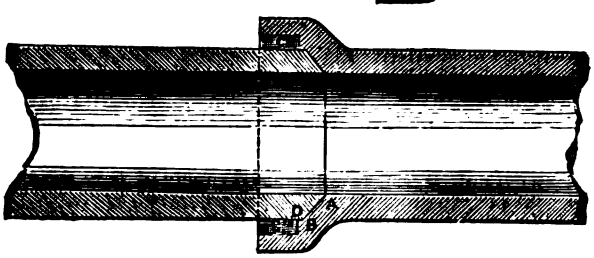

Fig. 3.

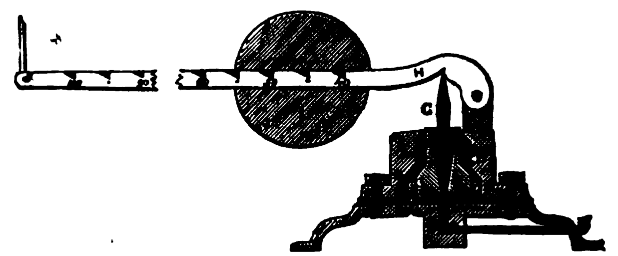
This invention is intended to remedy the defects of the old joint of drain-pipes in use up to the present time, complained of generally in consequence of the stoppages. These are found to take place by the accumulation of the more solid part of the refuse at the joints. In the old pipes, there are two causes which create accumulation of solid matter: either, first, a lateral opening of the lower part of the joint, by which a crevice is formed, wherein any small solid may fasten, and thus becomes the nucleus for an accumulation of solid refuse; or secondly, a vertical settlement of the upper pipe by undue pressure on the cement or mortar used in the joint. In order to render the difference plain to our readers, we have engraved vertical sections of the old joint at present in use at fig. 1; of a portion of Mr. Jennings's patent improvements in the connection to drain-pipes at fig. 2; and the patentee's improved wedgeular joint at fig. 3. The old joints, including Mr. Jennings', are all rectangular, that is to say, their angles, as at A and B, fig. 1, are all right angles. The consequence being, that in the old pipe (fig. 1) the inner pipe has to be supported by the cement in the lower cavity C, presses on the same, and the result is, the depression of the inner pipe, and a raised shoulder at A, which acts as an impediment to the direction of the flow. When a lateral opening takes place, a vertical cavity or crevice is the result. The combination of a lateral opening or crevice with a vertical depression of the inner tube must be the means of choking the drain in a very short time. Mr. Jennings' invention does not obviate the lateral opening, which may be double in the case of his saddle, as he has a double joint instead of a single one, but remedies the possibility of a vertical depression by allowing the ends of the pipes to rest on the shoulders of an intermediate saddle. In fact, it is the old joint (as will be seen by a reference to fig. 2) without the cement or mortar space shown in the old joint in fig. 1. Besides the double transverse joint of the saddle, there are longitudinal joints, one of which is shown at A B, to connect the lower saddle with the upper one, the length of joint being thus three times as great as that of the old pipe; and as there is no allowance made for cement space, unless the whole of the saddle be imbedded in concrete, we are at a loss to know how the escape of the gases is to be prevented.

The improved wedgeular joint shown at fig. 3 is intended to remedy the evils of both a lateral opening and vertical depression. Instead of making the joint rectangular, Mr. Rovère has secured the right to substitute an oblique joint, which prevents the possibility of the objectionable vertical crevice taking place, and also thereby supports the inner pipe D, and prevents effectually any pressure on or compression of the cement or mortar in the lower space C, which is thus allowed to harden at the same density throughout the circumference of the joint. To prevent the escape of gas, and obtain an air-tight joint, Mr. Rovère proposes to introduce a thin coat of cement or creosote between the surfaces of the wedgeular joint A B, when the pipes are being fitted. The means thus afforded of supporting the inner pipe and fitting the joint permanently while the cement or mortar remains wet, enables the laying to be effected in much less time, and with certainty. The length of the joint remains at its minimum, as in the case of the old joint, fig. 1, and no additional pieces are required.

## REGULATOR FOR STEAM BOILER FIRES.

P. Clark, U.S. *Patentee*, January 3, 1853.



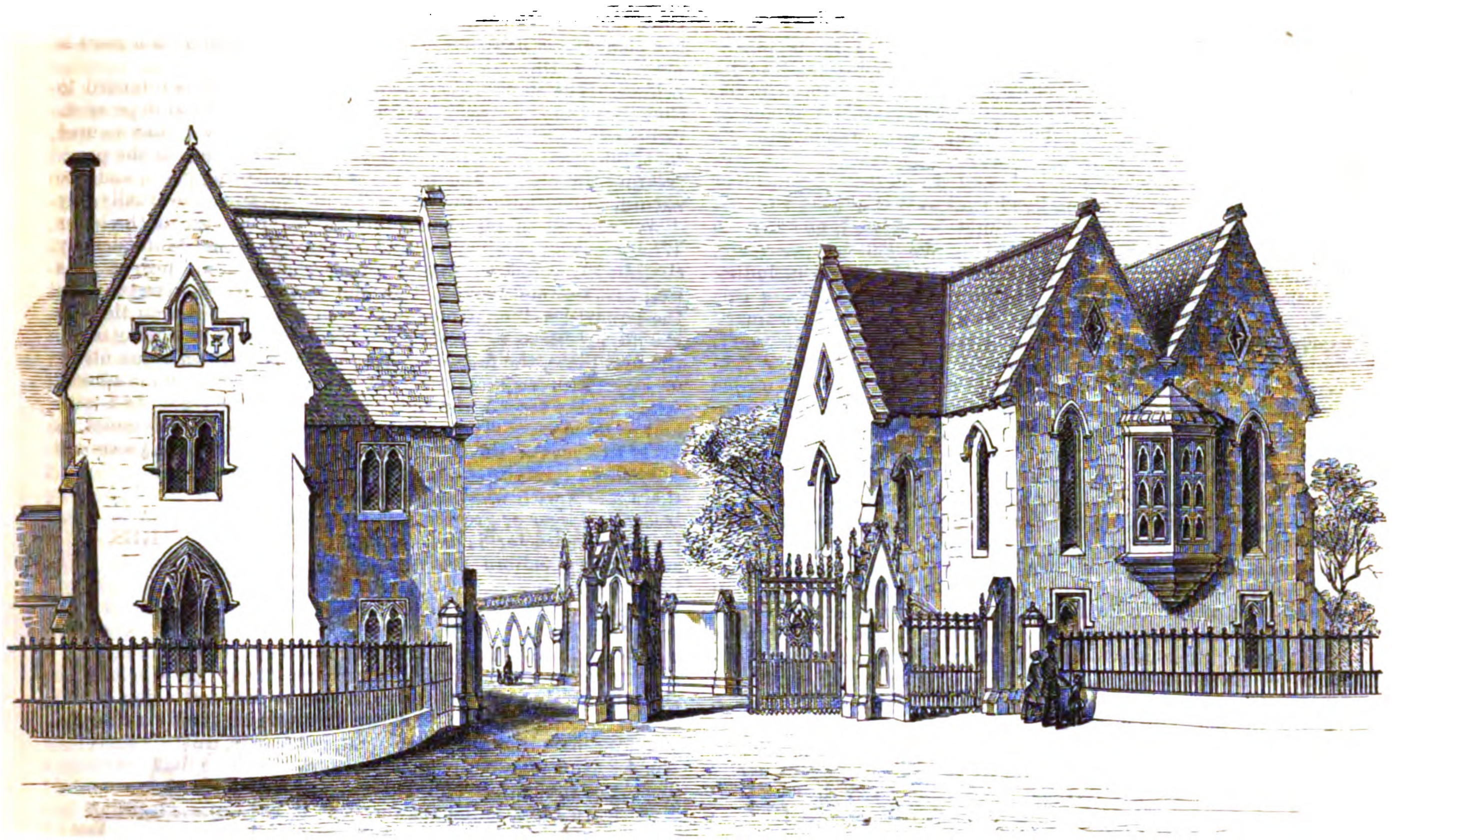
The annexed engraving is a view of an improvement in regulating the dampers of steam-boilers by the pressure of the steam. This invention consists in causing the damper in the chimney (or if a blower is used, the damper for shutting off the blast), to be acted on by the pressure of the steam, so that when the head of steam in the boiler has attained the pressure required, the damper will be closed, but when the pressure is less than that, say by one pound per square inch, the damper will be opened.

A, is a base of cast-iron, on which is fastened by means of screw bolts, the cylinder B, which is also of cast-iron. C, is the pipe leading from the boiler, connected with the cylinder at D. The pipe C, is bent like a syphon, to prevent the steam from coming in contact with the diaphragm E. This diaphragm may be made of vulcanised india-rubber, or any flexible substance, having considerable strength and being impervious to water. It is made cylindrical in form, of a length sufficient to allow of the piston F, moving through any distance required; and is surrounded by a flanch about one inch wide, which answers the double purpose of holding it to its place, and making a tight joint between the flanch of the cylinder, and the top of the platform upon which the cylinder rests.

The bore of the cylinder must be as much greater than the piston as will allow the diaphragm to expand in the chamber S. The piston F, fills the upper part of the cylinder B, loosely, and has a hole bored nearly through its axis from the top to receive the bar G. The bar is smaller than the hole in which it stands, to allow of its accommodating itself to the varying position of the lever H, which rests on the top; I, is a ball or weight made to slide to and fro on the lever. It is used to counterbalance the static pressure on the bottom of the piston; K, is a rod connecting the lever H, with the crank of a damper. The machine as described in the foregoing being put in connection with the boiler and damper, the piston will be acted upon by the pressure of the steam, and when the weight of the ball on the lever H, is little more than counterbalanced, the lever will be lifted, thereby closing the damper; of course, if the pressure now diminishes a little, the weight and lever will descend and open the damper.

## THE ST. PANCRAS AND ST. MARY'S (ISLINGTON) EXTRAMURAL CEMETERY.

Messrs. Barnett and Birch, *Architects.*



Some time since we illustrated the chapels erecting in the grounds of this by far the most extensive parochial undertaking, at present being carried out by the joint parishes of St. Pancras and St. Mary, Islington, under the provision of the New Burial Act. Our present engraving represents the principal entrance erecting in the high road from London to Barnet. The right-hand house consists of porter's lodge, office, and waiting-rooms, &c., on the ground-floor, and above is a large board-room, with the necessary offices attached thereto. This floor is connected with the ornamental terrace beyond, which is proposed to be used for monumental tablets, &c., and a public promenade, with flights of stone steps from the ground, at either end.

The other lodge is not erected, but is designed for the residence of the officiating clergyman, or the registrar and overseer of the cemetery, according as the Board may ultimately decide. The whole extent of the grounds is eighty-eight acres, and the various works under the direction of the architects, Messrs. Barnett and Birch, are fast progressing, in order that they may be completed by the latter end of July next, the time appointed by the Bishop of London for consecration.

## FILTRATION OF WATER.

By S. Trotman, Hydraulic Engineer.

The steady, unmistakeable signs of the approach of that deadly scourge, the Cholera, render it the paramount duty of all who can in any way direct attention to preventives and curatives, to lay such before the public eye, that at least the opportunity may be given for the avoidance of any course that may endanger the public safety, and the finger-post erected directing to wise measures, which, we conceive, are blessed by an over-ruling providence to the lessening of the fatal influence of this fearful visitation.

The most prominent sanitary *ignis fatuus* of the present day, and one the public devotedly follow, risking health and almost life in its pursuit, is that of a promised supply of pure water by the various metropolitan companies, on whom we are dependent for this invaluable element. And though it is somewhat surprising that science has not done more towards removing the apparent impracticability attendant on the supply of pure water, it is still more a matter to be wondered at and regretted that the public has not yet been directed to the best mode of obtaining the nearest approximation to the desired reality. In the *Times*, September 1853, on the "Laws of Cholera," is found the following important paragraph:—"People owe it to themselves and the establishments over which they have control, to secure an ample supply of water which has been filtered chemically as well as mechanically, having passed through charcoal (animal charcoal is the best), as well as through porous stone or gravel." We think this paragraph a good moral to the old fable of "Hercules and the Wagoner," and we only regret that a more detailed description was not given to those who would gladly have availed themselves of it.

It is our purpose, in the first place, to show, that although filtration by our companies is most needful, and the absence of it most reprehensible, yet it is a moral impossibility to render water, by their *present system* of filtration, sufficiently pure for human consumption; this therefore necessarily devolves upon the consumers themselves.

We next purpose to show, however good in themselves any media of filtration may be, yet, if improperly adapted (as is almost universally the case in the present day), all such embodiments commonly called filters are a source of trouble, expense, and vexation to those who use them; and that if a proper medium be properly adapted, a filter may be rendered indestructible by wear, automaton in its action, and free from any liability to become fouled or impregnated by the gross matters which it is destined to separate from the liquid to be filtered; and it should be a *sine quâ non* that all apparatus for filtration should be rather repellants of sedimentary matter than absorbents of and receptacles for the same. We wish it to be understood, that we merely intend to lay down the scientific principles upon which all filtering apparatus should be constructed and adapted. We have asserted that it is a moral impossibility for the companies to filter the water supply of London so perfectly as to render it fit for human consumption by the agencies at present employed; and we will venture to assert still further, that even if, at an enormous outlay, the filtration were rendered perfect, obstacles of an insurmountable character present themselves to the purification of the water by chemical agency, so as to deprive it of its poisonous constituents, and to render it really pure. The reasons, we think, will be obvious, on referring to the statistics of one of the larger companies. The daily supply from the company's main is four million gallons, or an average allowance of twenty-five gallons to each individual. Now, if we analyse the mode of consumption it might be rendered thus:—Water used for purposes that render it necessary it should be filtered, five gallons per diem; water needing no filtration, five gallons per diem. This is the average allowance for each individual, not including that used for manufacturing purposes or trade. Allowing this to be a fair average quantity, what becomes of the extraordinary overplus of fifteen gallons per head per diem? The answer is simply this, that it is wasted. Whilst this extraordinary proportion is run to waste, we cannot hold the companies responsible for the delivery of the water in a pristine state. Taking a pecuniary view of the question, the perfect filtration of four millions of gallons per diem would entail an outlay of eighty thousand pounds, the interest of which, rental of ground, staff employed, with necessary repairs and contingencies, would not amount to less than five thousand pounds per annum. Admitting that four-fifths only of the above water supply really demands filtration, we have a needless expenditure of sixty-four thousand pounds; or, in other words, the sum of four thousand pounds per annum would be expended in producing the most unsatisfactory results; and we conceive that the question is only to be met by the public providing for their individual establishments the necessary apparatus for filtration, adopting such measures as shall ensure an ample supply of water in a state of purity, not only as a beverage, but also for culinary purposes.

We have thus endeavoured to show in a few words our reasons for supposing that the water companies will not consent to any kind of filtration beyond that of passing the water through beds of gravel or other loose materials, which filtration is far from sufficient to purify the water for human consumption, such filter-beds allowing free passage to the spawn of the mollusca and zoophyte tribes, which is alone sufficient to condemn any such medium. The various methods now employed for the purification of water may be classed under three heads—mechanical, such as straining, usually termed filtering; chemical means artificially applied, such as antiseptic media, of which animal charcoal is by far the most effective; natural chemical means, such as oxidation or neutralisation by the ozone of the atmosphere, or by peculiar chemical combinations oxidising and precipitating the impurities. One of the methods employed for defecating water consists of an apparatus called the thunder-pump. This pump, rigged to a considerable height, throws down the water to be purified in a complete spray, thus bringing its particles infinitesimally in contact with the oxygen of the atmosphere. The mode of purifying the water of the Nile by precipitation is worth notice. A native woman provided with a handful of mish-mash, or the rind of a peculiar kind of apricot, violently agitates the water in a large receptacle, when a precipitate is thrown, and water, before turbid and unfit for use, is thus rendered quite drinkable.

It is evident, that any perfect method of purifying water should be rendered independent of all manipulation, and that the apparatus used must be self-acting. By self-acting we mean not for a month or two, but constructed on such principles that a collection of obstructive matter shall be impossible, and that the water to be filtered shall not become charged with the impurities of the preceding permeation.

It needs no stretch of mental exertion to comprehend the fact that the most perfect medium of filtration may be rendered useless by an unskilful adaptation. Leaving for the present any remarks upon the merits of the various mediums in general use, let us suppose we have one of a perfect character, with which the impurities of the water cannot amalgamate, and in itself not capable of decomposition; obstruction is then the only thing likely to interfere with its effective working. A most valuable medium of filtration—we speak of the artificial porous stone—has suffered much from this very cause, owing to the erroneous adaptation of the material. On the principle of *descension*, it is evident that if the medium refuse to absorb the impurities, they must remain on its external surface, and thus, as the water in its pure or cleansed state finds its way through the medium, the detritus separated from it necessarily becomes an obstruction to subsequent permeation, rendering ultimate stoppage, however slow, not the less certain. Now, suppose this same medium on the principle of *ascension*, the water rising to find its level, and permeating through the medium, leaves the gross particles behind. The more dense these particles, the more rapidly do they fall from the surface for permeation to the bottom of the receptacle in which it may be placed; and thus it will be seen, that the very law necessitating the fall of the detritus and creating an obstruction on the *descension* principle, assists the natural separation of the water from the detritus, and the immediate removal of all obstruction in the principle of *ascension*. Where it is a matter of expediency that the *principle* of *descension* shall be employed, we should rather choose a medium of filtration that became choked, from the fact of its refusing to admit the impurities, than a medium of such material as would allow the impurities to enter into combination with its particles. In the first place, the fact of choking indicates that an accumulation of impurities requires removal; this can be readily effected; while, in the second, the water may be rendered doubly impure, and in some cases even poisonous, from the decomposition of the gross particles retained. As an illustration, let us take an ordinary filter. Impure water is poured into the upper section; it there meets with what might be called scavenger No. 1, holding back the larger or grosser particles. Next, a stratum of a less pervious character is reached by the water, and particles of a second-sized calibre are retained by scavenger No. 2. The infinitesimal impurities are now supposed to be held back by a yet more dense and compact medium, performing the duty of scavenger No. 3. We have now to deal with the subtle combination of impurities held in solution, and here the case is met by a barricade of vegetable carbon occupying nearly the whole of the space illusively supposed to be devoted to the reservation of pure water. As experience has shown that this is not only a chemical, but a mechanical strainer, we must, in honesty, call this scavenger No. 4. Now comes the question, how do these four scavengers dispose of the impure and foul material they have thus retained? Experience supplies the answer, that it has become more or less amalgamated with their own substance, and can only be removed by taking the whole apart, and washing the several layers of which it is composed. Artificial porous stone takes the precedence over loose materials, and possesses this advantage, that it can never admit the impurities into its own substance; and being a silicate, is not liable to decomposition or decay: but with this material, perfect as a medium of filtration, we have an instance illustrative of the condemnatory effects of mal-adaption; for, admitting that the impurities cannot pass through the stone, have we not the impurities on the stone acting as obstructives, thus preventing the permeation? whilst, on the other hand, if adapted on the ascension principle, as we have before described, neither months nor years of permeation will influence the material in any way to reduce its daily yield. And more forcibly still is the value of this principle demonstrated by the fact, that an area of one foot superficial, yielding but one hundred gallons per diem on the principle of descension, under the same head of water has been known to yield from five to six hundred gallons per diem, on the principle of ascension. We would further remark that all apparatus designed for the purification of water should, if at all practicable, be immersed in the tank or other receptacle from whence the ordinary supply is obtained, in order to ensure the valuable desiderata of freshness and low temperature—such apparatus also filling themselves, yielding a far larger supply of water, and being free from breakage.

We hope the day is not far distant when filters will no longer hold the anomalous position they now occupy; but cheapness and perfection being combined, it will be a matter of ease as well as expediency for each one to provide for his own establishment an ample supply of pure water.

*Supply of Cannel Coal Gas in the City.*—At a recent meeting of the City Commissioners of Sewers, a letter from the Great Central Gas Company was read, stating their wish to take up, at a future time, the pavements in the streets of the City, to lay down new mains for supplying Cannel coal gas to their customers. After some discussion the matter was referred to a committee.

## ON THE DRAINAGE OF BUILDINGS AND STREETS IN THE METROPOLIS.

[*A Discussion held at the Royal Institute of British Architects.*]

(*Concluded from page* 208.)

Mr. FOWLER observed, that although there existed much greater activity and efficiency in house and street drainage, the result was, that the Thames was rendered a much greater source of annoyance and pestilence. He denied that the sewage matter was sufficiently diluted to be inoffensive, stating that the sewage, being lighter than the main body of the water, floated upon the surface, and was deposited at ebb-tide on the shores. But although this matter was offensive, it was valuable as a fertilising agent. Various schemes had been proposed for recovering the manure, but had not succeeded as commercial speculations. He further stated, that at the present time Mr. Wicksteed, Engineer to the East London Waterworks, is engaged in a very large speculation of this kind at Leicester. Another plan proposed was, to convey the sewage water by main pipes into the country, and then to distribute it over the land. With respect to the views of the government, to whom the decision of the question must eventually come, Lord Palmerston had declared that they would consider no general plan for the drainage of London effective which did not provide for saving the river from pollution, and at the same time preserving the products of the sewage for fertilising the country. If this were the right principle, it was obvious that the sewage should be carried by the shortest and most easy courses into the country direct; and therefore the majority of the plans proposed, suggesting as they did the concentration of the sewage at a spot some distance down the river, had a tendency to obstruct that principle, and were therefore unadvisable. Further, as these plans are proposed to make the Thames the receptacle of the sewage, both of the principles laid down by Lord Palmerston would be violated.

Mr. MOREWOOD, representing the Great London Drainage Company, stated, that the question before the meeting was the "outfall" for the drainage of the metropolis, and as the Board of Health plan dispensed with all the present arrangements, and consequently with the necessity for an outfall, it might be well to say a word in reference to their plan, as recommended by Mr. Fitzroy to the Metropolitan Commission of Sewers, which had been ascertained to be identically the same as that which the Sanitary Commission advocated in 1848. It consisted of "liquid distribution of sewer water," of "pipe-sewers" and "pipe-drains." Liquid distribution had been advocated for ten years, and was specially in favour in Greek-street in 1849, and yet up to this time there was not one instance of its being used in any one of the towns under the Board of Health. In fact he declared it to be entirely fallacious, and that it never could be carried out profitably. As to pipe sewers: Sir Christopher Wren built a sewer 20 inches by 14 from Cripplegate to Bridgewater-square in 1691, and in 1714 it had to be taken up and rebuilt 4 feet by 2 feet. Mr. Kelsey, the late very able surveyor to the City Commission of Sewers, stated, "it is not in the least improbable, that if drains and sewers are so wire-drawn as barely, and that with the most unremitting attention to their cleanliness, to suffice for the ordinary discharge of the foul waters of houses, and of ordinary showers of rain, another generation will not pass away before another re-modelling of such matters will be found imperatively demanded, as one may with tolerable certainty predict, that if sewers should be built into which a man cannot get to examine and repair as time shall gnaw them away, the evil day must and will come when the whole will have to be re-constructed." In reference to reducing the optional sizes of house drains to 12 by 9 inches, he said, "with what advantage or detriment time will show," and the very words which he used in respect to stoppages and failures were the same as those used in a report from the Board of Health in reference to Croydon. In cleaning the obstructed sewers, however, it has generally been found that the stoppages, whether in 4 or 6 inch pipes, have occurred from substances which ought never to have gained admittance to the sewers at all. From Mr. Simpson's evidence in 1846, it appeared that the Chelsea Waterworks Company had laid down a quantity of earthenware pipes, which, after a few years, had a dull sound when struck, and when they burst might be crumbled with the hand. At Croydon, some of the pipes were found to have become softened, and there was ~~moreover the Metropolitan~~ Commissioners' report of failures, with a vast number of illustrations. The Board of Health plan of liquid distribution of sewer-water of pipe sewers and drains was therefore entirely inadmissable. The recognition of that which the metropolis requires—a lower outfall than the Thames—was to be found in a pamphlet in 1839, emanating from an architect, who, after showing the existing levels in Westminster, states that it is quite impossible for the Commissioners of Sewers to remedy the evils complained of. They had for years past endeavoured to palliate the mischief; all the sewers in Westminster, for twelve hours out of the twenty-four, were merely cesspools or reservoirs, the mouths being closed by sluice gates; indeed, were it not for these gates, every house in Westminster, even those in Park-street and James-street, would at high tides be inundated with the filthiest of floods. In 1846, Mr. Donaldson gave very decided evidence in reference to the inefficiency of the present outfall into the Thames, and showed how readily the Westminster Commissioners of Sewers were availing themselves of the temporary lower outfall caused by the removal of old London-bridge; and in 1847 Mr. Wm. Hosking, in a postscript to his work, strongly warned the government against further clogging the sewers and the Thames, "unless the refuse can be certainly hurried on through the sewers, and in a diluted state to an *effective outfall.*" This lower "outfall," this removal of the sewage, Mr. Morewood considered, could alone be effected by the drainage plan with which he was connected, commonly known by the name of the Great London Drainage, which consisted of two tunnel sewers extending on each side of the Thames respectively, from Chelsea and Vauxhall to the marshes east of London, the sewers running under the streets and roads, as the Strand, Fleet-street, &c., to be made by tunnelling, and to be laid with an artificial or additional fall, so that the sewage might be passed away from the metropolis and pumped up at the terminal works, there to be formed into a dry manure, the refuse water being thrown on the top of the tide. He stated that this drainage plan had been prosecuted in the session of 1848, when it had been very favourably entertained by the government, but it was most unexpectedly stopped at the second reading on the 7th March, 1848. In 1853, the proposed works and estimates had been proved before a select committee of the House of Commons, and the minutes of evidence printed by the House, with a view to future legislation, and the chairman of the committee had stated to the House, that *they had fully approved* of the works proposed—viz., two tunnel sewers to deliver the refuse below the town. In reference to the Metropolitan Commission of Sewers, Mr. Morewood stated that their own report to parliament in 1851, fully identified them with these very works; the tunnel sewer on the north side being described as from Chelsea "to the pumping-station on the river Lea," and that on the south side as a "system of sewers between a point near the top of Woolwich Reach and Vauxhall, the main line and branches comprising upwards of thirteen miles." A report from the surveyors of the Metropolitan and City Commission of Sewers entirely approved of the line of those sewers as proposed by the Great London Drainage Company, declaring, in reference to the north side, that it was in some respects better than the alteration adopted by the Metropolitan Commission (in 1851); and respecting the south side, "the general levels of the district, as well as the levels of the inverts of its sewers, are such that the interception of the sewage can be effected by either scheme." Respecting high-level sewers, by which the question has since been complicated, they expressly said, "and it would in our opinion be found necessary at some future day to construct upper lines of intercepting sewers." The point of difference with the Commissioners was the guarantee of a contingent interest of 3 per cent. for twenty-five years; and also, the Commissioners, not having taken into their calculation that the tunnel sewers were never intended for Richmond and Croydon; that evaporation amounted to 32 inches when the rain-fall was 27 inches; that absorption materially reduced the quantity of rain water to be provided for by tunnel sewers; and that immense storage room was already in existence for storm waters, which would pass through the present channels into the Thames, when the quantity of ordinary sewage, ten or twelve million cubic feet, exceeded the thirty-seven millions for which the two tunnel sewers provided.

Mr. G. R. BURNELL, in reference to the deodorising of sewage water, alluded to the works which had been carried on at Cardiff, and said that Professor Way had informed him that there was a great difference between the sewage water of large and small towns, and that the sewage of London, when it had passed through great length of sewer, and arrived near the outfall, had lost so much by evaporation that it contained very little indeed of really valuable matter available for agricultural purposes. Seven years ago he had visited the works near Chelsea referred to by Mr. Fowler, and although they had been highly eulogised at the time, he found that they did not distribute sewage water at all, but merely the water from a canal.

Mr. Fowler explained that that had been the case only in the commencement of their operations, the main was afterwards laid into the wall. Mr. Burnell had been misinformed; in 1852, the company distributed a great quantity of sewage water.

Mr. Burnell considered the general question to be purely of an engineering nature, and that the Home Secretary was travelling out of his path in deciding that an uniform system should prevail, when in fact nothing was clearly known upon the subject; and scientific men declared that the sewage of small towns was fit to be profitably used, whilst that of large towns was not.

Mr. Fowler believed that the government merely asserted a general principle, which did not involve any engineering question. It was simply a question of economy, and one that might be properly taken up by the government. They had not gone so far as to dictate any particular mode of carrying out their principle. Mr. Fowler added, that the discharge from the King's Scholars' Pond sewer had been found to possess fertilising qualities in a very high degree.

Mr. Haywood observed, that if the treatment and recovery of the sewage could be made to pay 5 or 6 per cent., small manufactories might be established at the mouth of every sewer. If the drainage was not to flow into the Thames, intercepting sewers were necessary; and if, though flowing into the Thames, its reflux was to be prevented, it must be carried sufficiently low down to prevent its returning with the tide. With regard to irrigation with sewage waters, he had no doubt of its advantages, but questioned whether it could be made to pay. The magnitude of the drainage of London (amounting, exclusive of rain, to 12,000,000 cubic feet of water every twenty-four hours), was a serious obstacle to any purifying scheme, but even that would be surmounted if it would pay 5 per cent. The plan of intercepting sewers had no particular novelty; its supporters considered that the chief fault in the plan of the Great London Drainage Company was, that it was not sufficiently comprehensive, and did not allow for the extraordinary influx of storm-waters. They also objected to the pumping on Mr. Morewood's plan, preferring drainage by the natural force of gravitation as a cheaper system, and less liable to accidental interruption. Messrs. Bazalgette and Haywood proposed to discharge the sewage at Woolwich only with the first two or three hours of the ebb-tide, in which case none of it would return so high as the point at which it was discharged. The sewage was an infinitesimal quantity compared with the water of the river, and far less injurious than the public imagine. Four minutes of ebb-tide at London-bridge would suffice to carry down all the real fæcal matter of the twenty-four hours, if collected, and much of the effluvium which arose at low water was in consequence of the sewers discharging their contents upon the shore, instead of being conveyed by culverts to parts below low-water mark. Mr. Haywood considered 50,000*l.* would be well-spent in determining the value of this matter when relieved of 700 times its bulk of water. All the illustration of its value had been drawn from places where its dilution was not one-third or one-sixth so much as in London, In Edinburgh, the distribution of the highly-concentrated matter over the country had become a fearful nuisance, but it had been argued, that in London all the smell would be lost in two minutes and a-half.

Mr. Austin produced a drawing of his proposed plan of sewerage,* which consisted of a large tunnel below the streets, 26 feet in height by 18 feet in width, providing at the same time space for gas and water pipes, and a tramway for connecting the different lines of railway. He also produced a plan of drainage by means of two tunnels under the bed of the river on each side, proposing that only the flood or rain water should pass directly into the Thames.

Mr. Garling read an extract from a letter written by himself in 1824, in which he proposed intercepting sewers, thus showing that he originated that idea at an earlier period than John Martin, to whom it is generally ascribed, and that his (Mr. Garling's) views were then similar to those of Messrs. Bazalgette and Haywood.

Mr. Morewood observed, that a very similar plan had been suggested by Mr. Dodd fifty years ago. He stated that the Great London Drainage Company contemplated the formation of high-level sewers in addition to low-level sewers, as the size and population of London increased, and that their plan was fully adequate to provide for the ordinary rainfall in the metropolis.

After some further unimportant discussion relative to pipe sewers, the question was brought to a close.

* The proposition of Mr. Austin is in most respects identical with that of Mr. John Williams, who obtained a patent for sub-arch railways in 1822, but as his ideas were rather crude and undigested they failed in obtaining the attention they deserved.—Ed. C.E. & A. Journal.

## THE CANADA WORKS, BIRKENHEAD.

The land on which the Canada Works are erecting at Birkenhead is of an irregular form, and the buildings 900 feet long by 36 feet wide. The land abuts on Wallasey Pool, near the bridge. Mr. G. Harrison, manager of the engineering department (formerly a resident in Birkenhead), arrived a year ago from America, to initiate and conduct these works for Messrs. Peto, Betts, Brassey, and Jackson. The progress of the works has been most rapid in every way, as within a year they have been erected, and two engines built and shipped.

There are 400 men at work in the engineering department, and 123 in the bridge-building department, and the latter is to be considerably increased. Of what are technically termed "pits," or places where engines are built, there are ten, and there are five passenger and five goods engines in course of construction. The works are able to manufacture forty per year. The railway will require for its own uses this rate of manufacture for the next seven or eight years, or 300 locomotives. All the work, except the tubes and some smaller matters, is made on the premises; and it is an interesting sight to see a place which but twelve months ago was a piece of waste land, covered with buildings and railways, and the ground strewed in all directions with boilers, tenders, wheels, engine-frames, and the other parts of locomotives. There are two modes for shipment of the engines when complete—one by water, 20 feet deep, at the back of the yard, and the other by the dock railway, which runs into the workshops.

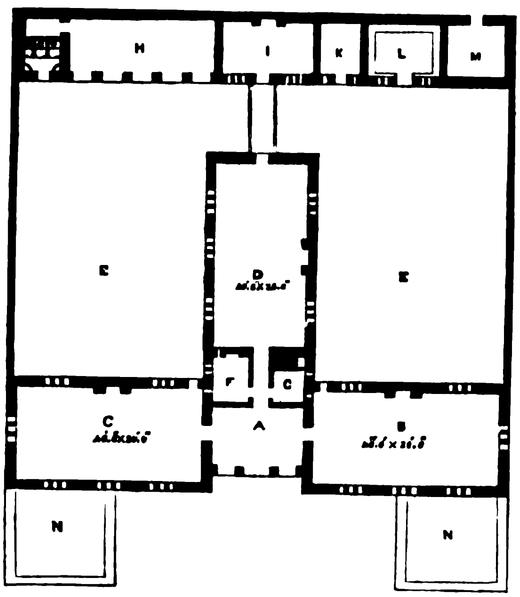
On the opposite side of the yard is the bridge department, for the construction of the great tubular bridge to cross the St. Lawrence, which is similar in design to the Britannia, but immensely larger. It is making in a shed 215 feet long by 48 feet wide, and one span of 155 feet has already been shipped. There is a 35-horse power high-pressure engine in this shed. In this department, the iron is delivered by railway, and the plates are rolled, punched, and subjected to such manipulations as will prepare them to be put together when they arrive out at Canada. The parts are so numbered and packed that when they arrive out there will be no difficulty in riveting them together.

The first engine made at the Canada Works, Birkenhead, was subjected to a trial on the 29th of May, previous to shipment for the Great Canadian Railway. The engine, which is the first locomotive engine made in Birkenhead, was built as No. 1, and each successive engine will be numbered onward. It was named after Lady Elgin, Mr. William Jackson, M.P., christening it. The second will be called the Lord Elgin, and both will be despatched by the steam-ship *Ottawa*.

The railway is between the narrow and broad gauges in width—viz., 5 ft. 6 in., which will make the carriages more commodious, and add greatly to the steadiness of the trains. The engine has a cylinder 15 inches diameter, and 20 inches stroke, with driving and trailing wheels, the latter 6 feet diameter, and the leading-wheels 3 ft. 6 in. diameter. The engine is tubular, having 178 tubes, each 1⅞ inch diameter, which is equal to 872 feet of heating surface. In the fire-box the heating surface is equal to 78 superficial feet; making a total of 950 superficial feet of heating surface. The American principle of a "spark-catcher" has been adopted, as the steam will be generated by wood fires, which throw sparks up the chimneys, and which require to be intercepted, so as not to damage or set fire to the forests through which the engines travel. This engine will be able to take twenty-two or twenty-three carriages forty miles an hour. The principals of the establishment celebrated the event by dining together at the Woodside Hotel.

## ERRIS FISHING SETTLEMENT, MAYO, IRELAND.

T. C. Tinkler, Esq., *Architect.*



In September 1849, the Erris Fishing and Industrial Settlement was commenced, with the view of employing the boys of the peasantry in various labours, and of imparting to them a sound education. Boys from ten to sixteen years of age are instructed in the improved modes of deep-sea fishing, the manufacture of fishing nets and lines, boat-building, and agriculture. The Erris coast is peculiarly adapted for these purposes, having "good, capacious harbours, excellent anchorages, sheltered from all winds in bad weather; a port, the egress and ingress to which is unattended with danger, and always under the lee with the prevailing winds; and also an abundant supply of fish." The canal between Blacksod and Broadhaven is also an advantage which most other places do not possess.

The Society has therefore been happy in its selection of a site for their establishment, which is represented in the annexed engravings.. The main body of the building, as at present existing, is of a T form; the central building is higher than the others, and has a belfry on the roof ridge, and an open porch in front. In the ground plan, A, is the porch; B, school-room, 40 feet by 20 feet; C, the dormitories, of the same dimensions; D, is the dining-hall, also 40 feet by 20 feet; E, E, are the open yards; F and G, the master's rooms. At the rear of these buildings is a range of offices, consisting of a working shed H; kitchen I; scullery K; lavatory L; and cow-house M. The two portions of the front buildings marked N, are not yet in existence, but will be erected as soon as the Society's funds admit.

The institution is well worthy of support, and, from the practical nature of its endeavours, is likely to ameliorate the position of the Irish peasant in that respect, as well as to render service to distressed vessels on that portion of the coast.

## WATERFORD AND KILKENNY RAILWAY.

### Engineer's Report.

From an examination of the works throughout the line during the past week, I am enabled to submit the following report for your information. In my last half-yearly report, dated 21st November 1853, I anticipated that the Waterford end of the line (which is being constructed by the Waterford and Limerick Railway Company), would have been completed early in the present year, but I am sorry to say that, owing to a very reduced rate of progress in the works taking place shortly after the date of my report, as well as from the unexpected difficulties which ensued by the sinking of the embankment through the marshy lands, my expectations were not realised, and the line is yet incompleted. During the past fortnight, however, Mr. Dargan, the eminent contractor, has employed a very large number of additional workmen on this part of the line, and it is evident that the greatest exertions are now being made so as to complete the works and station within the shortest possible time. On a great length of the line nearest Waterford, the Limerick Company has commenced the laying of the permanent way of their line, and as the permanent way of the Kilkenny line is to be executed by your Company, it is necessary that immediate steps should be taken for carrying on the same contemporaneously with the works of the Limerick Company; otherwise that Company will be in a position to complete their line into Waterford before you. Judging from the present activity in the works, with long days and summer weather, I have no doubt that the Waterford end may be completed by the first week in July next. On Saturday last, I very carefully examined the timber superstructure of the Nore viaduct, accompanied by your resident engineer. On comparing the levels of this work, as recently taken by Mr. Atkinson, with those previously observed by him from time to time, I find that the rate of deflection in the curvature of the lattice framing has not increased during the past year; and therefore for your guidance, I may remark, that, if the same rate of deflection should continue as it has done during the past three years, it would occupy a further period of seven years from this time before the framing would arrive at a horizontal line, and consequently there is now no cause whatever for supposing the viaduct to be in danger. The original defect in the construction of this superstructure by not trenailing the lattices together, causes considerable vibration throughout the work on the passing of the trains over it, which motion necessarily tends to compress the joints of the lattices where they pass through the horizontal beams, and hence the case of a slight deflection in the structure constantly going on. In my report to your board on the 25th February 1852, I pointed out this defect in the work, and it was afterwards explained to Captain Moorsom, who considered it was then too late to insert the trenails, more particularly as he expected at the time that the structure was then near a point of rest. I am of opinion that such an additional mode of fastenings to the lattice and horizontal timbers would prevent a great deal of the present vibration in the structure, the parallelism of the horizontal beams would be maintained, and the whole of the framing would be thereby made a perfect and complete truss, and I feel persuaded that the rate of deflection would be greatly reduced. The cost of the trenails I estimate at about 100*l.* Beyond the insertion of these fastenings I do not think it would be advisable at present to incur any other important expenditure on the work, for the structure cannot be considered otherwise than secure for seven years to come, at least, and it is very probable before that time a great deal of the timber in the framing will require to be renewed, so that I consider it would be advisable not to incur any large outlay on the present viaduct, but hereafter to substitute a substantial as well as durable structure; more particularly when it is considered that it would require a large sum of money to make the present work permanent. On the 13th inst. the contractors, Messrs. Ellis and Husler, delivered up the maintenance of their contract, so that now the works of the entire line are being maintained by the Company's workmen, and under the superintendence of your resident engineer. The permanent way is maintained in good and efficient working order. The roof of the passenger shed at Kilkenny has been recently painted, and the platform of the station thoroughly repaired. The working gear of the four locomotive engines that were last delivered have recently undergone a thorough overhauling and repair, so that the engines are in excellent condition.

*May* 31*st*, 1854. Charles Nixon, C.E.

## ON THE SYSTEM OF DRAINAGE PURSUED IN THE METROPOLIS.

REPORT *to Viscount Palmerston, upon the System of Drainage Pursued in the Metropolis.* By RICHARD JEBB, Chairman of the Metropolitan Commission of Sewers.

MY LORD—Having received your Lordship's instructions to furnish you with my observations with reference to the Reports from Rugby, Sandgate, Tottenham, St. Thomas's Exeter, and Barnard Castle,—copies of which were transmitted, by your Lordship's directions, to the Metropolitan Commissioners of Sewers, on the 8th and 26th of November last;—also, with reference to Mr. Fitzroy's letter on the 18th ult., conveying your Lordship's opinion that the system recommended by the Board of Health is that which ought to be adopted, as combining the greatest degree of efficiency with the greatest degree of economy, and transmitting a copy of a letter from Mr. F. O. Ward;—and generally, with reference to the respective merits of the two systems:—

I beg, in the first place, to apprise your Lordship that, by order of the Commissioners, their Engineer Mr. Bazalgette, visited the five towns above referred to, and in his Report* are embodied the results of his observations with regard to the nature and expense of the works there executed; those results being such as to qualify the conclusions which might, without explanation, be drawn from the Reports of the Local Boards of the places named. From his Report the following facts may be collected: that in each of the five towns there is a double system of sewers,—1, a set of old brick sewers originally constructed for surface drainage, and now maintained for that purpose out of the public rates; 2, a set of newly-constructed pipe sewers, chiefly or exclusively for the reception and discharge of house-drainage. The entire sewerage of the town comprehends both sets of sewers; and its cost is really the cost of both, and not the cost of the new pipes merely, as a person deriving his sole information from the Reports sent to your Lordship might possibly suppose. I may here remark, that a like observation applies to several other places drained under the supervision of the General Board of Health, where pre-existing brick sewers are still maintained, and used as a part of the system of sewerage; whilst the Reports, holding up the drainage works in those places as models of cheapness, make mention only of the new works.

At St. Thomas's, Exeter, as respects a considerable part of the town, the average cost per house of putting in house drains, &c., would appear, on the face of the Report from that place, to be exceedingly low. This apparently low average is obtained by dividing the entire cost of all the house drains amongst the houses, whether drained or *undrained*. Mr. Bazalgette estimates the proportion of the undrained houses at about half the entire number.

It further appears from Mr. Bazalgette's Report, that the cost of executing works of the same character is necessarily greater in London than in the five towns referred to. This arises from two causes:—First, all kinds of workmanship are dearer in London than in country towns. This observation cannot apply to Tottenham, but it applies to the other places. Secondly, and chiefly,—in London there are several heavy items of expense, which either do not occur at all, or occur in a very slight degree in country towns. In London, sewers, whether of pipes or of brick, must generally be laid at a much greater depth; the trenches carefully fenced, watched, and lighted; the large and weighty and closely packed houses shored up; gas and water-pipes protected and made good; and costly pavements removed and restored. These, and like matters, add very materially to the expense of making sewers in London; and the amount is but little affected by the nature of the structure.

It is important to observe, that the cost of sewering a town is not simply in the ratio of its size. Thus, the sewerage of a town of 100,000 inhabitants will cost more than that of ten towns of 10,000 inhabitants each, because the accumulated sewage of the higher parts must be conveyed through the lower parts, demanding an enlargement of the sewers of the latter, beyond their own special requirements. I will here give the population of the five places particularly in question:—

| | |
|---|---|
| Tottenham | 11,000 |
| Rugby | 8,000 |
| St. Thomas's, Exeter, excluding Exwick, whose drainage is entirely distinct ... | 5,300 |
| Barnard Castle | 4,600 |
| Sandgate, besides a fluctuating population of uncertain amount, resorting to the village in the bathing season ...... | 1,400 |
| Total | 30,300 |

As to the alleged efficiency of the works: from Mr. Bazalgette's Report it appears that in none of the five towns named have the works of *private* drainage been commenced more than two years and a half; in some they have been commenced much more recently; and in none are they yet complete. In none has sufficient time elapsed to give the system a full trial. In four out of the five towns there have been failures; at Sandgate to a considerable extent.

Adverting now to Mr. Ward's letter, of which I append a copy for the convenience of reference,* the general assertions it contains require to be dissected; and then they will be found to represent anything but the accurate state of the case. I shall have occasion to notice some of them presently. But I will come at once to what I conceive to be the main question between the Commissioners of Sewers and the Board of Health.

In a vast city like London, the greatest difficulty with which a body charged with its drainage have to grapple is its surface drainage, as contra-distinguished from its house-drainage. Now, without asserting that the Board of Health leave surface drainage wholly out of their consideration, I still venture to say, that they devote their chief attention to house-drainage; and not unnaturally, seeing that they have to deal mostly with small provincial towns, where surface-drainage does not hold the same relative importance as in and about London.

In a small country town, not already provided with surface drains, you may often, with comparative safety, allow the rain to a great extent to flow over the surface of the streets, or along the open side channels, till it reaches the nearest ditch or brook, especially where, as is frequently the case, there are no basements to the houses. In London, the *whole* of the surface drainage is, or ought to be, carried to its ultimate destination in covered channels under ground, which must be deep on account of the basements, and for other reasons. To show approximately the relative quantities of house and of surface drainage which ought to be provided for, I must trouble your Lordship with a few figures. The quantity of house sewage in London may be estimated by the quantity of water supplied to the houses. This should be, though in point of fact it is not nearly so much, at the rate of 5 cubic feet, or about 31 gallons, per head per diem, so that, looking forward to a considerable increase of population, *i. e.* allowing for a prospective population of 3,000,000, and an adequate water supply, provision should be made for 15,000,000 of cubic feet per diem; but as the flow of house sewage during about six hours of every day is double its general average, the provision of house drainage sewers should be equivalent to an equable daily discharge of 30,000,000 of cubic feet.

The amount of surface drainage is measured by the quantity of rain which falls. Whatever may be the case in small country towns, in London it will not answer to provide sewers for merely ordinary rain-falls, not exceeding at any time a-quarter of an inch per diem: provision at the rate of two and a-half inches per diem must be made for storms. This rate will give for the entire metropolitan area of 114 square miles, under the jurisdiction of the Commissioners, 662,000,000 of cubic feet per diem, the quantity for which surface drainage sewers ought to be provided.

The requirement, then, for house sewage is to that for surface water as 30,000,000 to 662,000,000, or as 1 to 22; whilst the Board of Health pay great attention, and very properly, to 1 part in 23, they appear to under-estimate the importance of making due provision for the 22 other parts.

The mode of conveying this entire mass of sewage, amounting to 692,000,000 of cubic feet, into the Thames, its present receptacle, claims consideration in the next place. Every road which has houses on each side of it, would require, according to the Board of Health system, three sewers at least, one running under the road to receive its surface drainage, and also to serve as an outfall of the entire drainage of all sorts of the districts higher up, and two other sewers, one on each side, behind the houses.

* See *Journal, ante* pp. 126, 177.

See *Journal ante* p. 125.

These two latter sewers receive from behind, the drainage of the individual houses, and also, I assume, the rain which falls in their rear; they are of pipes commencing with the size of 6-inch diameter, and gradually enlarging to 9-inch and 12-inch, &c., according to the length they run; but I presume they would not be allowed to run for any great continuous length; at each convenient opening, I take for granted, they would be brought round from the right or the left, and connected with the central sewer under the road. This central sewer, before it has traversed any considerable length of the five miles between the water-shed on the margin of the basin of the Thames and that river, would receive such accessions of sewage and water from the above mentioned sewers on each side, as well as from the road itself, that it would soon greatly exceed, in magnitude and importance, the side house sewers; of course its size would vary considerably, being small near the water-shed line and large at its outlet into the Thames; but its mean capacity, or rather discharging power, would require to be about sixty times that of each of the pipe house sewers behind the houses. Its size, at no very great distance from the water-shed line, must exceed the capability of pipes, and, consequently, it must thenceforward be made of brick, and it is necessarily placed under the road, where expense of every kind attends its construction; it therefore constitutes not only the most important, but the most costly part of the entire system of sewerage.

In spite of all the considerations here pointed out, the advocates of the Board of Health system either entirely overlook or make light of this most important sewer. It may, perhaps, be overlooked or made light of in small country towns, in London it must not.

I have spoken of its relative capacity in comparison with the rear sewers; its average absolute capacity, I am not in a position to state; that must depend chiefly on the breadth of the area which it drains. Assuming, for the moment, that all the London sewers could at all times be rendered "self-cleansing" and self-repairing, so as to render it unnecessary for men ever to enter them, then the question of size becomes simply an hydraulic question.

Viewing the existing sewers merely in this aspect, it would appear that, until lately, in determining their sizes, hydraulic science had been exercised either not at all, or very scantily. Some of them are, beyond a question, unnecessarily large; still more of them are too small; the consequence of which latter defect is, that basements are flooded, and property destroyed, to a very large amount annually. Some of such sewers, therefore, where they cannot be relieved, will have to be re-constructed of a larger size. In most cases, however, this necessity will be avoided by the construction of the Great Intercepting Sewers, recently designed by the Engineers of the Commission, which, by dividing the present drainage area on each side of the river into separate zones, will in effect create so many distinct and parallel water-shed lines, in lieu of the present single line, and will on those lines intercept the existing sewers, relieving the lower parts of them which are now gorged by the excessive quantity of sewage flowing from the higher parts. In an economical point of view, this collateral benefit ought not to be overlooked, in considering the advantages to be derived from the expenditure of the 3,000,000*l.* which the main drainage works will cost.

Of late, in laying down new sewers, hydraulic science has been rigorously applied, with a view to prevent either a defect or an excess in their size. And here, my Lord, I feel bound to observe, that the Commissioners have not accepted the hydraulic tables which are understood to be adopted by the Board of Health, those tables being in a large measure at variance with the results both of science and experience, English as well as Continental, and being such as, if adopted for London, would entail the most serious consequences to the health and property of its inhabitants, by giving rise to the construction of sewers too small to answer the purposes intended.

But there is an ulterior consideration which has compelled or induced the Commissioners, in a very large number of instances, indeed generally, to make the sewers larger than purely hydraulic considerations would require; and that is the necessity or advantage of enabling a man to enter them, for the purpose of cleansing or repairing both them and the house drains. The Board of Health questions, I believe without any qualification, this necessity and advantage. The necessity must be patent in one large class of cases, namely, where the sewers, of whatever construction or material, must *inevitably*, from their position, become more or less "Sewers of Deposit." This happens with reference to the lower parts of all, or very nearly all, the sewers of London, the mouths of which are now closed for about eight hours of every tide, or about two-thirds of the entire day. The depths at which they must be kept enable them to discharge into the river only at low water; the rest of the time they are closed up, and therefore stagnant for a considerable length from the river. During the periods of stagnation, deposits unavoidably form and accumulate, which can only be removed by manual labour: flushing would not effect it. Now the accumulation of deposit, under such circumstances, has nothing whatever to do with the size or material of the sewers; it would equally take place with pipe sewers of the very best material and workmanship. I must, therefore, beg leave at once to dispose of the largest proportion of Mr. Ward's comparison, wherein, as if with a tacit reference to an imaginary similarity of circumstances, he characterises pipe sewers as "self-cleansing," whilst he asserts that "the big street sewer is nine times in ten an elongated cesspool." A second deduction must be made from his comparison in respect of sewers of antiquated form, constructed many years or even generations ago, and condemned universally by the present generation; such sewers are never made now. A third deduction must be made in respect of those sewers which are subjected to unfavourable circumstances, equally, or in a greater degree, producing stoppages and deposit in pipe sewers themselves, such as bad workmanship, a bad fall, or a deficiency of water,—misfortunes which are always pleaded as excusing a stoppage in a pipe sewer. There remain only those sewers which are of proper form, well built, with a fair fall, and sufficiently supplied with water; such sewers rarely accumulate deposit, more rarely than pipe sewers under similar circumstances. I say this advisedly, as being the result of large London experience. When deposit does form in the large brick sewer (and this will now and then happen, not only in brick, but also in pipe sewers), the means are at hand of entering it, and removing the obstruction, without the necessity of breaking up the street,—a highly inconvenient as well as costly expedient in London.

There are cogent grounds for believing that a much larger proportion of the London sewers than the Board of Health appear to suppose, would be found not one whit larger than simple hydraulic considerations imperatively demand.

It is only for the remainder that any apology is needed; for those near the river, the justification of their size rests upon the absolute *necessity* I have before pointed out of men being enabled to enter and cleanse them; for those higher up, a good reason is offered in the general principle advocated by engineers —that inasmuch as every machine, however perfect, is liable to occasional derangement, each part of it ought, if possible, to be rendered easily accessible for the purpose of repair or adjustment. For a description of the construction of the ordinary modern brick sewer, and of the several purposes for which it is adapted, I beg leave to refer your Lordship to Mr. Bazalgette's Report on Rugby, &c. Against the alleged superior efficiency of pipe sewers, I have to urge the contrary experience of the Commissioners and their officers. But I venture to submit, that the simple consideration of the form of the ordinary sized brick sewer will almost serve to demonstrate its equal, if not superior efficiency. At its lower part, it is neither more nor less than an 18-inch barrel, the upper part merely of the circle being removed and its place supplied by a larger and higher structure. So long as the sewage does not rise higher than the lower part of the circle which is left, the channel is practically the same as in an 18-inch pipe, the same degree of smoothness being soon attained, as shown in Mr. Bazalgette's Report. When the sewage rises higher, the advantage is decidedly in favour of the brick sewer, as the upper frictional surface is partly removed and partly thrown outwards, thereby increasing the hydraulic depth.

I have dwelt thus long on the central sewers under the roads and streets, because it is upon them that the main controversy between the Board of Health and the Commissioners of Sewers really turns. I have endeavoured to show your Lordship that, even assuming the system of combined back drainage to be universally adopted in London, these central street sewers are necessary; that, in all roads and streets running towards the Thames, they must, on the average, be of large size, and therefore of brick; and that, in those districts at least which border on the Thames, including a large proportion of London, it is absolutely indispensable, and that elsewhere it is convenient, that they be of a capacity sufficient for a man to enter. That the advocates of the exclusive use of small pipe sewers are unconscious of the true importance of the large sewers I speak of, may be attributable to the more narrow and partial views naturally attendant on mere provincial experience.

If the preceding statements be well founded, the question of combined back drainage assumes a very subordinate place in the controversy. In truth, it is not an engineering question: it is a question of mere detail, concerning the mode in which the house drainage should be arranged. The Commissioners have no objection to back drainage abstractedly: their substantial objection is to the dangerous and disastrous notion of attempting to substitute it for the important street sewers already described. They permit it in many cases. Applications for leave to adopt it are made almost daily, and the engineer has very seldom been obliged to refuse permission for its adoption. But, in truth, the system is not a favourite one with the more respectable London builders, who prefer a separate drain for each house, running under the latter, and then half way under the street, into the sewer in front, just in the manner described and so strongly censured by Mr. Ward. Even in towns drained under the auspices of the Board of Health it is not always adopted. If your Lordship refers to Mr. Bazalgette's Report, you will find that at Rugby and Sandgate it has been generally repudiated. In the metropolitan districts, the cases where it is most strongly contended for are where speculative builders of an inferior grade run up blocks of small houses in the cheapest and slightest manner that the law will permit, with a view to get them off their hands as soon as they can. Such persons, of course, struggle hard for the cheapest system which can pretend to the name of drainage, without much regard to its permanent efficiency.

Mr. Ward cites Lambeth-square as an instance where combined back drainage has been beneficially and successfully adopted. It is proper to observe, that the mode of drainage is, in some respects, not accurately described; but such as it is, I beg to state, that Mr. Bazalgette considers this to be one of those cases in which he would now recommend that system in preference to separate front drainage. Again, Mr. Ward alleges the expense to have been one eighth of the cost of separate drainage. A calculation has been made of what each system would now cost; the cost of the combined mode would be to the cost of the separate mode as 1 to about $1\frac{1}{4}$, instead of 1 to 8. It will not be difficult to show your Lordship that a like misapprehension commonly prevails as to the relative expense generally of the two systems.

The remarks I have already offered with reference to the central or street sewers, must tend to show that such sewers essentially form the basis of both systems, and that the size of those sewers does not depend upon the adoption of either system. We may, therefore, leave them out of the comparison, and contrast only those subordinate sewers and drains which are peculiar to each system.

The separate system then has, at all events, the advantage of simplicity. It consists of a single house drain running from the back of and under each house, across half the street, to the sewer in front; the length of the drain being about equal to the depth of the house and half the breadth of the street.

The combined system, wherever there is a basement to the house, which is ordinarily the case in London, embraces three lengths of pipe; 1, that portion of the pipe sewer at the rear which corresponds with the extent of the house in front; 2, a short branch pipe from the rear of the house to that sewer; 3, *a pipe branch from the front of the house, half-way across the street, to the sewer in front, for the drainage of the front area.* This last mentioned drain is sometimes given in the statements and diagrams of the Board of Health, and sometimes omitted. I must crave leave to insist on its being included as a general rule, where London is in question, because there the houses generally have front areas, and the kitchens must not be exposed to flooding for want of a drain in front. It is true that occasionally, perhaps generally, the Board of Health, instead of separate front area drains for each house, substitute a single line of pipe sewer running along and parallel to the whole length of the houses, and like the sewers in the rear, joining the central sewer at a certain interval. This, however, will make no material difference in the cost; the only difference will be some diminution or increase of the length of pipe attributable to each house; according as the street happens to be broad or narrow, as compared with the front of each house. In this case, the area drains are dispensed with, and their place is supplied by two additional sewers, making five in all, viz:—two pipe sewers at the rear of the houses, two others in front, and one large central sewer under the middle of the street.

Now, comparing the relative cost of these two systems, omitting the common central sewer, and estimating the cost of each by the length of pipes required, it will readily be seen that the breadth of the street, the length and the breadth of each house, as compared with each other, must decide the question. In some cases these elements will give the result in favour of one system, sometimes in favour of the other.

I trust I have now said enough to make it appear at least probable that the alleged great superiority, in point of cheapness, of the system of combined back drainage is a mere illusion, arising chiefly from inattention to the indispensable necessity, under any system, for large street sewers; and partly, but in a less degree, from an occasional forgetfulness of the necessity of draining front areas; and in some degree, also, from an unfair comparison of country with London prices, and an oblivion of the costly precautions, repairs, &c. peculiar to the streets of London. Of course I must be understood as speaking only of London drainage: with the drainage of country towns I have no concern.

In considering the relative efficiency of the two systems, it must be borne in mind that, after all, the question turns upon a comparison merely of one set of pipes with another set of pipes; and that the street sewers are not involved in it. Indeed, it may be affirmed, that combined drainage must be attended with more hazard, because the sewage, from the time it leaves the house at the rear till it reaches the main sewer in front, traverses a longer and more circuitous route than that which is traversed in the house-drains under the separate system. A well-constructed single house-drain has been found in practice to be unattended with the nuisance or inconvenience alleged in Mr. Ward's letter; obstructions seldom occur in such a drain, if of sufficient capacity; and when they do take place, they are readily and inexpensively removed from within the street sewer, without tearing up the street or the kitchen floor.

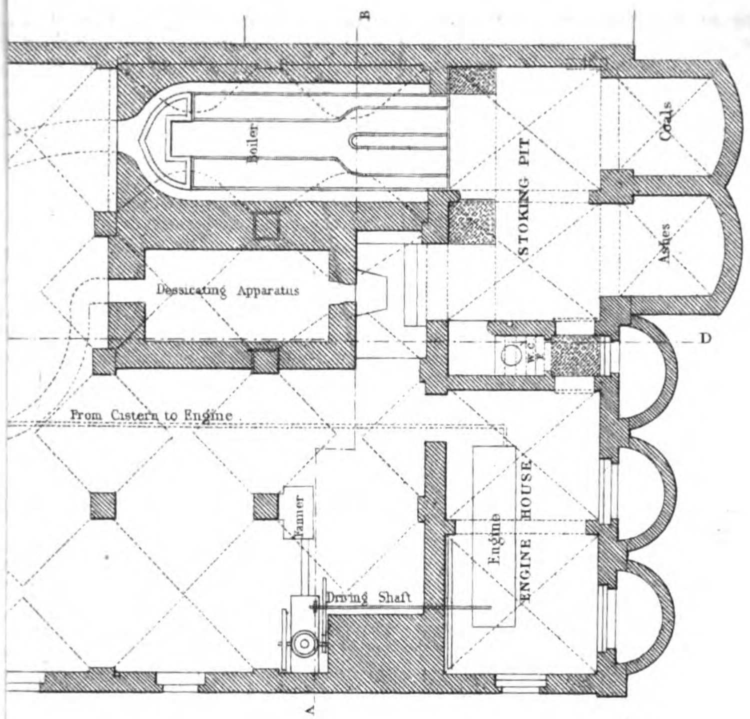
Were the system of combined back drainage to be generally adopted in the denser parts of London, it would frequently become inevitable to pass under some one house the pipe forming the common outlet of the entire block. In addition to the inconveniences enumerated in the same letter, and which are practically found much more serious than the writer represents, the system confers upon the occupant of one house the dangerous and often abused power of cutting off or otherwise prejudicially interfering with the drainage of his neighbours; and the Commissioners experience considerable difficulty in dealing with such cases in the present state of the law, which does not contemplate combined drainage works.

Neither can the Commissioners acquiesce in the expediency of using pipes of so wide a range, in point of size, as that indicated in the same letter. It is found that the 4-inch pipe stops, and the 20-inch pipe breaks. The Commissioners have come to the conclusion that it is not expedient to use pipes smaller than 6 or larger than 12 inches in diameter.

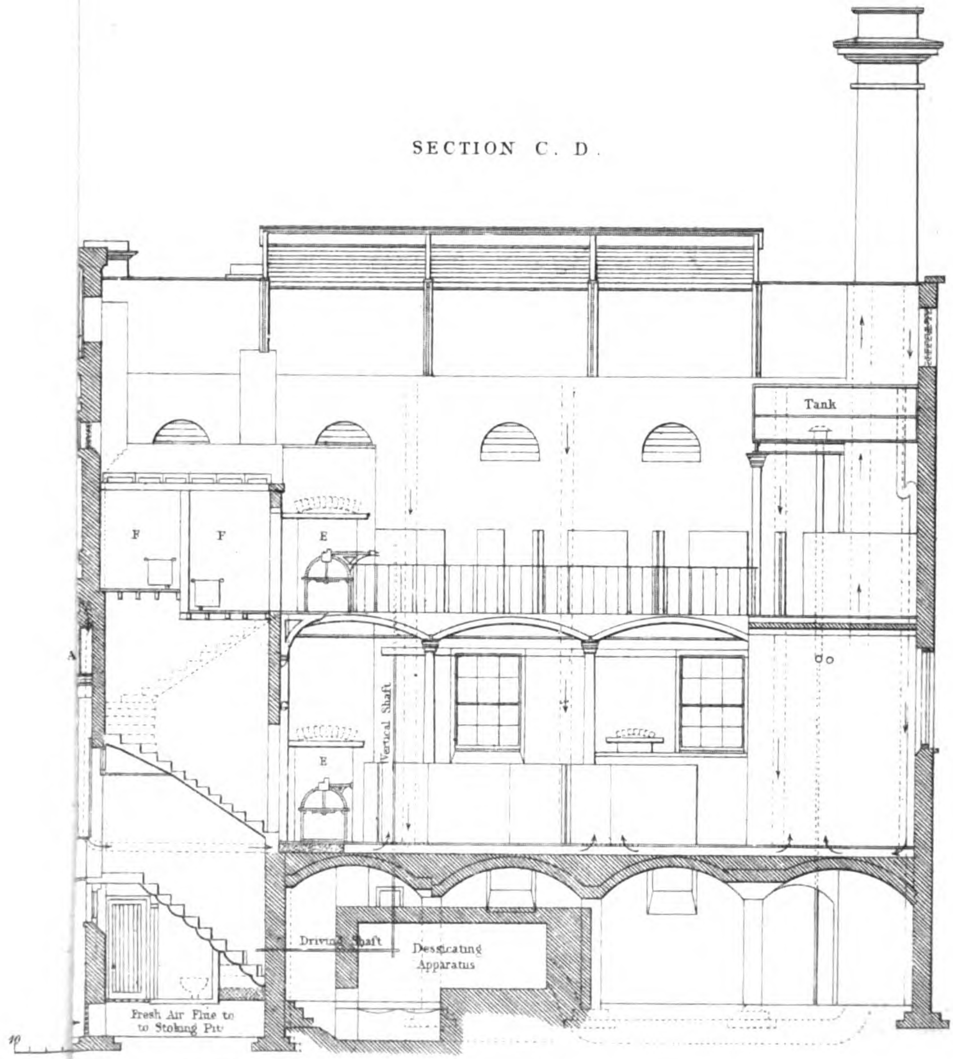
There are, doubtless, many instances in which combined back drainage is for particular reasons admissible; but it is impossible to classify them under general heads for practical application. The Commissioners, some time ago, finding great diversity of practice upon this, as upon other points, prevailing amongst the surveyors who had charge of the several districts, and thinking it desirable to introduce something like uniformity, laid down certain *general* rules for the ordinary guidance of their officers, whose discretion they wished to restrain within prescribed limits. But they never intended thereby to tie their own hands, their object being to reserve the exceptional cases for their own immediate judgment, or that of the superior officers of the Commission. The result of their experience is, that, in the great majority of instances, separate drainage is the best system for London, especially in the denser parts. In the suburbs principally, but occasionally even in the centre of the town, exceptions are liberally permitted.

The restriction placed by the Commissioners upon the use of pipes for small sewers, except in certain favourable situations, has been based not upon any objection to pipes abstractedly, but upon their proved insufficiency in point of strength. The manufacture of them, however, has, within the last twelve months,

OOL.



SECTION C. D.



been materially improved, owing to the regulations of the Commissioners themselves. A year ago the best pipes procurable were generally too thin to be safely used under roads: they are now better, the Commissioners, after much and pertinacious opposition, having succeeded in inducing the manufacturers to make them of good material, and well burnt, 1¼ inch thick; and the Lambeth manufacturers are now preparing to make them still thicker. When this is accomplished, it may fairly be anticipated that the use of them may be safely extended to situations where the Commissioners have been hitherto under the necessity of constructing small half-brick barrel sewers. The justification for the restrictions hitherto established in the use of pipes is to be found in a large body of well authenticated facts. These are derived from various sources, and amongst others, from Mr. Bazalgette's Report on the failure of pipes in the Metropolis, referred to by Mr. Ward,—the accuracy of which has been most unjustly impugned, both in his letter, and in a blue book of last session, No. 1009, being the further Report of Mr. Austin, on the Croydon Drainage, laid before your Lordship.

Any remaining topics touched upon by Mr. Ward are purely matters of detail. He seems to lay much stress on the use, for house drains, of 4-inch pipes (the size which the Board of Health prescribe), on account of their having a more concentrated flow, and therefore a greater scouring power. The Commissioners prefer 6-inch pipes, because, whilst the difference of cost is very trifling, and whilst the loss of scouring power is practically insignificant, the 6-inch pipes allow more readily of the passage of those innumerable substances which are so often "improperly admitted," and which will continue to be improperly admitted by careless or mischievous persons in spite of better knowledge. The experience of the Commissioners has satisfied them that where pipes of the smaller diameter are used, stoppages more frequently occur requiring the taking up and reconstruction of the house-drains at a serious cost. Three or four years ago, the use of 4-inch pipes was largely enforced in the Metropolis by the then Commissioners, often against the urgent remonstrances of the house owners. In many instances those pipes have failed: in some instances, after a first failure, they have been reconstructed and have failed a second time, and have ultimately been replaced by 6-inch pipes. It may, perhaps, be alleged that the failures were owing to bad workmanship; no reason appears for attributing them to such a cause; which, if it did apply, would apply equally to, and produce a like result in the case of 6-inch pipes, which is not found to be the case.

Much more might be urged in support of the regulations of this Commission; but it has been thought better to draw your Lordship's attention to the more prominent features of the subject, and not to enter into more minute detail than was absolutely indispensable for forming an accurate estimate of the relative value of the systems under discussion.

1, *Greek-street, Soho, March* 8, 1854. RICHARD JEBB.

## NEW WASH-HOUSE, FREDERICK-STREET, LIVERPOOL.

(*With Engravings, Plate* XXV.)

THE general arrangement of the wash-house is as follows:—A, is the pay-office, with a window and pay-table to the entrance lobby. On entering, the washer receives a ticket from the clerk, stating the number of the washing compartment to be occupied and the time of taking possession. The compartment is pointed out by the superintendent of the wash-house. When the washer has finished her work, she hands the ticket to the superintendent, who writes on it the hour at which she leaves, and the length of time that the compartment has been occupied. The washer, in going out, hands the ticket to the clerk at the office, who calculates the amount which she has to pay, and receives the money. The pay-office has another window, looking into the wash-house, which, with the pay-window and half-glazed door, affords the means of supervision of the whole establishment. A clock, with one dial to the pay-office, and another to the wash-house, is placed in the wall over this window. The washing compartments on the ground-floor are arranged as shown in the plan. There are three passages or avenues, one in the centre and one on each side, with washing-stalls right and left; this forms the second-class portion of the establishment. Three compartments are partitioned off from the others by a half-brick wall, and have a separate entrance. These form a separate wash-house B, for infected clothes during the prevalence of disease, and have connected with them a drying-closet C. For the general purposes of the wash-house, drying-rooms D, D, are provided. They are fitted up with wooden clothes-horses travelling on rails laid in the floor. E, E, are Manlove and Alliot's patent hydro-extractors, by means of which hand-wringing, with its injurious effects on clothes, is entirely obviated.

The washing compartments in the gallery floor, which constitute the first-class portion of the establishment, are arranged round the walls. The central area is entirely open, and lighted from the roof; and a projecting gallery of Yorkshire stone, carried on cast-iron brackets, forms the communication between the two side galleries. At the further end of the building, supported by a continuation of the iron columns of the gallery, is a tank of boiler-plate, capable of containg 7000 gallons of water.

Each washing compartment contains a square washing-tub and a circular steaming or boiling tub, each supplied with cold water and steam *ad libitum*; a brass plug in the bottom of each tub conveys the waste water to the drains. In addition to these tubs, some of the compartments around the walls have a dolly-tub, a favourite system of washing in this part of the country.

F, are waterclosets fitted with Kirkwood's common closets. The working machinery of the establishment is contained chiefly on the sunk floor, over which the whole area of the building within the external walls is carried by a system of groined arches on brick pillars 18 inches square. The unconfined and uninterrupted working of the whole apparatus is thus obtained, with a ready means of access to the drains and water and steam-pipes without disturbing the arrangements or marring the cleanliness and order overhead. The steam-boiler is one of Galloway's patent. Adjoining the boiler is Davidson and Co.'s patent desiccating apparatus. The hot air from this ascends to the drying-rooms by the flue G, with a branch flue to the drying-closet C, of the infected clothes wash-house. The machinery is driven by a horizontal engine of 5-horse power. The fly-wheel shaft, passing through the wall of the engine-house, communicates its motion to the fan of the desiccating apparatus, and to a vertical driving-shaft running through both floors to the hydro-extractors E, E; and in a very small space high velocities are obtained by the use of Parker's system of banding-pulleys. The pipes for the supply of water and steam to the building are shown lined on the section and dotted on the plan of the gallery floor. They are hung to the cast-iron beams with wrought-iron slings, securing free action for the pipes in expanding and contracting. Vertical branches from these pipes lead to the compartments on both floors. Ventilation is provided for by main ventilating flues under the passages on the ground-floor, with gratings at regular intervals in the floor, to which fresh air is conducted by flues descending the walls round the building and under the floor from the street front. To prevent water lodging in the main flues, each has a communication with the drains. A flue is likewise carried from the areas of the cellar windows through the engine-room to the front of the boilers, securing a moderate temperature even in front of the fires. A pipe from this flue communicates with a cavity all round the brick pillar, imbedded between the boiler and the furnace, where, from the strong heat from these two fires, it would otherwise be liable to be destroyed, and endanger the stability of the arching overhead. Flues from the ceiling of the engine-room and from the front of the furnace lead along the spandrils of the arches to the external air. Near the roof and along the front and one side of the building are semicircular openings, and in the back wall is a circular opening, all fitted with galvanised iron louvres.

The building is of brickwork, with red freestone dressings in front; the steps and landings of Yorkshire stone. The roof is of galvanised iron, segmental in form. It is glazed on each side of the centre for nearly its whole length; the vertical spaces between the roof and the glass are filled in with galvanised iron louvres, made to open and shut by cords from the gallery. The whole of the fittings, the roof, and a large portion of the building materials were obtained in taking down wash-houses previously erected in connection with Cornwallis-street Baths, in the immediate neighbourhood, their site being required for extension of these baths now in progress.

The whole of the works are from the designs and under the direction of Mr. Newlands, Borough Engineer; Mr. Pennycook acting as draughtsman and clerk of the works. Mr. Tomkinson is the sole contractor.

## SLIDING CAISSON AT KEYHAM DOCKS.

By Samuel Clegg, jun.

[*Lecture delivered at the United Service Institution, June 14th*, 1854.]

I have much pleasure in answering a request that has been made to me by your Council, that I should give a lecture upon "Caisson Gates for Docks." I will to the best of my ability illustrate the subject, and trust that I shall be able to give the desired information.

Caisson Gates for Docks is a subject of great interest to engineers, and to those connected in any manner with shipping and commerce. To engineers, because their construction and arrangement involves principles which have only of late years been practically applied to such purposes, and his best energies are in consequence enlisted;—to sailors and dock-officials, because the safety they already ensure, and the prospect they hold out of increased facilities for docking and undocking vessels, permit them to look for still greater improvements and advantages, not only in the docks themselves, but in the magnitude of the ships they are destined to accomodate.

All machinery and contrivances connected with docks are of positively recent origin. The changes that have taken place for the better, since the commencement of this century, are enormous. London had then no docks,—may not we ask what could our trade have then been, that it could put up with the difficulties and delays which must have attended the loading and unloading of ships in mid-river, and the still greater obstacles such a want must have thrown in the way when repairs had to be done? London, I say, at the commencement of this century, had no docks, unless we except one at Blackwall, and the Greenland Dock, built by Mr. Perry and Mr. Wells respectively, both private shipbuilders. Does not this seem incredible?—that this city, unquestionably the first in the world for its opulence, its commerce, and public spirit, and possessing within itself the powerful internal means of supporting docks, and all other conveniences that trade and shipping might require on the most extensive plans, has been the last to try the experiment of docks. Notwithstanding the total inadequacy of legal quays, which subjected the merchants to incalculable losses and delays, and in many cases proved absolutely ruinous; notwithstanding the effect of the heavy, expensive, and fatal embarrassments experienced regularly on the arrival of the West India fleets, and the annual losses by plunder in the river, it was not until the year 1799 that prejudices and private interests were so far removed, as to enable the merchants concerned in the West India trade to obtain an Act of Parliament to carry into execution a plan of docks, quays, and warehouses, on the Isle of Dogs, for the convenience of that trade.

The Docks of Liverpool were the first of the kind that were constructed in this kingdom, by virtue of an Act of Parliament passed in 1708. From that period the town of Liverpool has rapidly raised itself from a poor fishing village and a port for coasting vessels, to be the second commercial town and port in the empire; and the improvements lately carried into execution, of enlargement and better arrangement of the docks, will, when thoroughly developed, render it for convenience in this respect the *very* first, London not excepted.

Docks have assisted materially to develope our national commerce. Its constant increase and the attendant requirements have rendered it expedient to increase the size of our ships; therefore our docks and dock entrances are now far larger than they were a very few years ago. Not only, however, have our merchant ships been enlarged both in length and beam, but our war-ships also; and as the dock entrances and gates which have to admit these monsters are from their size the most interesting at present, and since the caisson gate I shall have presently to describe has been designed for a royal dockyard, I shall confine myself to that which relates to them.

It was at one period thought (and that time not years ago) that our dock entrances would have to be widened to admit the paddle steamers, which were gradually being made larger and larger; but I speak with confidence when I say, that paddles will become matters of history, and only seen in museums—for the screw propeller, although even yet in its infancy, has succeded so wonderfully, that its universal adoption (at all events to sea-going vessels) may be expected with certainty. Again, it is true that steamers may be built of such magnitude as to require paddles as well as a screw to move them—such a one is now being built. We must wait the result; and if, in addition to the enormous beam of the vessel itself, paddle-boxes *must* be added—why, our dock authorities must expect greater demands for accommodation than has even yet (except, I believe, at Birkenhead) been provided, or even contemplated.

To make my remarks more intelligible to those of my hearers who may not be perfectly conversant with such matters, I will explain the different kinds of docks prepared for the reception of shipping, so that by understanding the various forces that at different times act upon their gates, the precautions necessary to be taken in their construction may be better appreciated.

Docks, then, are of three kinds,—viz. Tidal, Wet, and Dry. With the first we have nothing to do; it is simply a space enclosed by quay walls at which ships may load and unload, with greater safety and facility than in a river or open harbour. This space is not closed by gates, and consequently the tide rises and falls within it, to the same extent as it does without: such docks can therefore only be made in situations where at low springs the water may be deep enough to float the vessels frequenting them. Such docks are commonly termed "tidal basins," and with them both wet and dry docks often communicate.

If, at ebb tide, a "foreshore" is left between the low-water line and the place conveniently situated for docks, and it be essential that the vessels therein be kept afloat, the water which has flowed into them during flood tide must be retained by means of gates, singly or in pairs as the case may require. If there is sufficient depth at other times of the tide than at high water, double gates are erected, so as to form a lock, as on a canal. All the docks on the Thames are provided with such locks; indeed, the single gate is seldom available, except in cases such as the following. Suppose a tidal dock, and that it was necessary to provide accommodation for vessels of extraordinary draft of water, only capable of being taken into dock at high-water: a second dock would then be required to be made beyond the tidal basin, divided from it by single gates or a caisson. These gates would retain the water in the inner dock at the high-level. Thus larger vessels would remain afloat, and the general trade of the outer dock be uninterfered with.

The strength of gates for the kind of service I have been describing, when in sheltered situations, will simply have to be proportioned to the pressure of water due to the difference of level between high and low springs, extra solidity not being necessary to resist extraordinary shocks from sea waves. But when they are exposed to this force, which is often of considerable magnitude, their dimensions must be increased. The first is easily arrived at by direct calculation; the latter can be determined only from the results of practice, for no systematic or intelligible attempt has been made practically to measure the force of the waves, so as to furnish the engineer with a *constant* to guide him in his attempts to oppose the inroads of the ocean. The only experiments, indeed, on the subject, are those of Mr. Thomas Stevenson, who had long entertained the idea of registering the force of the impulse of waves, and lately contrived an instrument for the purpose which he has applied at various parts of the coast. The results he detailed in the Transactions of the Royal Society of Edinburgh, of 20th January 1845.

It would naturally be expected that the force of the waves should vary according to the season of the year, and the nature of the exposure; and this expectation is fully justified by the indications of the marine dynamometer. Thus it appears, that during five summer months of 1843 and 1844, the average indications registered at different places near Tyree and Skerryvore, gave 611 lb. of pressure per square foot of surface exposed to the waves; while the *average* for the winter months for the same places during those two years, gave 2086 lb. per square foot, or upwards of *three times* that of the summer months. It also appears that the *greatest* result as yet obtained is 6000 lb. per square foot; but these experiments have not been continued long enough, nor as yet applied to a sufficient variety of places, to render them available for the engineer. In the present state of our information, therefore, we cannot be said to possess the elements of exact investigation, and must consequently be guided chiefly by the results of those numerous cases which observation collects, and which reason arranges in the form which constitutes professional experience.

In determining the dimensions for strength, we must not in any case venture to approach very near the limit of stability, so long as we continue to labour under our present disadvantages of defective information on some of the most important elements in the inquiry. "A little stronger than strong enough," is an engineering maxim very applicable to works having to resist the impact of waves. To give some idea of the enormous force of the sea, I may mention that a mass of rock 5 feet thick and about 40 feet long, weighing nearly 300 tons, was, at Fetlar in Zetland, lifted over a point of land, into the sea at the other side: but it must be remarked, that the form of this block rendered it very susceptible of a sliding motion, and must have greatly aided its transport. The effects produced upon the Plymouth breakwater may, therefore, be considered quite as remarkable; for although the weight of a stone might not have exceeded 10 tons, the comparatively small surface compared to their weight which they presented to the sea, would be greatly in favour of their stability. We are told, that during the storm of November 1824, a length of 796 yards of finished work of this breakwater was completely overturned, and the remaining parts slightly injured. The seaward slope, which was constructed so as to be 3 feet horizontal to 1 in perpendicular height, was altered by this storm to 5 to 1, which slope it was determined to adopt. Again, in 1838, large quantities of stones of 15 or 20 tons weight each, were torn from below low-water, and carried completely over the top of the breakwater. Instances have also been given of vessels being driven high and dry upon the beach, far beyond high-water line; and I have had pointed out to me the spot upon the Chesil beach, some 200 yards wide and 12 yards high, where a vessel was driven from the sea outside into the harbour within.

In the determination of the necessary strength for dock gates, we must also not lose sight of the concussions they are liable to, from portion of wreck being driven against them, and from the vessels themselves which enter the docks.

I find I have been carried away from my subject, and will now describe *Dry* or *Graving Docks*, upon which I shall only detain you a very short time. This kind of dock is especially designed for the purpose of repairing the bottoms of ships; and they either become dry by the ebbing of the tide, when the gates are left open, or by shutting the gates at low-water, and pumping out whatever water may remain in it at that time. Before graving docks were contrived, any defect below the light line of flotation had to be got at by careening the ship over; and if this defect happened to be near the line of the keel, the force required to be exerted to heave the vessel down "keel out" was so great as to strain its framing seriously. There was danger, too, in this process, as I believe the *Royal George* was lost at Spithead while undergoing this operation: and I am sure, naval men must have rejoiced exceedingly when this barbarous system was abolished.

In *Wet Docks*, the water is required to be kept *in*; the sills of the gates therefore are made to point inwards. But graving or dry docks, the water having to be kept *out*, have their gates pointing *outwards*. When caissons are employed, the same form serves of course for both varieties. In order to save the time and expense of pumping (there being no tide), the graving-docks at Sebastopol are situated considerably above the level of the water in the Black Sea. The ships are raised into a general dock-basin by a series of three locks, each having a rise of 10 feet, the height of water in the basin being 30 feet above the level of the sea. The water for supplying the basin, for filling the docks, and for working the locks, is brought a distance of twelve miles by a canal from a mountain stream, which has a sufficient elevation for the purpose. A vessel can thus be taken into either of the docks, after it has been elevated by means of the three locks into the general basin.

This arrangement offers great facility for repairing ships, for after the dock-gates are closed, a valve can be opened, and the water be let out very quickly into the sea through a subterranean culvert, leaving the ship high and dry. I trust that Admiral Dundas will do as little damage as may be to these docks, for we shall find them very convenient for executing repairs, the largest of them being capable of receiving a ship of 120 guns.

The gates were originally intended to have been constructed of timber, but owing to its naturally rapid decay, coupled with the apprehension of the destructive ravages of the "teredo navalis," it was deemed expedient to construct them of metal, as they could be made to perform their duty better, from their greater accuracy of workmanship and their increased durability, which in the end would more than repay the first outlay. These excellent gates were made entirely by machinery. The gross weight of metal in the nine pairs of gates was 1760 tons, and 72 tons of metal were taken from them by planing and drilling.

The gates of graving-docks, presuming the same rise of tide, must be stronger than those for wet docks, having a certain depth at low water, because they have to sustain the entire pressure of the water on one side only, and have not the lower portion up to low-water mark in equilibrium. The method of ascertaining the amount of pressure caused simply by the water on the entire surface, or upon any one point in the surface of dock-gates, is extremely simple. A non-elastic fluid, like water, presses equally in all directions. Its pressure downwards is equal to its gravity multiplied by its perpendicular height. Its pressure upwards is best exemplified by its efforts to float vessels, the line of flotation being determined by the difference between the gravity of the material of the floating substance (supposing it solid) and the water. Or, to speak by the book, a body immersed either wholly or in part in water, and at rest, receives from the water pressures which are together equal to a vertical force directed upwards through the centre of gravity of the water displaced by the body, and equal to the weight of a quantity of water so displaced by the immersed part of the body.

This is further practically illustrated by the camel used to lift ships having great draught of water, over shoals, as at Cronstadt; also by ice, which is lighter than water, coming in contact with caissons, and lifting them out of their seats. Its pressure sideways, or its horizontal pressure, may be illustrated by taking a tube bent like the letter U, and putting a vertical diaphragm closing the bore of the tube at the lowest point, so that water, filled to a certain level in one of the limbs, be retained there; upon removing the diaphragm, the water will rise in the other limb, the surface of the water in each being on the same level; the pressure therefore against the diaphragm was that due to the column of water contained in the first limb. The total pressure against such a surface as a dock-gate is equal to a prism of water whose base and perpendicular height is equal to the depth of the water, consequently the pressure increases as the squares of the depth of the immersed gate. A gate 20 feet deep, having to sustain a pressure equal to four times that upon one 10 feet deep, each being of the same width; and to find the whole pressure in pounds, the square of the immersed depth must be multiplied by $62{\cdot}5 \div 2$, or $31{\cdot}25$ lb. Thus the total pressure upon each foot in width of a gate 20 feet deep will be $20^2 = 400 \times 31{\cdot}25$, or 12,500 lb.; on a gate 10 feet deep, 3125 lb. If the moments of all the pressures were accumulated at one point, called the centre of pressure, it would be found to be at a point equidistant between the sides of the gate, and at a depth of two-thirds from the surface of the water, that being the position where the horizontal pressure resulting from the centre of gravity of the prism of water would be accumulated. And if the gate has to be shored up, or chains attached to open it by, it is on this line they must be secured to produce the greatest effect.

To calculate the direct weight or pressure that any of the bars of the gate will have to sustain, it is simply necessary to multiply the weight of a cubic foot of water, 62·5 lb., by the width of the gate, and the product by the depth of the bar below the surface. The determination of the strengths of the various bars of a gate, then, as suggested by theory, is, to give a safe dimension for the bottom bar, and let the others gradually diminish in strength to the top, in the same ratio nearly as the diminution in the depth of the water. Or, which is the more usual practice, make the bars of the gate of the same dimensions throughout, but put them closer together at the bottom. In a large gate both may be done.

The dimensions thus obtained are those necessary to resist simple pressure merely; but, as I have before observed, gates are subject to concussions, wear and tear from abrasion (especially if of timber), and unequal strains, which nothing but experience will enable an engineer to counteract by economical dimensions; and economy is all important—indeed, the reputation of an engineer often depends upon the *commercial* success of his labours.

An inquiry of some interest is opened when an engineer has to decide upon the use of turning gates or of caissons,—they both have their advantages, and both their disadvantages. For openings up to 60 feet wide, where the water does not rise higher than perhaps 20 feet, turning-gates, I think, would be preferred to the common caisson gates, since they are always in their places, and the time required to dock or undock a ship is less than that occupied in lifting, floating away, and returning the caisson. With the *sliding* caisson, as designed by Mr. Scamp for the Keyham Dockyard, these objections do not exist; but then there must be space enough in the thickness of the wall dividing any two dock entrances to admit the caisson,—and this cannot always be.

The disadvantages of large dock-gates are—First, their original cost, which is greater than that of a caisson. Secondly, they are more frequently in need of repairs; and if the rollers at the bottom, or the step of the heel-post get damaged, their depth below water is a serious obstacle to their renewal. It is very true that all rollers are made to adjust from above, so that ordinary wear and tear is of no consequence; it is their replacement which is so difficult. The third disadvantage of large and deep turning-gates is, their liability to buckle and leak; and it is not a difficult thing to imagine that such large surfaces are sometimes pressed out of truth, and any want of parallelism between the heel and mitre posts will prevent them from meeting with that precision absolutely essential to prevent leakage. There is of necessity some leakage even through those gates exposed to the least depth of water. The leakage through equal opening increases with pressure arising from increased head; and as the difficulty of keeping gates tight also increases with their vertical and longitudinal dimensions, it follows that there must be some practical limit to the use of turning gates; and if we assume this limit to be 70 feet in opening and 25 feet in depth of water, we shall have to use a caisson-gate for openings of greater width and depth. I do not venture to say that the dimensions I have stated are *positively* the limits to the use of turning-gates—more especially if those gates be made of iron; but I *do* say that the liability of such sized gates to derangement, together with their expense, would induce me to look very favourably upon caissons.

The first instance, I believe, of a caisson being employed was for a temporary purpose as a cofferdam, during the construction of the London Docks. A collier was cut down, and a second bow substituted for the stern, to enable it to fit more closely to the aperture it had to close. I do not know the exact particulars of the case, nor do I know that I am correct in stating that it was from this application of a floating vessel for a gate that General Sir S. Bentham took his idea of using such vessels for the closing of dock entrances. I am perhaps not doing the gallant General justice; certain it is, however, that the first caisson-gate in this country was employed at Portsmouth Dockyard at the suggestion of that officer.

The transverse section of dock entrances may be said to approximate to that of the largest class vessels which they are destined to admit. The side walls are built to a curved batten, and are connected together at the bottom by an invert of masonry; this arrangement being adopted to preserve the form of the work perfect, and prevent unequal settlement. Of course, where turning gates are used, square recesses have to be provided for them to fall into, so as to leave the entire opening of the entrance available. This provision necessitates a departure from the perfect form of wall and invert, which, on bad foundations, may be mentioned as a defect—a minor one, it is true, but still a defect, since extra material must be used to gain equal strength at every part. The keel of the caisson is made to fit the curve of the walls and invert accurately, and upon this keel the caisson is built as a deep and narrow boat would be; indeed, a floating-gate is essentially a boat, ballasted like one, and floating like one at various draughts of water, according to its load. We will suppose a caisson launched and ballasted so as to float with stability; its proportions must be such, that with this quantity of ballast its line of flotation, at the lowest state of the tide at which it is likely to be moved, will keep the keel clear of the grooves cut to receive it. It is now brought near to its proper position, and by means of ropes or chains secured on shore, and to capstans on its deck, moved vertically over its grooves. The valves provided for the purpose at the bottom are then opened, and the water allowed to flow in, which settles it firmly in its place. The valves on the outer side are left open until the caisson has to be removed, that the tide may ebb and flow within it; because if it did not do so, as a matter of course, it would lift the gate, the line of flotation with the same weight remaining constant in the same vessel. To remove the caisson, the water on each side of it must be suffered to become of equal depth, proper sluices being generally provided in the masonry for this purpose: or pipes passing through the caisson, fitted with proper valves, may answer the same purpose; only when the dock which has to be filled is large, the time occupied by this arrangement would be inconvenient, since to pass the water very rapidly, the pipes would have to be made either very large, or their number increased, which would be more expensive than a sluice within the masonry. The water on each side of the caisson, then, being level, the valves are shut, and the water contained in it is pumped out until it floats clear of the groove, when it is towed or hauled away clear of the dock entrance, to allow of the vessel to pass in or out, as the case may be. It may perhaps be useful if I give the principal dimensions of a large iron caisson of this kind. I will take one for a 68 feet opening, and a depth of water of 28 feet, used at the New York Navy Yard.*

The plan of its deck was that of a vessel 68 feet long with a beam of 16 feet; its sheer plan corresponding with the figure of the groove in the dock entrance. The iron ribs are 2 feet apart, and are 6 inches deep by 1 inch thick at the keel, diminishing gradually until they are 3 inches by ½-inch at the rail of the upper deck. The plates forming the sides diminish from ⅝-inch to ⅜-inch thick, the bulwarks being ¼-inch thick. Near the bottom is the kentledge-deck, on which 95 tons of iron ballast is secured. The filling-pipes are four in number and 14 inches diameter, extending through the vessel; each pipe is provided with two valves, so that the water may be passed either from one side of the vessel to the other, or into it. The two pumps for discharging the water are 16 inches bore and 14 inches stroke, worked like a fire-engine. From the main deck there are connected with the pumps two pipes 3 inches diameter, to be used for washing out the caisson, and in case of a fire in the neighbourhood or on board of a ship in dock.

A lining of india-rubber, 8 inches wide and 1 inch thick, was fastened to the outer surface of the keel and stems, with countersunk screws before the caisson was launched, to prevent as far as possible the leakage of water between the vessel and the masonry of the dock. This, I understand, answered the purpose very well as long as it lasted, but it got destroyed by abrasion, and oak plank was substituted. This caisson cost in America about 18,000*l*. (at least so it is stated in General Stuart's work on the Naval Dry Docks of the United States), which seems a prodigious sum, seeing that the sliding caisson at Keyham, being 14 feet wider and 14 feet higher, cost only about 10,000*l*.

As pumping out the water from ordinary caissons to lift them takes much time and labour, Mr. Scamp has designed a floating caisson, to obviate this defect; and since the arrangement can be adopted wherever there is a supply of water distributed through the mains of a waterworks, it will perhaps rarely happen that it *cannot* be applied. The arrangement is simply this. The caisson is ballasted so as to float safely, as in the case before described. The top deck of the vessel, which is on a level with high-water springs, is made to form the bottom of a water-tank, the dimensions of which must be such as to contain the required weight of water to sink the caisson into its seat. This tank is filled from the waterworks' mains; and as the water in the tank is above the water in the docks, it can be let out through valves when the caisson is required to be floated, thus doing away with pumping; and the only remaining defect of such a gate is the necessity of turning it and floating it away clear of the dock entrance when a vessel has to be admitted. This the sliding-gate at Keyham gets rid of, and unless it has defects of its own, it may be called *practically* a perfect gate.

In order fully to understand the value of this gate, I must explain that it closes the outer end of the entrance to the south basin at Keyham, which entrance is made as a lock, 260 feet long, 80 feet wide, and 43 feet deep; and the inner extremity being provided with a caisson of the ordinary construction, the water can be pumped from between the gates, and a dry dock obtained. The sliding-gate on such an occasion has to sustain a pressure of about 1700 tons, arising from the entire depth of water at spring tides, which is about 38 feet or 39 feet. The strength of its various parts had therefore to be very carefully considered, and the nicety with which the entire structure had to be put together in order to ensure perfect unity, required excellent workmanship; and when I say that it was executed by Mr. William Fairbairn, of Manchester, I need say nothing more.

The arrangements of the caisson, which enables it, without pumping, to be drawn from across the dock entrance into the recess prepared for it in the masonry, or *vice versa* from the recess across the dock, are simply these. The whole of the bottom or hold is formed into a perfectly tight air-chamber, constituting what Mr. Fairbairn terms the *lungs* of the vessel, of such capacity as to make the vessel buoyant to the extent of 10 or 12 inches from the bottom; and being thus free from contact

* A description, with engravings of the iron floating gate at the New York Navy Yard, will be found in the *Journal* for 1852, Vol. XV., p. 321.

with the sill, it is easily floated into the recess. Above this air-chamber is what is called the tidal ballast compartment, into which the water has admission through two sluices, and permitted to ebb and flow with the tide, thus neutralising the buoyant principle of the *lungs*. The third compartment forms a tank capable of holding sixty or seventy tons of water, which, being filled from hose-pipes connected with the water-mains of the dockyard, sinks the caisson into its place.

Near the bottom, four large pipes, fitted with slide-valves, run through the vessel, and act as scouring-sluices to clear away any deposit left by the flood-tide upon the sill; and also, at low water, to create a current sufficient to carry into deep water the sand or silt which may have accumulated in front of the caisson. To aid the effect of the scour, the sill is made to slope each way from the centre. To explain the working of the caisson, I cannot do better than take Mr. Fairbairn's own description:—

"It is drawn in and out of the recess by chains attached to each end, and to small drums on the working gear. There are also two guide-ropes, which, after passing through the caisson immediately below the upper deck, are secured to the north recess by spring-hooks upon links fixed in the masonry. The ends of the guide-ropes are connected with the machinery of the hauling-chains, and are wound upon barrels in the south recess.

"In order to remove the caisson from its position (assuming the entrance to be closed), and to draw it into the chamber, the ends of the guide-ropes require to be secured to the north recess, and the two small barrels on the shaft are then employed to tighten the ropes, and being fixed by their pauls, the hauling gear is then detached from the tightening drums by sliding clutches, which operation liberates that portion of the machinery required for the purpose of drawing the caisson into the recess. Before commencing the hauling process, however, it is necessary to float the caisson (which hitherto has rested upon the bottom), and this is accomplished by opening a valve 12 inches diameter in the bottom of the upper water or ballast tank, and discharging the necessary quantity of water into the tidal compartment below. The caisson then rises gradually to a height of four or five inches from the floor, when it is ready for being drawn into the recess, a process which occupies a few men at the capstan about eight minutes.

"When shut, the whole of the caisson is supposed to be filled with water to the level of the tide, excepting only the air chamber, which, it will be observed, is the only buoyant principle it possesses for raising it to a height sufficient to float it into the recess; and the water having free access through the tidal compartment, will stand at the same level on both sides of the caisson.

"The admission of the water into the tidal ballast compartment is effected in two ways, either by opening the slide-valves, or by allowing the free working of the flap-valves on the back of the slides, which open inwards; they therefore, open and shut by the pressure of the water, as it may stand higher or lower on either side of the caisson. These flap-valves are added for safety, for if the slides were not opened at the proper time, a rising tide might affect the stability of the caisson.

"When the vessel has entered the dock, the caisson is drawn from the recess by the working gear on the opposite side of the chamber, the guide ropes being used as before. The water-tank is filled with water, and the caisson sinks quietly into its place on the sill."

When the caisson has to be removed for painting or repairs, and it becomes necessary to float it away, the tidal and water chambers must be emptied at low-water, the flap-valves secured from opening, and a valve opened to admit water into the air-chamber, which then becomes for the time the ballast chamber, containing about 300 tons. The only peculiarity requiring further to be explained is this. Supposing the caisson to be ballasted at 2 inches above the floor at low-water; at *high*-water it will, of course, have a buoyancy equal to the displacement of the materials of which it is constructed, for the space of the rise of the tide, which is equal to about 15 tons. If ballasted at high-water, it will sink on the floor at low-water with an equal weight. To counteract this, ballast-trucks are provided in the chamber at each end, and level with the deck, and these are brought out as may be required to suit the depth of water the caisson is required to work in.

As it may be interesting to know some of the principal dimensions of the iron of which this excellent piece of work was made, I will in few words give them. As I have before casually mentioned, the length of the caisson at the top is 82 ft. 6 in. and at the bottom 68 ft. 6 in., the height being 42 feet exclusive of the falling handrail; the masonry of the entrance is 80 feet wide at the top, and 65 ft. 8 in. at the bottom, so that when closed the gate has an overlap on each side of 1 ft. 3 in. at the top, and 1 ft. 5 in. at the bottom. Along the bottom and ends, and on each side of the caisson, oak lining timbers 15 inches by 8 inches are bolted and made perfectly true, in order to fit closely against corresponding timbers fixed in the masonry, and make a joint as nearly water-tight as possible: the caisson would, of course, be pressed against one or other of the linings, as the level of the water was high or low on one side or the other. The beam of the vessel is 13 ft. 6 in., and with the timber linings therefore 16 inches more, or 14 ft. 10 in. The distance between the two plane faces of the masonry is 15 ft. 6 in. allowing a clearance of 8 inches for the width of the caisson.

The vertical frames are 18 inches apart, formed of strong angle iron; to them are riveted with butt joints the iron sheathing plates $\frac{9}{16}$-inch at the bottom, gradually decreasing to $\frac{3}{8}$-inch at the top. The side plates project 12 inches all round the bottom and ends, in order to admit the bolts for securing the wood frames which fit the masonry on the outside. In addition to the interior frames *of the bottom and the ends*, a series of strong plate beams are riveted to the projected sheathing outside, so as to prevent the external pressure from causing any yielding of those parts. Along the bottom the cross beams are not so close as those up the ends, in order to insert strong wooden keelsons on which the caisson rests when in its place. The whole is surmounted by a timber deck, forming a bridge of communication between the opposite sides of the lock when the bridge is closed.

You will perceive that the sides of this caisson being flat, it does not possess the advantages of a curved body to resist the strains upon them; they therefore, in addition to the framing I have been describing—which is simply that required for a curved caisson—have powerful stringer-plates 2 ft. 6 in. wide, at each deck, and gussets at the angles; indeed the structure is as stiff as it almost *can* be. The amount of deflection was proved at different heights of water from 18 feet to 38 ft. 4 in. The deflection, with 18 feet of water was $\frac{1}{16}$-inch; with 38 ft. 4 in. of water it was $\frac{9}{16}$-inch, which was the greatest deflection observed.

It is a question, whether making this caisson slide on *rollers* would not be an advantage, as they would guide it at the bottom; but Mr. Scamp's objection to rollers was, that if they got out of order, they would be difficult to repair at so great a depth beneath the water;—and the choice between rollers and no rollers must be left to the judgment of the engineer.

In conclusion, I may observe, that the use of caissons of the old construction, when pumping is necessary, is objectionable by reason of the time and labour necessary to be expended in the operation of docking or undocking any ship, whereby a tide may perhaps be lost. That, under ordinary circumstances, where economy is a consideration (and when is it not?), and when dock entrances of large size have to be closed, and also where the position would not impede the floating of it away, Mr. Scamp's "self-acting" caisson (if I may use the term) may be employed. And also, that the sliding caisson (which it has been the immediate object of this lecture to introduce) possesses the advantage of speed in working, and may be used in any situation.

The conditions required for this caisson were:—

1st. To resist a pressure of about 40 feet depth of water.

2nd. To make a perfectly water-tight joint, the lock having sometimes to be used as a dry dock.

3rd. To be worked across the entrance with facility and great dispatch.

4th. To avoid the usual labour, and cause of great delay in the working of ordinary caissons by pumping.

That all these conditions have been successfully carried out, I think you will have gathered from the observations I have made upon it. And I also think you will appreciate the talent of the engineer who contrived so excellent a work, and the skill of Mr. Fairbairn who executed it.

---

Subjoined are further particulars respecting this dock and caisson.

The dimensions of the entrance to the lock are 80 feet wide at the top, and 43 feet deep from the coping line to the top of sill. The low-water line of spring tides is about 18 feet above the sill, and high-water line about 36 feet. The lock entrance was designed with a view of admitting vessels at every state of the tide.

The joint for the whole length, with any depth of water outside, and the lock dry, is at all times perfectly water-tight. The operation of working is performed by a few men only at a capstan, and it can be taken out across the entrance or back again into the camber, in from eight to ten minutes. Pumping is not necessary, as the caisson is ballasted to the depth required, and the tide is permitted to rise and fall within.

The only peculiarity requiring further to be explained is this. Supposing the caisson to be ballasted at 2 inches above the floor at low water, at high water it will have a buoyancy equal to the displacement of the materials of which it is constructed, for the space of the rise of tide, which is equal to about fifteen tons.

If ballasted at high water, it will sink on the floor at low water with an equal weight. To counteract this, ballast-trucks are provided in chambers at either end, and level with the deck, and are brought out as may be required, to suit the depth of water the caisson is required to work in. An upper ballast-tank is provided, which is filled from the fire-main, for cases when the caisson is required to be kept across the entrance, the lock being used as a dry dock.

The permanent ballast in the bottom of the caisson may be regulated for any depth by opening a man-hole for access to the air-chamber, in which the permanent ballast is placed. This man-hole is near the bottom of the caisson, and accessible when the lock is empty.

Besides the sliding caisson, there are five others, one at the inner end of the lock, one between the two basins, and three to dock entrances; these are, in form, construction, and general management, similar to ordinary caissons, differing only in dispensing with the great labour and delay required for ordinary caissons by pumping. By the following brief explanation the method adopted for avoiding the great expense and delay of pumping will be clearly understood.

The caisson is ballasted to the depth required for obtaining stability; at about that depth sluice-doors are provided, one on each side, the bottom being about an inch above the water-line, and at the same level the deck of tidal-chamber is formed. An upper ballast-tank is provided above the highest water-line, with a trunk communicating with the lower tidal deck, and to the bottom of this trunk a valve is provided.

When it is required to sink the caisson, water is supplied from the fire-main to the ballast-trunk, which will sink the sluice-doors below the water-line; the doors are then opened, and the water will flow in, and the caisson will continue to sink; the valve at the bottom of the tank is kept closed.

For lifting the caisson, the sluice on each side is opened, and the valve at the bottom of the trunk; all the water above the tidal line will pass from the tank. The caisson being relieved of that load, will rise, and the water from within will continue to flow out until the whole has escaped, and the sluices are above the water-line, and the tidal-deck is free; the sluices are then closed, and the caisson is perfectly under control. During the operations of sinking and lifting the caisson, care is required to guide the stems accurately in the grooves. When the caisson is sunk in its place, as much water as may be necessary is supplied from the fire-main to the upper ballast-tank; and when it is required to lift the caisson, the valve below is opened, the water escapes, and the caisson floats.

The despatch with which caissons of this kind are managed, will depend on the provision made for supplying water from the mains, and for admitting the water by the sluices. Ample provision for these purposes being made, a very short time only is necessary for sinking or lifting caissons of this description.

---

In connection with this subject, we append some observations relative to the Keyham Caisson, by Lady Bentham, addressed to the Council of the Institution of Civil Engineers:—

At the meeting of this Institution, on the 9th May, 1854, the paper read was "A Description of the Sliding Caisson at Her Majesty's Dockyard, at Keyham, Devon," by Mr. William Fairbairn, C.E. This paper related, that "Caissons for closing the wide entrances of docks were first suggested in this country by General Sir Samuel Bentham; that since his time they have been somewhat extensively used, although the objection of occupying a considerable time in having the water pumped out of them, and it being necessary to float them entirely away from the opening before a vessel could pass, rendered them only applicable for special localities." It is to these objections that the following observations are principally limited.

It appears that the caisson at Keyham was designed by Mr. Scamp, and that the iron work for its construction was confided to Mr. Fairbairn. The means he employed for giving it strength add a feather to the rich plume which adorns that gentleman's cap. It is Mr. Scamp's originality of invention that is questioned, as relates to valves, the means of giving buoyancy to the caisson, and of sinking it into its place without need for *pumping* water into or out of it.

Sir Samuel's first proposal for a floating dam, as it was then called, was in 1798, for closing the entrance of the great basin in Portsmouth Dockyard; his plan was approved of by the Admiralty, the caisson built accordingly, and put into its place at the opening of the basin 12th January 1801. A copy of the General's proposal was printed in No. 1317 of the *Mechanic's Magazine*, November 1848; as was also the copy of a private letter from the master-shipwright of Portsmouth Yard, giving an account of the successful first employment of the caisson.

On reference to that proposal, it will be seen, that after speaking of the ballast requisite to give the caisson stability, the General went on to say: "What little additional weight it will require to keep the vessel from rising out of the groove at the time of high water, is to be obtained by letting water into one or more of the cisterns formed in the vessel immediately under the deck. This water would of itself run out of the cistern at the time of low water, even at neap tides, by means of the *panstocks* or *valves*, as shown in the profile."

From that proposal, it is evident that no pumping was requisite for raising water out of Sir Samuel's caisson at Portsmouth. However, he being scrupulously exact in providing for extreme cases, added, that if "at the time of high water it should be required to open the gate on the sudden, the water in this case must be pumped out of the cisterns." In similar circumstances, it does not appear that the water in Mr. Scamp's cisterns could be got rid of otherwise than by *pumping*.

From the above, it seems clear, that in respect to valves for draining the Keyham caisson from water, no advance has been made upon the established practice of half a century; but to assure myself of accuracy in this particular, I applied to a gentleman who had been for many years the master-shipwright of Portsmouth Yard; he has in consequence informed me, that "in regard to any novelty in the idea of admitting water to the caisson by means of *panstocks* or *valves*, I have to say, that I have never known a caisson without such an arrangement. It is a notorious fact, that the caissons at the Royal Dockyards are weighted with water admitted in such a way, and that the water is let out by opening the *valves*. Some alteration has been made since the introduction of iron caissons in the method of opening the valve—a screw is used for that purpose, but that is only a simple mechanical contrivance to carry out the same principle; and that General Bentham had no less the merit of the valve than he had of the caisson itself." It was in respect to the valve that Sir Samuel's caissons differed from foreign examples, as in those water was *pumped* out.

Sir Samuel's caissons being said to be applicable only to special localities, has been negatived by his having introduced them in the appropriation of an old work, the boat-camber in Portsmouth Yard, to docks for one, two, or three frigates at pleasure, the entrances to which at their different lengths were closed by the same caisson; but as other difficulties are alleged, it was thought desirable to obtain information from a gentleman who had had long experience in our principal dockyards. To inquiries on this subject the reply was, "I have much pleasure in informing you that I never found any inconvenience in floating this caisson (General Bentham's) out of its place, either at Portsmouth or any other yard where I have been."

The time consumed in opening or closing an entrance remained to be ascertained. At Keyham, it is stated to be effected in ten minutes for the opening, and eight minutes for the closing; but whether this be the *average* time, or only some special occasion, is not mentioned. The reply I obtained from Portsmouth was as follows: "The *average* time required to float the caisson out of or into its place is about ten minutes." Thus, in regard to time, the difference between the original caisson and that at Keyham is hardly appreciable, seeing that in one case the time is on an *average*, in the other (apparently) but one occasion. If, as has been said, the water at Keyham is supplied by the fresh-water pipes, that may cause the two minutes' difference in sinking the caisson.

As to the superior advantages of a rectangular caisson, that must remain an engineering problem. In the proposal of 10th September 1798, it is stated as follows: "Instead of a flat bottom of woodwork and side walls of masonry, the whole is of masonry, in the form of a reversed arch...... A *floating dam* is made to fit water-tight into a groove wrought in the arch of masonry, by which means the entrance will be shut up, and the water will be kept in or out of the basin...... This floating dam, which is built much in the form of a navigable vessel," &c. in continuance of its description, afterwards goes on to say, "the curvature given to the sides, at the same time that it affords a degree of capacity to the vessel sufficient to make it support the weight of the superincumbent bridge, together with a sufficient quantity of ballast to give it stability, enables the sides likewise the better to resist the pressure of the water at the greater depth."

## SCIENTIFIC TRAINING FOR PRACTICAL PURSUITS.

*A Farewell Address delivered to the Students in the School of Engineering, Trinity College Dublin*, 1854. By ROBERT V. DIXON, A.M.

As my official connection with the University is drawing to a close, and I am now addressing you for the last time from the Chair of Natural Philosophy, I am anxious to avail myself of the present opportunity to make a few remarks on some matters connected with your studies here. These remarks will mainly refer to the character of the training by which this school seeks to prepare its students for the arduous and responsible duties of the profession they purpose to follow, and my chief object in laying them before you is to satisfy you of the soundness of the principles on which that training is conducted, and to stimulate and encourage you to avail yourselves, honestly and earnestly, of the advantages now offered you. Such an appreciation of the true character of the studies in which he is engaged is always valuable to the student; it tends to reconcile him to many an irksome and tedious task, braces him to encounter many an apparently insurmountable difficulty, and raises him above a mere routine discharge of his prescribed duties. But in the case of the studies in which you are engaged, this knowledge is specially important. Until very lately, the utility of scientific instruction—instruction, that is, in principles—to persons embarking in what are called, emphatically, practical pursuits, such as the occupations of the Engineer, the Machinist, and the Manufacturer,—has been, if not expressly, at least practically denied in this country. Latterly, indeed, more correct views on the subject are beginning, though slowly, to make their way, but still it is far from being generally recognised that the only sound and legitimate mode of preparing a candidate for the practice of any art or occupation whatever, is, first, to teach him the principles on which the processes in such art are based, and then to train him in the application of those principles.

The correctness of these views has, however, long been felt in those continental states where engineering and manufacturing works of national importance are carried on under government supervision, as, for instance, in Holland, where the very existence of a large part of the country depends on the efficiency of the embankments and drainage works; in Northern Italy, where the fertility of extensive districts depends on their irrigation; and in France, where large and important manufacturing and mining operations are objects of national care and of government regulations. In all these cases, the superintendence of the responsible works alluded to is entrusted to pupils trained in scientific schools, and the wisdom of this procedure has been fully established by experience. Nor is it only for national works that pupils are thus trained in those states. Scientific instruction is given in their public educational institutions, in all branches of arts, or, in other words, students are instructed there in the principles of all those processes. I use this latter form of expression because, in the perception of its propriety is involved a forcible argument in favour of scientific systematic training for the practical arts. Many may be led from a want of sufficiently accurate information, or from a hasty view of the subject, to doubt the utility of a scientific education for a practical man, but none can deny that a knowledge of the principles on which a process is conducted will enable an operator to manage it more successfully. Of two manufacturers, one who knows what steps are essential to a process, and why—will, it must be admitted, be better able to guard against failure, if not to command success, than one who merely follows, without intelligence, a prescribed formula. Of two machinists, one who understands the nature of the force to be employed in a machine, and the principles of its action, must be a better artist than one who only makes the machine from plan and model. Of two engineers, one who comprehends the equilibrium of structures, and the action of material forces, must be a more able designer than one who merely works by empirical rules. My chief object in the following remarks is to justify and illustrate the application of these views to the particular case of the profession of the Civil Engineer.

And as the term Engineer, in its popular use, is an ambiguous one, being applied to makers of engines as well as to constructors of railroads and similar works, I think it necessary first to define the sense in which I employ it in the following remarks. I use the word, then, to denote a person whose professional occupation it is to design and superintend the construction of those great highways by which intercourse is effected, and trade and traffic carried on between different countries and different parts of the same country. This includes the making of roads, railways, and canals, with the construction of bridges, viaducts, aqueducts, docks, harbours, &c., and everything necessary for their completeness and permanence. I thus exclude from the duties of the engineer the making of the engines by which locomotion is effected by sea and land, and I think the term mechanist, or, more properly, machinist, should be employed to designate a person devoted to such occupation. I exclude also the functions of the architect and the builder; and the progress which has been of late years made in the division of labour, justifies me also in separating from the profession of the engineer the duties of the contractor. While thus detaching, however, these various branches of art from the business of the engineer, I must not be understood to imply that they have no connection with the latter, or that they all stand in the same relation towards it. Lord Bacon remarked long ago, that no science can be successfully cultivated by itself, and the same may be said of the arts. For not only is it true that any given art depends directly on others for its existence or its perfection, but there is also an indirect relation between them, similar to that referred to by Lord Bacon as existing between the sciences, by which their mutual progress is materially affected. Still, notwithstanding this intimate connection between various arts, not only may they be abstractedly considered as distinct, but experience and history have shown that the tendencies of the increase of civilisation, of the growth of capital, and of the progress of knowledge, have always been to isolate them in practice. Nor have these causes the effect merely of separating arts and professions previously combined, but also of producing new ones, by creating a demand for works or results of such importance and of such extent as to call for the services of a special class. Thus the progress of civilisation, and knowledge, and wealth has separated the professions of the oculist, the aurist, the dentist, and the surgeon; of the conveyancer and the pleader; of the common law and the equity barrister; has divided machinists into makers of locomotives and stationary steam-engines, and these latter into makers of land and marine engines. And the most striking instance on record, perhaps, of the creation of a new profession is in the case of engineers, a class which has been called into existence in these countries within the last thirty or forty years. For although individuals have followed the occupation at various periods during the last 120 years, as Brindley, Smeaton, and others, yet the calling did not attain the position and permanence of a profession until within the period I have mentioned; and since its establishment, with the rapid progress which characterises the development of all the recently-discovered arts and sciences, it has already detached itself from various branches of art accidently or necessarily connected with it at first. The earliest engineers were generally either machinists or builders, according to the nature of the works which they were called upon to execute; but by their labour, and ingenuity, and skill, aided by the requirements of the times, they gradually constructed a new profession, and further trained up a body of contractors, themselves constituting a distinct class, remarkable for their enterprise, intelligence, and zeal.

I have stated that the duties of the engineer are distinct from those of the machinist, the architect, the builder, or the contractor. I purpose now to inquire more particularly what those duties are, and to show that they may be taught scientifically,—that is, as I explained before, that the principles on which they depend are known, and may be communicated systematically to the student; and further, that he can be trained in the practical application of those principles where it is necessary that he should apply them himself, and in the mode of ensuring their application where they are carried into effect by others. And as I proceed, I will briefly notice the means provided in our School to effect these several objects.

The first duty of an engineer who is called on to construct a line of communication between two given points, whether by railway or canal, is to ascertain the course he will follow. To determine this, he must have a map or survey of the intervening country, with trial sections along the most desirable routes. On the accuracy of such surveys and sections much of the value of his decision will depend. It is accordingly essential that he should be able to test their accuracy either by personal examination, or by the aid of assistants of whose competence he has assured himself. The importance of this duty, moreover, and the liability to errors in the performance of it, arising either from wilful or unintentional neglect, especially in districts not previously examined with care, will always render it one which the young engineer will be liable to be called on to discharge in person. The art of surveying and levelling, therefore, with the necessary and indispensable adjuncts of plotting and mapping, is one in which he must be not merely acquainted with the principles, but also an adept in the practice. And there is probably no subject connected with his profession, on both the principles and practice of which more has been written, proving that in this department at least there is a very general impression that much valuable information can be conveyed to the student in a scientific and systematic form. But here I must take the opportunity of warning you against the not uncommon mistake of supposing that when a person understands how a thing is to be done, he can necessarily do it; that when he comprehends the principles and method of an operation, he will necessarily, and without practice, be an adept in the performance of it. This is, as I have said, not an uncommon, but not the less a most mischievous error. Wherever therefore, as in the present case, it is necessary for you to possess practical skill in any branch of your profession, remember that it can only be acquired by practice—that you can only attain to the power of doing a thing by doing it. Accordingly, you know that you are not merely taught here the principles of surveying and levelling, but that you are also required to practise those arts; that you are sent into the field, day after day and term after term, to make sections and surveys, at first under instruction, and afterwards by yourselves. This is one of those duties which, after you have mastered its principles, must always appear irksome and tedious; for this reason I dwell upon its importance now, and for this reason the Professor at the head of the School is so urgent with you, at the cost of much personal labour and fatigue, for the due performance of it. And, thanks to his indefatigable zeal in the discharge of this and the other onerous duties of his office,—and, I must add, to the diligence with which you and your predecessors in this School have devoted yourselves to this branch of your studies,—we are able to refer with satisfaction to convincing proofs of the skill attained by your pupils in this department.

The requisite surveys and trial sections having been carefully made and mapped, the choice of a route will, in most cases, be a choice between steep gradients and heavy works. The judgment of the engineer will be exhibited in the decision he will come to on this point. To guide his judgment, he will require, in the case of a railway, for instance, to know, on the one hand, the capabilities of locomotives and the expense of their working as affected by various gradients; and on the other, he must be able to calculate the cost of all the incidentals of the construction of a line, including its earthworks, embankments, bridges, viaducts, &c. For the former point he should know the theoretic capabilities of the locomotive engine, and also how far the mechanical difficulties preventing their development have been overcome.* He should know the theoretical relation between the power applied and the resistances to its action, and he should be acquainted with the experiments instituted to determine the value of the latter. Thus alone will he be able to interpret correctly the results of past experience, and apply them to new cases. Thus experiments are made, we will suppose, with locomotives of different constructions, on lines of different gradients, with various loads at different velocities, and in different states of weather, and the respective quantities of coal consumed, are ascertained. Now, it is only by applying the principles of mechanics to determine the relation existing between the force expended and the opposing resistances, that we can distinguish the effects of the latter, and determine their separate amounts, and so ascertain the expenditure of force necessary to overcome new combinations of resistances. It is for this reason that you are instructed in the theory of the steam-engine, and taught how to calculate its effects in the different forms in which it is employed. You have been taught how much is certain in this theory, namely, the mechanical principles, and how much is only probable, namely, the action of the steam when in motion and expanding, and the limits of the consequent uncertainty in the final results have been pointed out to you. You have also been shown how the ordinary resistances have been experimentally investigated, and to what different degrees of certainty their values are known.

With reference to the different structures requisite for the completeness of a railway, you have in like manner been first instructed in the mechanical principles involved in the determination of the conditions of their equilibrium. The application of these principles would be, in most cases, a matter of little difficulty, if the forces whose equilibrium we investigate acted merely on material points connected by rigid mathematical lines. This, however, is very far from being the actual state of things, and hence rises considerable difficulty in the application of mechanical principles. The structures, in fact, of which we are at present speaking, are all designed to support weights and resist strains. Besides these forces, however, the material masses of which they are composed are themselves in all their particles subject to the action of gravity, and of those molecular forces to which we give the names of cohesion, attraction, and elasticity, and to which what is commonly designated the strength of materials, is due. The amount and nature of these latter forces, the knowledge of which is obviously essential to the determination of the strength and permanence of structures composed of materials subject to their action, can only be learned from experiment; and considerable attention has been devoted to this subject in recent times. The labours of Professor Barlow and Mr. E. Hodgkinson in this department have been specially brought under your notice, and a form of apparatus of the same construction, and on the same scale, as that employed by the latter gentleman in one department of his investigations, has been provided for the use of the School, and you are thus enabled to repeat and extend his experiments. Besides this, you have had your attention directed both by the Lecturer in Mechanics and the Professor of Engineering, to several theoretical and experimental investigations on the same subject in these countries and on the continent, both by individuals and by public commissioners, and you have thus been put in possession of the most recent and most accurate information on this important point. Besides the knowledge of the abstract principles on which the equilibrium of structures depends, and the nature and strength of the materials of which those structures are usually composed, you have also been instructed in the ordinary forms in which those principles are applied and those materials employed, as well as in those more remarkable and striking applications of them which are justly regarded as the triumphs of modern engineering skill. And for the clearer comprehension of the subject, models of all these different structures are being provided for the School, and a large collection is already in our possession.* These, with the numerous drawings amassed since the formation of the School, leave little to be desired in the way of illustration, and the labour which you have expended in copying several of them has at once improved your skill as engineering draughtsmen, and familiarised you with the countless details involved in actual work.

And now, the route of our railway being determined, and the requisite works designed, it is necessary to make an estimate of the expense, and draw up specifications for the use of the contractor. To instruct you in this department of your business the Professor of Engineering has compiled a list of the prices at which some public works have recently been executed, and also a collection of the most approved specifications of various important works, exhibiting not only the form in which such documents should be prepared, and the minuteness of the details into which they should enter, but also giving examples of the actual points to be attended to in them, the nature of the foundations, the materials to be used in the work, the manner in which these should be prepared and combined, and the cements with which they should be united.

And further to perfect you in this department, you are required, before presenting yourselves for the final examination, to complete a project of a railway or some similar work, in an assigned locality, furnishing complete and perfect surveys and sections of the line, its plans, estimates, and specifications of all the requisite works. This differs from what you may be required to do, in the actual practice of your profession, only in the absence of responsibility; I trust however, that the want of this stimulus to care and accuracy will be supplied by a conscientious anxiety honestly to discharge the duties imposed upon you here.

In most cases the active duty of the engineer terminates with the drawing up of the contract specifications, and it is only necessary for him afterwards to ascertain, on the part of his employers, their due fulfilment. This is owing to the fact that the great demand for the formation of extensive works has of late years called into existence a large and intelligent body of contractors, who stand between the designer and the artist, who carry out the plans of the former by the labour of the latter, and who thus occupy a position midway between the intellect which conceives and the hands which execute. As the interpreter of the gods of Olympus was a deity himself, and at the same time most eloquent in the language of men, so must the contractor be a man of superior intelligence, and at the same time intimately acquainted with the details of the mechanical crafts, essential for the execution of the plans which he is commissioned to carry into effect. Without the intervention of such a class the operations of the engineer would be greatly limited, and his facilities of cultivating the higher branches of his art greatly diminished. While, at the same time, the increasing intelligence and skill of the contractor compels the engineer, as Mr. R. Stephenson lately remarked, to exert himself to the utmost to hold that position in his profession which he is entitled to claim, otherwise he must "perish by this people which he made." And the only way by which he can retain this position is by deepening and widening his knowledge of the principles of his profession, and extending their applications.

The minuteness to which the engineer must carry the details of his specifications will depend to some extent on the character of the contractors expected to undertake the works. Thus in some instances the plan of centering for arches is prescribed by the engineer; in others it is left to the judgment of the contractor; and so of other details.

* To supply the students with the means of becoming thoroughly conversant with the details of the construction of the locomotive, a very complete and elaborately-finished model of the 'Pyracmon,' a goods engine on the Great Western (broad gauge) Railway, has been provided for the School. It is made to a scale of one-fourth, and is 6 ft. 6 in. long, and 2 ft. 4 in. wide; its cylinders are 4 inches in diameter, and 6 inches stroke. All the parts of the model represent faithfully in form, proportion, and material, the corresponding parts of the original, and the surfaces of the several joinings, valve-casings, cylinder-covers, &c., are so fitted by the process termed *scraping*, that they form air-tight joints without the intervention of packing. The whole machine may thus be taken asunder, and its several parts exhibited in detail.

* Among these may be noticed an interesting and nearly complete collection of timber bridges and cofferdams, all copied from recent works, and made to scale, and a beautiful working model of the lifting apparatus of the Conway Tubular Bridge.

It must be borne in mind, however, that there are occasions on which the engineer cannot count on commanding the services of contractors. In works of special difficulty, of novel design, or of unexampled magnitude, the engineer must be prepared to undertake the construction of the work himself. He may always calculate, however, even in such cases, on carrying out considerable portions of his details by partial contracts, remaining responsible for the success of the combination, and, perhaps, personally superintending and perfecting the more novel or more difficult portions of his design.

Again, in remote districts, in the case of small works, which it would not be worth while for established contractors to undertake, and in new colonies, where local contractors are not to be met with, the engineer must, as in the former case, be to a considerable extent, or altogether, the constructor as well as the designer of his own works. It is even conceivable that in cases of this kind he may be obliged to a certain degree to teach and train the artisans employed in the details, and the possibility of such contingencies will always induce the intelligent student to familiarise himself with the mechanical operations of the different trades employed in the arts of construction. Independently also of the cases where such knowledge will be indispensable, it will be of the utmost utility in many others. Hence, you are instructed in many handicraft details, in the mode of shoeing, bolting, and securing framing timbers; in the bonding of brick and stonework; in making templets from drawings for the stones of the different arches of ordinary and skew bridges, &c., and you are encouraged to take every opportunity, which does not interfere with your more immediate business, of making yourselves acquainted with such details as can be learned only in the shop of the carpenter, the forge of the smith, and the shed of the mason.

In the preceding remarks I have chiefly called your attention to matters connected with the construction of railways and ordinary roads. There is, however, a large field of engineering practice, and well worthy of constituting a distinct branch of the profession, connected with water-works of different kinds, canals, docks, and breakwaters, mill-works, irrigation, and draining. All these may be included under the term Hydraulic Engineering, and from their importance and specialties deserve to be detached from the business of the ordinary engineer. The progress of the profession appears to be leading to this, and already there are several distinguished engineers in Great Britain who devote themselves chiefly, or exclusively, to this department. The distinction between the branches, however, is not yet generally recognised, and accordingly we include instruction in hydraulics in our Engineerin' Course. Hydraulics may be said to be almost altogether a science o experiment. Theory is compelled to deal with the subject of the motion of fluids in such a narrow and limited form, that its results are of little use in practice, and we are obliged to appeal to experience to correct and extend them. The subject has not as yet met with the attention in Great Britain which it deserves, and the best information we possess is to be obtained from foreign writers. To render the knowledge derivable from these sources available to you, the Professor of Engineering is at present engaged in compiling a work embracing the results of the most trustworthy experiments on hydraulics, and the Lecturer in Mechanics has supplied you with a valuable treatise on the application of the mechanical principles to the theory of the Equilibrium and Motion of Fluids.

Among the other specialties of hydraulic engineering must be mentioned the character of the constructions it requires. Water-tight canals, reservoirs, aqueducts, and mill-courses; consolidated beds of irrigating rivers; dock and quay walls built on sites ordinarily covered by the sea, and from which its waters are excluded by gigantic cofferdams, or whose foundations are laid in deep waters by the aid of the diving-bell; and piers and breakwaters, in whose construction the engineer is engaged in an almost constant struggle with the most powerful forces of nature. The history of engineering supplies records of the triumph of ingenuity and skill over all the difficulties connected with works of this kind, and furnishes the educated student with the means of overcoming similar obstacles.

The remarks which I have made on the duties of the engineer will suffice, I trust, to explain and justify the course of study prescribed for you in this School. It is unnecessary for me to recapitulate or enumerate more particularly the subjects included in this Course. I should mention, however, that besides those to which I have referred in the preceding observations, it contains some others, a knowledge of which, if not directly essential to the engineer, is of the utmost utility to him. These are, Chemistry, Geology, and Experimental Physics. A knowledge, indeed, of portions of these sciences cannot be dispensed with; and the more complete an engineer's acquaintance with them is, the more perfect is his professional education. The engineer cannot be ignorant of the properties and mode of action of that great power, whose application to locomotion has, it may be said, created his profession. He must be acquainted with Physics, therefore, so far at least as concerns the science of Heat; and the universal agency of this force over all the materials employed in his constructions renders this knowledge still more necessary. Again, an acquaintance with the laws of Geology, so far at least as they concern the distribution of minerals, is of the greatest service to the engineer; and in new countries, where the sources of iron and coal are as yet unknown, it is all but necessary: and a practical knowledge of Chemistry is essential, so far as will enable the student to ascertain by analysis the properties of minerals, and of the materials requisite for the composition of cements.

Such is a brief sketch of the character of the instruction given in this School, and of the subjects included in its Course. It only remains for me now to say a few words on the results which we expect it to produce; for it may be said, "You have shown that the course of instruction prescribed for students in your School is necessary, but is it sufficient? Will it supply the place of genius, or remedy the want of experience? Are your men to be compared with those who, like Brindley and Smeaton, and Telford and Stephenson, by the force of their genius covered the land with trophies of their skill; or can they take their stand beside those who have acquired their knowledge, not from books, but from actual experience?" To these demands I would reply, that the objections implied in them might be brought with equal force against all our professional schools,—against those of Divinity, Law, and Medicine, as well as against that of Engineering. It is a mistake, as I remarked to you on a former occasion, to suppose that the latter profession is more practical than the former, and consequently requires a different method of training for its students. Every profession, in fact, may be regarded in the twofold aspect of an art and a science. It is an art so far as it has a practical aim and object; it is a science so far as the rules for the attainment of that object have been reduced to system and method The man of the greatest genius will derive advantage from a knowledge of the principles deduced from the results of the able men who have preceded him. By the possession of such knowledge he will be placed in the same position as if he had himself centuries of experience; and the man of inferior genius will be enabled to repeat at least what has been done before him by others, if not to achieve new triumphs and overcome new difficulties. Instruction in the principles of the science of a profession will not place the man of original talent and the man of moderate abilities on the same level in the practice of the art, but it will raise them both to positions far above those to which they could have respectively attained without it.

Again, no amount of theoretical instruction will make a man an adept in an art. To be a successful practitioner, he must have had practice. In all properly constituted professional schools, therefore, the students are trained in the practice of those duties which they may be called upon to discharge personally when they commence the practice of their profession; skill in the higher branches they must acquire during their professional career. Thus I have shown that special provisions are made to give you practical instruciotn in all those operations which you may be required to execute in person when commencing your professional course. In fact the only reason why other modes of training professional students are called and assumed to be more practical, than those adopted in scientific schools, is not because they are really more practical, but because they are merely practical.* They only show how things are done, we both show thisand also why they are so done. They give the rule alone, we give the rule and the reason. And so they are styled practical because they are nothing else, and we are assumed not to be practical because we are something more.†

You will conclude, then, from what I have said, that we profess to train students here so that on leaving the School they will be able to conduct and superintend such works as are ordinarily intrusted to young men commencing the practice of their profession. Their subsequent progress of course will depend on their natural aptitude for the pursuit they have chosen, as well as on the information they have acquired, and the training they have undergone here. They are started with great advantages; they may be distanced by competitors who have had less, but who would certainly have distanced them far more rapidly had they also possessed similar advantages at the outset. And as some of our students may be wanting in natural aptitude for the practice of their profession, so others may be unable to avail themselves to the full extent of the advantages of their training here. Those who are materially deficient in this respect are stopped at the annual examinations, and never obtain their diploma. Of those, however, who leave our School after completing its Course, and receiving its attestation of their professional acquirements, though some, owing to the causes alleged above, may never rise to distinction in their profession,—we feel confident that none will bring discredit on themselves or the School, by failure in the discharge of routine duties.

In a word, then, we cannot create genius or aptitude for this or any other profession, but we can develope it where it does exist, and we can remedy the want of it to a certain extent by teaching the results of the genius of others. We can train the powers which a student does possess, and render them much more efficient, whether in the case of genius or mediocrity, than they would have been without our teaching, and

* Thus Unitarians are so called, not because they, as distinguished from Trinitarians, believe in the unity of the Deity, but because they believe merely in the unity of the Godhead, and not in the plurality of the Persons. And again of two brothers, both equally good lawyers, if one be also a mathematician, he will be distinguished among his friends by the latter appellation, and the other will be called simply the lawyer.

† The fallacy consists in inferring that because a person possesses a certain quality, to the exclusion of all other qualities, he therefore possesses it to the exclusion of all other persons. That because X equals Y only, therefore X only equals Y.

we can prove that our method of training is superior to any mere empirical method, in developing the native powers, and supplying their deficiency. As to practical instruction, again, we profess to render our students adepts in all those branches in which the young engineer must possess skill when commencing his profession, and we facilitate his acquisition of skill in the higher branches during his professional career. It is, however, in the independent practice of the latter alone, that our students, or those brought up under any other system, can acquire complete professional skill. We can no more give these opportunities of independent action before a man is started in his profession, than we can create natural aptitude; but we can in the former, as in the latter case, supply to a considerable extent its want, and prepare the student to derive the full benefit from it when he obtains the opportunity.

I have not alluded on the present occasion to the advantage you enjoy in this School from the facility afforded you of pursuing along with your professional studies the Course in Arts. Of the importance of this Course to general intellectual training, to the development of the faculties and the cultivation of judgment and taste, as well as its connection with the professional studies of the schools, I have treated at some length on a previous occasion, and accordingly I do not consider it necessary to detain you by any further reference to the subject at present.

It remains for me, in conclusion, to bring under your notice a few facts connected with the history and progress of our School. It has been in operation nearly thirteen years, and was three years later in its origin than the Engineering Schools of Durham and King's College, London, the first established in Great Britain. It is as yet the only School of the kind connected with any of the older Universities. Since its formation it has admitted 242 students, and issued seventy-eight diplomas. In 1849 the plan was adopted of granting special honour certificates to such students as distinguished themselves at their final examination. Of these ten have been granted for proficiency in the immediate business of the profession, five in Mechanics and Experimental Physics, and thirteen in Chemistry and Geology. These twenty-eight certificates have been awarded to seventeen students, several obtaining more than one. Of the seventy-eight pupils who have obtained the diploma of the School, some have abandoned the profession, but by far the greater number are now engaged in the practice of it, and are scattered over all parts of the world. These are all making their way in their profession by honourable, independent exertion; for such success as they are enjoying they are indebted to no patronage or favour beyond that which granted them an opportunity of showing their qualifications and their skill. I hope, however, that when the character of this and similar educational establishments is better known and appreciated, and when the services which they render to the profession and the public are consequently recognised, the diploma of our School will be regarded, not indeed as an absolute test of professional merit and skill, but as not only furnishing an evidence of respectable professional attainments, but also as giving a claim to special patronage and encouragement. That it will, in a word, hold the same rank and enjoy the same privileges that the diplomas of medical and surgical schools hold in their respective profession, and that government and other public bodies will recognise it in a similar manner.

And now, Gentlemen, I take my leave of you and of the Engineering School. I thank you for the attention with which you have listened to me on the present and on all past occasions. During sixteen years' experience as a College and University Lecturer and Professor, I have never met with more diligent, more attentive, or better conducted students than those in the Engineering school. I heartily wish you that success in your profession which such a course of conduct here entitles your friends to anticipate for you hereafter, and I trust that through your professional career you will be influenced not only by an honourable ambition to obtain professional eminence, but also by the higher motive of a desire to improve to the utmost the talents committed to you by your Creator, and that you will refer all your actions to His most holy will, as to His gracious Providence you owe all your powers.

## RAILWAY SIGNALS.

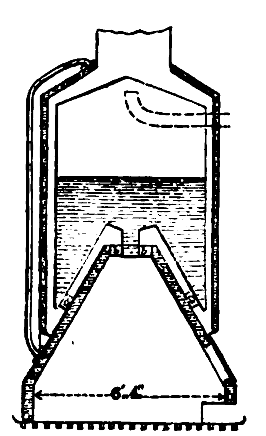
Bernard Cowvan, *Patentee*, October 11, 1853.

This invention consists in placing, at suitable intervals along the entire length of railway, a number of bells or sounding apparatus in connection with endless wires, having a series of cranks so connected to them, that on the movement of a lever at any portion of the line, the whole of the bells will be caused to ring, and thus indicate in each direction that a stoppage has occurred. This wire may also be connected by cranks and wires with a series of semaphore arms, the lower ends of which are forked, in order to conceal when down lamps attached to the semaphore posts.

## THE BEE-HIVE BOILER OF LAKE ERIE.*

By Thomas Drew Stetson.

The steam navigation of the lakes of North America is distinguished by the occasional employment of a form of boiler, locally known by several different appellations, among which the "bee-hive" is, perhaps, the most strikingly descriptive. The annexed engraving is designed to represent a vertical section through the whole structure, and also through a "water jacket," with which the larger sizes are invariably provided, and which may be considered, in fact, as it certainly is in effect, a part and parcel of the boiler. The boiler proper is in two portions, one above the other, with suitable connections, to allow a free circulation of the contents. A connection is made by a copper pipe leading from the topmost point of the jacket to a position near the base of the main shell, down which the full heated water and a small modicum of steam is assumed to be continually flowing. This pipe is the only means of communication. The check-valve, not shown in the engraving, is attached to the jacket near its lower rim, and although the vessels are rarely propelled with independent feed-pumps of any description, the arrangement renders it practically certain that this important appendage will remain at all times nearly or quite filled with water. There are four connections *a a*, located at equidistant points in the horizontal plane. The connections *b b*, are two in number, and serve to convey the current of steam and highly-heated water from the lower into the upper shell, while the lower and more liberal passages may be supposed, in some cases at least, to convey a current in the opposite direction. It may be sufficient to know, however, that the deposit, in all cases, settles to the bottom of the lower shell, at which point, as well as at the lower edge of each of the outer portions, ample provision is made for its removal. In the fresh clear water of the lakes, these boilers have been uniformly successful, and although difficult of repairs, may very naturally be inferred from the novelty of the form, and the whole might be, for various theoretical considerations, pronounced necessarily short-lived and troublesome, the experience of the few years it has been in use, seems to indicate a rather unlooked-for durability, and the style has won itself a degree of local popularity which might, perhaps, be more widely extended.



The boiler of the propeller *Troy*, from which the engraving is prepared, has been now more than three years in service without any expenditure for repairs.

The *Boston*, a small propeller of some 16-inch cylinder, running between Cleveland and Ogdensburgh, was the first on which this boiler was adopted, and the repairs have, to this day, cost about 250·00 dols. The whole credit of the experiment is due to Mr. L. Parmalee, a boiler-maker, of Cleveland, by whom most or all of this description yet in use have been constructed. The heating surface is somewhat more efficient than the same extent in any of the usual forms, the actual evaporation being taken as the index. The boiler of the *Troy* presents about 700 square feet of fire surface, aud 31½ grate area. This supplies plenty of very dry steam at a pressure of 80 lb. above atmosphere, to a cylinder 3 ft. 6 in. stroke, and 28 inches diameter, making 55 revolutions per minute, and cutting off at ⅝-ths of the stroke from commencement, the throttle being always wide open.

The boiler of the *Troy* having been constructed when the material was quoted at a much lower figure, the cost would be no data for comparison. A boiler now building in this form, and of almost precisely similar dimensions, is to cost 2250 dols. The form and proportions allow a very considerable fluctuation in the water level, without exposing any surfaces to the direct action of the fire, and the large unobstructed water surface allows, what is rarely obtained in upright boilers, tolerably perfect separation of the vapour from the water, the per centage of water mechanically

* From the 'Journal of the Franklin Institute.'

suspended, being, for obvious reasons, much less than in any of the ordinary forms. The steam is withdrawn from a point near the apex of the upper shell, the pipe bending down and coming out through the side, as indicated by the dotted lines.

Clothing with felting, or other non-conductors, is a refinement not yet introduced to any considerable extent, either on these or other steam boilers in those localities. Under all the circumstances, with natural draught and ordinary firing with hard wood, the results in several propellers most readily accessible, are as follows, the steam in every case being represented as "plenty" at a pressure of from 68 to 80 lb.; throttle-valve never used:—

The *Niagara*, with a fire surface of 575 square feet, a grate surface of 28·3, and a cylinder 3 ft. 6 in. by 22 inches, makes 58 revolutions, cutting off at ⅝ths.—The *Forest Queen*, fire surface 537, cylinder 3 ft. 6 in. by 28½, makes 56 revolutions, cutting off at ½.—The *Westmoreland* (propeller, 200 feet in length), fire surface 710, grate 44, cylinder 3 ft. 6 in. by 28 inches, makes 58 revolutions, cutting off at ⅝.—The *Prairie State*, *Michigan*, and *Ogdensburgh*, each presenting 700 feet of heating surface, and 38½ feet grate area, with cylinders 3 ft. 6 in. stroke, and 22 inches diameter, make from 54 to 60 revolutions, loaded, cutting off respectively at ½, ⅝, and ½ stroke.

The consumption of fuel in the furnaces of these boilers, which are termed "conical vertical," in the Official Reports of the Inspectors, are recorded as follows:—*Niagara*, ¾-cord of wood per hour; *Forest Queen*, ⅞-cord; *Westmoreland*, 1 cord; *Boston*, ¾-cord; *Prairie State*, 1 cord; *Michigan*, ¾-cord; *Ogdensburgh*, ¾-cord.

There are now floating on the waters of Lake Erie, eleven or more of these boilers. The water-spaces adopted are uniformly 4 inches thick around the furnaces. The water-jackets are somewhat thinner at the base, diminishing to only about 2 inches thickness at the top. The iron is ⅜-inch thick for the principal boilers, and ¼-inch for the jacket, stayed every 5½ inches. Water bottoms can probably be fitted without difficulty, but are not yet much employed, the bottom being usually a simple water pan supported on plain bars about two inches square.

This bottom affords a trifle less direct protection to the keelsons, but gives free access to water in case of accident, and allows a fire to make itself apparent in less time than does a brick bed. The size of the boiler now in use, ranges, in external dimensions, from 4 ft. 6 in., to 7 ft. 4 in., and in perpendicular height, from 10 feet to 17 feet. Its use is unobstructed by patent, or any "intention" to monopolise whatever advantages it may be found to possess.

## MEANS OF ECONOMISING THE USEFUL EFFECT OF PRIME MOVERS.

— BANNER, *Patentee*, October 31, 1853.

THE economy of power, or of the useful effect produced by prime-movers generally, is a subject which has attracted the attention of practical men perhaps more than any other. While others have devoted their thoughts to finding new means of "creating" power, with a view to superseding water and steam power and animal force, such men as Babbage, Rennie, and Stephenson have endeavoured, by experiments, inductive reasoning, and practical applications, to economise the means already at hand. Economy of power is an economy of means, and if the fractions of the units of force be taken care of, the pounds and horse-powers will in time take care of themselves. That much power is lost at present in the greater number of cases where steam or water power has to be substituted for animal force, is evident to all who are practically acquainted with the details of the construction of machinery and the formulæ by which the force required is calculated. It has been a received maxim, even among the most practical men employed in such works, to "keep on the safe side," and indeed so important has the necessity of this error on the right side been deemed, that what is called a "horse-power" in mechanics represents a much *greater* force than that given by the dynamometer when applied to the animal itself. "One 'steam' horse-power is equivalent to 33,000 lb. avoirdupois raised one foot high per minute, but an 'animal' horse-power is equivalent to only 22,000 lb. raised the same height in the same time, or in other words, to drag a canal-boat 220 feet per minute, with a force of 100 lb. acting on a spring; therefore, a 'steam' horse-power was originally made (practically, for the purpose of erring on the safe side) equivalent in working efficiency to one living horse, and one-half the labour of another,—so that a 60-horse power engine had to be calculated to do, according to the formula, the work of 90 horses."* We do not hereby mean that all practical men make this allowance, but when Watt fixed the steam horse-power at 33,000 lb., it was because *up to his time*, a loss of 45 to 50 per cent. was taking place between the practical results and the original theoretical calculations, as founded on his experiments. But this amount of 50 per cent. is not all that is allowed by practical engineers when the power of an engine required to put into motion certain combinations has to be ascertained. There is friction and inertiæ of the masses to overcome; and although one portion is set in motion before the remainder of the machinery is geared on, yet in many cases the fly-wheel has to be set in motion at first starting, and *invariably* some little allowance must be made for "lost force."

The consideration of the economy of force in all such cases becomes a matter requiring the serious attention of our scientific men, and is one of the greatest possible importance to manufacturers and artisans generally; but unfortunately, we are so much in the habit of using that which has been found to answer in practice, without that due observance in the application of the changes which strict economy would dictate, that much loss of power, and consequently waste of capital, are the necessary results.

The means by which power can be economised, and made to yield a maximum amount of mechanical useful effect, is one which has not occupied the attention of practical men so fully as it deserves; a few have done little more than call the attention of others to certain facts under our daily observation, but little has been done towards settling formulæ for actual construction. Mr. Babbage, in his chapter on the Accumulation of Power in his 'Economy of Machinery,' says: "Whenever the work to be done requires more force for its execution than can be generated in the time necessary for its completion, recourse must be had to some mechanical method of preserving and condensing a *part of the power* exerted previously to the commencement of the process; this is most frequently accomplished by a fly-wheel, which is in fact nothing more than a wheel having a very heavy rim, so that the greater part of its weight is near the circumference; it requires great power applied for some time to put this into rapid motion, but when moving with considerable velocity the effects are exceedingly powerful." "In some of the ironworks, where the power of the steam-engine is a little too small for the rollers which it drives," continues Mr. Babbage, "it is usual to set the engine at work a short time before the red-hot iron is ready to be removed from the furnace to the rollers, and to allow it to work with great rapidity until the fly has acquired a velocity rather alarming to those unused to such establishments. On passing the softened mass of iron through the first groove, the engine receives a great and very perceptible check, and its speed is diminished at the next and each succeeding passage until the iron bar is reduced to such a size that the ordinary power of the engine is sufficient to roll it." Here we have an instance of increased useful effect caused by increased velocity, and this means of increasing the momentum is very frequently used, but the wear and tear is considerable, and it can only be applied in such cases as will admit of increased velocities. If, however, instead of increasing the momentum by an increased velocity, we produce the same result by adding to the weight of the fly-wheel, we obtain the additional advantage of working at a uniform speed governed by a regulator.

We need scarcely remark, for the use of ordinary readers, that "momentum," which represents the force or power of the body in motion, is ascertained by the multiplication of the weight or gravity by the velocity, and that by increasing either the one or the other (the weight or the velocity), the result of the calculation can be brought to be precisely the same, under totally different circumstances of weight and velocity. Mr. Babbage gives us an instance of greater power being obtained by increased velocity; and in existing systems, such as the arrangements at ironworks, the only means left, without some addition to those arrangements, is, by increasing the velocity;—but more efficient means of economising the power at hand would at once be acquired if arrangements were made for increasing the momentum without increasing the velocity. The plan proposed by Mr. Banner, and for which he has obtained a patent, consists in increasing the momentum of the main shaft A, (fig. 1) of the machinery by the addition of a supplementary fly-wheel B, after the works have been set in

* See Dr. Ure's 'Philosophy of Manufactures.'

motion and their inertiæ overcome. The great advantage of this mode of increasing the momentum is, that the uniformity of speed regulated by the governor C, is not interfered with. As regards new works, it will lead to a more just appreciation of the

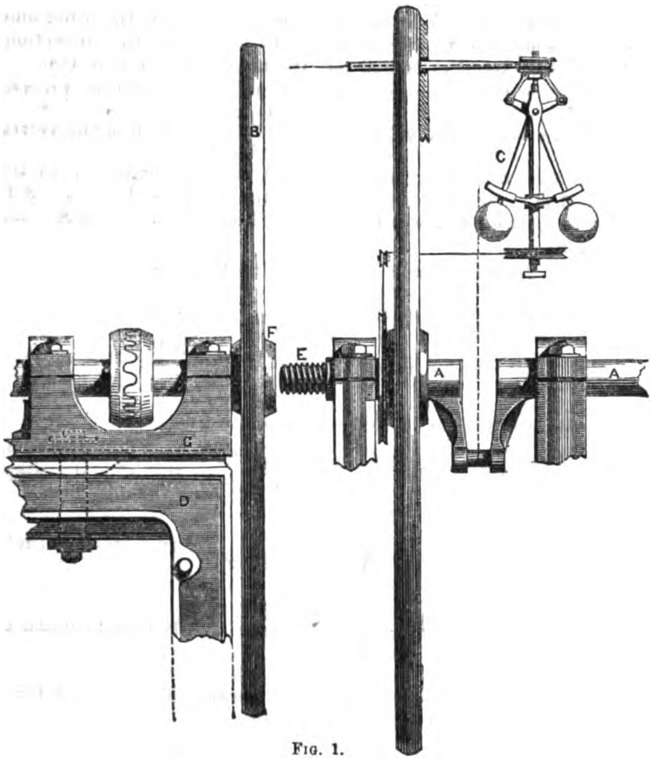


FIG. 1.

minimum power required to produce the necessary results,—while, when applied to present machinery, a gain of power will be realised.

As there are many instances existing where the prime-mover is not found sufficient with the present arrangements for the requirements of the proprietors, the means proposed will be valuable to effect what otherwise would require new combinations. The supplementary fly-wheel B, proposed by Mr. Banner can be geared on to the main shaft A, in the ordinary way; but in his specification he secures the means of bringing the supplementary wheel on a small stage D, working upon rails, or otherwise, with little friction, up to the end of the shaft. He then makes use of a thread, cut in the end of the shaft at E, which is allowed to work in a female-screw in the boss F, of the supplementary wheel. The wheel is allowed to move longitudinally along the bed G, of the stage, until taken up by the main shaft. The motion thereby communicated to the secondary wheel has the advantage of being gradual.

The improvements introduced by the patentee in the construction of water-wheels are chiefly applicable to the overshot construction, and consist in the increase of power caused by keeping a maximum weight round nearly the entire half of the periphery of the wheel on its falling side, which in Mr. Banner's wheels is in most cases *reversed* by, firstly, substituting curved instead of straight or polygonal buckets, differing from the curved shapes introduced of late by Poncelet, Rennie, and Fairbairn, in so much that the line of direction of the centre of gravity of the mass of water in each bucket is, at all times during the rotation, at right angles to the horizontal tangent of the curve; and secondly, by keeping a constant pressure of water on very nearly the whole of the loaded or falling side of the wheel, as shown in the general vertical section, fig. 2, where A, is the axis; B, the wheel; and G, the buckets. The supply is allowed to flow in at C, after being regulated by means of the sluice H, and to escape at B; and waste is prevented by the solid retaining wall, buttress, or other convenient means, according to particular cases of construction, the lower part of the curve of which is brought near to the working parts of the wheel, without being sufficiently so to touch or in any way impede its action, whilst the upper part of the wall is made either vertical or with an inward batter, to lessen the cubic quantity of water in the space I. This arrangement allows of the direct action of a body of water pressing vertically on the tangential parts of the curves of the buckets, and thereby the supply is economised, and the maximum power of leverage

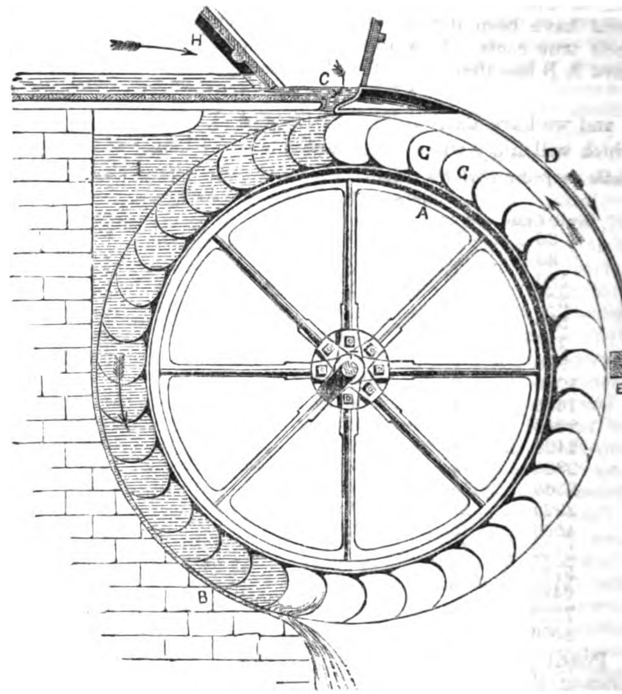

FIG. 2.

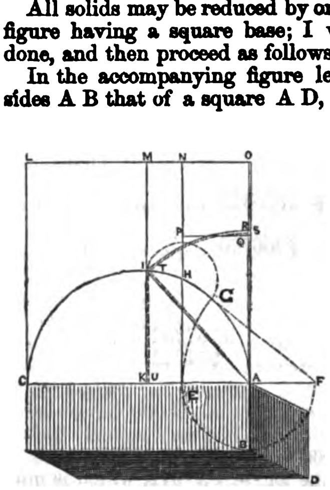
exerted on the periphery of the wheel. At D, is shown a protecting plate of zinc or other material fixed to the cross-beam E, for the purpose of carrying off ice when the supply is excessive; the aperture C, being protected by a grating.

## GEOMETRICAL EXTRACTION OF THE CUBE-ROOT.

SIR—As mechanics and others are often desirous of knowing the side of a cube equal to a given solid, I send you herewith a simple method of finding the same, which, when the correction is employed, gives the result generally true to the $\frac{1}{10000}$th part of the root sought; or, if the root were equal to an eighth of a mile long, the error would not amount to an inch, and more often not to $\frac{1}{10}$-inch.

All solids may be reduced by ordinary methods to a rectangular figure having a square base; I will suppose this to have been done, and then proceed as follows:—

In the accompanying figure let the solid D C have one of its sides A B that of a square A D, and let A C be the other side.



Produce A C to F, and make A E, A F, each equal to A B; on A C describe the semicircle A H C; from the centre F describe the arc E G, cutting the semicircle at G; draw E H perpendicular to A C, cutting the semicircle at H; make H I equal to H G; draw I K perpendicular to A C; *then* A K *is the side of the cube required very nearly.*

When it is desired to have the root much more correctly, continue as follows: Complete A O L C the square of A C, and produce E H, and K I to meet O L at N and M; join A M, cutting E N at P; draw Q P parallel to A C to meet A O at Q, and make A R equal the radius A I; make R S equal to one-third of Q R, and with radius A S cut the semicircle at T; draw T U perpendicular to A C; *then* A U *is the root required, and true to the* $\frac{1}{10000}$*th part generally.*

To do what is here described takes much less time than the description does. As the proof of the above depends upon a very tedious and intricate calculation, I subjoin a table of cubes whose roots have been determined by this method, giving alongside their true roots. It would appear from them not advisable to have A B less than $\frac{1}{10}$th of A C. The method described gives

$$AU^3 = AC \times AB^2;$$

and we have also, $AT^3 = AC^2 \times AB$,

which will apply when the square side is the longer of the two.

*Table to prove that the Method described gives a very close Approximation to the True Cube Root.*

| Given Cube. | A B. | A K. | A U. | True Root. |
|---|---|---|---|---|
| 20 | 1· | 2·5932 | 2·7172 | 2·7144 |
| 80 | 2· | 4·3424 | 4·3090 | 4·3089 |
| 180 | 3· | 5·7401 | 5·6469 | 5·6462 |
| 320 | 4· | 6·9451 | 6·8406 | 6·8399 |
| 500 | 5· | 8·0218 | 7·9374 | 7·9370 |
| 720 | 6· | 9·0127 | 8·9622 | 8·9628 |
| 980 | 7· | 9·9427 | 9·9329 | 9·9329 |
| 1280 | 8· | 10·8270 | 10·8577 | 10·8577 |
| 1620 | 9· | 11·6770 | 11·7447 | 11·7446 |
| 2000 | 10· | 12·5000 | 12·5995 | 12·5992 |
| 2420 | 11· | 13·3016 | 13·4251 | 13·4257 |
| 2880 | 12· | 14·0858 | 14·2282 | 14·2276 |
| 3380 | 13· | 14·8558 | 15·0081 | 15·0074 |
| 3920 | 14· | 15·6118 | 15·7682 | 15·7675 |
| 4500 | 15· | 16·3625 | 16·5101 | 16·5097 |
| 5120 | 16· | 17·1025 | 17·2359 | 17·2355 |
| 5780 | 17· | 17·8353 | 17·9466 | 17·9463 |
| 6480 | 18· | 18·5620 | 18·6433 | 18·6434 |
| 7220 | 19· | 19·2834 | 19·3275 | 19·3276 |
| 8000 | 20· | 20·0000 | 20·0000 | 20·0000 |

Possibly, with a more extensive table of logarithms than I possess, the value of A U might have proved even nearer the truth than this Table shows.

When the cubic contents of a solid are given numerically to find the side of the cube, it may be solved geometrically, thus:—Divide the given cube by any square number, whose root represents one of the sides A B of a rectangular solid equal to the given cube, and the quotient will be the remaining side A C. The Table shows that, when the best diviser is taken, A B will be rather less than $\frac{1}{2}$ A C. Set off the lengths of these sides with a scale, and proceed to find the root by the method described.

*Example.*—Let 571787000 be the given cubic contents. Divide this by any square number, say 422500, whose square root, 650, is one of the sides, A B; the quotient, 1353·342, is the other side A C. When the process is complete, including the correction, A U will be found to be 830·046, the true root being 830·000.

To prove the numerical value of A U by calculation, proceed as follows:—Find the value of $\frac{3\,AB^2}{AC + 2\,AB}$, which is the versed sine of the angle A G; also, $AE = AB$ is the versed sine of the angle A H. By the construction of the figure $<AI = 2<AH - <AG$, from which A K, the versed sine of the angle A I, can be found.

Now the line $AI = AR$ is $= \sqrt{AC \times AK}$,

And, by proportion, $AQ = \frac{AB \times AC}{AK}$;

Hence, $AS = AT$ is $= \frac{AQ + 2AR}{3}$;

And, finally, $AU$ is $= \frac{AT^2}{AC}$.

From the preceding data we derive the following formulæ to determine the value of A U:—Put $b = AB$; $c^3 =$ the given cube, whose root is $c$; and $x =$ sine of $\frac{1}{2} < AI$.

(*a.*) Sine of $\frac{1}{2} < AG = \sqrt{\frac{3\,b^6}{c^3\,(c^3 + 2\,b^3)}}$; hence, $\frac{1}{2} < AG$ may be found by a table of sines.

(*b.*) Sine of $\frac{1}{2} < AH = \sqrt{\frac{b^3}{c^3}}$; hence $< AH$ may be found by a table of sines.

(*c.*) $< AH - \frac{1}{2} < AG = \frac{1}{2} < AI$; hence, sine of $\frac{1}{2} < AI = x$ may be found by a table of sines.

(*d.*) Then, $\frac{1}{9c^3}\left(\frac{b^2}{x^2} + \frac{2\,c^3 x}{b}\right)^2 = c = AU$, the required root.

The given example is worked out by logarithms as follows:—

(*b.*)
$b^3$ ......... 2·812913 × 3 = 8·438739
$-c^3$ .......................... = 8·757234
2) — 1·681505
$\frac{1}{2} < AH$ = 43° 52′ 13″·3 .............. — 1·840752
× 2
$< AH$ = 87 44 26·6
$\frac{1}{2} < AG$ = 36 34 58·7 ............................................................ — 1·773872

(*a.*)
$b^6$ ......... 2·812913 × 6 = 16·877478
3 .......................... = ·477121
17·354599
$-c^3$ ......... 8·757234
$-(c^3 + 2b^3)$ ...... 9·049620
— 17·806854
2) — 1·547745
— 1·773872

(*c.*) $\frac{1}{2} < AI$ = 51 9 27·9 or, $x$ = ·778875, whose log. is — 1·891468.

(*d.*)
$b^2$ ......... 2·812913 × 2 = 5·625826
$-x^2$ ......... — 1·891468 × 2 = —1·782936
696450 .......................... 5·842890

$c^3$ ......... 8·757234
+ 2 ......... ·301030
+ $x$ ........ — 1·891468
8·949732
$-b$ ......... 2·812913
6·136819

+ 1370310 ............................................................ 6·136819
2066760 ........................ 6·3152896*
× 2
12·630579
$-c^3$ ......... 8·757234
$-9$ ......... ·954243 ——— 9·711477
2·919102 .................................. 830·046, the root.

If from the logarithm 6·315289 (*) be taken 1·477121 (= log. 3), then $\frac{1}{2}$ the sum = 2·919084 is the log. of 830·012, which is much nearer the true root. This is equivalent to

$$\sqrt{\tfrac{1}{3}\left[\left(\frac{AC \times AB}{AI}\right)^2 + 2AI \times AB\right]} = \sqrt[3]{AC \times AB^2},$$

an equation which admits of accurate geometrical construction.

It must be understood that the preceding complicated calculation is only intended to prove the accuracy of the geometrical method, for one-third the logarithm of the given cube number would give the root at once.

J. B. HUNTINGTON.

3, *Furnival's Inn, June* 7, 1854.

## MEMOIR OF WILLIAM LAXTON.

We regret to announce the death of William Laxton, Esq., the founder and proprietor, and until recently the editor, of this *Journal*.

William Laxton was born in London, on the 30th March, 1802, and was the son of William Robert and Phœbe Laxton, descended from an old midland counties family. His father was an eminent surveyor, and, after receiving a sound practical education at Christ's Hospital (Blue-coat School), he was brought up to the same pursuits. Having a strong sense of duty, as well as great love for his profession, he set himself steadily to work, and gradually made himself master of every department. His talents were not shining, but he possessed a mind of great capacity, and liberal and enlightened views, so that, both in the extent of his acquirements and mode of their application, he had advantages which few men possess; and had he continued in full practice as an engineer or architect, he would have left behind him works of a valuable class. Few persons came into communication with him who did not recognise his sound practical knowledge; but only those more intimate were aware of his earnestness in all professional pursuits, not only to execute everything thoroughly and soundly, but likewise to carry out that development and those improvements of which the undertaking might be susceptible. Although not disposed to launch out into the regions of speculation, he was always disposed to regard every subject by its higher considerations; and it is perhaps to be regretted that he was on many occasions so far diffident that he gave way in such respects to the convictions of those of less enlarged mind. We dwell upon these traits of his character, because, although he left behind him no great engineering or architectural work, yet during a long period he exercised a very considerable influence, directly and indirectly, on the minds and views of professional men.

We revert to his early training, because in that consisted his peculiar advantages for the career he subsequently pursued, and because it affords an example well worthy of the imitation of the student. In the days of his pupilage, there were not the advantages we now possess. Self-study was then the sole resource of the well-disposed pupil; and although he who succeeds under such circumstances acquires at the same time strong self-control, and a good and independent discipline, yet those wanting in strength of mind are apt to give way, and forego the advantages of learning for the allurements of idleness or pleasure. Almost the only Society, in those days, for promoting scientific knowledge was the "City Philosophical Society," which held its meetings at the house of the celebrated lecturer, Mr. Tatham, in Dorset-street, Salisbury-square, of which Mr. Laxton was an active member, and in which many scientific men of the present day learnt the rudiments of their profession. Now, there are few towns without a school of design or drawing-school, and a mechanics' institute and moderate library, and no great town without special institutions of a higher class. In the metropolis we have now public schools in which the rudiments and accessories of professional education can be acquired, and where the indolent have the spur of rivalry and the supervision of teachers to restrain them to a right career; while those of ardent mind find in our noble institutions the means of gratifying the most zealous love of knowledge. William Laxton, like many other distinguished members of the profession in the present day, had, by self-teaching, to make himself a master in his profession; to learn day by day, and never to the last moment to relax in the study of pursuits wherein the accumulated exertions of men of genius of many nations are constantly introducing modifications, changes, and improvements, applications of new substances, and original modes of construction. Thus, in railway construction he began at an early period; and nevertheless, in the present day, it may be said that all the knowledge of the past is superseded and worthless, and, unless a man had been continually learning, he must begin anew. In a brief generation a new profession was created, and carried to a great height of progress and prosperity, bringing with it its own authorities, its own forms, and its own influence. The architect can still revert to Vitruvius and Palladio, and he finds not a book in his library which is obsolete or unprofitable; but he nevertheless has come to a time when new branches of study have had to be acquired, and when the disposal of new materials has to be determined. In the progress and movement of architecture which we have of late years witnessed, some men have been prepared to take part because they have been the authors of the movement, and it has been by their means maintained; but others have had to learn and study to keep pace with the requirements of the age. No young man therefore must think that a few years of schooldom will thoroughly fit him for any branch of the profession, or that his studies can ever cease while anything yet remains to be learnt; and in William Laxton he will find an example of a man who, with a moderate education and limited means, and while constantly absorbed in active practice, nevertheless made himself master of the highest branches of professional knowledge, and was able to exert a very great and beneficial influence on that portion of society of which it was his lot to be one of the members.

At an early period, Mr. Laxton took a part in railways, with the importance and rapid progress of which he was fully impressed. He surveyed and laid down several lines at various periods, but he was not so fortunate as to obtain the construction of any line. Among other undertakings, he was connected with the Hull and Selby, City and Richmond, Surrey Grand Junction, Hull, Lincoln, and Nottingham, Gravesend and Brighton, Lynn, Wisbeach, and Ely, and Thames Embankment Railway. He also designed a viaduct to overcome the difficulties of Holborn Bridge.

Hydraulic engineering was a favourite pursuit of Mr. Laxton, and one in which his acquirements were very great. It is to be regretted that he did not complete a work which he had designed on this subject, and for which he had prepared extensive materials. In all communications on hydraulic engineering, in its several branches, which appeared in this *Journal* he took a deep interest, and many valuable suggestions proceeded from his pen. On subjects of internal improvement connected with this branch he was much consulted, and of late years his practice had become much connected with it. He designed and laid out the waterworks at Falmouth and Stonehouse, in which he introduced many improvements, and designed works for Penzance and Brighton. In the movement for the improved supply of water to the metropolis he took a leading part as a professional man, and was joint engineer with Mr. Robert Stephenson, M.P., in the promotion of the Watford Water Company, for supplying London with water from the chalk formation; he was also much consulted by the Wandle Water and Sewage Company, and gave evidence for both Companies before the parliamentary committees.

Although a man of quiet and unobtrusive manners, Mr. Laxton was a man of much earnestness in his views and opinions; and as his time was wholly and sedulously given to his business, so his thoughts very naturally were similarly directed. Devoting himself very steadily to his own improvement, he looked with much interest on everything that conduced to the advancement of his own profession; and he was led seriously to consider the manner in which the profession was represented, and the channels available for the circulation of professional information. About eighteen years ago, the only architectural periodical was the *Architectural Magazine*, a work of much merit, edited by the late J. C. Loudon, but which, from its plan, was not calculated to take in a sufficiently wide and varied range of subjects. Mechanical engineering was only represented by the *Mechanic's Magazine*, and civil engineering had no especial organ. It appeared to Mr. Laxton that a work of a new character and scope would be appreciated by professional men, and would be calculated materially to advance professional interests; and after careful consideration, he determined on establishing this *Journal*. To this undertaking he was led by no speculative bias, and he carried into it those habits of application and of perseverance which marked him in all pursuits. It was his object to establish a journal which, while it afforded a medium for ready communication and correspondence, should be of a standard character as a work of reference and authority. He adopted a larger size of page, in order that he might give, in addition to wood-engravings, plates of buildings and machinery.

For the task of editing such a journal Mr. Laxton was well fitted, by the extensive range of his acquirements in every branch of professional, practical, and theoretical knowledge, while, with a progressive and liberal mind, he brought to bear a calm and sound judgment and well-tempered disposition. He had few preferences or prejudices to contend with, and none of a personal nature; and, what is very difficult among professional men and artists, he was able to maintain an independent course, although tempted by many occasions when sectional feeling ran high. If at any time he displayed a warmth of tone, it was when professional or public interests were at stake. In such a career there were few men of whom he earned the ill-will, of many the respect.

In a public course pursued during so many years, and embracing so many measures and events of interest, it is difficult to give any other than a general character, but there are nevertheless several marked features deserving of observation. In the defence of professional interests and the organisation of a professional constitution, there can be no doubt that this *Journal* has exercised a very material influence, and the recognition by the government of the claims of professional men, partial though it be, is owing to the spirit infused by it. The successful resistance of the marine engineers to an insidious measure of the Board of Trade was celebrated by a public dinner to Mr. Laxton, as the Editor of this *Journal*, and honorary secretary to the Associated Engineers. The division of labour which has taken place by the separation of the civil and mechanical engineers was likewise much assisted by the co-operation of the *Journal*. His own experience of the condition of practical hydraulics caused him to take a very active part in promoting that organisation of hydraulic engineering which seems likely to result in its constitution as an established art and as a distinct profession. At all times he was most active in resisting the usurpations of the government on independent practitioners, and the substitution of military engineers for civilians. Had the resistance been persisted in, or were it now resumed, the policy of the course recommended with regard to the military engineers would be fully justified, and the services of those valuable officers be confined to that sphere of honour where they are so much required, and the Ordnance survey be committed to competent civilians of high professional reputation.

Setting aside other services to architecture, Mr. Laxton was materially instrumental in contributing, on every suitable occasion, to the growth of that new and energetic spirit which distinguises our architects in the present day, and more particularly in raising the tone of architectural criticism. On this head, he was always exceedingly desirous of obtaining suitable co-operation, and of enlisting the contributions of those desirous of promoting this object.

It was a source of very great gratification to Mr. Laxton, that not only was his design fully realised, but his exertions attended with reputation and success. Not only has the circulation of this *Journal* been large, and its columns been quoted and translated in every part of the world, while it has received the contributions and co-operation of many of the most distinguished members of the profession.

Many of the communications in the *Journal* have been published in a separate form, including the "Life of Robert Stephenson," by Mr. Hyde Clarke; the translation of Arago's "Life of Watt," a "Life of Trevithick," "Contributions to Railway Statistics," and other works by the same author; "Meteorological Observations," by Dr. Drew; "Lectures on Architecture," by Samuel Clegg, jun.; &c.

In connection with the *Civil Engineer and Architect's Journal*, Mr. Laxton took part in some other publications. He purchased the weekly publication, *The Architect and Building Gazette*, and conducted it for some time, till he united it with the *Journal*.

A work, which originated with his father, and has been conducted for thirty years by Mr. Laxton and his brother, was the *Builder's Price-Book*, bearing his name, and into which he introduced many improvements, and has been for a long time considered a standard work in the profession and in the courts of law, and is so well known as to be circulated all over the kingdom.

These literary occupations required much time and attention, but Mr. Laxton, nevertheless, was deeply engaged in other pursuits. The numerous connections he acquired in relation to the *Journal* caused him to be entrusted with numerous commissions, which were the foundation of a large agency for the procuration of British and foreign patents and registration of designs.

Among other appointments, Mr. Laxton was intrusted with the surveyorship to the Baron de Goldsmid's estate at Brighton, and laid out, under the Baron's direction, a large part of the new town adjoining the west end of Brighton, in the parish of Hove, on which he built and designed many of the houses and effected many improvements. His design for the new church was not however carried into execution. From the period of its formation, Mr. Laxton was also surveyor to the Farmer's Fire and Life Insurance Company. On technical points in surveying he was much consulted as an authority, and was employed in many important cases.

The labour devoted by Mr. Laxton to these various pursuits, there can be no doubt, undermined his constitution, and, after suffering from two severe attacks, he died on the 31st May, of epilepsy, at the age of fifty-two. His remains were privately interred in the family vault in St. Andrew's burial-ground, Gray's-inn-road; the funeral being attended by the builders from Brighton, and by many who held him in high esteem, to whom his decease became known, and who were desirous of manifesting their respect for his life and labours.

The only son, Frederick William Laxton, F.S.A., was brought up under his father, and was a matriculated student in the Department of Applied Sciences of King's College, but afterwards commenced a course of legal studies in the chambers of an eminent special pleader, and was called to the degree of barrister-at-law by the Honourable Society of the Middle Temple. The younger brother of William Laxton, Henry Laxton, was likewise brought up as an architect, and having taken a considerable share in his brother's occupations, has succeeded to the conduct of his various professional engagements.

Mr. William Laxton was a citizen of London and a liveryman of the Haberdashers' Company, admitted in 1823.

## REVIEWS.

*On the Atmospheric Changes which produce Rain and Wind, and the Fluctuations of the Barometer.* By Thomas Hopkins, M.B.M.S. (Second Edition.) London: Weale. 1854.

Science having now attained nearly the limit of possibility of discovery in the region of distant worlds, and having descended into the bowels of the earth till she has exhausted every variety of geological formation, seems to have bethought herself at last, that there may yet be something worth her attention in that mixture of gases constituting the air we breathe, and that it may be as well to discover by what laws the vital air is regulated. We are happy to find symptoms of increased attention to the subject of meteorology, and though our own opinion is, that before we can generalise, we need more extensive series of observations, and those reaching through long periods; yet we thank every man who, with modesty and in a philosophical spirit, contributes his quota towards the explanation of atmospheric changes—changes, wonderful and at present inscrutable for the most part, on the causes of which the best observers hold conflicting opinions. Mr. Hopkins has done good service by publishing the work at the head of this article,—he has carefully examined hypotheses, showing the inconsistency of several with observed facts, and in some cases has brought forward opinions of his own, which deserve study and consideration. His object is truth, and his sentiments are expressed with a modesty and carefulness which recommend them to the attention of all who take an interest in the subjects on which he treats.

The author commences with an explanation of the production of wind, in which he endeavours to show that the usual theory on the subject—namely, the unequal heating of the surface of the globe, and consequently of the air near it by the sun—does not produce those powerful winds which blow within the tropics. "The heating of the surface of the globe and of the air near it by the sun is not," says he, "a sufficiently powerful cause to produce those winds;" and he proposes to show, "that the heat which is taken up by vapour in the process of evaporation, is carried away to various parts of the atmospheric regions, and in those parts is liberated on the vapour being condensed; and that it is this liberated heat which produces that inequality of temperature which causes the greater part of those aerial movements, called winds, on different parts of the surface of the globe." A considerable portion of the author's labours go to establish this theory, upon which we shall pronounce no decided opinion,—it is certainly suggestive, and the cause he assigns no doubt produces some of those variations in atmospheric temperature which are the immediate cause of the rise of some portion of the air, and the in-rush of a colder stratum below. But many other points of very general interest are discussed in this volume, and they are handled with ability, and will ensure attention from his readers. As meteorology has only just begun to be studied, we welcome this book, and shall be glad to see the subject frequently discussed; at the same time, we would point to the fact that what is wanted are observers—let their number be multiplied, and their observations carefully taken with approved instruments. Thus we shall have in the course of time a more extensive collection of facts, whereby we may more readily arrive at general laws. At present, we consider meteorology to be a science of observation, and observation only; and we shall be happy if our remarks tend to add to the number of active members of the Meteorological Society, from whose unobtrusive labours the science is deriving most valuable assistance.

As a specimen of the author's style in describing natural processes, we subjoin the following account of the diurnal process of evaporation (p. 191):—

"When the sun advances above the horizon it warms the surface of the globe, and not only increases evaporation of water, but heats that portion of the atmospheric gases that is near the surface—which portion rises probably in separate streams or columns—cooler columns at the same time descending to the surface and taking the place of the warmer. This process goes on as the sun rises higher, until at some particular time, depending on the locality and the season, the ascending columns reach a height sufficient to enable the expanding gases to cool and condense some of the vapour which is intermingled with them. This ordinarily takes place from 9 to 11 o'clock, or say at 10 in the morning, from which hour condensation is warming the atmospheric mass in the locality. This warmed mass, a mixture of gases and vapour, as it ascends, is acted on by the different laws of cooling, of condensation, and of expansion by heat, which the constituent parts of the atmosphere obey; and the result is the formation of a buoyant column of cloud, of greater or less thickness, according to the quantity of vapour that has been condensed. The whole local column being thus made lighter by the liberated heat, presses with less force on the surface of the earth, and consequently on the barometer. This diminished pressure is however effected through the liberated heat driving a portion of the material of the atmosphere, the gases, from the heated part to other parts of the atmospheric space; and thus we find that the heat just liberated by the condensation of vapour counteracts the increased pressure of the aqueous matter, which is at the same time passing into the atmosphere in the form of vapour. For it is here contended that the vapour that had been produced from 4 to 10 in the morning, is, soon after the last-named hour, not only raised but condensed,—deprived of a part of its heat, and converted into minute particles of water, which float in the gaseous atmosphere as a cloud, and as such, undoubtedly form a part of the whole atmosphere and contribute to its weight. It is not therefore through a reduction of the quantity of aqueous matter in the local atmosphere at this period of the day, that the barometer falls, but that fall is caused by the expanding power of liberated heat driving from the heated vertical column a part of the ponderable gases which previously existed within it, and, in that way, by removing a part of the material of the atmosphere, causing the remainder to press with less weight on the barometer."

In parting with our author, we would strongly recommend his book to all who are interested in the subject, assuring them that they will here find material for thought and sound information on various points which are only to be found scattered through the publications of various learned societies.

---

*The Practical Surveyor's Guide, containing the necessary information to make any person of common capacity a Finished Land Surveyor, without the aid of a Teacher.* By ANDREW DUNCAN, Land Surveyor and C.E. London: Sampson Low. 1854.

WE have received from the other side of the Atlantic a professed new royal road to learning—"A means to make any person of common capacity a finished land surveyor, without the aid of a teacher;" which said means, so far as we can gather from our perusal, are nothing more or less than a *rechauffé*—a gathering of old formulæ culled from the best and well-known authorities. We, however, leave Mr. Duncan to state his own merits, premising that several of the methods and improvements that he claims to have invented have been frequently employed in this country. The work will be found to contain, amongst a variety of other matter, Mr. Duncan says, "A description and design of a new instrument whereby distances are found at once without any calculation. A new method of surveying any tract of land by measuring one line through it, with a geometrical demonstration of the same. A geometrical method of correcting surveys taken with the compass, to fit them for calculation. Description of an instrument by the help of which any gentleman may measure a map by inspection, without calculation. A new and short method of calculation, wherein fewer figures are used than in the common method; also, the Pennsylvania method. Laying off lots with a pole, plummets, &c. &c."

## STEAM ENGINES.

JOHN MILNER, *Patentee*, October 6, 1853.

(*With Engravings, Plate* XXVI.)

IN an engine constructed in accordance with this invention, the Patentee employs two working cylinders with pistons, piston-rods, and connecting-rods constructed in the usual manner, and connected to two cranks placed at right-angles to each other on the same shaft, preferring to make one of these cylinders of greater capacity than the other. The cylinders are provided with valves worked by cams or eccentrics, and so arranged that steam may be admitted from a boiler into the top of the first or smaller cylinder until the piston has made half its stroke, and then shut off. A communication is then opened between the top of the first cylinder and the top of the second one, whose piston is then at the top of its stroke. Both pistons will now descend until the small one has reached the end of its stroke, when the second piston will be at half stroke. The motion still continues, and the first piston begins to return, and reaches its half stroke when the second piston has completed its stroke. The steam which was at first contained in one-half of the first cylinder, will now have expanded so as to fill the whole of the second cylinder and one-half of the first cylinder. The steam is now discharged into the condenser or into the atmosphere. When the first piston reaches the end of its stroke, as above mentioned, the steam from the boiler is admitted to the bottom of the first cylinder until its piston has made one-half of its stroke. The steam is then cut off, and the half-cylinder full of steam is allowed to expand into the bottom of the second cylinder in the manner above described. Thus the second cylinder is open to and receiving its steam from the first cylinder during the whole of the stroke of the second piston. For reversing the engine, a passage or passages and a valve or valves are arranged so as to connect the top of the first cylinder with the bottom instead of with the top of the second cylinder, and *vice versa*. The relative dimensions of the two cylinders, and the point at which the steam is cut off from the first cylinder, may be varied according to the degree of expansion required. The position of the cylinders may be vertical, horizontal, or inclined, and the angle of the cranks may also be somewhat varied.

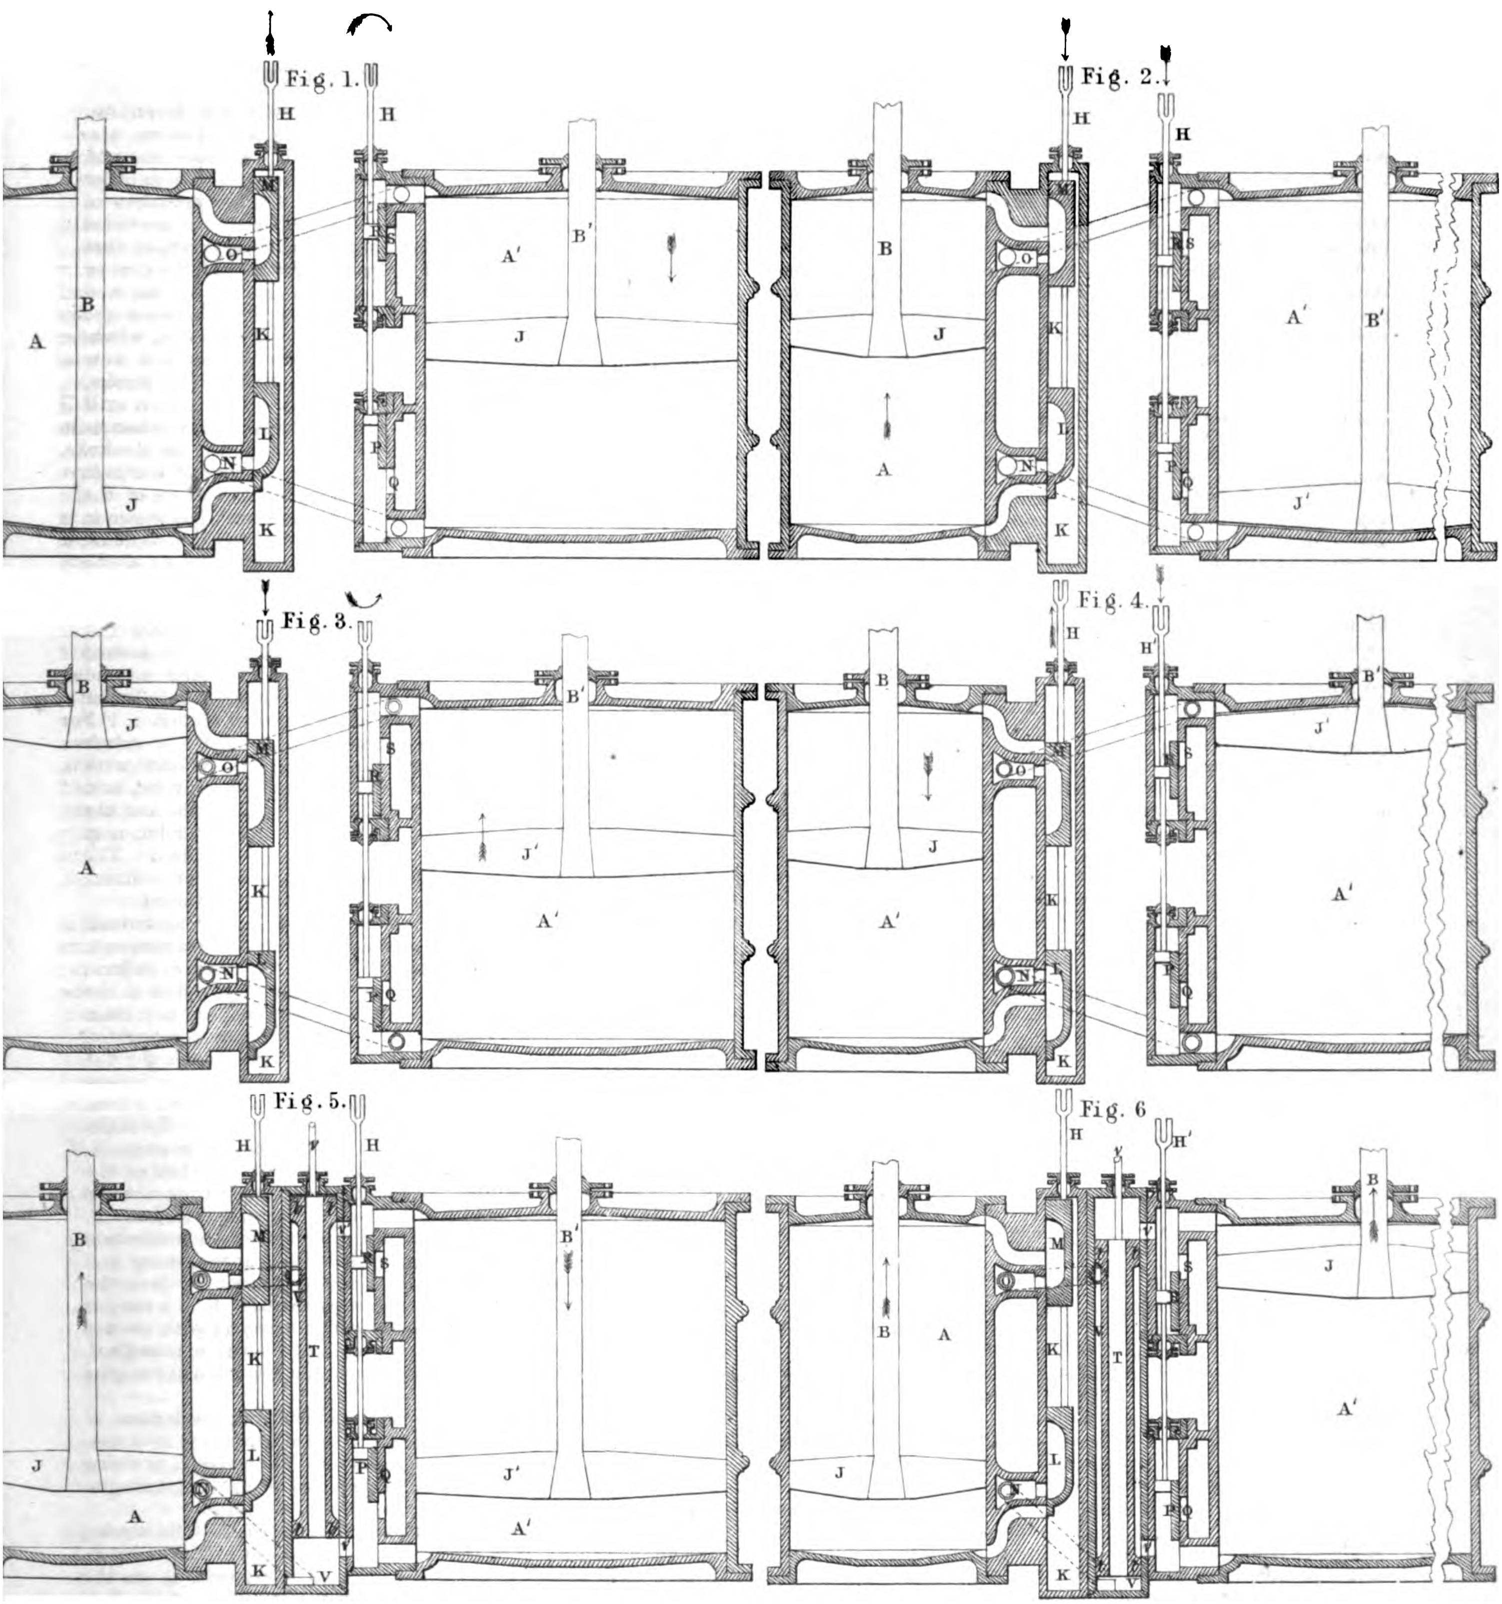
Figs. 1, 2, 3, and 4, in the annexed Plate, are longitudinal sections of the cylinders and valves, showing the arrangements for producing the required effects. A, A′, are the cylinders; B, B′, the piston-rods; C, C′, the connecting-rods attached to the cranks D, D′, placed at right angles to each other on the main shaft E. F, F′, the eccentrics, and G, G′ their rods, connected respectively to the valve-rods H, H′. I, I′, are guides for the piston-rods. J, J′, the pistons of the first and second cylinders respectively. K, a valve-box which is supplied with steam from a boiler, which steam is admitted by means of the slide-valves L, M, into the first cylinder. The eduction passage N, from the bottom valve L, communicates with the bottom of the second cylinder A′; while the eduction passage O, from the top valve M, communicates with the top of the second cylinder. P, is a plain flat slide-valve working in a valve-box in communication with the bottom of the second cylinder A′, and opening and closing a passage Q, leading into the condenser, or into the atmosphere when the engine is non-condensing. R, is a similar slide-valve, working in a valve-box communicating with the top of the second cylinder A′, and opening and closing a passage S, leading into the condenser, or to the atmosphere when the engine is non-condensing.

In fig. 1, the piston J, of the first cylinder is at the bottom of its stroke, and the piston J′, of the second cylinder is consequently at its half-stroke or thereabouts. The valve L, is rising in the direction shown by the arrow, and is just beginning to admit the steam from the boiler under the piston J.

In fig. 2, the piston J, has made about one-half of its stroke, and the piston J′, is at the bottom of its stroke. The valve L, is now descending, and, having shut off the steam, is on the point of opening the communication from the bottom of the first cylinder A, to the bottom of the second cylinder A′

In fig. 3, the piston J, has arrived at the top of its stroke, and the piston J′, is consequently at or near its half-stroke. The communication between the bottoms of the two cylinders is still full open. The piston J, now begins to descend until it reaches its half-stroke or thereabouts, when the piston J′ has completed its upward stroke, as shown in Fig. 4. The steam which at first

# MILNER'S IMPROVEMENTS IN STEAM ENGINES.



J.R Jobbin

was contained in one-half or thereabouts of the first cylinder A, has now expanded so as to fill the half of the first cylinder A, and the whole of the second cylinder A'. The valve P, is now opened, and the steam escapes from both cylinders to the condenser. Both pistons descend until the piston J has reached the bottom of its stroke, as shown in fig. 1, when the valve L, ascends, shutting off the communication with the second cylinder, and admitting steam from the boiler into the bottom of the first cylinder as before. The eduction valve P, continues open until the piston J' has reached the bottom of its stroke, as shown in fig. 2, when the steam from the bottom of the first cylinder is again admitted as before. The valves M, and R, at the tops of the cylinders, act in a similar manner to the valves L, and P, at the bottoms of the cylinders.

The steam is thus caused to expand in the proportion which the sum of half the contents of the first cylinder and the whole of the contents of the second cylinder bears to half the contents of the first cylinder. In the figures the cylinders are so proportioned that the contents of the second cylinder are about two and a-half times the contents of the first cylinder, so that the steam will thus be expanded to about six times its original volume. The relative dimensions of the cylinders may be varied to obtain different proportions of expansion.

In the above description the engine is described as continually moving in the same direction; but in some cases it is required to have the power of reversing the engine. For this purpose the eccentrics F, F', are made loose upon the shaft, and are driven by stops fixed on the shaft. When the motion of the shaft is reversed, the one set of stops leave the eccentrics, which remain stationary until the other stops come in contact with them, and carry them round in the reverse direction. In addition, however, to this motion of the eccentrics, it is necessary to alter the course of the steam, so that in lieu of its passing from the bottom of the first cylinder to the bottom of the second cylinder, and from the top of the first to the top of the second cylinder, it may be compelled to pass from the bottom of the first to the top of the second cylinder, and from the top of the first to the bottom of the second cylinder. Figs. 5, and 6, are sections of the cylinders and valves, showing also a reversing valve T, adapted for producing the aforesaid change in the course of the steam. U, is the valve-rod which passes through a stuffing-box. The valve T, consists of a tube having a piston *t*, at each end, packed to fit the valve-box V. The steam from the eduction passage N, at the bottom of the first cylinder A, is conveyed by a pipe or passage (indicated by dotted lines) to the bottom of the valve-box V, and is thus put in communication with the interior of the valve T. The steam from the eduction passage O, from the top of the first cylinder is conveyed by another pipe or passage (also indicated by dotted lines) into the space between the valve-box V, and the exterior of the valve T. Two passages or ports *v*, *v'* communicate from the valve-box V, respectively with the bottom and top of the second cylinder A'. When the valve T, is raised into its highest position, as in fig. 5, the steam from the bottom of the first cylinder passes to the bottom of the second cylinder, and the steam from the top of the first cylinder passes to the top of the second cylinder, and the effect is the same as before described in reference to figs. 1, 2, 3, and 4.

When, however, the valve T, is made to descend into the position shown in fig. 6, the course of the steam is reversed so that the steam from the bottom of the first cylinder passes up through the tubular valve T, and enters the top of the second cylinder while the steam from the top of the first cylinder descends between the tubular valve T, and the valve-box V, and enters the bottom of the second cylinder. The motion of the valves L, M, P, R, is at the same time changed by the eccentrics shifting their positions on the shaft, as already mentioned. In fig. 6 it will be seen that steam is entering below both pistons, which are consequently both ascending as shown by the arrows. The motion of the crank shaft will thus be in the opposite direction to that indicated by the arrows in fig. 5.

*Claim.*—The inventor does not confine himself to the particular construction or arrangement of valves shown, as the same may be varied, and the valves may be driven by cams or otherwise, instead of by eccentrics. But what he claims is: the constructing steam-engines with two cylinders whose pistons are in connection with two cranks placed at right angles to each other, or which are otherwise so arranged that when one piston is at the end of its stroke, the other piston may be at or near to the middle of its stroke; such cylinders being provided with valves and valve gear so arranged as that the first cylinder may be about half-filled with steam, and that a communication may then be opened between that end of the first cylinder, so filled with steam and the second cylinder, such communication remaining open during or nearly unto the end of the stroke of the second piston, and until the first piston has made one-half or thereabouts of its return stroke, when the steam which has thus been expanded is discharged into the atmosphere or into the condenser.

## METROPOLITAN WATER COMPANIES' REPORTS.

These reports show the progress made by the several water companies, up to the latter end of April last, in the preparations for complying with the Metropolitan Water Act (15 and 16 Vic., cap. 84), which provided that no water shall be taken from any part of the Thames below Teddington Lock.

### *New River Company.*

This report states that no part of the supply furnished to the metropolis by this company has for many years been taken from the river Thames, but the whole is taken from the river Lea, or from chalk springs upon the course of the New River between London and Hertford. Since the passing of the Act works have been undertaken for the diversion of the sewage of the town of Hertford, so as to guard against its pollution.

Two of the contracts for covering the reservoirs at the New River Head, Highgate, and Maiden Lane, are executed between the company and the contractors; the work of the third cannot be executed until the other two are in action, so as to dispense for the period of construction with its use; but the whole will be finished before the period named in the Act, the 31st Agust 1855.

With regard to the arrangements for filtering, the contracts for the filtering beds have been executed; and the filtering will be in efficient operation before the period named in the Act, the 31st December 1855.

Contracts have been also executed for carrying out the system of constant supply and high service.

The expense entailed by the provisions of the Metropolitan Act will be very much greater than was anticipated, and the outlay of 400,000*l.* provided for by the Act of 1852, will not be sufficient; but 300,000*l.* more will be necessary, making a total of 700,000*l.*

### *Grand Junction Waterworks Company.*

This company obtained a Special Act enabling them to comply with its provisions. Under the powers of that Act they purchased land in the parish of Hampton as a site for the works necessary to draw water from that part of the stream of the Thames prescribed by the General Act, and took immediate steps for the execution of such works, and for bringing the water thus procured to their existing works at Kew Bridge. For this purpose they entered into the following contracts:—For the supply of 13,000 yards of 33-inch pipes from the Iron works at Middlesborough, in Yorkshire—For laying the 33-inch main from Hampton to the works at Kew-bridge.—For two engines and six boilers at Hampton, from the Hayle Foundry, Cornwall.—For construction of engine and boiler-houses, reservoirs, &c. at Hampton.—For the construction of one depositing reservoir and two filter beds at Kew-bridge. Up to this time the progress made in the execution of the several contracts is as follows:—5570 yards of the trunk main have been laid. The works at Hampton are in a forward state, the more important portions of the engine and boiler houses having been completed, and the two subsiding reservoirs about two-thirds finished. Of two additional filter beds at the Kew-bridge works, one is completely, and the other nearly finished. There is also a new subsiding reservoir at the Kew works almost completed.

The water delivered daily by the Grand Junction Waterworks Company for seven days in the week, agreeably to the average of the last twelve months, amounts to 5,518,342 imperial gallons. The number of houses in the district is 16,417. Deducting the supplies for baths, railways, road watering, and flushing sewers, the mean quantity delivered per house would amount to 303 imperial gallons per diem. The company will have the power, when their works shall be completed, of increasing their supply in any degree required, as the engine power at Hampton and the trunk main are capable of delivering 20,000,000 imperial gallons per diem.

The site selected for the source of supply is above the village of

Hampton, six miles above Teddington Lock, and one and a half mile above Hampton Lock.

*West Middlesex Waterworks Company.*

This Company procured a special act to enable them to obtain a supply of water from the Thames at Hampton, nearly six miles above Teddington Lock; where they have purchased the freehold land requisite for the construction of their new works, and have entered into contracts for the engines, engine house, and mains necessary to convey the water from this source to their present large subsiding reservoirs at Barnes.

These works are in a very forward state:—The engines are being made; the engine house is in course of erection; and nearly five miles of their 36-inch main (out of eight and a half miles) have been already laid. The directors therefore fully expect that their district will be supplied with water taken from the Thames at Hampton in the early part of next year, which will be considerably within the time allowed by the Metropolis Water Act of 1852.

Contracts have been entered into for the construction of three filter beds at Barnes, in addition to the present subsiding reservoirs. Two of these filter beds are already completed, and the third is nearly so; by which the directors will be enabled immediately to deliver filtered water from their present source of supply, which is about one and a quarter mile above Hammersmith-bridge. The sum of 74,761*l.* has been already paid the contractors on account of the new works.

*East London Waterworks Company.*

This Company state that the whole of the works undertaken by them, in accordance with the requirements of the Act, are in such a state of forwardness, that previously to the period fixed for completion, the Works will be finished, and in operation.

*Southwark and Vauxhall Waterworks Company.*

By the special act this company obtained powers to raise additional capital, to purchase land in the parish of Hampton, and to execute the works necessary to bring water from the new site to their works at Battersea. With a view to the immediate execution of such works, the following contracts were entered into:—With Messrs. Bolckow and Vaughan, of Middlesborough, Yorkshire, for the supply of 23,000 yards (about 11,000 tons) of iron pipes of 36 inches diameter.—With Messrs. Harvey and West, of Hayle, Cornwall, for the construction of an additional engine at Battersea and two lifting engines, with six boilers, at Hampton.—With Mr. John Aird, for laying the 36-inch main, including the passing under the Thames at Richmond, and likewise for the erection of engine and boiler houses, and the formation of reservoirs at Hampton.—With the same contractor, for the formation of the new filter bed and other works at Battersea. —The term fixed in the contracts, as well for the execution of the works as the supply of mains and engines, was the 29th September 1854.

The progress actually made to the present time is as follows:— The works at Hampton, consisting of engine and boiler houses and two subsiding reservoirs communicating by a culvert with the Thames, are about two-thirds finished; but in the portion completed all the heaviest work of the engine and boiler houses, consisting of the foundations and substructions for receiving the engines and boilers, is comprehended. Nine thousand yards of the great main have been laid; the crossing the Thames—a work of great difficulty—is all but accomplished, and in a very satisfactory manner. The pipes are laid on a solid bed of blue clay, and sufficiently beneath the bed of the stream to be quite safe from accidental disturbance. The new engine at Battersea will be erected and ready for work in a few weeks. The intended addition to the boiler houses (almost doubling the former boiler power) is complete. The new filtering reservoir at Battersea is completed and at work.

The water delivered daily by the Southwark and Vauxhall Company to their district may be taken at 8,000,000 gallons. The number of houses in the district is 40,296. The quantity served to each house (the supplies for trades, railways, road watering, and flushing sewers being deducted) is on the average 173 gallons, and the registrar's returns showing that about 6½ souls may probably be the mean number of occupants of houses in the company's district, twenty-six and and a half gallons per diem are given per head of the population.

The new works will, however, afford the means of more than doubling even this supply. The 36-inch main, with the engine power provided at Hampton, will deliver at Battersea 20,000,000 gallons in the twenty-four hours. The company's works at Battersea and Hampton occupy twenty-seven acres; the net area of the four subsiding reservoirs is 349,500 superficial feet; of the three filtering reservoirs 200,000 superficial feet. The area of filtration, it may be remarked, is more than would be required for a much larger supply than the company now gives. The site selected for the source of supply is above both Hampton Court and Hampton village, nearly six miles above Teddington and one and a half mile above Hampton Lock.

The distributing apparatus of the company consists of upwards of 420 miles of mains, varying in size from three inches to twenty-seven inches diameter, but the pipes are in constant process of extension, almost daily applications for that purpose being made to the company. Wandsworth and Putney have recently had mains and services laid down at the requisition both of the parochial authorities and the inhabitants of those villages.

*Lambeth Waterworks Company.*

This company has completed the construction of entire new works at Seething Wells, above Kingston-on-Thames, and removed the old works. Such new works have long since been brought into full and satisfactory operation and the old works wholly abandoned, so that this company's district is now entirely supplied according to the Act.

*Chelsea Waterworks Company.*

The requirements of the Act have compelled this company to provide for the construction of entire new works at Seething Wells, above Kingston-on-Thames, prior to the abandonment of the old works at Chelsea, it therefore became necessary for the company to acquire possession of a new site for their pumping station, of a line of way for the aqueduct or main pipes from Seething Wells to Chelsea more direct in several places than the existing public roads, and of lands on Putney Heath for the construction of large covered reservoirs. Considerable difficulties have presented themselves in connection with the purchase of the various properties required by the company; but in the autumn of 1853 they succeeded in obtaining possession of the necessary sites, and have since been proceeding with the erection of the requisite new works, which the court of directors have no doubt will be completed and in operation in the spring of 1856.

*Kent Waterworks Company.*

This company does not take its supply from the Thames, but from the Ravensbourne, a tributary stream to that river. The water is taken above the highest point where the tide flows. Before the passing of the Metropolis Water Act, 1852, the company effectually filtered all water supplied by them for domestic use, and they do so now; and they were then, as they are now, prepared to give a constant supply for the domestic use of the inhabitants of houses supplied by them, subject to the conditions specified. The company have already, therefore, complied with all the requirements of the Act referred to, so far as the same apply to their district.

Since the passing of the Act the company have at great expense purchased additional land, and are constructing upon it additional filtering apparatus, and erecting a new Cornish engine, with the view of enabling them to afford to new tenants in their rapidly increasing district the constant supply of filtered water contemplated and required by its provisions. These new works are nearly completed, and will be in operation in a very few months.

*Hampstead Waterworks Company.*

This company had commenced a new artesian well in Kentish Town previous to the passing of the Act. The works were undertaken by Messrs. Degoussée and Laurent. The well varying from 9 to 6 feet in diameter, has been carried down 540 feet. From this point the boring was commenced, and has been continued day and night without intermission, since June last. The total depth now reached is 886 feet, and as the boring is now proceeding through the marl, which constitutes the base of the chalk formation, there is every reason to believe that the estimate of Messrs. Degoussée and Laurent as to the thickness of the chalk stratum under London will be completely verified, and the greensand found within 200 feet of the depth now attained.

The steam power necessary for lifting the water to the elevation required for distribution in the company's district has been provided and fixed, and before the expiration of this year an ample supply of water from the new works will be rendered available for the public use.

## NEW PARLIAMENTARY STANDARDS OF LENGTH AND WEIGHT.

In 1841, the Commissioners appointed to consider the steps to be taken for the restoration of the standards of weight and measure, presented their report to both Houses of Parliament: in which they recommended the appointment of a committee of scientific men to superintend the construction of the new parliamentary standards. In accordance with this recommendation a committee was appointed in 1843, consisting of the Astronomer Royal, G. B. Airy, Earl of Rosse, Marquis of Northampton, the Lord Wrottesley, F. Baily, Esq.; J. E. D. Bethune, J. G. S. Lefevre, Esq., Sir J. W. Lubbock, Bart., the Rev. G. Peacock, Dean of Ely, the Rev. R. Sheepshanks, Sir J. F. W. Herschel, Bart., and Professor Miller.

This committee presented their report in March 1854, in which they have fully discussed the most expedient methods and materials for constructing the various standards, and also in consideration of the inadequacy of the present arrangements to maintain the national standards in a state fit for the public wants, as regards either the sufficiency of number of the Exchequer standards, or the state of preservation of those standards, or the nature of the comparing apparatus and the methods used in their applications, or the provincial dissemination of copies of the standards, or the inspection and occasional comparison of all for the purpose of insuring their accuracy; the committee recommend the appointment of a permanent scientific officer: whose business it shall be to keep a constant watch on the state of the primary standards, the secondary Exchequer standards, the local standards, the equipments of the standard offices, the relations of British and foreign standards, and the state of the law generally as applying to standards; and to memorialise the government from time to time, as the occasion may arise, on any of these points.

This recommendation was proposed in Lord Carysfort's Bill, which suggested that four commissioners should be appointed, with an establishment of eight clerks and a sufficient number of workmen; and although their duties as described do not *totidem verbis* include the employments stated above, yet it is plain that an establishment of this liberal character was intended to maintain the standard department in a perfectly efficient and reputable state. This Bill, however, never passed into law, the appointments never were made, and the management of the standards has fallen entirely into the hands of subordinate officers of the Exchequer.

The committee held its first meeting in 1843, when it appeared that the construction of the standard of length had been undertaken by Mr. F. Baily; and that of weight by Professor W. H. Miller; but, on the death of the former gentleman, his task was entrusted to the Rev. R. Sheepshanks. The committee had access, for purposes of comparison, to the length, scales, and weights belonging to the Ordnance and several royal societies, which had been compared with the lost imperial yard standard, and the lost imperial troy pound. They decided to continue the adoption of one yard as the length of the parliamentary standard.

The following are the Length-scales which had been compared with the lost Imperial Yard Standard:—Two three-feet iron bars belonging to the department of the Ordnance Survey; Shuckburgh's scale, in the possession of the Royal Society; the brass scale of the Royal Society, No. 46; and the brass tubular scale of the Royal Astronomical Society.

The following are the Weights which had been compared with the lost Imperial Troy Pound standard:—The brass Troy pound of the Exchequer Office; the brass Troy pounds from the cities of London, Edinburgh, and Dublin; the platinum Troy pound and the two brass Troy pounds then in the custody of Professor Schumacher; and the platinum Troy pound of the Royal Society, No. 48.

The committee also had access to the following length-scales and weights:—The ruined Imperial Yard Standard (in custody of the Speaker of the House of Commons); Troughton's five-feet scale (presented by W. Simms, Esq., and now preserved at the Royal Observatory, Greenwich); Ramsden's twenty-feet bar, and Roy's three-feet bar (purchased by the committee, and now deposited at the Royal Observatory, Greenwich); two troy pounds, formerly in the possession of Mr. Bingley; the troy pound used by the late Mr. Robinson of Devonshire-street, Portland-place; and the troy pound formerly belonging to Mr. Freeman (now the property of Messrs. Vandome and Titford).

### *Construction of the Standard of Length.*

The first important question which presented itself to the committee, was, whether the measure of length should be defined by the whole length of a bar, or by the distance between two points or lines marked on it.

The most celebrated of the standards constructed in modern times is the new Prussian standard, made by the late astronomer, Bessel. In this standard, the whole length of the bar is adopted as the measure of length. The reasons which induced Bessel to substitute a standard of this construction (or standard *à bouts*) for the standard in which the measure is defined by the distance between points or lines upon its surface (or standard *à traits*), which was the principle of construction of the former Prussian standard, were first, that if a flexible bar be supported on two points, the extreme length of the bar from the centre of one end to the centre of the other end is not sensibly altered by its flexure, but the distance between two points or lines upon the upper surface may be considerably altered. Bessel has himself, however, remarked that this objection to line-measure is removed if the lines be engraved on surfaces which are depressed to the middle of the thickness of the bar (a principle long since employed in English standard bars); and, moreover, the tendency to alter the apparent length, whether at the surface or the middle of the thickness, may be destroyed by proper adjustment of the points of support, and perhaps still more surely by supporting the bar at numerous points by lever-frames which will insure equal supporting forces at all the points, or in special experiments by floating the bar in quicksilver. A second reason assigned by Bessel is, that the principle of end-measure is more convenient than the line-measure for the production (that is, practically, the comparison,) of copies of the standard. It appears probable that this remark is well founded, as regards the construction of secondary standards for commercial purposes, but it is doubtful whether it applies to secondary standards for scientific purposes, and it can scarcely apply to primary standards, in regard to which the consideration of convenience (in the few comparisons that may be made at intervals of many years) has no weight, when contrasted with the consideration of conservation of the standard length. Another reason is, that it is more convenient for use; but the members of the committee, who have witnessed the operation of measuring a geodetic base by means of bars carrying the line-measure, have been led to form a high estimate of the convenience of the line-principle in that instance. It would appear, too, that in Captain Kater's measurement of the pendulum, and Mr. Baily's comparison of the mètre *à traits* with the yard, no inconvenience from that cause was found by either observer. It is moreover to be remarked, that the whole of the British geodetic bases have been measured by bars constructed on the line-principle; and a standard which is intended to apply advantageously to them must be constructed on the same principle. The end-measure has never, so far as is known to the committee, been applied to any scientific determination in England.

These considerations induced the committee to adopt the line-standard, or measure *à traits*, for the parliamentary standard of length.

The point which next engaged their attention was the material of which the new standard of length should be formed. The requisite qualities are invariability and durability. It was remarked by the committee, with reference to the fusible metals and alloys, that copper is soft, and is not easily cast; that cast brass is considered unsound until it has been hammered; that gun-metal is easily cast, and may be made (by due proportion of its component metals) pretty hard and elastic, and is free from liability to corrosion; and that cast-steel is perfectly manageable; also, that platinum, although it possesses the advantageous properties of being very durable, and little affected by changes of temperature, is inconveniently heavy and soft; but that iron, whether cast or forged, is manageable, and probably invariable. It was considered that the choice of materials was practically limited to the following metals and alloys: Gun metal in proportions of copper, tin, and zinc to be determined by experiment); cast steel; cast iron; and forged iron. These metals all possess the qualities of invariability.

A series of experiments was made by Mr. Baily on gun-metal formed of different proportions of the simple metals. It was found at length that an alloy formed in the following proportions, copper 16, tin 2½, zinc 1, appeared to possess every desirable property. It is hard; it is highly elastic, recovering its form (as to sense) perfectly after every strain, until the weight placed on it is sufficient to break it, when it breaks without bending; it is also strong. Gun metal being also less liable to injury, or even total destruction from rust, the committee determined on adopting it, when composed in the proportions above mentioned, as the material of the standards of length.

The form adopted for the standard of length and for all its copies is that of a solid square bar, 38 inches long and 1 inch square in transverse section. Near to each end a cylindrical hole is sunk (the distance between the centres of the two holes being 36 inches) to the depth of 0·5 inch. At the bottom of this hole is inserted in a smaller hole a gold plug or pin about 0·1 in diameter, and upon the surface of this pin there are cut three fine lines at intervals of about 0·01 inch transverse to the axis of the bar, and two lines at nearly the same interval parallel to the axis of the bar. The measure of length is given by the interval between the middle transversal line at one end and the middle transversal line at the other end; the part of each line which is employed being the point midway between the longitudinal lines. The other transversal lines were used, in the operations of comparison, only for assigning the scales of the micrometers.

The selection of authorities for the reproduction of the imperial standard was a matter of considerable difficulty, arising from the imperfections in and discrepancies between existing standard measures; the scale of the Royal Astronomical Society was proved to have undergone considerable change. This discovery necessarily took away all authority from other scales of a similar construction. From this and other causes, Mr. Sheepshanks determined, first, that no scales ought to be used for restoration of the value of the imperial standard, except those which had been compared *directly* with the imperial standard; secondly, that among these the only admissible scales are, the Royal Society's brass scale No. 46, and the two 3-feet iron bars of the Ordnance Department.

The definition of a length, as represented by a standard bar, requires a statement of the temperature at which the standard bar is to be used. It appears, upon examing the amount of the expansion of a metallic bar for a given change of temperature, that the effect of a change of 0°·01 or 0°·02 Fahr. is sensible in the measure of the length of a bar; and it was therefore necessary to employ methods of ascertaining the temperature which should be certain to that degree of accuracy. No thermometer in England, at the time of commencing these experiments, could be trusted to such a nicety.

In accordance with a recommendation in the report of 1841, Mr Sheepshanks commenced a series of comparisons of Bronze 28 with numerous bars, in order to select from them five bars, which, in respect of the distinctness of the engraving, their floating evenly in quicksilver, and their near approach to the length of the lost imperial standard, might seem well adapted to be taken as parliamentary standards, and copied. It was discovered during these observations that there was a difference between the comparisons of different observers far exceeding the uncertainty inferred by the theory of probable errors from the observations of each observer taken separately.

The expansions of these bars corresponding to a given change of temperature had been sufficiently determined in the course of the experiments; and it was then judged expedient, instead of stating the difference in the length of the selected bars at the same temperature, to infer the difference of temperature which would cause all to represent the same length, by the application of which it would be possible to assign the specific temperature at which each bar represents precisely the length of one yard. Thus it was found that the length of one yard as given by the lost imperial standard is represented with no sensible uncertainty, except in the measures of the imperial standard itself, by the following bars, at the temperatures placed opposite to them:—

| | |
|---|---|
| Bronze 19 or No. 1 at 62·00 Fah. | Bronze 7 or No. 4 at 61·98 Fah. |
| Bronze 20 or No. 2 at 61·94 „ | Bronze 10 or No. 5 at 62·16 „ |
| Bronze 2 or No. 3 at 62·10 „ | Bronze 28 or No. 6 at 62·00 „ |

The degrees of temperature for the use of these standards are defined as proportional to the corresponding apparent increase of volume of quicksilver in the thermometer tube; the degree 32° representing the freezing-point of water; and the degree 212° representing the temperature of steam under Laplace's standard atmospheric pressure, or the atmospheric pressure corresponding to the following number of inches in the barometric reading reduced to 32° Fahr. 29·9218 + 0·0766 × cosine (2 latitude) + 0·00000179 × height in feet above the sea; and the degree 62° denoting the temperature which produces in the quicksilver an apparent expansion equal to $\frac{30}{180}$ of the expansion between 32° and 212°; and so in proportion for other degrees.

The committee proposed that the bar No 1 be adopted by the legislature as the Parliamentary Standard of One Yard; that Nos. 2, 3, 4, 5, be adopted as parliamentary copies; and that No. 6 be retained by some officer of the government for the comparison of other bars, or for other scientific purposes in which reference to the standard may soon be required.

*Construction of the Standard of Weight.*

In the construction of the standard of weight, the committee decided on employing platinum as the metal least susceptible of injury from oxidation or other chemical action, or from heat, and as least liable to uncertainty in the results of weighings, on account of its great specific gravity.

The form recommended by Professor Miller, and adopted by the committee, is that of a cylinder nearly 1·35 inch in height and 1·15 inch in diameter, with a groove or channel round it whose middle is about 0·34 inch below the top of the cylinder, for insertion of the points of the ivory fork by which it is to be lifted. The edges are carefully rounded off.

For the comparison of weights, Professor Miller procured from Mr. Barrow a balance of the utmost delicacy. This instrument was mounted in a cellar beneath the Mineralogical Museum at Cambridge, and there all the operations of weighing the representatives of the lost standard, the new primary standard, and the copy of the French standard were performed.

It was decided that the weight of the new standard should be adjusted to correspond (in the proper proportion) to that of the old troy standard, on the supposition that both are weighed in vacuo. This understanding is the same which had been adopted by Professor Schumacher and other accurate observers. In order to carry it out fully, it became necessary to decide on the specific gravity of the lost troy standard. Upon this element there is some uncertainty. The specific gravity of Vandome's pound at 18° centigrade was found, by weighing in water, to be 8·1505; and this was adopted by Professor Miller as the probable specific gravity of the lost pound, inasmuch as the form of this pound appeared to be very similar to that of the lost standard, as represented in drawings. The specific gravities of Mr. Bingley's pounds were found by the stereometer to be 8·427, 8·358. That of Alchorne's pound (supposed to be the same as Mr. Bingley's second pound), as ascertained by weighing in water, appears to be nearly 8·375. The lost troy pound was described in Lord Carysfort's proposed bill as a piece of "fine copper." The specific gravity of the lost troy pound in that case was about 8·895. No other standard weight, however, has been found in this or in any other country, whose specific gravity approaches to this value. At the same time, the doubt as to the specific gravity of the lost standard leaves no uncertainty whatever on its weight when the weighings are performed in air, or on what may be called the commercial weight of the lost standard.

A repetition of the comparisons of the eight troy pounds, which had been compared with the lost troy standard, among themselves of the pounds in each group left no doubt that the brass pounds had gained in weight, while the platinum pounds retained precisely the same relation as before. There appeared to be no doubt that the increase of weight of the brass pounds arose from oxidation. Professor Miller therefore decided to base his restoration of the standard pound on the platinum pounds only. A troy pound was accordingly prepared, by the use of these platinum pounds, representing (with a very small assigned error) the weight of the lost standard in air.

In the report of 1841, Article 25, it was recommended that the future standard of weight should be the avoirdupois pound or pound weight of 7000 grains. The following auxiliary weights were therefore prepared by Professor Miller:—4 of 1240 grains each (nearly); 1 of 800 grains; 1 of 440 grains; 1 of 360 grains; 4 of 80 grains; 2 of 40 grains.

These weights were so chosen that the larger weights can be compared with combinations of the smaller (thus 80 grains may be compared with twice 40, 360 with four times 80 and one 40, and so on), and that the weight of 5760 grains can be compared with four of 1240 and one of 800, and that of 7000 grains with 5760 and one of 1240.

Expressing the error in the 40-grain weight by an algebraical symbol, the error of every weight in this series is determined from comparisons of the weights, and is expressed by two terms, of which one is numerical, and the other is a mutiple of that symbol; and the error of $4 \times 1240 + 800$ is also expressible by a numerical term and a different multiple of the same symbol. These weights being compared with the troy pound of 5670 grains, the value of the symbol was obtained, and therefore the error of any of the 1240 grain weights was known; and then a pound of 7000 grains was formed by adding the troy pound and a weight of 1240 grains.

Five platinum pounds were thus prepared by Professor Miller, marked respectively, P S 1844 1 lb., No. 1 P C 1844 1 lb., No. 2 P C 1844 1 lb., No. 3 P C 1844 1 lb., No. 4 P C 1844 1 lb., the specific gravities of which were found to be as follows:—

| | |
|---|---|
| P S | 21·15702 |
| No. 1 P C | 21·16634 |
| No. 2 P C | 21·16334 |
| No. 3 P C | 21·16128 |
| No. 4 P C | 21·15549 |

Comparing P S with the representative of the troy pound in the manner just described, it was found that in air of the temperature 65°·66 Fah., under the pressure of 29·750 inches of mercury (these being the means of the temperatures and pressures at which Von Nehus compared the ancient troy standard with the two platinum pounds),

$$\text{P S} = 0{\cdot}6341 \text{ grain} + \frac{7000}{5760} \times \text{lost standard},$$

and this may be considered as the commercial weight of P S.

Assuming the specific gravity of the lost standard to be the same as that of Vandome, and that P S and the lost standard are compared in vacuo, P S = 7000·000238 grains, of which the lost standard contained 5760. This may be considered as the philosophical weight of P S. Also,

| | |
|---|---|
| No. 1 P C = P S + 0·00052 grs. | No. 3 P C = P S — 0·00178 grs. |
| No. 2 P C = P S — 0·00088 grs. | No. 4 P C P S — 0·00314 grs. |

The committee recommends that P S be adopted as the Parliamentary Standard of One Pound, and that No. 1 P C, No. 2 P C, No. 3 P C, No. 4 P C, be adopted as parliamentary copies.

In conformity with the recommendation of the committee, the parliamentary standards of one yard and one pound have been deposited in the office of the Exchequer. The copy of length standard, No. 2, and the copy of weight standard, P C, No. 1, in the Royal Mint. The copy of length standard, No. 3, and the copy of weight standard, P C, No. 2, have been transferred to the Royal Society. The copy of length standard No. 5, and the copy of weight standard, P C, No. 3, are deposited in the Royal Observatory of Greenwich. The copy of length standard, No. 4, and the copy of weight standard, P C No. 4, are immured in the sill of the recess on the east side of the Lower Waiting Hall in the New Palace at Westminster.

The only comparisons of the British standard weights with foreign standards have been made with the French Kilogrammes des Archives; in comparing which with our standard pound weight, it appeared that the weight was by direct comparison, 15432·3482; by indirect comparison, 15432·3488.

The committee would not recommend the reference of the values of the measure and weight represented by the standards to natural elements; but consider the ascertaining of the earth's dimensions and of the length of the seconds' pendulum in terms of the standard of length, and of the weight of a certain volume of water in terms of the standard of weight, as philosophical determinations of the highest importance.

The committee in addition to the standards *à traits*, purpose constructing a standard *à bouts*, equivalent in length to the parliamentary standard *à traits*. It is to be formed of steel, with ends of hardened steel, or hard stone, as quartz or sapphire, or some sufficiently hard and incorrodible material. The end surfaces to be curved, forming portions of one sphere whose centre is the centre of the bar. They further recommend that copies of the standard should be deposited in each of the British Islands, the principal British dependencies, and most foreign countries.

Respecting the scale of multiples and subdivisions proceeding from the values of the primary standards, and the decimal scale, the committee adopts to the utmost extent the recommendations contained in the report of 1841, tending to alter the linear measures of the chain and the mile, to diminish the confusion between avoirdupois weight and troy weight, and to banish the stone of 14 lb. and the hundredweight of 112 lb. Stating that at the present time the facilities are great for introducing the decimal scale of coinage, weights, measures, and length.

The Bank of England has spontaneously adopted a decimal scale of multiples and subdivisions of the troy ounce for weighing gold and silver,—which has been followed by the Royal Mint, and by bullion dealers in general, and which has been sanctioned by parliament.

In the Custom House of London it has also been found necessary to adopt a series of weights in the millesimal scale of subdivision of the avoirdupois pound, in order to facilitate the calculations of tare upon ribbons and other goods in numerous small packages, upon which duty is payable on the net weight only.

Remarking that a decimal scale ascending from the pound weight is called for on one side, and a decimal scale descending from it is required on another side, and that thus an entire decimal scale based on the pound weight may be considered as likely to be soon established; remarking also that the decimal subdivisions of the pound weight, down to the one-thousandth part, are expressed by integral grains; and conceiving that the co-existence of two decimal systems (based one on the pound weight, and the other on the troy ounce) offers very great facility for the abrogation of one, and the complete introduction of the other; the committee considers that there is now a prospect of attaining the long-desired simplification of the British system of weights, by the entire suppression of troy weight; and for this reason (in addition to those founded on the extreme convenience of a decimal scale in any special system of weights) it is desirous that every facility should be given to the introduction of the decimal scale based on the pound weight.

On these several considerations the committee recommends that the following secondary standards of length be lodged in the office of Exchequer, for public reference:

- A mural standard of 100 feet.
- A mural standard of 22 yards, or the land chain.
- A mural standard of 20 yards.
- A mural standard of 10 feet.
  (The best form for each of these will probably be, two steel projections inserted in a wall, and defining the required length by the interval between the inner faces).
- A standard *à traits* of one yard, extended to 40 inches, and divided into inches; with a microscopic apparatus for comparisons.
- A standard *à traits* of one foot, decimally divided; with similar apparatus.
- A standard *à bouts* of one yard, with a multiplying-lever-apparatus for comparisons.
- A standard *à bouts* of five links or 1·1 yard.
- Standards *à bouts* of two feet, of one foot, of 0·5 foot or six inches, and of 0·25 foot or three inches, with similar apparatus for comparisons.
- A standard *à bouts* of the French mètre.
- A standard *à bouts* of the Prussian yard.

Also, that the following secondary standards of weight be lodged in the Exchequer, in addition to those which are now in that office, for public reference:—

- 100 lb., 200 lb., (if judged necessary).
- 10, 20, 30, 40, 50 lb.
- 1, 2, 3, 4, 5 lbs.
- ·1, ·2, ·3, ·4, ·5 lb.
- ·01, ·02, ·03, ·04, ·05 lb.
- ·001, ·002, ·003, ·004, ·005 lb.
- 100, 200, 300, 400, 500, 1000 grains.
- 10, 20, 30, 40, 50 grains.
- 1, 2, 3, 4, 5, 6, 7 grains.
- Small decimal subdivisions of the grain, for verification of the balances.
- 100, 200, 300, 400, 500 ounces troy.
- 10, 20, 30, 40, 50 ounces.
- 1, 2, 3, 4, 5 ounces.
- ·1, ·2, ·3, ·4, ·5 ounce
- ·01, ·02, ·03, ·04, ·05 ounce.
- ·001, ·002, ·003, ·004, ·005 ounce.
- A copy of the French kilogramme.

Professor Miller has already taken steps for preparing the 10 lb. weight, the various troy weights, and the kilogramme.

In regard to standards of capacity, the committee see no necessity for departing from the recommendations of the report of 1841, which would provide standards of 9 gallons, 5 gallons, 3 gallons, quart, $\frac{1}{2}$ gallon, pint, in a conical form; and bushel, $\frac{1}{2}$ bushel, peck, gallon, $\frac{1}{2}$ gallon, quart, pint, $\frac{1}{2}$ pint, gill, $\frac{1}{2}$ gill, in a cylindrical form.

## PRICE'S PATENT CANDLE COMPANY'S WORKS, BROMBRO', CHESHIRE.

THE new candle manufactory is situate on the left bank or the Eastham side of the pool, fronting the Mersey, the water of which has been allowed to flow in its wonted course alongside the works, and under the bridge on the Chester road. An excellent view of the proportions of this huge manufactory may be seen from the steamer on its passage to Eastham. The building, which in itself covers an extensive area of ground, is constructed of brick, and is formed into large divisions, to carry on the various processes connected with candle making. It has no fewer than thirteen segment-shaped roofs, made of corrugated iron, and painted white. All these roofs are nearly finished, and some hundreds of men are now employed in the different departments, hurrying on the works to completion. An enormous tank has been formed immediately at the rear of the candle works, with warehouses underneath, and adjoining there are weaving sheds and other appurtenances. A range of offices is now building. A strong wooden wharf, supported by piles, on which there are three cranes, has been also constructed at the back of the manufactory, alongside which small vessels may load and discharge their cargoes. The company will manufacture their own gas for the use of the works, and will also extend it to the cottages of their workpeople, at some distance from the manufactory. In fact, the whole concern betokens an undertaking replete in every convenience and improvement which science, wealth, and labour can introduce. On the elevated ground to the south of the manufactory, 32 neat and comfortable cottages, for the workpeople and their families, have been erected, and are all occupied. These houses have been built in blocks of four, and each has an allotment of ground for a comfortable garden. The foundations for 16 more houses are now being excavated, and their erection will be immediately proceeded with by Mr. Allport, of Bootle, who is the contractor. These cottages are very pleasantly situate, having extensive views of the river and of the picturesque scenery on both sides of the Mersey. Upon the completion of the factory, the number of these cottages will be increased to 200, all of which will be supplied with water and gas from the main works at the pool. Quantities of piping are strewed about the ground, showing that, in addition to a supply of water and gas, the health of the inmates will be attended to by having their habitations efficiently drained. A large plot of land has been appropriated to brickmaking and brickburning, and a great number of persons are employed in converting the clayey soil of that locality into material for the erection of houses. We hear that it is the intention of this spirited company to erect a number of villa residences on their land immediately fronting the Mersey, and also to form a promenade close to the river, similar to the one at Rock Ferry.

## EDUCATIONAL EXHIBITION.

IT is reported that the applications from intending exhibitors for space are very numerous, and that 1200 square feet of horizontal space, and upwards of 32,000 feet of wall space had been asked for, being about four times the space at the disposal of the committee. That these applications were irrespective of the space required for the foreign exhibitors. All the leading educational societies and educational establishments would exhibit, and information had been received that articles were coming from France, Holland, Belgium, Sweden, Denmark, Holstein, Hanover, Seven Cantons of Switzerland, and the United States of America; sent by the respective governments of those countries, as well as from private individuals. From Canada, New Brunswick, and Malta, articles have already arrived. The State of Connecticut, the governments of Denmark and Sweden have respectively appointed the Hon. H. Barnard and Messrs. Fogh and Siljeström as their representatives at the Exhibition: the two former gentlemen have already arrived. All foreign articles intended for exhibition are to be admitted duty free, arrangements have been entered into with Messrs. Cubitt and Company, for fitting up St. Martin's Hall for the reception of the goods. Dr. Whewell, master of Trinity College, Cambridge, has undertaken to deliver the inaugural lecture, "On the Material Helps of Education," on the 10th July, at three o'clock, to be followed by a series of seven lectures, "On the Sequence of the Sciences," by Professors De Morgan, Playfair, Forbes, Huxley, Henfrey, Dr. R. G. Latham, and Professor Creasy. Numerous other lectures on subjects connected with schools and education will be given by eminent men while the Exhibition is open.

The Exhibition is to be opened with a conversazione, on the evening of the 4th July, at which H.R.H. the President had intimated his intention of being present; a private view will take place on the 5th, and the Exhibition will be open to the public daily, on and after the 6th.

It is calculated that the total expenses of the Educational Exhibition, with the accompanying Lectures, Conversazioni, Conferences, &c., if it receive the full development which its great importance requires, will not be less than 2500*l*.

## IRON CHURCHES FOR AUSTRALIA.

Two iron churches in the building yard of Robertson and Lister, Glasgow, are now completed. They are similar in size and general appearance, with the exception that one has two spires, one on each side, and the other one spire, springing from the centre of the pediment. The chief feature of the front elevation is an arcade of ornamental columns and arches, standing out in bold relief, supporting a pediment, and flanked at the side by massive towers, in which are placed the stairs leading to the galleries. The lower series of columns is roofed by a balcony, forming an open porch, whence access is had to the church and to the stairs of the galleries. The dimensions of each church are 73 feet in length, and 45 feet in breadth. The interior is lighted on each side by a series of circular-headed windows, each 20 feet in length: and at the back by two large stained-glass windows. The vaulted ceiling, supported on cast-iron arched girders springing from iron columns, rises to the height of 40 feet. In the crown of the arched ceiling will be placed iron or zinc perforated gratings, for the ventilation. The external roofing is formed of corrugated iron.

## NOTES OF THE MONTH.

*Erratum.*—In the description of Milner's Steam-Engines, we have omitted the figure in which the parts referred to by the letters from C to J inclusive were indicated, they being neither new nor necessary to explain the invention.

*British Association for the Advancement of Science.*—The next meeting is fixed for Wednesday, September 20th, at Liverpool, under the presidency of Lord Harrowby.

*Archæological Institute.*—The annual meeting of this Society takes place at Cambridge, on Tuesday, July 4th. The annual meeting of members and meeting for reading memoirs will be on the 11th.

*Geological Society.*—At the general meeting held at Somerset House on the 24th May, M. W. J. Hamilton was unanimously elected President, Professor Forbes having resigned in consequence of his appointment to the Chair of Natural History at Edinburgh.

*Architect to Ecclesiastical Commissioners, Ireland.*—Mr. Alexander Hardy, of Armagh, has been appointed architect under this Commission.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated February* 20, 1854.

406. W. Melville, Lochwinnoch, Renfrew—Improvements in printing textile fabrics and other surfaces

*Dated February* 24.

450. W. Macnab, Greenock, Renfrew—Improvements in steam-engines of the class usually termed trunk engines

*Dated March* 1.

500. S. Roussel, Rue Caumartin, Paris—New system of painting and colouring glass, being an imitation of old and new church window-glasses, called "Typophanic"

*Dated March* 6.

536. A. Barclay, Kilmarnock, Ayr—Improvements in condensing steam-engines

*Dated March* 8.

554. L. J. Barnetche, Bordeaux, France—Improvements applicable to the prevention of accidents on railways

*Dated March* 9.

562. J. Smith, Liverpool—Improvements in baking-ovens

*Dated March* 17.

638. T. J. Herapath, Bristol—Improvements in the manufacture of manure from sewage, which are also applicable to other artificial manures

*Dated March 20.*

658. C. A. B. Chenot, Paris—Improvements in the manufacture of steel, iron, and different alloys, cast, welded, and moulded

*Dated March 23.*

686. M. Poole, Avenue-road, Regent's-park—Improvements in preventing alterations of bank-notes, cheques, and other documents. (A communication)

*Dated March 27.*

710. G. Collier, Halifax, York—Improvements in looms for weaving terry and cut pile fabrics

*Dated March 29.*

724. F. W. Harrison and H. G. W. Wagstaff, Pollard's-row, Bethnal-green—Improvement in the construction of wicks for candles

*Dated April 1.*

748. A. E. L. Bellford, Castle-street, Holborn—Improvements in breech-loading fire-arms. (A communication)

*Dated April 5.*

782. J. Howden, Glasgow—Improvements in the manufacture of rivets, bolts, spikes, screw-blanks, and similar articles

*Dated April 8.*

827. J. Platt, Oldham, Lancaster—Improvements in machinery for preparing cotton

*Dated April 11.*

846. J. Childs, Belmont, Vauxhall—Improvement in subjecting fatty and oily matters, and matter containing oils or fats, to pressure

850. T. S. Whitworth, Salford, Lancaster—Improvements in the mule for spinning and doubling cotton and other fibrous materials

*Dated April 18.*

892. J. Rowley, Camberwell—Improvements in the manufacture of a material as a substitute for leather

*Dated April 29.*

969. C. Kingsford, Buckingham-street, Strand—Improvements in solidifying or indurating peat, soft, small, or pulverised coal, and other substances of a like oleaginous or bituminous nature, and machinery and apparatus for effecting the same

*Dated May 1.*

972. W. A. Waddington, Stonegate, York—Improvements in the construction of sounding-boards for pianofortes and other like stringed instruments

973. W. A. Archbald, Stanhope-street, Gloucester-gate—Improvements in the manufacture of concrete cane-juice, and sugar

*Dated May 2.*

980. W. Hutton, Portland-town, St. John's-wood—Improved machine for the manufacture of bricks

986. R. J. Maryon, York-road, Lambeth—Improvements in the construction of and manufacture of anchors

*Dated May 4.*

998. C. Mee, Bath — Improved foundation for working out ornamental designs or patterns

1000. C. Barlow, Chancery-lane—Improvements in meters for accurately measuring water and other fluids discharged from pipes, sluices, or vessels. (A communication from J. R. Taylor, New York)

1002. J. Manley, Chacewater, Cornwall—Improvement in ventilation, and in treating smoke so as to prevent the ascent of the denser particles thereof into the atmosphere

*Dated May 5.*

1004. W. Exall, Reading, Berks—Improvements in machines for cutting straw and other such materials

1006. E. Haseler, Wolverhampton—Improvement or improvements in ornamenting metals, papier-mache, horn, and shell

1008. A. M. P. Barbette, Paris—Improvements in the manufacture of brass-topped nails

1010. A. Warner, New Broad-street—Improvements in the manufacture of metal sheets for sheathing ships and other vessels, and for other uses

*Dated May 6.*

1020. R. Bulkley, New York—Extinguishment of fires in steamers, vessels, houses, and buildings of all descriptions

1022. J. H. Johnson, Lincoln's-inn-fields—Improvements in the construction of railway carriages. (A communication from A. F. J. Doebs, Toulouse, France)

1024. J. Bernard, Club-chambers, Regent-street—Improvements in machinery or apparatus for sewing, stitching, or ornamenting

*Dated May 8.*

1026. C. Pfersdorff, South-row, Kensall New Town—New toy or aeriel top

1028. G. F. Logan, Glasgow—Improvements in templates to be used in constructing iron ships, boats, boilers, and other metallic structures

1030. G. Thomas, Osnaburgh-street, Regent's-park—Improvements in the construction of the framework of upright pianofortes

1032. C. B. Normand, Havre, France—Improved machinery for sawing wood

*Dated May 9.*

1034. F. P. Berques, Richmond-road, Dalston—Improvements in cooking and heating stoves, and in generating heat therefor

1036. C. Liddell, Abingdon-street, Westminster—Improvements in the permanent way of railways

1038. E. N. Horsford, Massachusetts, U. S.—Removal of chlorine from substances and fabrics

*Dated May 10.*

1040. P. A. Sparre, Salisbury-street, Strand—Improved mode of preventing the alteration or falsification of written documents

1042. R. Reece, Athy—Smelting of iron by means of turf or peat simultaneously with the combustion of the peat and collection of the products therefrom

1044. J. Anthony and W. T. Chafe, Devonport—Improvement in machinery for the manufacture of pipes and tubes from lead and other soft metals and alloys

*Dated May 11.*

1047. R. Miles, Stoke Hammond, Bucks—Improved coupling joint or connection for tubing or other purposes

1048. E. Brown, Sheffield—Improvements in the manufacture of scissors from steel and other metals

1050. J. Cundy, Carrington, Nottingham—Improved reflector globe or shade for gas candle, oil, and other artificial light

1051. W. Delarue, Bunhill-row—Improvements in distillation

1052. H. Doulton, High-street, Lambeth—Improvements in kilns used in the manufacture of stoneware, earthenware, and china

1053. A. V. Newton, Chancery-lane—Improvement in the construction of carriage-wheels, and in the mode of mounting them on their axles. (A communication)

1054. E. W. Abbott, Regent's Quadrant—Improvements applicable to the manufacture of umbrellas and parasols, and cases for containing the same

*Dated May 12.*

1055. J. Platt, Oldham, Lancaster—Improvements in apparatus or machines for forging, drawing, moulding, or forming spindles, rollers, bolts, and various other articles in metal

1056. J. Penton and J. Mackay, Chipenham, Wiltshire—Improvements in the construction of railway wheels and tyres

1057. W. Waite, Gloucester-street, Regent's-park—Improvement applicable to the construction of sewers, drains, and pipes, for the conveyance of sewage, water, or gas

1058. C. N. Nixon, Ramsgate, Kent—Improved modes of attaching rudders to floating vessels

1059. D. Campbell and J. Barlow, Accrington, Lancaster—Improvements in looms for weaving

1060. T. L. Holt, Warwick-square, Paternoster-row, and W. C. Forster, Hatton-garden—Making paper

1061. H. Crowley, Manchester—Improvements in machinery for grinding bones. (A communication from C. T. Egeberg, Christiana, Norway)

1062. M. Poole, Avenue-road, Regent's.park—Improvements in machinery for splitting leather. (A communication)

1063. C. W. F. Aubusson, Warren-street, Fitzroy-square—Improvement in ferrules

1054. M. Poole, Avenue-road, Regent's-park—Improvements in engraving and printing on glass, and of figuring and ornamenting the same. (A communication)

1065. M. Poole, Avenue-road, Regent's-park—Improvements in fire-arms. (A communication)

1066. A. E. L. Bellford, Castle-street, Holborn—Improved method of retarding the process of decay in flour, meal, grain, and other vegetable substances. (A communication)

1067. A. E. L. Bellford, Castle-street, Holborn—Improvements in carriage-axles and their boxes. (A communication)

1068. W. K. Westley, Leeds—Improved construction of railway, and carriages to be employed thereon; applicable chiefly to farm purposes

1069. F. S. Hemming, Woodside, Birkenhead—Improvements in the manufacture of iron houses; part of which improvements is applicable also to the construction of sheds and fences

1070. F. Smith, York-street, Lambeth—Improved arrangement of furnace for consuming smoke

1071. A. V. Newton, Chancery-lane—Improved mode of separating granular substances of different degrees of fineness. (A communication)

*Dated May 13.*

1072. E. Barsanti and F. Matteucci, Florence, Tuscany—New or improved mode of applying the explosion of gases as a motive power

1073. J. A. Drieu, Patricroft, Lancaster—Improvements in machinery or apparatus for cutting fustians, velveteens, and other similar fabrics, to produce a piled surface

1074. C. Garforth, Dukinfield, Chester—Improvements in apparatus to be employed in the construction of the permanent way of railways

1075. R. C. Burleigh, Northumberland-street, Charing-cross—Improvements in steam-engines and other engines worked by the pressure of gaseous or other fluids, which are also applicable to pumps

1076. T. G. Shaw, Old Broad-street—Improvements in apparatus to facilitate the decanting of wine and other liquids

1077. H. H. Russell, York-buildings, Adelphi—Improved and ready mode of coupling, connecting, or joining

1078. H. Y. D. Scott, Queen's-terrace, Woolwich—Improved cement applicable as a plaster, or for moulding purposes

*Dated May 15.*

1079. J. V. H. de Ste Marie, Paris—Improvements in the means and apparatus for fixing capsules on bottles, vessels, or flagons

1080. L. F. Saugrin, Paris—Improvements in apparatus for the production of stereoscopic and photographic pictures

1081. R. A. Brooman, Fleet-street—Improvements in the manufacture of wheels for railway carriages. (A communication)

1082. R. Scott and T. Rowland, Basford, Nottingham—Improvements in machinery employed in the manufacture of knitted fabrics

1083. P. Prince, Derby—Retarding railway trains on the approach of danger, and for other purposes

1084. J. Chedgey, Grove, Southwark—Improved manufacture of rollers and cylinders, applicable to various kinds of machinery where a smooth, hard, and regular surface is required

1085. W. E. Newton, Chancery-lane—Improved machinery for cutting or shaping wood or other materials. (A communication)

*Dated May 16.*

1087. T. W. Miller, Queen's-place, Southsea, Hants — Improvements in railway-sleepers

1088. G. E. Dering, Lockleys, Herts—Improvements in obtaining motive power by electricity

1089. A. H. A. Durant, Tong Castle, Salop—Improvements in apparatus for sweeping chimneys and flues, and for extinguishing fires therein

1090. T. W. Miller, Queen's-place, Southsea, Hants — Improvements in railway-sleepers

1091. G. Mainwaring and W. A. Summers, Southampton—Improvements in supplying water for waterclosets, for the flushing of drains, and for general purposes

1092. J. P. Baker, Wolverhampton—Improvements in the construction of railway and other bridges, and in the method of lifting the same after sinking

*Dated May 17.*

1093. W. Smith and W. B. Hayes, Manchester—Improvements in power-looms for weaving

1094. R. Harris and R. W. Harris, Birmingham—Improvements in the manufacture of articles in glass

1095. G. Cheadle, Wolverhampton—New or improved lubricating composition

1096. H. Cornforth, Birmingham—Improvement or improvements in shaping and ornamenting metals

1098. A. V. Newton, Chancery-lane—Improved construction of tenon, and of machinery for forming the same, applicable to the manufacture of boxes for other analogous uses. (A communication)

1099. C. Catlow, Clitheroe, Lancaster, and T. Comstive, Burnley—Improvements in shuttles for weaving

1100. S. Diggle, Radcliffe, Lancaster—Improvements in looms for weaving

1101. L. J. Wetherell, Percival-street, Clerkenwell, and A. J. Hoffstaedt, Albion-place, Surrey—Improved construction of pump

*Dated May 18.*

1102. W. Coulson, Fetter-lane, York—Improvements in machinery for mortising and tenoning

1103. J. Worthington, Cardiff, and F. Allman, Adam-street, Adelphi—Improvements in boring, mining, and blasting, and in the apparatus connected therewith

1104. J. Horsfall, Birmingham—Improvement or improvements in the manufacture of wire for pianofortes and other musical instruments

1105. J. Beads, Pendleton, Lancaster—Improvements in machinery or apparatus for preparing, spinning, doubling, and twisting cotton, woollen, silk, linen, or other yarns

1107. W. Miller, Musselburgh, Midlothian—Improvements in bleaching flax, hemp, and other fibrous substances

1108. O. Maggs, Bourton, Dorset—Improvement in applying shafts to agricultural implements and carriages

1109. J. C. March, Barnstaple—Improvements in vices

1110. J. H. Johnson, Lincoln's-inn-fields—Improvements in printing telegraphs. (A communication from M. Theiler)

1111. J. Maclean and T. Finlayson, Glasgow—Improvements in the manufacture or production of ornamental fabrics

1113. J. C. Robertson, Glasgow—Improvements in the preparation and roasting of coffee and other substances
1114. J. Hinchcliffe, jun., Dam Side, York—Improvements in apparatus for regulating or governing the speed of steam-engines
1115. C. Barlow, Chancery-lane—Improvements in the manufacture of metallic capsules for covering or securing bottles and other vessels (A communication)
1116. J. Cunningham and W. Ashley, Liverpool—Improved apparatus for ventilating ships
1117. E. A. D. Guichard, Paris—Improvements in the manufacture of ornamental fabrics for decorating walls or other surfaces

*Dated May* 19.

1118. J. A. Haberhauffe, Grossmuhlingen, Germany—Improvements in fire-arms and projectile weapons
1119. E. J. Feuillatre, Paris—Improved apparatus for cleansing the wheels of carriages
1120. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in connecting the permanent rails of railways. (A communication)
1121. T. M. Gladstone, Salford, Lancaster—Improved traverser or machine for shifting railway carriages from one set of rails to another
1122. C. Rands, Shad Thames, Surrey—Improvements in machinery for regulating the feed of millstones

*Dated May* 22.

1123. T. Allston, Moorgate-street—Improvements in the construction of flues and chimneys for steam-engine boiler furnaces and other furnaces
1124. K. Rose, Commercial-road, Stepney—Improvements in buttons
1125. A. E. L. Bellford, Castle-street, Holborn—Improvements in looms for weaving. (A communication)
1126. A. E. L. Bellford, Castle-street, Holborn—Improvements in pianofortes. (A communication)
1127. W. Church, Birmingham—New or improved projectile
1128. W. Crighton and A. Crighton, Manchester—Improvements in machinery or apparatus, technically called "beaters," used for opening, cleaning, or otherwise preparing cotton, wool, or other fibrous substances
1129. E. Crossland, W. Holiday, and J. Heaton, Bradford, York—Improvements in apparatus employed in the manufacture of cast metal pipes or tubes
1130. J. Crossley, Newton-moor, near Hyde, Chester, and W. Crossley, Failsworth, Lancaster—Improvements in Jacquard machines
1131. J. Blake, Greenock, Renfrew—Improved shackle-hook
1132. R. A. Balbirnie, Great Malvern, Worcester—Improved mode of mounting ships' compasses. (A communication from W. A. Orr, Melbourne)
1134. W. England, Dudley, Worcester—Improvements in pneumatic and hydraulic wheels and fans
1135. L. Sauter, Paris—Improvements in lighthouses, and in lamps for lighthouses and other places
1136. H. S. Rogers, New Oxford-street—Improvements in fire-arms. (A communication from E. Whitney, U. S.)
1137. F. Clark, King-street, Whitehall—Improvement in fixing the spindles of door and other knobs and handles
1138. A. P. Rochette, Brighouse, York—Improvement in the manufacture of soap
1139. J. B. Spencer, Shooter's-hill-road, Kent, and A. J. Melhuish, Bowater-place, Greenwich—Improvements in photographic apparatus
1140. R. Oram and W. Oram, Salford, Lancaster—Improvements in hydraulic presses
1141. C. Bostock and S. Greenwood, Manchester—Improvements in machinery or apparatus for cleaning and doubling silk
1142. T. Storey, Phœnix Foundry, Lancaster—Improvements in stench-traps

*Dated May* 23.

1143. T. W. Atlee and G. J. Atlee, Birmingham—Improvements in printed or other forms, applicable for bankers' cheques, orders for goods, wharfingers' and carriers' receipts, taxes and rates collectors' receipts, and various other parochial, commercial, and private purposes, whether such forms be bound up into books or not
1144. F. Jenks, Handsworth, Stafford, and T. Brown, Birmingham—Improvement or improvements in saddletrees
1145. J. Biggs, Ightham—Improvement in the mariners' and other compasses by isolating and rendering them insensible to the disturbing influence of local attraction of iron, steel, and other bodies
1146. W. White, Cheapside—Improvements in hats and in hat-blocks
1140. J. Kucsynski, Rue de Rivoli, Paris—Improvements in preparing baryta and its salts
1148. E. Radigon and R. G. Grimouville, Paris—Improvements in glasses, shades, and smoke-plates, used in gas and other lighting
1150. R. Reyburn, Baker-street, Greenock—Improvements in refining sugar
1151. C. Levey, Little Queen-street, Lincoln's-inn-fields—Improvements in weaving bags and other tubular fabrics
1152. J. Lawson, Sidmouth-street, Gray's-inn-road—Improvements in the manufacture of cut pile fabrics
1154. J. Livesey, Bury Lancaster—Improvements in machinery for preparing or forming slivers of cotton, wool, and other fibrous materials for spinning or other purposes
1156. J. Smith, Henry-place, Bride-street, and F. S. Thomas, South-terrace, Walworth—Improvements in steering ships and other vessels

*Dated May* 24.

1157. F. Lipscombe, Strand—Improvements in guiding ships and boats
1158. J. Lillie, Manchester—Improvements in looms for weaving
1159. T. Clarendon and O. J. Gilsen, Dublin—Improvements in the means or apparatus for working breaks on railway carriages
1160. T. Ball, Nottingham—Improvement in manufacturing ornamented looped fabrics
1161. J. G. Jennings, Charlotte-street, Blackfriars, and R. Davenport, Jonathan-street, Vauxhall—Improvements in the construction of kilns for burning pottery and other ware

*Dated May* 25.

1162. E. O. Aston and G. Germaine, Millwall—Improvements in mariners' compasses to counteract the effect of local attraction
1163. J. M. Chevron and C. V. F. de Roulet, Paris—Improvements in textile fabrics, and in machinery for manufacturing such fabrics
1164. J. Harrison, Fitzroy-square—Improvements in pianofortes
1165. E. Everall and T. Jones, Henrietta-street, Brunswick-square—Waterproofing all kinds of cloth, clothing, silk, and leather, without injury to their respiratory properties, flexibility of fabric, colour, or appearance
1166. E. C. Mantrand, Paris—Improvements in the manufacture of phosphorus
1167. L. M. F. Doyere, Paris—Improvements in purifying grain
1168. J. W. Jeakes, Great-Russell-street—Improved construction of stove-grate
1169. J. Packham, Western-road, Brighton—Improvements in boilers used for heating and circulating water
1170. J. McGavin, Liverpool—Improvements in metal casks and tanks

*Dated May* 26.

1171. A. Livingston, jun., Portobello, Scotland—Improvements in earthenware pipes for drains and sewers
1172. J. A. Corwin, Newark, New Jersey—Improvements in knitting machinery
1173. G. Chilson, Boston, U.S.—New or improved furnace or heat generator and radiator, to be used for warming buildings or apartments, or for various other useful purposes
1174. S. Sweetser, Massachusetts, U. S.—Improvement in preparing skins or hides for the application of tanning thereto, or for being tanned. (A communication from W. A. Simonds, Massachusetts)
1175. M. Loomis, Massachusetts, U.S.—Improvement in the manufacture of artificial teeth
1176. W. Gossage, Widnes, Lancaster—Improvements in smelting or reducing copper ores, and certain other metallic compounds

*Dated May* 27.

1178. H. Distin, Cranbourne-street, Leicester-square—Improvements in drums for musical purposes, and in the mode of supporting and keeping them in the required position when in use. (A communication)
1179. J. Schmoock, Oxford-street—Improvements in the construction of children's and other carriages moved by manual power
1180. J. Hipkiss, Dudley Port, Stafford—Improvement or improvements in puddling-furnaces used in the manufacture of iron
1181. J. Murdoch, Staple-inn—Improvements in toy pistols. (A communication)
1182. W. Stenson, jun., Whitwick Collieries, Leicestershire—Improvements in steam-engine valves

*Dated May* 29.

1183. J. Stevenson, Grasless, Northumberland—Improvements in ploughs
1184. T. Bazley, Manchester—Improvements in and applicable to furnaces, and vessels used in connection therewith, for the manufacture of glass
1185. H. Kraut, Zurich, Switzerland—Apparatus applicable to cocks, taps, and valves
1186. J. Evans, Abbots Langley, Hertford—Improvements in the manufacture of ornamental paper and paper bands
1187. C. J. Pownall, Kensington—Improvement in communicating intelligence from one part of a railway train to another
1188. T. Taylor, Eddingley, Nottingham—Improvements in machinery or apparatus for distributing manure and vegetable substances

*Dated May* 30.

1191. J. Ridsdale, Minories—Improved means or methods of communicating between different parts of ships and other vessels
1192. F. Mordan, Frederick-place, Goswell-street-road—Improved inkstand. (A communication)
1195. E. Heinhold, Paris—Improvements in diurnal and nocturnal indicating apparatus
1196. H. Doulton, High-street, Lambeth—Improvement in the manufacture of junctions for sewers and drains
1197. M. Scott, Great George-street, Westminster—Improvements in joining or connecting pipes
1198. L. S. Middleton, Glasgow—Improvements in the manufacture or production of ornamental fabrics
1199. L. Wertheimber, Paris—Improvements in apparatus for preventing sea-sickness
1200. H. Colby, New York—Improvements in instruments for taking altitudes, levels, and angles, which he designates "Colby's Altimeter," or self-adjusting quadrant or sextant
1201. E. Loysel, Rue de Gretry, Paris—Improvements in grinding or pulverising vegetable substances, and in obtaining infusions or extracts from tea

*Dated May* 31.

1202. J. MacFarlane, Renfrew—Improvements in steam-boilers
1204. J. Kent, St. James's-square, Notting-hill—Improvements in harbour and river boats and other floating vessels, also in paddle-box boats
1206. W. E. Wiley and E. Lavender, Birmingham—Improvements in the manufacture of certain kinds of metallic pens
1208. C. C. E. Minnie, Paris—Improvements in projectiles

*Dated June* 1.

1212. D. Duncan, Crofton, York—Improvements in railway points or switches and crossings
1214. J. Arrowsmith, Bilston, Stafford—Improvements in steam-boilers
1216. W. Westrup, Old Ford—Improvements in the manufacture of wheat into flour
1218. S. Schwabe, Manchester—Making sulphate of soda or Glauber's salts. (A communication)
1220. O. Rowland, Lloyd-square—Improved apparatus for damping papers, labels, and other like articles

*Dated June* 2.

1222. T. Greenshields, George-street, Derby—Improvements in railway-chairs
1224. B. Stratford, Earl of Aldborough, Stratford Lodge, Wicklow, Ireland — Improvements in locomotion on land and water; part or parts of which are applicable to the raising of weights and the working of machinery
1226. M. Poole, Avenue-road, Regent's-park—Improvement in cop-tubes for mule and other spindles, and machinery for making such cop-tubes. (A communication)
1228. I. Taylor, Stanford Rivers, Essex—Improvement in producing thin metallic shells adapted to printing
1230. W. Wilkinson, Nottingham—Improvements in stamping, raising, or printing patterns upon leather, textile, thread, cut pile, or other similar fabrics, and also for dressing textile, cut pile, and other similar fabrics, previous to the stamping and printing

*Dated June* 3.

1232. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in the construction of umbrellas and parasols. (A communication)
1234. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in producing a useful substitute for leather in various applications. (A communication)
1238. J. S. Forstier, Carlton-hill—Improvements in railway-breaks, and in machinery connected therewith. (A communication)
1240. A. Chavanes, Rupert-street, Haymarket—Improvements in apparatus for indicating the time a public carriage is, and is not, engaged for hire. (A communication)

*Dated June* 5.

1242. J. B. Lindsay, Dundee—Mode of transmitting telegraphic messages by means of electricity through and across a body or bodies of water
1244. W. Crum and P. Stewart, Thornliebank, Renfrew—Improvements in machinery and apparatus for beetling or finishing woven fabrics
1246. H. Bordier, Orleans, France—Improvements in the manufacture of alcohol. (A communication)
1248. E. Maniere, Bedford-row—Improvements in getting peat, and in manufacturing peat with other matters into fuel. (A communication)
1252. S. S. Alison, Park-street, Grosvenor-square—Manufacture of a new material to be used for external applications in medicine

*Dated June* 6.

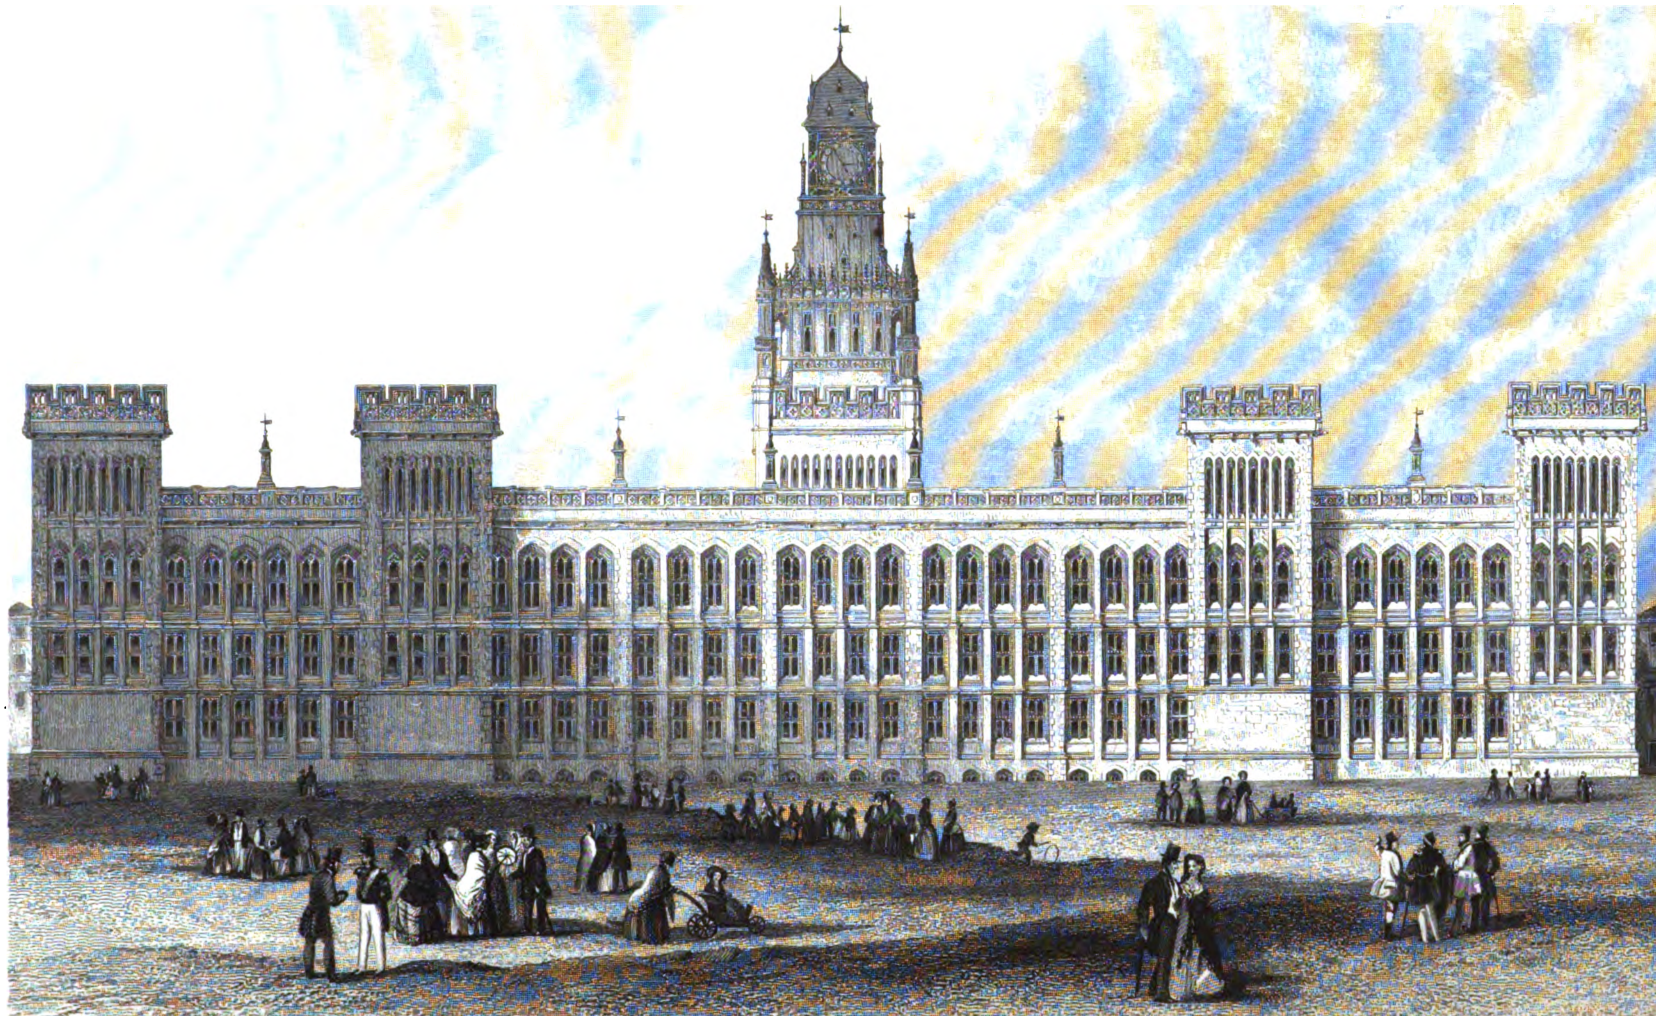
1254. W. T. Parkes, Aston-juxta-Birmingham—Improvement or improvements in the manufacture of the ornamental parts of gas-fittings
1256. D. Atkinson, Seaham Harbour, Durham—Improvements in printing, and in the machinery or apparatus to be employed therein or connected therewith

---

## PATENTS APPLIED FOR WITH COMPLETE SPECIFICATION.

1153. J. Cox, Birmingham—Improvements in the manufacture of percussion-caps.—May 23
1257. N. Brough, Birmingham—Improvements in the manufacture of buttons, and in attaching them to articles of wearing apparel.—June 6

Pl. 27.



THE NEW RECORD OFFICE.

## NEW RECORD OFFICE, ROLLS BUILDINGS.

J. Pennethorne, Esq., *Architect.*

(*With an Engraving, Plate* XXVII.)

We present our readers this month with an engraving of the new Record Office, which the dangerous state of the national records so long imperatively demanded, and which have been hitherto scattered in a variety of places, exposed to destruction by fire or other causes, and always difficult of access. They are deposited, some in the White and Wakefield Towers in the Tower of London, others in the Rolls House, the Carlton Ride, and the Chapter House, Westminster. Some faint idea of the immense mass of national records may be gathered from the fact, that the Master of the Rolls has in his custody considerably upwards of 122,000 cubic feet of documents, to which will be added those from the Palace Court, the Durham records (already upwards of 40,000 cubic feet), together with an incalculable amount from all the holes and corners in which public records have been buried.

The building represented in our Plate is but partly erected, and stands between Chancery and Fetter lanes, on the Rolls estate. Its north front is intended to face a proposed new street, to run from the City to the West-end, coming out through the closely-packed district at the back of Drury-lane into Long-acre. In 1832, Mr. Deering prepared plans for a fireproof building, such as the present, for the late Record Commissioners, which were not acted upon, but other and more comprehensive plans devised by Mr. Pennethorne, from which the present structures have been erected. These consist only of the central portion included between the two wings of the building, which, including the basement, consists of eighty fireproof chambers, each 17 feet by 25 feet, and 15 feet in height; fifty-two of which are to be immediately fitted for the reception of records; twenty in the basement are to be arranged as workshops, or to contain documents not classified; and eight on the ground-floor to be searching-rooms, and offices for the requisite assistant-keepers and clerks.

The eastern wing, when erected, is to include forty-eight of these cubical spaces; and the western wing, which will occupy the sites of the Rolls House and Rolls Chapel, is to contain 100 chambers, making an aggregate of 228 cubical spaces: 200 of which will be eventually allotted to the reception of books and records; twenty for the use of the official establishment, and the remaining eight will be required for wells for two staircases. The 200 chambers are calculated to hold about 500,000 cubic feet of records.

The building is Late Gothic in style, and, from the depth of the buttresses (necessary on account of the number and dimensions of the windows diminishing its resisting capabilities), and the projections of the cornices and stringcourses, &c., it has a bold and substantial appearance. Two windows are provided to each room, and as these rooms are divided by galleries or iron floors, the windows are made proportionately lofty. The floors are formed with wrought-iron girders, supporting flat brick arches of nearly five feet span, laid on the top with white Suffolk tiles. The floor of each room is estimated to weigh about 26 tons, to which will be added a weight of about 64 tons of records, fittings, &c. This circumstance enforced the adoption of the dimensions of the rooms as already stated, instead of making them 15 feet by 27 feet as at first proposed. The brick walls will be coloured inside, without plaster. Externally the walls are of Kentish rag stone, dressed with Anston stone. The hall, entered from the south side, is to be lined with Portland stone, with a zinc panelled and emblazoned ceiling.

The sashes and door-frames are of metal, the doors themselves being formed of slabs of slate. The roof is iron. The clock-tower (already built to the height of the third story) is over the entrance on the opposite side to that shown in our engraving, and will, when complete, materially add to the effect of the building, and relieve the somewhat monotonous appearance of the multiplicity of buttresses and windows of which the main body of the structure consists.

The contractors for the building are Messrs. Lee, and for the iron work Messrs. Grissell. The estimate for the portions already built amounts to 40,000*l.*, not including the clock-turret.

## THE EDUCATIONAL EXHIBITION, ST. MARTIN'S HALL.

In compliance with a promise made at the conference of the representatives of various societies and institutions in union with the Society of Arts, an Educational Exhibition has been opened at St. Martin's Hall, of the utility of which those who have been engaged in instructing the young will bear faithful and willing testimony. There may be little in it to attract the worldly or the gay—the lover of sight-seeing, or one who cannot look below the surface of things; but the thoughtful and reflective will perceive in the materials here brought together the results of the combined efforts of England and foreign countries to explain to youth the truths of science, and open their mind to the beauties of art.

The original proposition for the formation of the Exposition embraced—

1. Plans, models, and drawings of complete sets or portions of buildings for educational purposes; the modes of warming, ventilating, draining, and lighting being explained in detail.
2. Specimens, plans, or models of the various fittings and articles of furniture required for the accommodation of teachers and their pupils.
3. Specimens or samples of materials and apparatus of a cheap and simple description, applicable to the use of schools with limited funds, or of superior schools for teaching practical sciences.
4. Books, maps, prints, and diagrams.
5. Results: including specimens, from schools, of drawing painting, and needlework done by pupils in schools.
6. Projects for supplying desiderata.

After some days spent in careful scrutiny of the materials composing the Exhibition, we can faithfully affirm that the whole of these objects have been carried out by the exhibitors; and we are anxious to direct the attention of our readers to the Exposition generally, and in particular to those parts of it which bear upon art—the department in which they may be presumed to take the greatest interest.

The call of the committee has been responded to in England by the National, the British and Foreign, the Wesleyan, and Congregational Educational Societies, and they exhibit to public view the materials by which the pupils in their schools are instructed in science and art; the same has been done by France, Belgium, Holland, Norway and Sweden, Switzerland, the United States, and nearly thirty cities of Germany. Of our public schools intended for the upper classes, Woolwich would seem to be the only one represented in the Exhibition, and that sustains, we are happy to say, the credit of the country We are presented with books used in the various courses of study, fortification and military drawings and plans, done by the cadets with great taste and skill; the whole series so arranged and laid open that visitors are enabled, by inspection, to form an accurate judgment of the entire plan of education pursued in the first military college in the British empire.

We would call the attention of parents and guardians to the remarkable fact, that nearly the whole of the educational apparatus to be met with in the Exhibition, would appear to be extensively used in educating the children of the poor; and we suggest, as a matter worthy of inquiry of those to whom they entrust the education of their sons, whether equal pains are taken to make them acquainted with natural and experimental science, as the national schoolmaster adopts with the child of the peasant or artisan. We very much fear that the middle class will fall behind in the career of improvement unless greater exertions on the part of the teacher, and greater demands on the part of the parent, should compel the adoption of those methods of illustration which are here brought, in such abundance, before the view: we trust that the apparatus and illustrations, so excellent of their kind and procurable at so small an expense, will be most extensively used in places of education which rank much higher in the social scale than National and British schools, and that public attention will be aroused to the necessity of making demands of at least equal attention, in this respect, from those who conduct schools intended for the middle and higher class of society.

Among the subjects to which the attention of the National Society has been especially directed, is that of offering school materials at the lowest possible price. In the catalogue will be found a list, with the prices of each article attached: one may be quoted. A pair of school 18-inch globes may be procured by members for 5*l.* 10*s.*, by non-members for 7*l.* 10*s.*; the specimens shown indicate them to be of very excellent quality, and indeed ornamental—though the stands are not finished with the elegance of a piece of drawing-room furniture.

The numerous articles illustrative of natural philosophy, would seem to show the tendency of the age towards the practical application of nature's laws. The time seems to have passed, as regards England, France, and the Teutonic nations, when it was considered sufficient that the philosopher in his study should alone investigate natural forces. Pneumatic apparatus, the mechanical powers, sections and models of the steam-engine and electrifying machines, may be met with in various parts of the Great Hall. The British and Foreign School Society exhibits largely this class of apparatus, and their illustrations may be advantageously compared with those from Norway which stand in juxtaposition. Mr. Highley supplies a valuable and extensive series of illustrations of the various sciences connected with natural history and geology; but we apprehend that they are of such a character that they will only find purchasers among professors of colleges, seeing that they are more adapted for young men than for school boys: we decidedly bestow upon them the highest approbation.

As it is not our intention in this paper to enlarge upon the general scope of the Exhibition, but rather to take up that part of it to which our readers may be expected to pay most attention, we shall conclude this portion by expressing a grateful feeling to the Committee of the Society of Arts, to whose labours we are indebted for the collection in one spot of so many valuable adjuncts to the art of teaching. Here the schoolmaster from the country may inspect the best books, maps, and diagrams which London publishers can supply, all of which are conveniently arranged in a room by themselves, and, from the numerous visitors usually met with, we should apprehend that the value of the collection was duly appreciated. The catalogue, in this department, is full and explicit; and thus nothing is wanting to complete the accommodation of those for whose advantage the Exhibition was designed.

The architect who is called upon to provide school accommodation may advantageously consult the various plans and models which are here laid before him: to enter into a discussion on the advantages of each would be beyond our province; but we would direct attention to the model of the Borough Road School, of the Greenwich Hospital School, and of a very complete scholastic building suited for a large parish, models and plans of which are exhibited by Earl Granville. Comparison may be instituted between these and foreign plans, of which many have been sent from various nations, and thus with little labour a great assistance may be obtained. Desks for masters and pupils, easels for slates, and other contrivances to facilitate the internal arrangements of schools, are to be met with here; and as these are matters of great importance, and not such as frequently come under the notice of architects, they will be found most useful. Their dimensions are the result of experience, and are such as that best of all teachers has shown to combine convenience of accommodation with economy of space.

Among the means of warming and ventilation are exhibited school and cottage grates,—those especially by Mr. Pierce, of Jermyn-street, which obtained a medal at the Exposition of 1851, demand attention not only from the builder, but from any one about to furnish a house: he may here inspect "fire-lump grates" of all sizes and prices, from the simple cottage, 24 inches wide, price 11*s.* 6*d.*, to the complete range fit for a large family. The plan on which they are constructed seems perfectly consistent with sound principles,—the supply of air enters in front, and there will be the greatest heat; which point, in grates of the usual construction, is at the bottom of the fuel, where abundant heat is useless. Instead of the fire being surrounded by iron, which abstracts the heat, it is walled-in with fire-brick, which, being a bad conductor, retains the heat and radiates it forth into the room.

We were pleased to see the whole series of progressive lessons in drawing and painting taught at the Marlborough-house School of Design. We have specimens of the examples supplied to the pupils and of the pupils' work, all of which are excellent of their kind. The series commences with outlines, and proceeds by regular gradations till it arrives at drawings from the cast and from life with colour; and we are rejoiced to find that the study of art, on the best principles, is thus rendered available to a large class who, till lately, have had no opportunity of forming a correct taste. We trust, and fully expect, that a few years will produce a great improvement in the public taste in the form of ornamental articles of furniture, the patterns of carpets and paper for walls; in which manufacturers have hitherto failed, or succeeded only by accident. The beautiful forms of nature have been preserved in casts by Brucciani, who has retained in plaster the form of leaves and fruits most accurately, and we cannot but approve of these, as examples to be put before the student, in preference to many of the models which foreign countries would seem to adopt: those from Darmstadt, for instance, consist of unnatural combinations of geometrical solids—a cylinder intersecting a cone, a cone a sphere, and other anomalies of that nature. Such would certainly require great practice to be represented by a student, and may induce correctness of eye and hand; but since, in the fine arts, the imagination must be allowed free scope, we cannot but think that beauty should be the predominant idea in all their productions,—and certainly that is wanting in such almost impossible forms. If a student copies a sphere, there is beauty in the form and shading; still more in the exquisite forms of vegetable life; and greatest of all in the cast of the human figure. Hence, after a certain facility of hand has been attained, the right method is that which seems to be adopted at Marlborough-house, to lead the pupil at once to elegant natural forms, and thus to allow a knowledge of light and shadow to spring up in the mind at the same time that the taste for the exquisite receives cultivation. For general use in teaching landscape drawing, we would recommend the models by Harding, which may be seen in the Gallery; by various combinations of the most simple geometrical forms—the cube and the prism—he renders it possible to produce varieties of structure, such as cottages, houses, and churches, in copying which the pupil must of necessity follow the laws of linear perspective, of light and shadow, and acquire a breadth of shading which is most important in the practice of the art of drawing. It is in this very breadth of shadow that the specimens sent from the Academy of Arts at Cadiz are especially deficient, while in some of those from France the excellence is remarkable; a few sketches from the frieze of the Parthenon, on half-tint paper, with white and black chalk, are striking examples—with little work an effect is produced which is highly gratifying to the spectator, while the finished specimens in ornamentation and from the cast, which France exhibits, are among the most beautiful productions of art in the Exhibition, and will well reward an attentive study. We will not say that these drawings cannot be matched by the Marlborough school specimens, but certainly no foreign nation approaches them in freedom and beauty of execution.

On the question of art, alas! for the United States. Morally and commercially, America is a great nation. On the sea her ships compete with ours,—on the land her energy subdues the forest, and renders the desert a habitation for man; but as regards a conception of the grand and beautiful, she is yet a child. The United States have sent samples of the drawings of her youth, the incorrectness of which we could readily pardon, were it not that the examples put before them, as shown in the "American Drawing-Books," are of so mean and worthless a character that, in our capacity as public critics, we are compelled most emphatically to condemn them. We hardly know how to account for the entire want of taste which these exhibit, seeing that no country can boast of finer scenery or more beautiful natural forms in vegetable life. It would seem to be a necessity, that for man to appreciate nature he must be well instructed in art; that, as in the polished intercourse of the best society the manners are most natural, so in the cultivation of the fine arts the ultimate end of education ought to be a true appreciation of what is beautiful in nature herself. It must be either that an over-weening self-satisfaction prevents America from seeing her deficiency, or that, from want of specimens of the antique or of the great masters of art accessible to the million, she has yet to learn to see with the eye of an artist, and to discriminate between the false and the true. With all friendliness, we would urge upon the government representative a close inspection and comparison of the contributions of the European nations; and would hope that, if wisdom guides him, he will carry back with him some of our best examples, and hurl, one and all, his "American Drawing-Books" to the winds.

In the arrangement of the physical characteristics of a country, we apprehend English geographers may take a useful lesson from a series of maps of Scandinavia, for which we are indebted to Sweden. The first of the series shows, in the usual method of shading, the mountains, the valleys, and the plains; the second exhibits sections through every degree of latitude and longitude, whereby a scale of comparison is supplied for ascertaining the relative heights of each district of the country; the third distinguishing, by colouring of blue and green, the relative amount of verdure and water; while the fourth shows the political divisions of the country. The style of execution of the whole is good, as indeed are most of the contributions for which we are indebted to that country. In Sweden, the science of botany has, since the time of Linnæus, been cultivated with assiduity. For a pupil to enter the University from the middle school of Stockholm, he must present a *hortus siccus* of the plants of the country, collected and arranged by his own hand; we have one here laid before us, as well as the simple tools with which he is supplied to root the hardy plant from the rock, or gather it from the utmost boundary line of vegetation in the neighbourhood of perpetual snow. The *hortus siccus* supplies examples of form for students in the art of drawing, and thus, from the first, a taste for natural beauty is cultivated in the youthful mind. The whole of the contributions from Norway and Sweden are worthy of attentive inspection; and as regards the progress of art, we are led to conclude, from the specimens before us, that these our northern brethren are in advance of the central German States.

Any attempt to explain the laws of linear persective deserves commendation; two especially attracted our attention in the Exhibition. Mr. Kimber, a gentleman well known as an intelligent tutor, includes his subject within a rectangular glass box. Having fixed his point of sight, he draws the outline on the vertical side which is between it and the object, which will of course be seen through the glass. The standing lines of the outline, when viewed from the point of sight, will be found exactly to correspond with the boundary of the object, and thus the student will be convinced of the truth to nature of the laws determining perspective delineations.

Mr. Uddell, of the Training College, Homerton, arrives at the same result by different means. Between the object and the spectator he places, vertically, a wire-gauze screen; having fixed his point of sight, threads are extended from it to all the angular points of the object, the outline of which, being drawn on the screen, will be found to coincide with the object seen through and beyond.

Any person of experience in tuition will have found a difficulty in rendering clear to the comprehension, the truths involved in the "doctrine of the sphere." A small armillary sphere invented by Dr. Sujection, the government deputy from Stockholm, simplifies the matter in this respect, namely, that whereas in our contrivances to represent the sphere of the heavens, we elevate or depress the pole to an altitude corresponding to the latitude by means of the brass meridian, and thus give a movement of which there is no example in nature; in the sphere before us the horizon has a movement whereby it may be adapted, as in truth it ought, to any place on the globe.

In this survey of some of the most remarkable objects supplied by the Exhibition, it has been our desire to direct the attention of our readers to the Exhibition itself, which we hope will be visited by all who can command the opportunity. We have touched on the most prominent objects, especially those bearing on the practice of art; omitting those relating to education in general, among which, however, will be found many to interest every parent, guardian, or well-wisher of the young. During the century of its existence, the Society of Arts has done much to encourage invention, to stimulate exertion, and to reward merit in particular departments; it deserves and will receive the thanks of the community for its efforts in bringing together this practically useful Exhibition of the machinery of education. May it excite a desire in the minds of teachers to improve their style of instruction, and to aim at carrying out to the utmost the facilities here afforded them for illustration and simplification of great natural laws, for demonstrating the truths of science and art, and for rendering education a near approach to the definition of it by Dr. Whewell in his inaugural lecture, as "that which makes man a participator in all that the human mind has attained to, of the rational, the true, the beautiful, and the good."

## THE REBUILDING OF WESTMINSTER-BRIDGE.

REPORT *to the Lords of Her Majesty's Treasury, on the Tenders and Contracts with Reference to the Rebuilding of Westminster Bridge.*

MY LORDS—I have the honour to bring under the consideration of your lordships' Board the proceedings which I have thought it my duty to adopt, with a view to carrying into effect the intentions of Parliament in respect to the erection of a new bridge over the Thames at Westminster.

Previously, however, to entering upon the immediate subject of these proceedings, it will conduce to a right understanding of the subject if I lay before your lordships a condensed account of the present bridge, and of the circumstances which have led to the necessity for the construction of a new bridge at Westminster within little more than a century after the completion of the present structure.

Westminster-bridge was commenced in 1739 and completed in 1750, at a cost of 389,500*l.*, of which sum 197,500*l.* was raised by lottery shares, and 192,000*l.* advanced by Parliament. The management of the bridge and of the bridge estates was placed under the control of Commissioners,* whose powers were transferred by Act of last session (16 and 17 Vict. 4th August 1853) to the Commissioners of her Majesty's Works.

Owing, it appears, to defects in the foundations of the structure, settlements took place before the bridge was completed, which rendered necessary the reconstruction of two of the arches, and great expenses have at various periods been incurred in attempts to maintain it in a state of security. According to a Report of a Select Committee of the House of Commons, dated 5th August 1846, these expenses, including watching, lighting, and repair of the roadway, appear to have amounted, between 1810 and 1838, to 83,097*l.*, and between 1838 and 1846, to 107,124*l.*, making a total expenditure up to the last-mentioned period of 190,221*l.*

The state of the foundations of the piers, and the change which had been progressively effected in the levels of the bed of the river subsequently to the removal of Old London-bridge, appear to have rendered the security of Westminster-bridge an object of anxiety to the Commissioners having charge of the structure, and examinations are accordingly found to have been made, and Reports to have been addressed to the Commissioners on the subject at various periods between the years 1823 and 1844.

Measures for securing the piers of the bridge appear to have been thereupon adopted, and to have been in progress from 1839 to 1843; and it having been decided during these operations to increase the width of the bridge 12 feet, it became necessary for that purpose that nine of the fourteen piers by which the superstructure was supported should be extended in length on the south side.

In a Report made in 1823 by the late Mr. Telford to the Corporation of London, on the probable effects of the proposed removal of London-bridge upon the regimen of that portion of the river, he drew the public attention to the expediency of making provision for the security of other metropolitan bridges under the circumstances of the intended change; and her Majesty's Commissioners for Metropolitan Improvements, in the course of their inquiry, in 1843, into the merits of various projects for the embankment of the Thames, caused sections of the river to be prepared and laid before them by Mr. Page, showing the alterations which had taken place in the bed within the period of twenty years which had elapsed since the date of Mr. Telford's survey. These sections were appended by the Commissioners for Metropolitan Improvements to the first of their Reports to her Majesty, bearing date the 27th January 1844, and presented to Parliament on the 7th February 1844, together with evidence deducing from these sections the impracticability of permanently maintaining Westminster-bridge in its then position.

It was towards the close of the inquiries of that Commission that symptoms of the failure of certain of the piers first manifested themselves; and that the Bridge Commissioners were induced to suspend the progress of the repairs, and to defer the proposed additions to the structure.

The attention of Parliament having been directed to these circumstances, Committees of the House of Commons have at various periods inquired into the condition of the bridge, the practicability of maintaining it for traffic, and the expediency of constructing a new bridge in its place. These Committees sat in 1844, in 1846, and again in 1850.

The Committee appointed in 1844 "to inquire into the present state of Westminster-bridge, and into the expediency of continuing the present expenditure thereon, or of erecting a new bridge on or near the site thereof," reported, after having taken evidence on the subject, "that no case had been made out to justify the Committee in recommending to the House the pulling down the present bridge and the constructing a new one." The Committee of 1846 † reported, that on the evidence

* According to the Report of the Select Committee of the House of Commons, 5th August 1846, the Commissioners were 94; 26 of whom sat by virtue of their offices, 57 by virtue of their seats in the House of Commons, as representing the metropolitan counties, and 11 sat under Bridge Act, 9 Geo. 2.

† The views of this Committee on the subject of a contribution from the State are

which had been laid before them, a sufficient case had in their opinion been made out to justify them in recommending the removal of the present bridge, the construction of a new one, and the transfer, by Act of Parliament, of the Estates and property of the Bridge Commissioners to the Commissioners of her Majesty's Woods and Works.

The Select Committee of 1850 were instructed to "consider and report specially on the expediency of erecting a permanent bridge on or near the site of the present bridge." The Report of this Committee recommended the erection, in case of need, of a temporary bridge across the river, and the institution by her Majesty's Government of an inquiry for the purpose of ascertaining the most economical mode of building an improved bridge on or near the present site.

The Commissioners appointed by your lordships (20th May 1851) divided their inquiries into two portions: the one, "having reference to the question of a site for the new bridge," the other, "as to its mode of construction." After having considered the relative advantages of crossing the river in the respective vicinities of Charing-cross, Richmond-terrace, the India Board, and the present line of Bridge-street, they submitted to your lordships the following recommendations, viz.:—

"That the present bridge should be used as a temporary bridge until the new bridge shall have been constructed.

"That the new bridge should be constructed adjoining, or as near as possible to the present bridge, either on the north or south side thereof.

"That it should not have more than five arches, which should be of iron, with stone piers.

"That the bridge should not be less than 60 feet in width; that it should have a headway at the centre arch of 25 ft. 6 in. above the high-water standard called 'Trinity Datum,' and

"That no time should be lost in making preparations for the commencement of the work."

In conformity with these suggestions, Parliamentary plans were deposited under instructions given by my predecessors, Lord Seymour in 1851, and Lord J. Manners in 1852, in both instances for a bridge to be erected on the present site.

Upon my being appointed First Commissioner of her Majesty's Works, the subject of a new bridge at Westminster was, at a very early period, brought under my notice. The site, the width, and the headway to be allowed for the navigation were of course the points which chiefly pressed for my consideration.

It was at this period of my inquiries that I received a suggestion from Sir Charles Barry for changing the site of the proposed bridge to one near Derby-street, Westminster, a spot essentially identical with that to which reference has been already made in this Report as being in the immediate vicinity of the office of the India Board.

Although the adoption of this suggestion would have been attended with some advantage, inasmuch as it would have relieved the Houses of Parliament from the immediate proximity of the intended structure, as it would have secured the use of the present bridge until the erection of the new one had been completed, and as it would have lessened the distance between Charing-cross and the Elephant and Castle (an important line of traffic on the Surrey side of the river), yet it would have been open to the same objections with the other two localities to which I have adverted in this Report; a total change of site would have involved, both in the purchase of property for the approaches, and in probable compensation consequent upon the diversion of the traffic from the present line, a large and unanticipated expenditure, such as, after duly considering the sacrifice to be incurred on the one hand, with the advantages to be obtained on the other, determined me to adhere to the site for which the Parliamentary plans had been already deposited.

In connection, however, with the adoption of this site, the plan proposed for its appropriation appeared to be susceptible of some improvements. So far as the appearance of the Houses of Parliament was involved, I felt it to be my duty, in common with that of my predecessors at this Board, to consult the opinions of the architect of the building on the subject; on the more important question of the land traffic of the bridge, as compared with that of the navigation, a series of observations were conducted under my direction by Mr. Page, the engineer in charge of the proceedings. The result of my inquiries was such as to satisfy me that both the appearance of the Houses of Parliament and the better accommodation of the land traffic of the proposed bridge might be promoted, without prejudice to the interests of the navigation, by the reduction of the headway at the centre arch from 25 ft. 6. in., recommended by the Commissioners of 1851, to 20 feet; and that in full accordance with both these objects, an agreeable promenade might be obtained for the public in one of the most crowded localities of Westminster, by increasing the width of the proposed structure from 60 feet to 80 feet.

Another suggestion made by Sir Charles Barry for placing the new bridge in a line at right angles to the river front of the Houses of Parliament, and thus accommodating the structure to the intended line of embankment on the Surrey side, was referred by me to several eminent architects, to ascertain their opinion as to the advantages which, as regards the appearance of the Houses of Parliament, would be attained by the adoption of the proposed modification.

The tenor of their reports, however, on that subject, and the interference which the change would have occasioned with property necessary for the approaches on the Surrey side, induced me to conclude that the advantages consequent upon the proposed change were not such as would justify me in authorising it.

Previously to bringing the subject of the reduced headway under the consideration of Parliament, I thought it right to acquaint the Lord Mayor of London, as Conservator of the River Thames, with my intention, and also with the considerations for the land traffic which had induced me to recommend this change. Upon the receipt of my communication, the Lord Mayor brought the subject under the notice of the Thames Navigation Committee, but as this Committee had fixed on 25 feet as the minimum amount of headway to be allowed for bridges in the metropolitan section of the river, the intended headway of 20 feet did not meet with their concurrence, and the Corporation of London, when the Bill came before the Committee, opposed it upon this point.

To show how the land traffic over the bridge, and the river traffic under it, would be affected by the proposed reduced headway, an accurate account was taken of both during five days preceding the sitting of the Committee; it resulted from these observations, that the average number of carriages of all descriptions which had passed over the bridge within twelve consecutive hours of each day was 9200, while only 50 sailing barges had passed under it, and these had, for the most part used an arch of the old bridge which had only 20 feet headway. This comparison, and the result of calculations which I had directed to be made as to the great saving of horse-power which might be effected by easing the gradients and reducing the headway as a necessary consequence of that step, were found to verify the representations made to me in favour of the adoption of a 20 feet headway, exclusive of the improved effect which would be given to the Houses of Parliament by the substitution of a structure, the roadway of which would be 10 feet lower than that of the present bridge.

The evidence given before the Committee in favour of the Bill, both by civil engineers and persons interested in the trade and navigation of the Thames, was such as induced the Committee to decide that a headway of 25 feet was not of such importance to the navigation of that part of the river as to justify so large a sacrifice to the interests of the land traffic, and the headway of 20 feet was finally adopted.

I should observe, that when it was determined by my predecessor, Lord John Manners, to deposit plans and sections for Parliament, it became requisite to decide upon the thickness of the crown of the arch at the centre of the bridge before the sections showing the gradients could be defined; and for this object, Mr. Page, the engineer to whom I had entrusted the preparation of those plans, made two designs of a character suited to the Houses of Parliament; one of these was for a bridge of three arches, the other for a bridge of five arches; on the last of them the estimate submitted to the Select Committee of the House of Commons was based.

The design for a bridge of five arches had been prepared in accordance with the recommendations of the Commission of 1851; but considering that arches of a larger span, with corresponding piers and spandrils, would not harmonise so well with the Houses of Parliament as arches and piers of smaller proportions, I decided (upon the assurance that the wants of the navigation would be amply provided for) to adopt a bridge having seven arches; which alteration, in addition to its other advantages, afforded better means of reducing the thickness of the roadway, and thereby reducing the inclination of the approaches. Besides the site, the number of arches, the headway, and the width of the bridge, there was another important element which governed my conclusions, and which it is right that I should mention to your lordships; I mean the embankment of the Thames. I am indebted to the labours of her Majesty's Commissioners for Metropolitan Improvements for much information upon that subject; a subject which, while it possesses but a partial interest in connection with that of the bridge, is one the importance of which to the welfare of the port of London cannot be overestimated.

The general embankment of the river, the formation of which is attributed to the Romans, has been proved by time to have been so judiciously executed as to secure to the Thames in regular navigable capacity (in breadth and depth), which constitutes the commercial value of a tidal river, a pre-eminence over all the rivers of England. This embankment inclosed the river, generally, within the limits which it now possesses, and brought into use or culture millions of acres of rich land con-

thus expressed in the Report:—"It is right to recollect that the case of bridges in the metropolis differs widely from the case of those in the counties of the empire; not only inasmuch as all the Queen's subjects have a common interest in their resort to her capital, and a share in the fame which its aggrandisement reflects on all her dominions, but especially because, perhaps from this cause, the State did in fact erect the only bridge which for centuries existed in London; and in the last century did create, directly and indirectly, by grants from the Treasury, and by money raised by lotteries, the very fund from which the present Westminster-bridge was actually itself built a hundred years ago. If, therefore, it be said that the nation does not erect bridges in the county towns of England, or did not erect the other existing bridges in the metropolis, it may be replied that the case of Westminster-bridge, built in a large part by annual votes from the Treasury, stands on different and now exclusive grounds; that the structure has been adopted by the nation, and that when Parliament enacted (*see* 9 Geo. 2, c. 29, s. 20), first, that it should be extra-parochial, and secondly, should not be a county bridge chargeable either to Middlesex or Surrey (*see* same Act, s. 21), it sanctioned its claim to be national, and to be sustained at the expense of the empire."

tained in the marshes between the embankments and the bases of the hills on each side of the river; a work the difficulty of which may be judged of by the fact that the levels of some of these marshes are as low as from 5 feet to 12 feet below the level of the highest tides.

The maintenance and repairs of these general embankments were managed, after the Norman Conquest, under Commissions issued direct from the Crown; but in modern times, within the limits of the metropolis, additional embankments, encroaching on the waters of the Thames, appear to have been permitted, in some cases without any authority whatever, in others by license from the Corporation of London, and in others by the authority of Parliament; which last class of cases, however, is limited to the forty-foot way constructed between the Tower and Allhallows, after the occurrence of the Fire of London in 1666; to the embankment made in front of the Temple in 1767, when Blackfriars-bridge was erected; to another carried out in front of the Adelphi in the year 1770; and to the embankment connected with the building of Waterloo-bridge in 1814.

The evils attending the want of some defined line of embankment, and the projection made into the river at the period of the commencement of the present Houses of Parliament, induced the Corporation of London to institute a general survey of the river in 1841. The line of embankment then projected under the authority of Mr. James Walker and others was approved by the Corporation; and although it has never been formally sanctioned by the Government, is the line of maximum projection at present generally adopted.

In the two instances in which lines of embankment have been laid down under the direction of her Majesty's Commissioners for Metropolitan Improvements, viz., that of the embankment between Westminster and Blackfriars Bridges, projected in 1844, and that between Battersea and Vauxhall Bridges, projected in 1845, and now in course of execution, the lines of embankment laid down on the Middlesex side of the river differ in certain points from the line which has been approved by the Corporation of London.

On the Surrey side of the river, although no line of embankment contiguous to Westminster Bridge can be said to have been adopted by the Government, yet as there appeared a probability that the line approved by the Corporation for the Surrey shore might at some future time be acted upon, and as I had been advised that it was practicable to form an embankment to this line, with advantage to the public, there appeared to me to be no sufficient reason for deviating to any extent from this line for the Surrey abutment of the new bridge. The fixing of this line, therefore, determined the length of the bridge proper, and its waterway, and enabled the engineer to state these elements before the Committee; the former he gave at 827 feet, the latter at 755 feet.

After the Bill had passed the Legislature, instructions were given to Mr. Page to prepare an elevation for a bridge of seven arches, and to place himself in communication with Sir Charles Barry during the arrangement of the architectural portions of his design.

The consideration which I had been enabled to give to the subject during the progress of these preliminary proceedings, induced me, upon Mr. Page's recommendation, to sanction further alterations in the general character of the structure; namely, an increase in its width from 80 to 85 feet, the introduction of flatter arches, and other modifications which, while they will be advantageous both to the public and to the appearance of the Houses of Parliament, will not, in execution involve a proportionate increase of expense.

The design having been at length completed, the working drawings and specification were made out, the quantities ascertained, and notifications issued to certain parties that the Board were prepared to receive tenders for the execution of the work. In the last-mentioned stage of these proceedings there were two arrangements open to my selection, each of them involving, as your lordships will be aware, a principle of great importance in the execution of large undertakings of this character. The one would have assigned the iron-work to the competition of the iron trade exclusively, the general services of the bridge, excepting services involving iron-work, being limited to that of experienced builders. This proceeding would have involved the necessity of two contracts in respect of the same undertaking, a division of responsibility between the respective contractors, and a risk of the works of one portion of the bridge being impeded in their progress by delay, or alleged delay, on the part of the contractor for the other. The second arrangement open to me was to obtain a contract in gross from one contracting party, which, whether representing an iron firm or a building firm, should be responsible to the Board for the due fulfilment of every portion of the work. The opinion of the Board's engineer having been favourable to the adoption of this latter course, and having been concurred in by one of the highest practical authorities on these subjects in the kingdom, I authorised applications for tenders in gross to be issued accordingly.

In the list of contractors applied to, most of the great iron firms were included. The great pressure of business, however, the uncertainty of the markets both in materials and in labour (especially the latter), and the fact that the undertaking would comprise so much work to which they were not accustomed, led to most of the great iron houses declining to enter into competition. It was owing to the same causes probably, and under some apprehension of the responsibility which would attach to the maintenance of the present bridge during the progress of the intended structure, that many of the building contractors adopted a similar course. Thus, on the day appointed for the delivery of tenders, offers from the following parties only were sent in, viz.: from Messrs. Myers, of London; Mr. Lawton, of Newcastle-upon-Tyne; and Messrs. Mare and Co., of London. Of these offers, that of Messrs. Mare and Co. was the lowest.

The correctness of the gross amount of the lowest tender had, thereupon, to be examined by reference to the detailed quantities and prices upon which, in common, the tenders had been severally founded; and this examination having been completed, and an omission in the tender of Messrs. Mare and Co. having been supplied, it was found that the amounts for the work, as intended to be executed, viz., with cast-iron piles and plates in the foundations, and with Cheesewring granite, as the material to be used in portions of the piers, were as follows, viz.: Messrs. Myers, 286,701*l.*; Mr. Lawton, 269,414*l.*; Messrs. Mare and Co., 207,438*l.*

For the maintenance of the present bridge, for the purchase of materials not used in the new bridge, and for the removal of the present bridge; the tenders were these, viz.:—

| | Maintenance. | Allowed by Contractor for remainder of Materials, and Removal. | Charge for Removal. |
|---|---|---|---|
| | £. | £. | £. |
| From Messrs. Myers ... | 3400 | Nothing. | 13,729 |
| From Mr. Lawton ...... | 1500 | 89 | Nothing. |
| From Messrs. Mare...... | 5000 | 6000 | Nothing. |

Thus, for building the new bridge, for maintaining the present bridge, and for the purchase of the remaining materials of the same, the tenders were—

| | £. | | £. | | £. | | £. |
|---|---|---|---|---|---|---|---|
| From Messrs. Myers . . | 286,701 | + | 3400 | + | 13,729 | = | 303,830 |
| From Mr. Lawton ...... | 269,414 | + | 1500 | − | 89 | = | 270,825 |
| From Messrs. Mare ... | 207,438 | + | 5000 | − | 6,000 | = | 206,438 |

The tender of Messrs. Mare and Co. was, therefore, 96,160*l.* below that of Messrs. Myers, and 63,158*l.* below that of Mr. Lawton. The amounts of the tenders from Messrs. Myers and Mr. Lawton were so great, and so much in excess of the estimate of the Board's engineer, as would have prevented me from accepting either of them under any circumstances, and the only tender which I felt myself justified in accepting was that of Messrs. Mare and Co., subject to two conditions, viz., that the examination of their detailed quantities and prices should verify the gross amount of their tender, and that the acceptance should have your lordships' approval.

Shortly, however, after this determination had been communicated to the parties, it was alleged by Mr. Lawton, that the tender of Messrs. Mare and Co. was deficient in certain particulars; that the deficiencies were such as to take it out of the list of tenders, under the terms of the specification, and, consequently, to render the tender of Mr. Lawton the lowest in amount.

I therefore caused an investigation to be made into the detailed quantities and prices on which the tender of Mr. Lawton had been founded, as well as into those which appertained to the tender of Messrs. Mare and Co., the result of which showed that in both cases there were certain omissions and irregularities which, on a strict construction of the conditions in the specification, would exclude the tenders of both these parties. I therefore came to the conclusion that it would be right to reject the tender of Messrs. Mare and Co., as well as those of Messrs. Myers and Mr. Lawton.

The amount of Messrs. Mare and Co.'s tender was, however, so near that of the estimate of the engineer, and the examination of their schedule had proved their prices to be so fair and reasonable, that considering the importance of taking advantage of the season, and of avoiding a probable increase of expense by recurring to competition, I deemed it right, in signifying the rejection of their tender, to leave it open to Messrs. Mare and Co. to make another offer for the execution of the work. This led to their re-examination of their schedule and tender, and to the filling up of certain omissions, the result of which was an offer from them to undertake the contract for the works of the new bridge, including the maintenance of the present bridge and its subsequent removal, for the sum of 206,438*l.* This offer I have, therefore, accepted, subject to the approval of your lordships.

I would here draw your lordships' attention to the estimates which have been laid before Parliamentary Committees at various times, by eminent engineers, for a new bridge at Westminster, on a site near to the present, and of a width varying from 44 to 60 feet. These estimates have been stated at from 90,000*l.* to 240,000*l.* for a bridge with iron arches and stone piers; and from 280,000*l.* to 360,000*l.* for a stone bridge. In referring, however, to the lowest of these amounts, I would observe that a lattice bridge, a girder bridge, and even an iron bridge with the stone balustrade of the existing bridge placed upon it, have formed the subject of suggestions at various times. The expense, however, of a bridge in this situation, as your lordships will be aware, must be determined in great measure by the conditions which govern the design, as the design itself must in fact be governed by that of the adjoining structure.

The estimate made by Mr. Page from the detailed quantities of the seven-arched bridge amounted to 203,826*l*., exclusive of allowance for contingencies and professional charges; for these, a sum of 10 per cent. is to be added, making the whole estimated cost of the structure 224,208*l*.

An expense will then have to be incurred (in accordance with the stipulations of the Corporation of London) for dredging the river to the depth of 12 feet below the level of low-water, to a distance beyond the limits of deviation shown on the deposited Parliamentary plan; for which service, for concreting round the piers, and for providing floating fenders, a further outlay of 10,792*l*. will have to be incurred, making the sum for which it will be necessary to provide for services of every kind 235,000*l*.

Taking the total estimated cost of the bridge therefore, including the various contingencies to which I have above adverted, at ... £235,000

The funds applicable to this service may be stated as follows, viz. —

| | | |
|---|---|---|
| I. Value of the Bridge Estate, according to a valuation prepared in the year 1844 by Mr. Hardwick, the Surveyor of the Bridge Commissioners ........................ | £172,571 | |
| II. Rents ........................................... | 7,497 | |
| III. Estimated produce of investments in stock, and amount of cash at present in the hands of her Majesty's Paymaster-general..................... | 36,162 | |
| | | 216,230 |
| Leaving an apparent deficiency of ................. | | £18,770 |

Your lordships will observe, that the amounts given under the first and second heads of the above statement are calculated on the assumption that the whole of the estate will have been sold before the termination of the present year; I propose, however, that the property shall be disposed of in portions only, and from time to time, as the state of the market shall suggest, and as occasion shall appear to require. It is probable, therefore, that the sum which will be ultimately realised in the shape of income from the property may be greater than the amount above stated; and I am, moreover, informed by Mr. Hardwick that the fee-simple value of the estate may be considered to have rather increased than diminished since the date of his valuation (already referred to as having been made in the year 1844); I have, however, no reason to believe that any increase which may be realised under these circumstances will be sufficient materially to reduce the present apparent deficiency; and as a portion of the fund invested to the extent of 8000*l*. has been set apart as a provision for the annuity granted by your lordships' Board to the late treasurer of the Bridge Commission, and may possibly remain unavailable until after the bridge shall have been completed, I would suggest to your lordships the expediency of Parliament conditionally appropriating to this Board a sum not less than 25,000*l*. in aid of its existing resources.

I have the honour to submit for your lordships' approval a plan and elevation of the proposed bridge, and to request your lordships' authority for proceeding with the execution of the work.

William Molesworth.

*Office of Works, &c., April 19th*, 1854.

---

P.S.—In a report to your lordships on a subject of such importance as the building of a great metropolitan bridge, it may not be out of place to make a brief reference to the bridges already erected over the Thames in the metropolis, for a comparison of their main features in dimensions and expense with the New Westminster Bridge.

Old London Bridge, the erection of which has been traced to the year 1176, consisted of twenty arches, with a lineal waterway of 450 feet above the starlings. Subsequently to the introduction of the great central arch in 1759, the waterway above the starlings was 545 feet, and below them 258 feet. The bridge had a row of houses on each side of its carriage-way, noble gateways, a chapel, and other buildings of architectural merit. The width between the houses was 20 feet, but after the removal of the houses in 1754, the total width of the bridge between the parapets was 45 feet.

The second bridge erected in the metropolis was the present Westminster Bridge, built of Portland stone, and completed in 1750. It consists of thirteen arches and two small culvert arches, and has a waterway of 820 feet at high-water mark. The height or headway at the centre arch was 26 feet above the Trinity datum. The width of the carriage-way is 28 feet, and of each of the two footpaths 7 feet; the steepest part of its approach was originally 1 in 15, which was reduced by subsequent alterations to 1 in 22. The sums expended on the bridge and approaches amounted, as before stated, to 389,500*l*.

The third metropolitan bridge was Blackfriars Bridge, begun in 1760, and completed and opened in 1769. It was constructed of Portland stone, at a cost of 180,506*l*., including the temporary bridge. It has nine arches, varying in span from 70 feet at the sides to 100 feet at the centre; a headway at the centre arch of 27 feet above Trinity datum; a width of carriage-way of 27½ feet, with two footpaths of 7½ feet each. Its steepest approach was 1 in 16, but that has been reduced to 1 in 24.

The fourth bridge in order of completion was Vauxhall Bridge, which was commenced in May 1811, and opened July 1816. The cost, including road and approaches, was 297,000*l*. It has nine arches of iron on stone piers, a waterway of 675 feet, and a headway at the centre arch of 26 feet above Trinity datum. The width of its carriage-way is 24 feet, and of each of its footpaths 6 feet. The steepest gradient of its approaches is 1 in 30.

The fifth bridge completed was Waterloo-bridge, commenced in October 1811, and opened in June 1817. It is constructed of granite, and has nine arches, each of which is 120 feet in span, giving a waterway of 1080 feet, with a headway of 27 feet above Trinity datum. The cost of the bridge was 572,415*l*., and of the approaches 337,972*l*., making a total of 910,387*l*. Its roadway is 27¼ feet in width, and each of the two footpaths is 7 feet in width. On the Middlesex side the approach is nearly level, but on the Surrey side the steepest gradient is 1 in 31.

The sixth bridge in the order of completion was Southwark-bridge, which was commenced in May 1815, and opened March 1819. It consists of three iron arches (centre arch 240 feet, each of the side arches 210 feet), resting on stone piers, and has a waterway of 660 feet. Its headway at the centre arch is 30 feet above Trinity datum. The width of its roadway is 28 feet, and of each of the two footpaths 7 feet. The cost of the bridge itself was 384,000*l*., that of the approaches and river-side property and miscellaneous expenses, 312,000*l*., making a total of 696,000*l*. This noble bridge is remarkable for the great span of its arches; but the necessity of adapting its approach on the Middlesex side to the low level of Thames-street, has entailed upon it a steepness of gradient in this approach which is very disadvantageous to the traffic. The steepest part of the gradient is 1 in 22.

The new London-bridge was commenced in 1824, and completed in 1831. It is constructed of granite, and has five arches, the united waterways of which amount to 691 ft. 9 in. The span of the centre arch is 151 ft. 9 in., and the headway above Trinity high-water is 29½ feet. The width of the carriage-way is 35 ft. 6 in., and that of each footpath 9 feet, making a total width of 53 ft. 6 in. The cost of the structure itself is stated at 542,850*l*., which is exclusive of the expense of removing the old bridge. The property required for the approaches, and the purchase of which enabled the Corporation of London to complete this great metropolitan improvement, which was effected at the time, added a sum of 859,084*l*. to the amount of the bridge. This, however, included the removal of the old bridge.

Hungerford Suspension-bridge, for foot-passengers only, was commenced in 1841, and completed in 1845. It consists of three spans, the centre of which is 632 ft. 4 in., and the total waterway of the three is 1256 ft. 4 in. The height of the bridge in the centre is 27 feet above Trinity datum. Its width between the chains is 12 feet, and the cost, including the approaches, was 112,850*l*.

---

*Treasury Chambers*, 27 *April* 1854.

Sir—I am directed by the Lords Commissioners of her Majesty's Treasury to acquaint you, that they have perused with much interest your report upon the New Westminster Bridge, dated the 19th instant, and that their Lordships are pleased to sanction your acceptance of the amended tender of Messrs. Mare and Co. for 206,438*l*.

My Lords are further pleased to authorise you to take immediate steps to carry this work into effect. With regard to the deficiency estimated at 25,000*l*. at the outside, my Lords will cause provision to be made in the Estimates for next year, or at such a time as the same shall be actually required for expenditure, and when the amount shall have been more accurately ascertained.

The First Commissioner of Works. C. E. Trevelyan.

## DRAINAGE OF THE METROPOLIS.

The following is the copy of a letter from the Chairman of the Metropolitan Sewers Commissioners, addressed to the office of the Secretary of State for the Home Department, upon the subject of the Drainage Works proposed by the Commissioners to be accomplished within the next twelve months, if they were allowed to raise a further loan of 300,000*l*:—

1, *Greek-street, Soho, July* 10, 1854.

Sir—With reference to the directions of Viscount Palmerston, which you communicated to me on the 8th inst., to send to his lordship, for presentation to the House of Commons, a detailed statement of the drainage works which it is proposed to accomplish with the money the Commissioners of Sewers would receive in the course of the next twelve months, if they were allowed to raise a further loan of 300,000*l*.; stating, also, the estimated expense of each work, the place in which it would be made, and the advantage which would result from it;

I beg to state, for his lordship's information, that the limited period within which the information is required to be furnished, precludes the possibility of assembling the Commissioners, and obtaining the decision of the collective body upon the question now proposed. At the same time, I am sufficiently possessed of the views of my colleagues to state what, in all probability, would be the decision of this Commission, if under fresh powers, they succeeded in raising a further loan of 300,000*l*. In the selection of works to be paid for by means of loans, the Commissioners have adopted the two following principles:—

1. To select for execution those works which are at once most urgently needed and calculated to afford the greatest amount of immediate relief, and which are, at the same time, of so costly a character as to exceed the means of being accomplished out of income.

2. To commence no work until the means of completing it are actually provided, or at least until there is a fair prospect of obtaining the funds necessary for completing it within a reasonable time.

The works which the Commissioners consider most signally to fulfil the former of these conditions, are the two great works embraced in the printed reports which I have the honour to enclose. Those reports, accompanied with plans, were presented to Parliament in an early part of the present session. Each of these works, though forming an essential part of the main drainage, or intercepting scheme, is so far independent of it as to be a perfect work in itself.

The first of these works is the Northern High Level (or Hackney Brook) Sewer, with its main branch, the course of which is shown upon the first map in the reports now transmitted, by the red lines traversing the area coloured yellow. The main line commences near Hampstead, and proceeds first in an easterly and then in a south-easterly direction, to the River Lea. The branch sewer commences at Kilburn, proceeds along the Edgware-road, then takes a north-easterly direction above the Regent's-Park, and joins the main line at Holloway.

| | Miles. | Feet. |
|---|---|---|
| Length of Main Line ........................ | 7 | 840 |
| Length of Branch.............................. | 4 | 4910 |
| Total .................. | 12 | 470 |

The entire cost, including all contingencies, is estimated at 300,000*l*.

The advantages incident to this work may be thus described:—

1. It will form the main line for the immediate drainage of an area of 14 square miles, comprising Hackney, Homerton, Clapton, Stoke Newington, Dalston, Kingsland, Highbury, Camden Town, Kentish Town, Highgate, Hampstead, Kilburn, and Portland Town; and it will afford an outlet for the immediate construction, out of the current rates, and also, to a large extent, at the cost of private individuals, of numerous local sewers now urgently needed for the benefit of entire districts, which are at present for the most part destitute of drainage.

2. It will render practicable the abolition of numerous foul open sewers, amongst others the Hackney Brook and a portion of the Fleet, which cannot now be dealt with for want of a proper outfall.

3. It will at once relieve all the main lines of sewers between it and the Thames, which are now greatly overcharged in times of rain, causing an extensive flooding of property; and it will enable many of those last-mentioned sewers, which are old and dilapidated, to be reconstructed of a smaller size at a proportionally reduced cost.

The second work consists of the entire system of drainage proposed in the same reports for the districts south of the Thames, and laid down in the other map. The outside cost is estimated at 750,000*l*.; though it consists of two great lines (with branches), viz., a high and a low level line, it must be regarded as one connected work; and the Commissioners, therefore, would consider it an improper course to enter upon the execution of either line, without a reasonable assurance of their being enabled to execute the other.

Supposing such an assurance to be obtained, then they would, in all probability, select the low-level line for immediate execution, as that which presents the prospect of the greatest immediate benefit. The cost of this lower line may be estimated at about 300,000*l*., including pumping station, engine power, &c. The advantages to be derived from this low-level line would be the following: it would provide a main trunk sewer, of sufficient depth for the drainage of the large district, coloured red, comprising seven square miles, and including Battersea, Clapham, Stockwell, Lambeth, Camberwell, Peckham, and other places, in which it is at present impossible to construct proper sewers, for want of a deep outlet. As in the case of the northern sewer, it would provide the means of abolishing numerous foul open ditches, and would afford considerable relief to the existing sewers which are present overcharged. To this may be added, that it would give an impulse to the construction of numerous sewerage works at private cost; and it would also, to a large extent, remove the sewage of the large area already described from the contiguous part of the Thames. The full utility, however, of this portion of the entire work, would not be developed until the high-level line should have been completed.

The execution, however, of any part of the southern works, must depend upon the ability of the Commissioners to obtain, by negotiation, on eligible terms, the land requisite for a pumping station near Deptford. If the Commissioners should have valid ground for the expectation that they would be enabled, at no distant time, to complete the whole of the two great works above described, it might become expedient that they should, with the proposed loan of 300,000*l*., execute a portion of each; a course which, it is conceived, would give satisfaction to the greatest number of persons.

RICHARD JEBB.

The Hon. Henry Fitzroy.

---

In a letter to Lord Palmerston, subsequent to the above, Mr. Jebb states that the Commissioners propose to devote 110,000*l*. of the 300,000*l*. which the bill now passing through parliament will enable them to borrow, to the construction of so much of the northern high-level intercepting (or Hackney Brook) sewer as will extend from the present outlet of the open sewer to High-street, Stoke Newington; with the remaining 190,000*l*. they propose to construct the whole of the low-level intercepting sewer, from Deptford Creek to Battersea, except its northern branch, which extends from High-street, Deptford, to a point near Paradise-row, Rotherhithe.

The sum of 200,000*l*. which the act of last year authorised the Commissioners to raise, and which brought their debt up to 300,000*l*. (now to be 600,000*l*.), was borrowed of the Rock Life Assurance Company, at 4½ per cent. on the security of the rates, the money to be advanced by the company in ten monthly instalments of 20,000*l*. each, beginning on the 1st of March last.

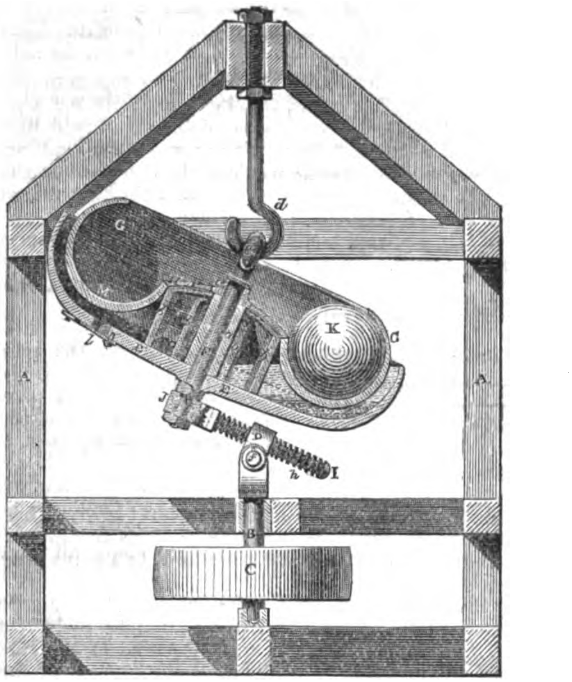
## MACHINERY FOR PULVERISING AND WASHING QUARTZ OR ORE.

AUGUSTE E. L. BELLFORD, *Patentee*, June 1853.

THE first part of this invention consists in the employment, for the purpose of pulverising quartz or ore, of a spherical ball placed within a circular basin, whose axis moves in such a way as to describe a cone around an imaginary fixed axis, but does not cause the basin to rotate. The basin is so formed that the ball nearly fits to its sides. The imaginary axis, round which the axis of the basin revolves, is intended to be vertical; and consequently, the bottom of the basin must always be in a similarly inclined position, though the position of the basin is constantly changing in such a way as to make all the points in any circle described from its axis, successively the lowest points in the said circle; every point moving as it were in a circular inclined plane. The ball will always descend by its gravity to the lowest place in the interior of the basin; but as every point in the circle of the basin in which the ball remains, commences ascending as it passes the ball, it has a tendency to carry up the ball with it. This tendency is overcome by the gravity of the ball, which causes it to rotate on its axis, in the same manner as a ball descending an inclined plane, and always keeps it at the lowest part of the basin, where, by its rolling motion, it is made to grind and pulverise the material placed in the basin. The peculiar movement of the basin admits of the quartz or ore being kept all towards the working point of the ball, and keeps the entire mass of its contents constantly and thoroughly agitated, so that all the particles are subjected alike to the action of the ball.

The second part of this invention consists in the combination, with a ball and basin, of an outer basin, placed below, with a space between it and the crushing-basin, moving with the crushing basin, and having communication with it.

The third part of the invention relates to a device for counteracting the too great centrifugal tendency which may be imparted to the crushing-ball by the revolution which it is caused to make around the axis of the basin and the imaginary axis round which the former axis moves. The axis of the basin receives its motion through a crank which acts at one end of it: and the increasing centrifugal force of the ball is made to shorten the effective length of this crank, and thus reduce the motion of the basin, and inclination of the plane which is presented to the ball.



The annexed engraving represents a section of this machine taken through the centres of both basins. A, is the frame of the machine, in the lower part of which is supported the driving-shaft B, which occupies a vertical position, and receives motion through a belt-pulley C, from any prime mover. The upper end of the shaft is forked to receive a block D, of metal, which is pivoted to it by a pivot F, passing transversely through the axis of the shaft. E, is the lower or amalgamating basin, of cast-iron and circular form, and having a hub *a*, projecting some distance from the inside of the bottom, which receives the shaft F, on which it is firmly secured. G, is the inner or crushing-basin, which is so formed as to make a trough or channel M, all round its bottom, to receive the ball. The raised circular part H, of the basin, within the trough, rests upon a number of bearing pieces *b, b*, which stand up from the bottom of the basin E; and it has a hub *c*, which fits to the shaft and rests on the hub *a*. The two basins are secured to each other and to the shaft by any suitable means. The raised circular part H, of the basin G, is open; the hub being merely united to the trough by radial arms, and the opening is covered by a screen L.

The upper end of the shaft F, is suspended by a hook *d*, and eye *e*. The lower end of the shaft is connected by a crank to the shaft B. This crank, instead of being a bar or block rigidly connected to the two shafts, consists of a rod I, which is fitted to work freely in a hole made in the block D, at right angles to the pivots F; at one end is pivoted a metal box J, which is bored to receive a journal *i*, on the lower end of the shaft F. A spring *g*, is applied between the block D, and a shoulder near that end of the rod I, to which the shaft F, is connected; and another spring *h*, is applied between the said block and a shoulder at the opposite end of the rod; both these springs exert their force by pushing from the block.

The operation of the machine is as follows:—The quartz, ore, or auriferous mineral, after being broken into small pieces, is fed in a suitable quantity to the basin G, and is there subjected to the action of the ball K. The stream of water which is let into the trough G, washes up all the finely-pulverised particles, and carries them through the screen L, to the basin E, containing the mercury, with which they are thoroughly amalgamated; while the quartz or other foreign mineral matter is washed away by the constant overflow at the lowest part of the edge of the basin E. The amalgam is withdrawn from the basin, through a suitable valve or trap *l*, in any part of the bottom.

The ball K, owing to the constant change in the position of the lowest portion of the basin, moves in a horizontal plane in a circle described from the imaginary central axis round which the axis of the basin moves, and thus acquires centrifugal force which tends to throw the lowest side of the basins from the centre. This centrifugal force is, in a certain degree, but not perfectly, counteracted by the gravity of the ball, which tends to lengthen the crank while the centrifugal force tends to shorten it. The shortening of the crank reduces the extent of the motion of the basin, and lessens the inclination of the plane down which it may be said to be descending, and thus arrests the centrifugal tendency. The springs *g*, and *h*, admit of the lengthening and shortening of the crank, and hold it at a desirable length when not otherwise unduly influenced, and also serve to prevent shocks to the machine in stopping and starting.

## BURSLEM TOWN HALL.

(*With an Engraving, Plate* XXVIII.)

OUR engraving exhibits a perspective view of the Burslem New Town Hall, the plans and description of which will be given in full next month. Mr. R. Hales, of Cobridge, Staffordshire, is the architect. Mr. Armstrong's design, which obtained the second premium in the competition, was in the Royal Academy Exhibition, and noticed by us at page 234.

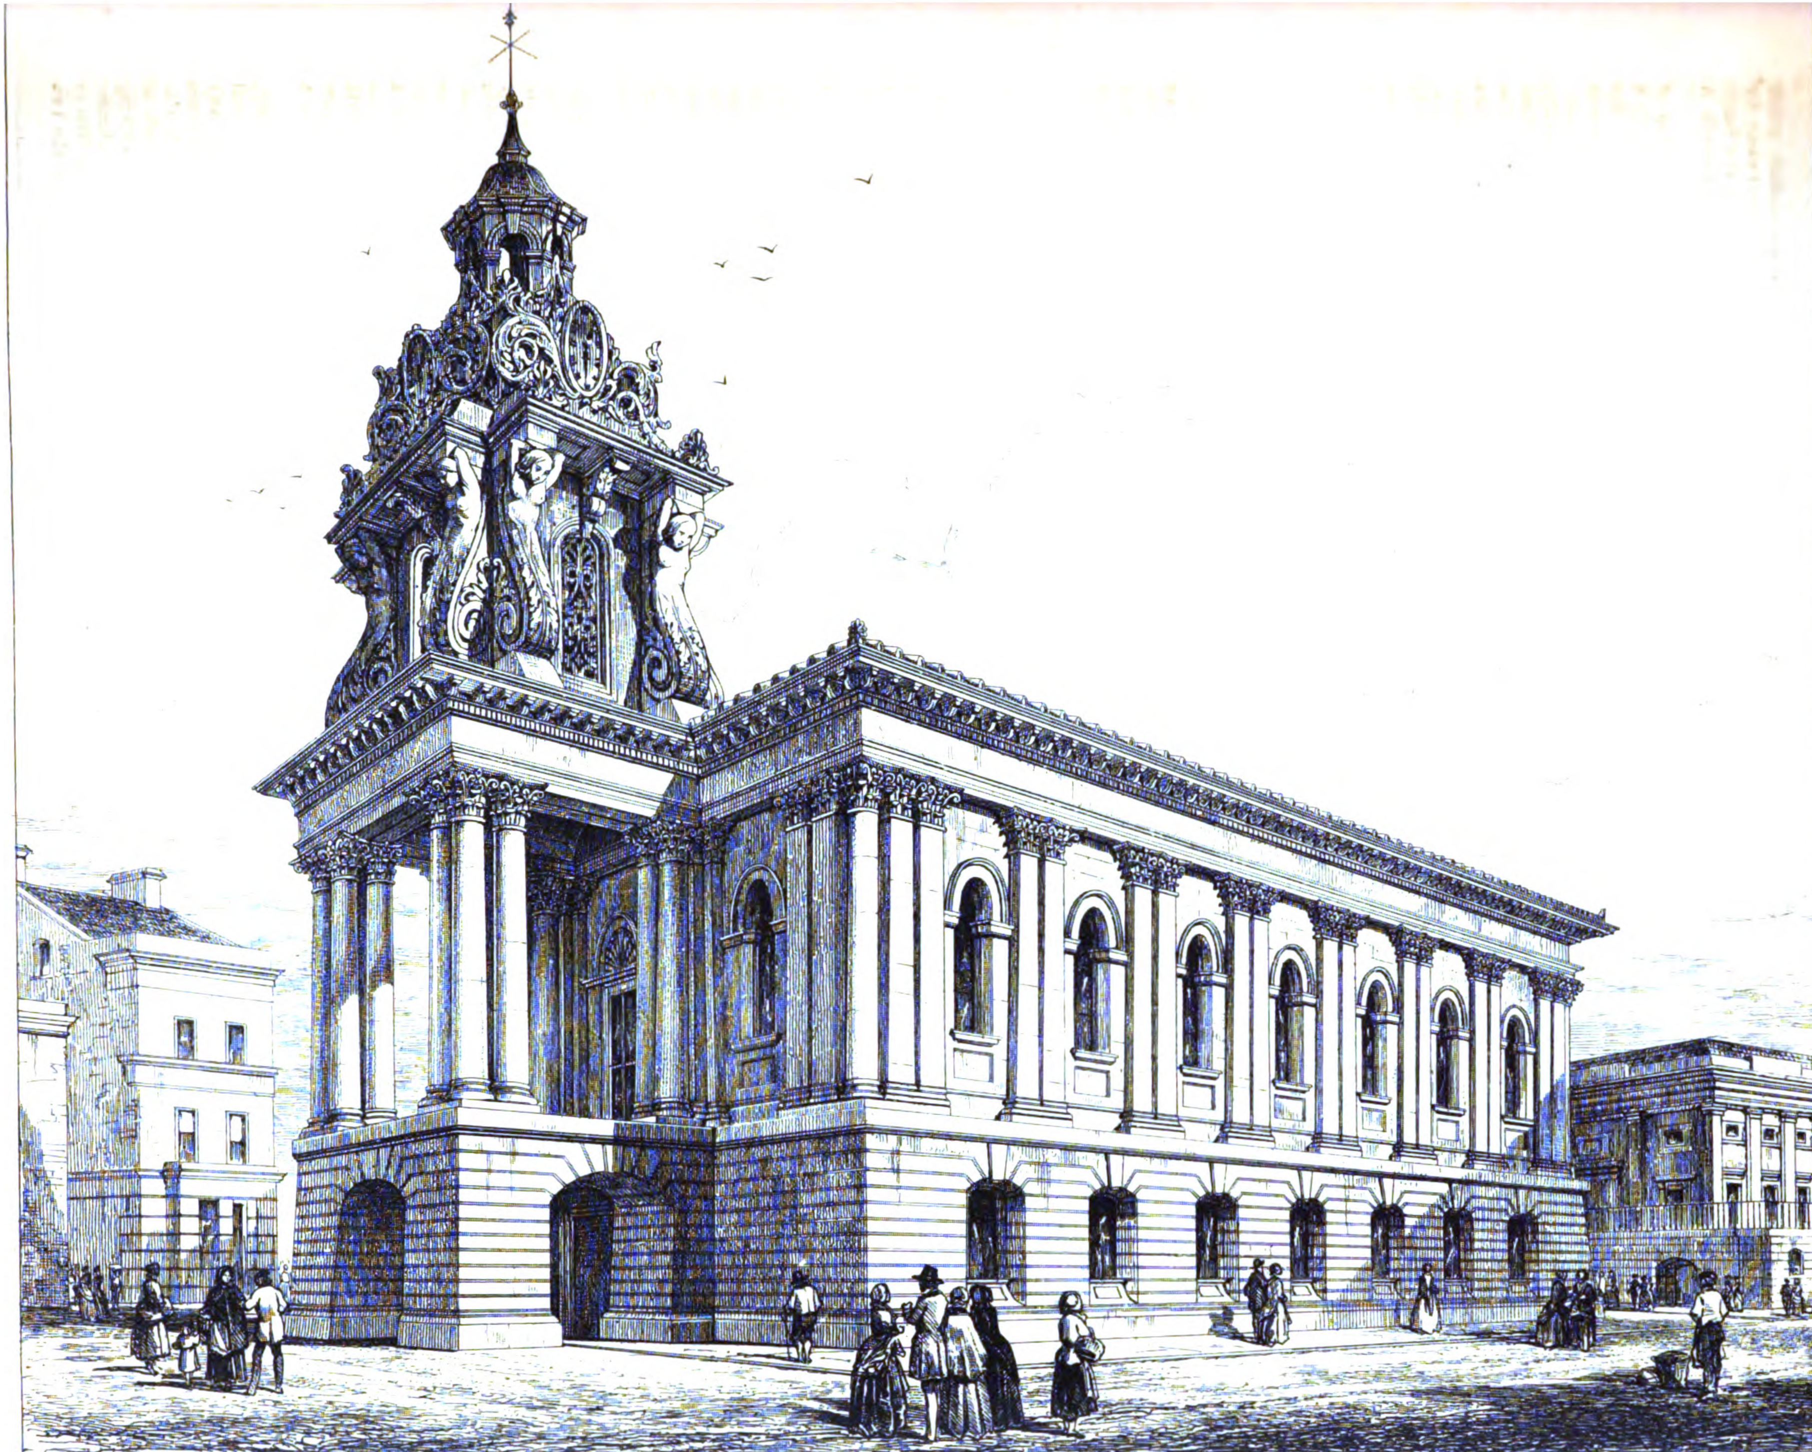
## VELOCIMETER FOR MEASURING THE SPEED OF SHIPS AND VELOCITY OF CURRENTS.*

THE object of this instrument is to measure the speed of ships, and the velocity of currents of air and water. Its principle is based on that of the vena contracta, which was discovered a century ago by Daniel Bernouilli, and has since been applied by Venturi in the double-cone tube which bears his name.

Mr. Overduyn, a Professor at the Royal Academy at Delft, has invented a velocimeter, the idea of which is based on the negative pressure, or rather the sucking action resulting therefrom, at the narrow gorge or section, where the two tubes of which Venturi's tube is composed, intersect each other. A tube, constructed on the same proportions as Venturi's, is fixed to the vessel in a direction parallel to its axis, the base of the smaller cone being turned towards the bow. A hole is made in the side at the intersection of the cones, into which a small pipe is fitted. As soon as the vessel is in motion, the negative pressure begins to exert itself, and increases proportionately with the speed of the vessel. All that remains to be done is to measure with precision this increasing negative pressure, whereby the increasing speed of the vessel is ascertained. This is effected by prolonging the smaller tube into a manometric case, on the plan used by Vidi in the construction of his aneroid barometer. Into this case is *inserted* the tube in which the sucking action takes place. The two ends of the case advance or recede according to the vacuum determined, and this vertical movement of the ends of the case is converted into a horizontal motion by means of a lever, and turns an index-point which marks on a dial the degree of velocity attained. It is almost useless to add, that these results may be turned to further advantage by the addition of a *totalisateur*, whereby the degree of velocity obtained after a given time may be arrived at.

In order to ascertain the velocity of currents in a river, &c., the tube must be immersed in the water, when the dial will show the velocity of the stream, which may be ascertained at any point of its depth by immersing the tube accordingly. Currents of air may be measured in the same manner; but when the double cone-shaped tube is used for this purpose, it should be made of larger dimensions, but in the same proportions. The sucking action of the tube may be rendered more powerful by enclosing it in a larger tube, care being taken to place the front orifice or mouth of the inner tube in the plane of intersection of the two cones of the larger tube.

* From the 'Moniteur Industriel.'



THE NEW TOWN HALL, BURSLEM.

G T ROBINSON, ARCH$^{T}$

## ON THE POSITION OF FIRE-PLACES.

By Dr. Neil Arnott, F.R.S.*

This is the fit place for remarking on the fashion lately introduced in this country of placing the firegrates much lower down than formerly—in some cases, on the very hearth—the reasons usually assigned being that a low fire burns better, or gives out more heat from the same quantity of fuel, than a higher; and because lower and nearer the floor, that it must warm the carpet better, and so lessen the evil of cold feet. Now, both these suppositions are curious errors or delusions, having their origin in popular misconceptions respecting heat, and particularly respecting the radiation of heat.

Radius is the Latin word for the spoke of a wheel, and anything which diverges or spreads around from a centre, in some degree like spokes, is said to radiate. Light and heat are of this nature; the portion of either which passes in a straight line from the centre is called a ray.

The simplest observation teaches all that a lamp placed in the middle of a room radiates its light and heat nearly equally in all directions; and most persons are aware that if an opaque mirror be placed close to a lamp on one side, it not only intercepts all the rays that fall upon it—and that means nearly half of the light given out—but it returns or reflects these rays back in contrary corresponding directions, and nearly doubles the illumination in those directions.

Most persons, also, have observed that if a fire, or a red-hot mass of metal, be placed in free space, it radiates its heat as well as its light nearly equally in all directions; but many do not learn, by their unaided observation, that if a surface of any substance, like firebrick, which strongly resists the passage of heat through it, be placed near a fire, it not only intercepts the heat-rays falling on it, but after absorbing them, and so becoming heated, often to redness, it then reflects and radiates back the greater part of the heat, almost as if it were additional hot fuel in the fire, and thereby nearly doubles the warmth felt in directions away from the surface.

Neither does common observation make persons aware of the truth, that of the heat produced by combustion in a common fire, one part—being somewhat more than half—is diffused, like the light, by radiation, into the open space around, and the remainder is given, by contact and conduction, to the air which supports the combustion, and to the solid material of the fire-place. Thus, with a common open fire-place, it is the radiant heat almost alone which warms the room, the remainder either at once combining with the burned air or smoke, and passing up the chimney, or being given by the heated grate to pure air, which touches that, then passing into the chimney with the smoke.

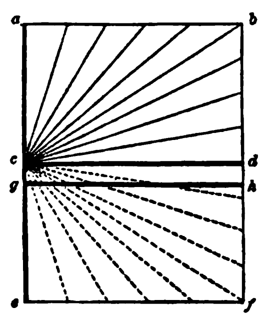
And, lastly, many persons do not at first learn the truth, that the rays of heat passing through pure or transparent air do not at all warm that air, but warm only the solid or opaque bodies by which the rays are intercepted, and that thus the air of a room is warmed only at second-hand, by contact with the solid walls and furniture which, having intercepted the heat-rays have themselves first become heated. Yet most educated persons know similar facts, such as that the sunbeams, bringing both light and heat to the earth, as they descend to warm the hottest valleys or plains of the earth, pass through the upper strata of the atmosphere, which are always of a temperature much below freezing. This is proved by the fact that all lofty mountains, even under the equator, are capped with never-melting snows, and that the higher the peaks are—and, therefore, the nearer to the sun—the colder they are. Thus, also, all persons who have attended to the subject know that aeronauts, in their balloon-car, if they mount very high, would be frozen to death but that they are protected by very warm clothing. Another fact of the same kind is, that a glass globe, filled with cold water, or even ice, may in the sun's rays be used as a burning-lens.

These explanations being premised, the two popular delusions respecting the low fires become at once apparent.

1st. The supposition that fuel burnt in a low fire gives out more heat, has arisen from the experimenter not reflecting that his hand held over the low fire feels not only the heat radiated from the fire itself, but also that reflected from the hearth close beneath it, which second portion, if the grate were high, would have room to spread or radiate downwards and outwards to the more distant floor or carpet, and to warm them.

2nd. The notion that the fire, because near the floor, must warm the carpet more, springs from what may be called an error in the logic of the reasoner, who is assuming that the hearth, floor, and carpet, being parts of the same level, are in the same predicament—the truth being, however, that in such a case the portion of the hearth which is within the fender gets nearly all the downward rays, and the carpet almost none—as a candle held before a looking-glass at a moderate distance diffuses its heat pretty uniformly over the whole, but if moved close to one part of the glass it overheats, and probably cracks that part, leaving the rest unaffected. A low fire on a heated hearth is to the general floor or carpet of a room nearly what the sun, at the moment of rising or setting, is to the surface of a field. The rays are nearly all shooting upwards from the surface, and the few which approach it slant obliquely along, or nearly parallel to, the surface, without touching, and therefore without warming it.

The annexed diagram serves to elucidate these facts. *c*, represents the fire-place or centre of radiation, with rays diverging from it into all free space around; *a c*, the wall in which the grate is set, and which can receive none of the direct rays,—as is nearly true of the floor also if the fire be on the hearth; *a b*, the ceiling; *b d*, the wall opposite the fire; *c d*, the floor, with the fire on or close to the hearth. If there were no floor at all, these rays would shoot as abundantly down to the bottom and walls of the room below, as to the ceiling and walls of the room above; but the hearth-stone of the floor *c d*, first intercepts all the inferior rays, and then radiates them up to the ceiling, leaving the floor unsupplied unless by secondary radiation from the ceiling and walls. *g h*, represents a floor at a moderate distance below the fire. It is seen, by where the ray-lines intersect this floor, that much of the heat of the fire must spread over it, and chiefly between the middle of the room and the grate where the rug is, and where the feet of the persons forming the fireside circle are placed.



Striking proof of the facts here set forth is obtained by laying thermometers on the floors of a room with a low fire, and of a room with a fire, as usual of old, at a height of about 15 or 16 inches above the hearth. An experiment tried in two such rooms, in both of which thermometers on the pianofortes, 4 feet above the floor; stood at 62°, showed the carpet, not far from the hearth, to be at 56° with the low, and at 73° with the high fire.

As would be anticipated by a person understanding the subject aright, low fires make cold feet very common, unless to those who sit near the fire with their feet on the fender; but deceived by their fallacious reasoning, the advocates are disposed to blame the state of their health or the weather as the cause, and they rejoice at having the low fire, which can quickly warm their feet when placed near it. A company of such persons seen sitting close around their fire with thankfulness for its warmth near their feet, might suggest the case of a party of good-natured people duped out of their property by a swindler, and afterwards gratefully accepting as charity from him a part of their own property.

Many persons have been prevented from detecting the truths connected with low fires by the fact, that where the chimney breast or opening is also made low, the mass or stratum of comparatively stagnant warm air in the room is deeper or descends lower than where the chimney opening is high, and the room thus arranged may be, except near the floor, warmer than before. But advantage from this arrangement is often missed by the chimney throat being left too wide, causing strong cold draughts below, and where there are many persons in the room, the possible good is more than counterbalanced by the ventilation above being rendered in proportion more faulty. In the new smokeless grate, there is the advantage of a low chimney opening, although with a high fire, and yet the ventilation is maintained perfect for any amount of crowd by the ventilating valve, placed near the ceiling of the room.

* The subject of this article was referred to by Dr. Arnott, at the Society of Arts, during the reading of his paper on the Smoke-Consuming Fire-grate, on the 10th May last (see *Journal*, *ante* p. 201); and as it has been deemed important, he has since given his remarks in writing (for publication in the Society's Journal), which may be taken as forming part of his original paper.

It may be observed here, that the smoke-consuming grate exhibited in the Hall of the Society of Arts, is of small size, fitted for a room of moderate dimensions, and was originally intended to be placed for inspection on the table, merely to show the principle, but the Secretary, judging that it would be more interesting if seen in action, desired it, although so disproportionate, to be fixed for the time in the fire-place of the large Hall. That grate was constructed by Messrs. Bailey, of Holborn, but the deviser hopes, as the whole arrangement is so simple, that intelligent manfacturers everywhere will be able to make it perfectly. He deems himself bound to publish soon, any further instruction with regard to it, which further and more varied experience may suggest.

## ON ARCHITECTURE AS REPRESENTED IN PICTURES.

By Henry Twining.

[*Paper read at the Royal Institute of British Architects, June 12th.*]

Pictures exhibit, in a convenient manner for study, the different styles of architecture in direct connection with different kinds of scenery. As we are thus enabled to appreciate the relation of architectural buildings to the climate and character of different countries, we have great facility in selecting those styles or orders of architecture which are best adapted to the scenery, as well as the climate and conditions of our own country. Moreover the architecture which adorns pictures is exempt from those trammels which considerations of economy and site, and other hindrances, impose on the work of the architect; and it therefore possesses every facility and advantage for realising the kind of edifice which, in the mind of the artist, appears most consistent and becoming.

As the kind of embellishment which architecture supplies for historical pictures was more resorted to formerly, than at the present time, it is by considering the old masters that interesting facts may be chiefly elicited. One of the most striking points in connection with this subject is, that architecture seems to have been generally treated by them as a somewhat conventional ornament, adapted to the effect of the picture, but without reference either to the country, or to the period of the event represented. The style of architecture most usually selected was the classic, which is frequently brought into connection with events taken from the Scriptures, and which therefore occurred chiefly in Judea. But notwithstanding the impropriety of introducing the classic style of architecture into subjects which are entirely Eastern, the association of the simpler orders of such architecture with scriptural subjects does not strike so offensively as might be expected, a proof, it may be considered, that this style is remarkable for its great purity, and for its suitableness for all dignified or elevated subjects. It would be difficult to believe that the Saracenic, the Renaissance, or any other elaborate style of architecture, could by any contrivance be made to associate with events so solemn, and at the same time so decidedly local, as those which are borrowed from Scripture.

Rafaelle was one of the Italian masters who had most recourse to architecture for the embellishment of his pictures; and although he did not always avoid the inconsistencies and anachronisms which contemporary artists were apt to commit, he showed an attention to circumstantial facts and particulars which very few equalled. One of the earliest and most beautiful of his works, known as "The Marriage of the Virgin Mary," now in the gallery of Milan, is adorned by an elegant building of sixteen sides with Ionic columns, probably intended for a synagogue, but not having anything Eastern in its style. Its appearance has however nothing offensive, but affords a pleasing accessory to this beautiful subject. In his painting of "Paul and Barnabas at Lystra," this great artist has shown the same attention to circumstantial details, and with the happiest results; for amongst the statues which decorate noble edifices, the statue of Mercury appears conspicuous, reminding the observer, at once, that the inhabitants believed St. Paul himself to be that God; and that they were about to offer sacrifice to him as such; it is plain how much the historical account is elucidated by such particulars. "St. Paul preaching at the Areopagus at Athens," likewise affords a successful proof how much Rafaelle enhanced the beauty of his historical pictures by means of tasteful architectural buildings, of which the classic orders, clearly defined, are perfectly and appropriately characteristic. In another picture (of which the cartoon is at Hampton Court) representing St. Peter and St. John healing the lame man at the gate of the temple which was called "Beautiful," he has introduced a number of spiral columns, richly and elaborately decorated, by which means he has marked impressively the characteristic splendour of the porch. But in this instance his attention to particulars does not appear to have been equally successful, for the effect is meretricious, and detracts from the solemnity of the subject. A simpler style of architecture, though perhaps less truthful, might have been better suited to the dignity of the composition.

Neither Michael Angelo nor Leonardo da Vinci, although the first was an architect, and the second an engineer, seems to have resorted much to architecture for the embellishment of their pictures. Nor did Correggio, who at Parma contributed so much by his frescoes to embellish the Duomo, avail himself of the beauties of architecture to enrich his most graceful subjects. The Venetian school of painting, however, borrowed a great deal from the sister art; and in this we may probably mark the influence of the architectural magnificence of the city.

Gentile Bellini was one of the earliest masters who painted architectural subjects; and during his residence at Constantinople he executed a large, and, at the same time, elaborate and highly finished picture of the church of Santa Sophia, which is now in the gallery of Milan.

Another picture of the Venetian school, very remarkable for its architectural interest, represents what was termed the "Miracle of the Ring," so famous in the Venetian annals. It was painted by Paris Bordone, and the background represents the beautiful and highly decorative architecture of the Palazzo Ducale almost as it now stands. But the artist of this school who gave the greatest importance to architectural ornament in his pictures was Paul Veronese. By the introduction of architectural monuments on a large scale he imparted great beauty and originality to his pictures. He often gave perspective depth and greatness to his compositions by representing these edifices at various distances. Further, by placing them on the most diversified situations he added in a remarkable degree to their picturesqueness. These architectural arrangements afforded him the means of diversifying the positions and attitudes of his figures, which he represented alternately ascending flights of steps, leaning over elevated balconies, or climbing up buildings, in order to overlook the principal scene of action.

The Dutch and Flemish, as well as the French painters, usually showed the same disregard for a style of architecture in accordance with Eastern subjects, as did the Italians. For instance, Rubens, notwithstanding his extensive information, and his high position in society, introduced the Doric order of architecture in connection with "The Murder of the Innocents." Nicholas Poussin, who largely availed himself of the advantages afforded by architecture, introduced columns, apparently of the Corinthian or Ionic orders, in paintings of David and Goliath. "The Murder of the Innocents" by Le Brun, now in the gallery at Dulwich, is likewise enriched by edifices of Roman structure, having columns of the Corinthian order. We might have expected rather more antiquarian knowledge or attention to facts, from so eminent and comparatively modern an artist.

But it is especially as an embellishment to the landscape that architecture attains the highest value, and often ennobles scenes which without such ornaments would appear tame or trival.

Among the landscape painters, Claude de Lorraine availed himself most effectually of the resources which architectural subjects afford; and by the frequent introduction of temples, arcades, palaces, and other buildings, into his landscapes, he imparted to them an elegance, and an air of classic dignity, which it would perhaps have been impossible to attain without the elevating influence of this class of accessories.

The two Poussins were especially fond of that kind of embellishment which is furnished by architecture; and Gaspar Poussin, who was essentially a landscape painter, added by such means greatly to the interest and character of his landscapes. For instance, he marked the strength of any lofty situation by walls and fortifications; the particular aptitude of any site for being inhabited by a large and populous city; and the loneliness of a retired spot by tombs, obelisks, and mausoleums. He thus stamped more impressively the local character of each subject.

The Dutch landscape painters, as Poelemburgh, Berghem, and Loutherburgh, introduced buildings and monuments chiefly as ruins, in which forlorn, but venerable condition, these greatly enhanced their small pictures. But there is a class of artists, who instead of making architectural buildings serve as an ornament to their landscapes, completely spoilt their compositions by great abuse of the resources which it affords. Amongst these may be mentioned, Marco Ricci, Lingelbach, and sometimes Pannini. They availed themselves of their sojourn in Rome to copy the numerous monuments of various periods which there abound. This they did, however, without taste and discernment; and in their pictures they introduced promiscuously, and in the greatest confusion, monuments of different periods, of different styles of architecture, indeed of the most opposite character, accumulating these incongruous elements with a confused profusion of which Rome itself does not afford an example. In some instances they rendered this heterogeneous assemblage more ludicrous by intermingling figures of different dates and costumes with the ruins.

Modern landscape painters have devoted themselves more exclusively to nature herself, and have availed themselves generally in a less degree of such means of embellishment as architectural buildings afford. However, the French marine artist of the last century, Joseph Vernet, introduced architectural buildings, especially lighthouses, bridges, and aqueducts, with great taste and effect; and his English contemporary, Wilson, realised corresponding advantages by the ruins of such monuments. I need not remark that the late Turner, when not led by the fascinations of colour to neglect the resources of ornamental form, availed himself most advantageously of the decorative beauty of architecture in his landscapes, as may be seen by the grace and elegance which his picture representing "The Building of Carthage" derives from its architectural monuments. We are aware that John Martin so completely commanded the resources of architecture that he thereby imparted a character of combined splendour and vastness to his compositions. In some of his pictures ancient cities surprise the observer by their extent, their remarkable situation, and the originality of the buildings. In others, as in "The Feast of Belshazzar," it is the magnitude of the palaces, and other edifices, which causes our admiration. In these subjects a style of architecture has been adopted, which though to some extent ideal, at least carries the mind at once to the time and the place of the event recorded, an attempt which had not been made by the landscape painters of olden times; and which, although till lately quite new in this branch of art, Martin carried out with the most complete success.

In the course of the discussion which ensued, Mr. Donaldson said he considered that the painters who had introduced architectural subjects into their pictures might be divided into two classes: the first were real painters of buildings, such as Canaletto and Panini; the others, as Raffaele, treated architecture merely in the light of an accessory, and to give contrast, by the repose of the structural masses, to the violent action and bustle of the figures. The Venetian School afforded good examples of the second class. It was obvious that though Raffaele had exercised great thought and discretion in such accessories, he had committed some incongruities, as in representing strictly Roman architecture in buildings forming the background of the cartoon of St. Paul preaching at Athens. The introduction of architectural subjects into pictures might naturally have taken place in a city like Rome, abounding in ancient remains, which would work on the imagination of the great men composing the brotherhood of practitioners in art which existed there in the fifteenth century. Michael Angelo was an architect by accident —painting and sculpture were more especially his forte,—and his particular case, Mr. Donaldson would adduce as a reason why he entirely disagreed with Mr. Ruskin as to painter-architects alone deserving the palm of excellence; Palladio, Sanmichele, and Brunelleschi, on the contrary, were highly successful as architects,—great play of contrasts was exhibited in their works —but they were not painters. The Beautiful Gate of the Temple shown in one of the cartoons, might perhaps have been more correctly shown with columns of Egyptian character; but it might be supposed that Raffaele was himself ignorant of the real architecture of the place which he had undertaken to represent. Claude, on the contrary, introduced subjects taken from Italian ruins; finely grouped, and with great propriety, into his landscapes, and his example had been followed by our countryman Turner, who, by desiring to have one of his pictures hung between two by Claude, in the National Gallery, had evidently implied the estimate on which he set his own painting; and yet it should be remembered that Turner had accomplished no more than Claude had between 200 and 300 years previously, without any predecessor to instruct him, from whose productions he could obtain hints, and learn to avoid errors. To Claude, innate taste and the study of nature had alone been assistants. The value to a painter of having seen and studied the ancient remains in Italy might be seen in the productions of Wilson the landscape painter. The training necessary to render an artist a good scene painter, in respect to treating architectural subjects with strict correctness, had produced good landscape painters in the persons of Stanfield and Roberts. The views of Daniell on the walls afforded a great lesson in the happy manner in which Indian architecture was composed and grouped to harmonise in all respects with nature—the deep shady verandahs and colonnades, surrounded by groves, and enlivened by cool fountains and glittering minarets, vieing, as it were, with the beauty of the Eastern climate.

## THE GENERAL BOARD OF HEALTH.

*Letter to* Viscount Palmerston, *in reply to the Report of the General Board of Health, on the Administration of the Public Health Act, and the Nuisances Removal and Diseases Prevention Act, from* 1848 *to* 1854.

My Lord—The members of the General Board of Health have lately published a Report of the manner in which they have administered the powers conferred upon them by the Public Health Act, and the Nuisances Removal and Diseases Prevention Act; and they have pointedly alluded to some of the scientific principles and administrative measures they have endeavoured to introduce. All the best qualified English engineers are, my lord, decidedly opposed to the application of the principles and the measures in question; because, from long study and practical experience, they find the former to be in contradiction with the facts observed by the most eminent authorities, and the latter they hold to be of an unconstitutional tendency. In common with the rest of the public they had, however, hoped that the present Session would not have been allowed to pass over without a full and deliberate investigation into the conduct of the new and as yet irresponsible branch of public administration created for the express purpose of carrying the above-cited Acts into effect, and had, therefore, refrained from taking any decisive steps to record their opinions. But as the Session has advanced to a late period, and it is not possible now to procure the investigation of a subject so complicated, and so important, in time to enable the legislature to act effectually upon the results of the proposed inquiry, it is to be feared that the only course which may be adopted may simply be to renew the existing powers of the existing General Board of Health. Entertaining in common with my brother engineers the opinions above stated, I have considered it to be my duty to address to your lordship a few remarks on what appeared to us to be the mistaken opinions, and questionable conduct of the acting members of the General Board of Health, with the hope that your lordship would adopt, before it is too late, such measures as should enable you to form more correct opinions on the subject than can be arrived at by following exclusively the inspiration of the advocates or the opponents of any absolute system.

In presenting these remarks to your lordship, I would expressly state that it is my intention to confine them to measures, and to avoid as far as possible allusion to men. It is, indeed, with pain, that I feel myself obliged to differ in opinion from the Earl of Shaftesbury, even upon matters of abstract science, so high is my estimation of the conscientious integrity with which he has adopted his conclusions, and of the pure and noble motives which induce him to accept the responsibility of the proceedings he has lately been connected with. When the public welfare is at stake such considerations of private delicacy must, however, be waived; and I am sure that Lord Shaftesbury himself will be the first to call for the inquiry I suggest, when he discovers that the opinions of the persons who have hitherto guided his official conduct in the administration of the Public Health Act, are entirely different from those of parties more competent to judge than they can possibly be, and whose experience has convinced them that the opponents of the technical details enforced by the General Board of Health have been justified in their conclusions by the practical results already obtained.

The principal reason cited by the General Board of Health as an attempted explanation of the course it has pursued, and as an argument for the necessity of a prolongation of its powers, is to be found in the assertion, that the ravages of the Asiatic cholera have been materially attenuated by the measures it has introduced. This is scarcely so, for unfortunately it would appear that the circumstances under which this fell disease operates, and the means of arresting its course, are as little known now as they were when it first appeared amongst us. The causes, to which it has been the fashion of late to attribute the development of the scourge, had been in operation from the earliest periods of our history to 1831, without producing the same results they are now said infallibly to occasion. The College of Physicians and the General Board of Health entertain views upon the diffusion of Cholera which are essentially different, for the latter persist in calling it an epidemic, whilst the former assert that human intercourse (*i.e.* contagion) has much to do with its diffusion. The General Board of Health prophecy a return of the disease this year—the College of Physicians show that nothing is known of a nature to warrant any *a priori* reasoning upon the subject. As it is, however, ascertained that *fear is a great predisposer to the disease*, we may fairly question the policy of the General Board of Health in thus maintaining in the public mind a constant and injurious state of alarm. With respect to the remedial measures it suggests, they are precisely the same as were recommended in 1832, and have been carried into effect by private persons, often at the risk of health and life, without any attempt to exaggerate the importance of their sacrifice. The General Board of Health has not discovered one new fact connected with this unaccountable visitation, nor has it proposed any one practical measure for its alleviation. Vague declamations upon the advantages of cleanliness, and the necessity for drainage, can hardly be considered merits in the country in which it is proverbially held that "Cleanliness is next to Godliness."

The objects for which the General Board of Health was established were avowedly to advance the execution of every description of sanitary works, but the Report shows that not only have many collateral investigations been allowed to divert its attention from its immediate duties, but that where it has operated, its proceedings have been arbitrary and obstructive. The subjects of Quarantine, of Interments, of Water Supply, &c., have in their turns, occupied the time, attention, and energy of the Board, although irrelevant to the duties for which they had been appointed.

What has been said with respect to the uncertainty overshadowing the origin and progress of the Cholera should make us pause before we admit the full extent of the value of the report on Quarantine; and indeed, notwithstanding the translation of this document into foreign languages, and its liberal distribution, doubtlessly at our expense, it is curious to observe that no foreign government has adopted the recommendations of that report. It is singular, too, that the Belgian Government should have lately issued a decree by which the sewerage of the towns of that kingdom is to be dealt with upon principles diametrically opposed to those recommended by Mr. F. O. Ward, whom we may suppose to have been the authorised representative of the General Board of Health, at the Sanitary Congress, lately held in Brussels. Evidently foreign authorities pay but little attention to our asserted new lights in matters of Engineering, or Sanitary, science.

But the most startling fact in the report of the General Board of Health is that is should dwell with somewhat of satisfaction upon its conduct in the case of the Metropolitan Interments Act, a more striking failure than which could not possibly be imagined. Many conscientious and able persons are disposed to question the propriety of state intervention in these details of domestic and private interest. Even on the Continent, from whence the General Board of Health drew its examples, the arrangements for the disposal of the remains of departed mortality are left to the care of municipalities. In no case does the Central Government intervene. If the State once undertakes to dispose of the bodies of the dead, there seems to be no reason why it should not also provide for the bodies of the living. Food should, on such principles be no more a subject of commercial speculation and profit than interments, and in the logical application of these doctrines society would become a general "Phalanstere." But if the abstract question be passed over, the fact will still remain that the, by them regretted, Metropolitan Interment Act was a complete failure.

A short history of this remarkable transaction, as it appears to the world, is as follows:—The scheme for the Metropolitan Interments had become law in spite of the opposition of the cemetery companies, and, as might have been expected, these latter declined treating by agreement with the General Board of Health when it became necessary to obtain possession of their grounds. The Board, after uselessly negociating and intriguing with some of the companies, was therefore compelled to give notice, under the provisions of the Metropolitan Interment Act, of their intention to take by compulsion the Brompton (or Westminster), and the Nunhead Cemeteries. In both these cases, the respective parties proceeded to determine the value by reference, and on receiving the award of Mr. Peacock, the eminent barrister, the General Board of Health desired to abandon the purchase, offering to pay all the heavy expenses incurred. This offer was refused by the Westminster Company, and it held the General Board to the terms of the award; but the Nunhead Company let the Board off its bargain, on the payment of at least 1000*l*. The price paid for the Westminster Cemetery was 74,921*l*., its annual maintenance is about 4000*l*., and it may fairly be considered to be a burthen upon the nation of the most useless and expensive nature.

So glaring indeed was the failure of the General Board of Health in the matter of the Metropolitan Interments, that Lord John Russell's government was forced to bring in a bill to remedy the mischief it had produced. Yet we find that the Board still casts a look of affection on its own abortive scheme, and cites its labours in this case as one of its excuses for having neglected its legitimate duties!

Hardly less unaccountable is the reference to the inquiry into the "New Sources of Water for the Metropolis, and new modes for its collection." The investigations before the Committees of the House of Commons, 1851 and 1852, must have enabled any unprejudiced person to discover that the sources proposed by the Officers of the Board could not yield the quantity of water required, and that the cost of conveying what could be so procured must be immeasurably in excess of the estimates presented. The results lately obtained at Sandgate and Rugby prove that these new modes of collection are open to serious, if not fatal, objections; whilst the recommendations of the Chemical Commission, composed of Messrs. Graham, Hoffman, and Miller, show that the waters now supplied to the Metropolis, so far from being objectionable, are, when properly filtered, of a superior quality. Their express words are:—"When in good condition the Thames water possesses the peculiar and agreeable brightness of chalk waters, arising from absence of colour, combined also usually with good aëration." "The Thames water may be described to be in circumstances not unfavourable to purity and coolness, a palatable water. *The amount and nature of its saline constituents, probably contribute to its general acceptability as a beverage.*" So that it would appear from the only impartial investigations which have been made in the matter, that the effect of the adoption of the recommendations of the General Board of Health in this case would have been to have involved the Metropolis in an incalculable outlay without any resulting benefit.

The General Board brings forward no valid arguments in favour of its own water theory, for the asserted savings in tea and soap from the use of soft water have been over and over again shown to be ridiculously exaggerated. But having accused all former professors and professional men of ignorance, it was of course necessary for the Board to start something new on its own account. Hence the scheme for obtaining soft water by means of underground drainage from gathering grounds: a scheme which may have the merit of novelty, but which experience has already shown to possess nothing else to recommend it. For at Rugby, and Sandgate, this favourite system of the Board of Health has entirely failed to secure either a good or a copious supply. It is therefore to be hoped that the interests of the Metropolis will not be again risked in the hands of persons so rash, so desirous of novelty, so inexperienced, so self-confident, and so self-laudatory.

Notwithstanding, however, the express terms of the report of the Chemical Commissioners, the General Board of Health repeat their conclusion, "that the Thames water is inferior as a supply for domestic uses on account of its excessive hardness." This might arrive from a pre-conceived or from a mistaken view of the philosophical question raised by themselves. But when the Board of Health publishes in 1854, that "the water taken by the Lambeth Company from the Thames, opposite Hungerford Market" is impure &c., it asserts what is positively untrue, what anybody might ascertain to be incorrect, and is manifestly guilty of wilful unfairness. *For more than two years not one drop of water has been pumped by the Lambeth Company from this source.*

In the letter which your lordship addressed to the Metropolitan Commissioners of Sewers, when you forwarded to them the communication you had received from Mr. F. O. Ward, your lordship expressed your concurrence in the views entertained by the General Board of Health, on the subjects of combined back drainage, and (the so-called) self cleansing pipe sewers, in opposition to (the so-styled) sewers of deposit. It was with considerable regret that members of the engineering profession observed that your lordship had thus appeared to have decided a physical question upon which the practical and theoretical Boards were respectively at variance, and they had hoped that the delay which has taken place in the construction of a New Board for the Metropolitan Sewers, indicated the intention of a further investigation of so important a subject. Such a course ought still to be adopted, but as was before said, it is to be feared that the session is too far advanced for any efficient inquiry before a select committee of the House. I would, however, respectfully protest against the substitution of any of the unsatisfactory and unconstitutional modes of investigation lately adopted. Before Royal Commissions, witnesses are examined in private, are not necessarily cross examined, the whole of the proceedings are not published, and it too often happens that only such evidence is taken as happens to suit that purpose of the leaders of the movement which has led to the inquiry. The great amount of property, and the immense number of persons to be affected by the conclusions to be arrived at, render it more than usually essential that the greatest possible degree of attention and impartiality should be brought to bear upon the investigations.

My lord, the greatest errors which can possibly be made in reasoning upon questions of engineering, arise from the acceptance of verbal formulæ for admitted facts,—the belief that limited laws are of invariable and inflexible application, and that a name is a veritable personification of a thing. It appears to many able persons that the Board of Health *does* commit all these errors. It calls pipe sewers "self cleansing," and brick sewers "sewers of deposit." But unless the former are well laid, with considerable inclinations, and receive an abundant supply of water, they cannot be *kept clean*: in no case whatever can they act to cleanse themselves. The phrase applied to pipe sewers is a mere clap-trap, as false in philosophy as it is incorrect in grammar. So with respect to brick sewers, they are by no means necessarily "sewers of deposit;" since it is notorious that, when properly executed, they can be kept cleaner than the others, and they certainly allow of being examined and repaired with greater facility. Indeed the results obtained at Croydon, Dartford, Morpeth, the Metropolitan Districts, and in the towns examined by Mr. Bazalgette, show that the pipe sewers are as often "sewers of deposit" as the ordinary brick ones. The application of a name does not indeed, my lord, prove a fact.

With respect to the combined back drainage, it is not denied that it *may* be preferable in some exceptional cases to other modes of laying sewers, but it certainly is not so in all, nor in many. In the case of the Metropolis, and all other large cities and towns, it is particularly objectionable, because the character of house property is continually changing; and it is practicably impossible to apply a system which exposes the inhabitants of a whole row of houses to be seriously inconvenienced by the whims, or carelessness, of the dwellers in one. The houses with gardens at the back this year, may be required to be converted or enlarged in the next: but if the combined back drainage has been executed this would be impossible, because the land over the drains would have become public or common property. As already said, in some cases this system may be applied. He who rejects it altogther is therefore exposed to find himself as much in the wrong as he who applies it indiscriminately. But it must be observed, that ordinary engineers had, long before the establishment of the General Board, been aware of this fact, and had exercised their discretion as to when to use, and when to avoid, combined back drainage. It required the erection of a New Court of abstract theorists to endeavour to enforce the universal adoption of a law which was in itself only partially and incidently correct.

The active members of the General Board of Health have perhaps done more mischief by the promulgation of their dogmas with respect to the size of pipe sewers than by any other of their proceedings. In the earliest period of their activity they enforced, literally *enforced*, the use of 4-inch pipe sewers to houses, and even, as at Croydon, in streets; and in that most astounding document—the report of the Trial Works Committee, they positively stated as the ground for this rule "that one gallon of water, through a 3-inch pipe, moved 1 lb.; through a 4-inch pipe, it moved 3 lb.: through a 6-inch pipe ½ lb. barely;" and a little further on it appears "that" (according to the Trial Works Committee) "an increase of inclination beyond 1 in 60 offers less advantage than has been commonly attributed to it." This reasoning is mere nonsense, my lord, and the experiments on which it was founded, although they cost the metropolitan public the sum of 5000*l*., were utterly worthless, because made by men who had no science, and could not observe. The results derived by the Board from both reasoning and experiments were in opposition to the laws of nature, and to the practical and scientific knowledge of all engineers of every nation. The application of the law so propounded, has led to the miserable failures to be met with throughout England. Surely men who could so rashly promulgate an impracticable theory; and enforce its application by a very unjust and tyrannical pressure on country towns, have but an ill grace when they accuse of empiricism those who differ from them, and still more, when they endeavour to shift the ground of the objections to their theories by applying names intended to provoke ridicule. A 4-inch pipe drain will not, my lord, suffice to carry off the sewerage of an average house; combined back drainage is decidedly objectionable in most cases; it is more advisable to resort to good river waters than to try new-fangled schemes of pot-piped gathering grounds, &c.; and a public body, or even a private individual, may reasonably object to the forcible application of any of these dogmas without being on that account *a lover of dirt*.

One illustration more of the incorrect assertions and the dangerously-distorted statements of the General Board of Health.

In the Report under consideration, the General Board of Health assert that upon the average, the cost of the water supply brought to every house in the towns where works have already been completed under its superintendence, has been about 1½*d*. per week; and that of main or sewer drainage (which, be it observed, is *rarely* brought to the houses, although the contrary is asserted in the Report) has been about 1*d*. per week. But it appears from Mr. Bazalgette's Report on the towns especially cited by the Board of Health, as having been supplied to its satisfaction, that the cost of the public works per house has been on the average rather more than 16*l*., whilst the private works have varied from 5*l*. to 50*l*. Assuming, however, that the whole cost is, in towns of magnitude, only 20*l*. per house, the average annual rate to pay the interest on the capital, and to form a sinking fund to be invested at compound interest at 5 per cent. must be 130,102*l*. per annum, or 6*d*. per week, and then the cost of maintenance, repairs, working staff, &c. must be added. If we take the case of a poor class of house, instead of a house of the average size, nearly the same result is found to occur. Thus, to quote only two of the instances selected by the Board itself as proving the superiority of its mode of action: at Rugby, where the special rate is 10*d*. in the pound for public works, and 4*d*. in the pound to consumers, the annual charge without any reference to the cost of the private works is upon a cottage rated at 10*l*. per annum, 11*s*. 8*d*., and if the interest and sinking fund for the private works be added, this becomes 17*s*. 11*d*. per annum, or above 4*d*. per week. At Sandgate, the water rate is 1*s*. in the pound, and the sewers rate 6*d*. in the pound, so that adding for the private works as before, the charge to a 10*l*. cottage would be at least 1*l*. 1*s*. 3*d*. per annum, or very nearly 5*d*. per week. In each of these there is a further payment to be made to the General District Rate.

As these instances are by no means exceptional, we are compelled to arrive at the conclusion, that the assertion of the General Board of Health, that the public and private works connected with drainage and water supply can be, or have been, executed in such a manner as to allow an average rating of 3½*d*. per house per week, is not correct. Your lordship has, indeed, only to read carefully Mr. Bazalgette's Report, to be convinced of the inaccuracy of the statement.

My lord, I have not yet touched upon the constitution and action of the General Board. These important topics must be reserved for a further communication; but for the present I conclude, by earnestly intreating your lordship to examine for yourself, with the aid of competent advice, both the doctrines and the practice of that unpopular authority.

GEO. R. BURNELL, C.E.

14, *Lincoln's-inn-fields, July 18th*, 1854.

## BRADFORD DRAINAGE AND SEWAGE.

THE Street and Drainage Committee of the town of Bradford having commissioned Mr. E. W. Shaw, the Borough Surveyor, to report upon the sewage requirements of the town, we are glad to find that he has determined on effectually and permanently providing for the thorough drainage of that rapidly-increasing district, instead of tampering with the question, as is too frequently the case, by proposing a complicated system of pipe sewers.

After a careful survey, Mr. Shaw proposes to construct a main trunk sewer, to run through the town and discharge itself temporarily into the Beck, until the requirements of the district demand its extension, or means are adopted to apply the sewage as a fertiliser. Mr. Shaw states that there is ample evidence in the state of the various brooks and of the canal, which intersect the town in different directions, to demonstrate that this question is of paramount importance; however bad the state of the streams may be, yet there is a far greater evil in existence—not the less an evil because unseen—viz., the complete saturation of the subsoil of the town with sewage matter which is now taking place. This is partly owing to the present sewers being constructed of rubble wallstone without lime, partly to many of these sewers being without outfalls, and lastly, to the vicious plan frequently adopted of constructing these sewers so as to take advantage of the numerous fissures in the rock formation, to allow the sewage water to escape through or rather into them.

In laying out the main trunk sewer, Mr. Shaw has kept in view the following principles necessary to a proper system of sewerage, and which are applicable to the construction of sewers generally:—

First. That the shortest practicable route be obtained for the main trunk sewer, and that all unnecessary angles be avoided.

Secondly. That the outfall and level of the sewer be so arranged as to secure the effectual under-drainage of every building within the district, and admit of the branch sewers being laid at such rates of inclination as to secure a rapid flow of water through them.

Thirdly. That the rate of inclination of the sewer be such as will prevent any deposit from taking place within it, and consequently ensure the constant motion of its contents, thereby avoiding, to a considerable extent, the evil effects of allowing decomposition to take place in the sewer.

Fourthly. That the form of the sewer be that which will afford the greatest amount of resistance to the external pressure of the soil in which it is placed, and the least amount of resistance to the flow of water within it; and at the same time that which requires the least quantity of material in its construction.

Fifthly. That the size of the sewer be of sufficient capacity to carry off the sewage water, surface drainage, and underground springs; and be gradually increased in size at the various junctions of the principal branch sewers, sufficient for the purpose, without such excess of capacity as would retard the current passing through it.

Sixthly. That the sewer be constructed of such materials as will present the smoothest possible surface for the passage of the water, and will at the same time prevent any of the liquid within it from percolating through the structure.

Seventhly. That all inlets into the sewer be effectually trapped, and that a thorough system of ventilation be adopted and carried out.

Eighthly. That all junctions with the sewer be made with curves of as large radii as possible in the direction of the current.

Ninthly. That the sewage be so disposed of that it will not pollute the streams or rivers in its vicinity, nor vitiate the atmosphere, but so as to be applied to the useful purpose of increasing the fertility of the agricultural districts.

Tenthly. That the sewer be enduring in its character, and not liable to require reconstruction during the course of a generation.

In selecting the route for this main trunk sewer, little difficulty has been experienced, owing to the peculiarly favourable nature of the district. The main valley line has been selected as far as Mr. Gath's warehouse, in Bridge-street, where it is proposed that the line shall leave the valley of the Bradford Beck, and then traverse that of the Bowling Beck. This is proposed in order to relieve a large and densely-populated district without the immediate necessity of any other works being constructed, excepting the temporary connection of the present sewers in the streets diverging from Manchester-road. The total length will be about 13,720 feet, or near 2⅗ miles. The curves are all remarkably easy; having radii extending from 350 to 800 feet.

The depth at which the sewer is placed is in some cases rather considerable; this is the case where it passes under Bolton-lane. Several causes have contributed to the necessity for thus placing the sewer—amongst others, the desirability of avoiding its passage through private lands—the situation of the new works of the gas company, and the risk of meeting with a large quantity of water in the gravel-beds had the sewer been diverted more to the east. Under all the circumstances, the proposed line is the most economical, and it has the further advantage of securing the most direct course and the avoidance of angles.

The nature of the district admits of a very rapid fall being given to the bottom of the sewer, securing a great velocity of water, and consequently a scouring effect, which will effectually prevent any subsidence from taking place; and it will be observed from the following statement, that the rate of inclination increases as the area to be drained, and consequently the bulk of water to be removed, diminishes—thus complying with the well-known law, that hydraulic depth compensates for want of declivity, and on the other hand, declivity compensates for the want of hydraulic depth.

The lengths of sewer at the various rates of inclination are as follows:—1 in 250 for 2660 feet, draining an area of 2091 A. 2 R. 10 P.; 1 in 185 for 5370 feet, draining an area of 1897 A. 1 R. 6 P.; 1 in 60 for 2600 feet, draining an area of 322 A. 29 P.; 1 in 30 for 3090 feet, draining an area of 182 A. 1 R. 21 P.

These rates of inclination contrast favourably with the trunk sewer at Leeds, which has a fall of 1 in 792; the King's Scholars' Pond sewer, London, which falls 1 in 2400; the central sewer, Preston, which falls 1 in 800; and the proposed northern intercepting sewer, London (Mr. Bazalgette's scheme, approved by Sir W. Cubitt and Mr. R. Stephenson, M.P.), which falls 1 in 2460.

It appears from experiments by Dr. Robinson, that a velocity of 180 feet per minute will remove angular stones the size of an egg. This is confirmed by Mr. Phillips, under the Metropolitan Commissioners of Sewers, who states that a constant flow of 2½ feet per second, or 150 feet per minute, is sufficient to prevent soil depositing in the sewers; in no portion of this proposed main trunk sewer will the velocity be less than 400 feet per minute when the sewer is full or half full; therefore all cause of uneasiness respecting the silting up of the sewer may be at once removed. In consequence of the great velocity of the current in the main trunk, decomposition in the sewer will be considerably checked, and the obnoxious matter will always be in motion, and conveyed at once to the outfall.

The favourable nature of the inclination of the sewer, together with other circumstances, determined Mr. Shaw in recommending that it should be made circular in shape, as the best form to resist both external and internal pressure, requiring the least quantity of material in its construction, and including within its perimeter a greater area than any other figure of equal perimeter.

In determining upon the size and capacity of the sewer, it is calculated to remove all house drainage equal to the supply of 5 cubic feet of water per head per diem, in addition to a rainfall of 1 inch per hour, added to the small quantity of spring water which may be obtained by subsoil drainage. The sewer will, in flood times, render a great service to the low flat ground in the centre of the town, by removing to a distance the surplus water from the Beck, thus preventing those disastrous effects which were witnessed some years ago, and the less serious damage to the goods and other articles which are deposited in the cellars and underground rooms of many warehouses and dwellings, which is produced by the ordinary flood waters. The total amount of covered area proposed to be drained is 2092 acres; this area provides for a large increase of population.

It is proposed to construct the sewer with radiated hollow bricks, equal in quality to those now made at Low Moor, the invert to be laid in Portland cement. The advantages to be gained by the use of hollow bricks are, increased strength, economy of materials, a saving of labour and cement, impermeability, a greater soundness in the burning, owing to the fire having access to the interior of the brick. Keys will be added to the exterior, thus giving the sewer greater power to resist internal pressure, to which it will sometimes be subject.

The inlets into the sewers will be effectually trapped by the employment of syphon traps at the heads of all house drains; and where gullies, for the purpose of conveying the surface drainage of roads and streets are proposed to be constructed, they will be in connection with a cesspit, which will prevent all improper substances from obtaining ingress into the sewers.

The sewers will be thoroughly ventilated through the aid of some of the numerous furnaces which exist in various parts of the town, or by the instrumentality of a furnace and shaft erected expressly for this object, in a manner somewhat similar to that in which the foul air is extracted from colliery workings.

The velocity of the water will be greatly accelerated if all the junctions be so made that the axes of the subsidiary sewers be portions of circles tangential to the axis of the main sewer, and the curves of the largest possible radii.

With regard to the disposal of the sewage, it is unquestionable that whatever its commercial value may be, hitherto no works on a large scale have been successful, although there are numerous places where the application of sewer water has produced very beneficial results; as, for instance at Edinburgh and Milan. Experiments are in progress at Cardiff Gaol under Mr. Higgs, and also at Leicester, under the superintendence of Mr. Wickstead. Mr. Yarrow has also a process by which he produces a very valuable manure from sewage. The great difficulty appears to be in securing in a permanent form the ammoniacal salts. The use of lime-water causes the precipitation of organic matter, but it appears that something else of a sufficiently preponderating affinity between the lime and the carbonic acid gas, to cause the latter to quit its combination with the ammonia to join the lime, is required. Mr. Stothert professes to accomplish this by the use of sulphate of alumina; and recently, an opportunity was given of witnessing his mode of operating upon the sewage derived from the Northumberland-street sewer, London, which, as an experiment, was eminently satisfactory, the water being delivered as clear as crystal. How far the result of its application on a large scale may justify his expectations it is difficult to say.

The estimate of the cost of constructing the proposed sewer amounts to the sum of 13,019*l.* 1*s.* 7*d.*; and a rate of something under one penny in the pound will suffice to pay off this sum, with interest at the rate of 5 per cent. per annum, in the course of thirty years.

## ON THE WARMING AND VENTILATING OF SCHOOLS.*

By Neil Arnott, M.D., F.R.S.

[*Lecture delivered at the Educational Exhibition, July* 13*th*.]

The lecturer began by remarking that it would be difficult to overrate the importance to this and all countries which have a cold winter season, of the art of warming and ventilating, but that as yet, although scientific men judge correctly in regard to them, the mass of the people nowhere suspect the true magnitude of the evils springing from the existing defects. The public may be shocked occasionally by hearing of multitudes perishing from jail or ship fevers, or cholera, generated in confined air, and may observe the temporary illness of persons who have been in crowded and ill-ventilated churches, concert-rooms, theatres, &c., but the more permanent injury to health, the early mortality, and the diminished enjoyment of life suffered by large classes who occupy ill-ventilated dwellings, manufactories, or schoolrooms, escape common notice. A century ago men did not suspect the possibility of there ever being on earth such steam-engines as we now possess, or railways, steam-ships, gaslights, penny postage, &c., all of which are the recent fruits of human ingenuity, and chiefly of the ingenuity of men in this country; but now, when all have perceived the extraordinary benefits obtained, and the evils avoided by these novelties, they would deem the world much less worth living in if such things did not exist; so the time is probably not far distant when in public estimation the sanitary arts of which we are to speak to-day will be regarded as things of high value.

* From the 'Journal of the Society of Arts.'

The lecturer then observed that nature warms by the sun, and is always ventilating, that is to say, removing from about persons the air rendered poisonous by their breathing or otherwise, through the agency of wind, and of the warmth given to the breathed air; this warmth, by causing dilatation of that air, or greater lightness under the same bulk, produces a movement upwards, and of the foul warm-air departure, urged by the pressure of the surrounding heavier pure air taking its place.

Art imitates nature closely. It warms by fire, and it ventilates by using partly the natural agencies of the wind and the lightness of warmed breath, but also by using the strong upward movement in chimney-flues of the hot air which has fed combustion below, and is called smoke. This air, by being made to fill the chimney-flue as a light column, is pressed up by the surrounding heavier atmosphere with force proportioned to the difference of specific gravity and the height of the chimney. A heated chimney with an open fireplace is therefore constantly changing the air in the bottom of the room.

The lecturer then referred to the new arrangement of the open fireplace described in a paper read by him two months ago in the hall of the Society of Arts, and which was favourably received by the scientific men there assembled. He briefly recapitulated and explained, by diagram, the chief peculiarities of that fireplace —1, its being smokeless; 2, its saving much fuel; 3, its having much stronger ventilating force than other open fires; and 4, its taking away the foul air collected near the ceiling of the room, instead of the purer air from below. He gave his opinion that this fireplace, having the dimensions of its parts and adjuncts adjusted to the purpose in view, will be found to be the best simple means of warming and ventilating schoolrooms.

The modifications required for a school are—

1. The chimney ventilating-valve to be larger.

2. The chimney-flue also from above the valve to be larger than below.

3. The chimney-top to be surmounted by a moving cowl, or one of the fixed wind-guards of kindred nature, which, when the wind blows, produces a degree of pumping action.

4. The large quantity of fresh air required for a schoolroom to be caused to enter in a distributed manner, or at various inlets besides the principal one near the fire—as from apertures in a tube placed near the cornice or across the ceiling—or in summer by the tops of the windows opened a little on the side towards the wind, or by openings near the floor; all considerable openings on the leeward side being closed.

He remarked, with respect to larger schools, that—

1. It may be necessary in winter to warm the air which enters at a distance from the fire, by letting it touch the surface of tubes or flat vessels of metal filled with water, circulating from a boiler at the fire.

2. It may be expedient to use, "at certain times of no wind and medium temperatures," the cheap ventilating pump, with light curtain valves, which has been adopted advantageously in passenger and convict ships. This pump injects or extracts any desired quantity of air with mechanical certainty, and is worked as easily as the bellows of a church organ.

3. It may be desirable to economise fuel by using the more complex pumping-apparatus (already proved, but not yet publicly exhibited) which causes the vitiated hot air in passing away from any crowd to give up its warmth to the pure air entering.

He then spoke of some other means of ventilating which are useful for particular cases, and under certain circumstances; but which, by unskilful persons, are often deemed universally applicable, and so are often employed amiss:

1. *Open Windows.*—Often allowable in summer; in winter dangerous if more than a chink at the top be opened. A thin sheet of cold air entering the room aloft will, in descending, so mingle with the hot air of the room as not to be felt by persons below.

2. *Perforated or Opening Window Panes, or Openings in the Wall.*—The same remarks apply to these as to the window opened. Such openings produce strong cold currents where there is an open fire, and foul air does not pass out by them.

3. *The Windsail of Ships.*—A capacious tube of canvas suspended from the rigging, and leading to the spaces between the decks; the mouth, expanded by a hoop or otherwise, is kept turned to the wind. This acts powerfully in strong winds, but in calms not at all.

4. A wooden or metallic tube or shaft leading from the open

air into a room, and surmounted by a moveable cowl or hood, of which the mouth always turns to the wind by the action of the wind itself. This may be regarded as a self-adjusting windsail of inflexible material.

5. Two such tubes opening into the same room or cabin; the mouth of one of the cowls being always towards the wind to receive fresh air; the mouth of the other being turned away from the wind to let used air escape. The two together act with double force.

6. Mines are commonly ventilated by two shafts, one having a fire at the bottom to render it the ascending air-shaft; the other, without fire, lets fresh air descend. If there were no fire, the ventilating action would be, in many cases, so imperfect, that workers would not be safe below.

7. In some mines a single large shaft is made to answer the purposes of two smaller. It is divided into two channels by a partition, called a brattice, made of iron plate or other fit material, and running down from the top to the bottom. One of the channels serves as the smoke-flue. This arrangement is objectionable on several accounts.

8. In imitation of this, a single short tube of metal, divided by a brattice or partition of metal into two channels, has been fixed through the ceiling of rooms, stables, &c., to ventilate them. It is much better than an open pane in the window or a hole in the wall; and either of these is much better than no ventilation at all: but it has many faults. It has no source of heat immediately in one channel, like the mine-shaft, to make it draw strongly. The most impure air approaching the opening to pass out is always rubbing against and mingling in a degree with the new air passing in. It injects and extracts much less strongly than the twin tubes described above at No. 5. When there is little wind and little difference of temperature in the two channels, there is little or no action. With closed doors and windows in the rooms below and a strong fire, both channels become inlets of cold air. The cold air entering by it is not diffused in the room, and may prove hurtful, like that from an open window. Yet, with all these defects, it will, in certain cases, prove a useful aid, because it is a high opening to the external air, and has tranquil action. The model containing one or more burning candles, to represent men, which has been use to illustrate its action, is calculated to give to ordinary observers a very fallacious notion of its nature and power.

## TROMER LODGE, DOWN, KENT.

(*With an Engraving, Plate* XXIX.)

The accompanying engraving, Plate XXIX., is a view of Tromer Lodge, Down, Kent, the country residence of the Rev. Robert Ainslie, showing the additions and alterations which have been and are about to be made.

Down is about sixteen miles from London-bridge, and, unlike what its name would imply, occupies a commanding situation; and from the top of the tower of Tromer Lodge an extensive view of the surrounding country is obtained. The Crystal Palace at Sydenham can be clearly seen from the ground-floor windows.

The additions to the old building are, the tower, porch and bow-window over, and the wing to the right-hand of the picture; all the dressings to the windows and the parapets.

The frontage, including wing and tower, is 65 feet. The tower is 10 ft. 4 in. square, the height up to the top of open parapet is 51 feet, and to the top of vane on turret 68 feet. The buildings are built of red brick, with Portland cement dressings, except the bow-windows, which are Bath stone.

The tower has been named Cæsar's Tower, in reference to the visit which the Roman Emperor, Julius Cæsar, made to that part of Britain, when he formed a camp on the common, about two miles from Down. Mr. Ainslie has in his possession very fine portraits of the twelve Cæsars, by Otho Van Veen (the master of Rubens), which will be hung in this tower.

The works have been executed by Messrs. Hopkins and Roberts, builders, from the designs and under the superintendence of Mr. John Tarring, architect.

## METROPOLITAN GAS-WORKS.

TO THE RIGHT HON. VISCOUNT PALMERSTON, G.C.B., M.P.

My Lord—May I be permitted to lay before your Lordship the following statement of an evil seriously affecting the health of London.

During the summer of last year a committee of gentlemen, with Mr. James Simpson, the President of the Institution of Civil Engineers, as chairman, employed me as their engineer to investigate and report to them upon the scientific and commercial feasibility of a plan for making gas for the supply of London beyond the limits of the inhabited districts, and supplying it into the gasholders of the existing companies, to be distributed from thence.

The manufacture and purification of the gas are now conducted, scarcely without exception, amidst dense populations; all the poisonous and other deleterious influences arising from these processes are inhaled by those who live within their reach, and the inevitable dust and smoke attending upon the distillation of the coal prevents cleanliness in houses situated even at a considerable distance from the vicinity of the gasworks.

The sanitary advantages arising from a change of this system must be at once evident.

Another sanitary advantage, but which is not so apparent at first sight, is, that the gas, being made at one well-selected and commodious spot, with every appliance for conducting the process efficiently, could be distributed in a purer state to the consumers, and the character of the emanations from the street mains and services, at present so injurious and offensive, would be to a great extent improved.

The quantity of gas now made at most of the metropolitan works is larger than their apparatus will afford with economy to themselves and advantage to the public. The extent of ground occupied by the works is entirely covered with the machinery used for the present production and storage of the gas; and since the demand for gas is rapidly increasing, the evils resulting from confined space will be augmented in the same ratio, and instead of a greater demand, as in other processes cf manufacture, bringing with it greater facilities, enabling the commodity to be produced at less cost and in greater perfection, advantageous both to the producer and consumer, the contrary is the case; and the greater the demand for gas, with the present means at the disposal of each company for its production, the greater will be its impurity, its price, and the nuisances evolved from the factories.

Gasworks are, with very few exceptions, surrounded by property so valuable that their extension is almost impossible, in a commercial sense; for the enormously increased capital which would be required would not be compensated by the saving in the cost of producing the gas.

In the new contract entered into between the Prefects of the Seine and the six Parisian gas companies, it is expressly stipulated, that *in* 1858 *all the gasworks are to be removed out of Paris*; a practical proof of the evils resulting from the presence of such works in crowded towns, since the above stipulation has only been made after mature consideration.

The Parisian gas companies will have to remove their works at their own cost. We propose to remove the London works without calling upon the companies to contribute in any manner towards the expense of doing so.

Under these circumstances, it appeared to the above-named committee, that if so desirable a sanitary reform could be effected in such a manner that the revenues of the existing companies would not be reduced, and a sufficient return for the capital required for the new works be insured, a case would be established which would not only justify the promoters in asking the public to come forward as shareholders in the new company, but would be entitled to the support of her Majesty's government.

My investigations have proved that such an undertaking is commercially practicable. The engineering features are described on the accompanying plan.

I have ventured to lay this matter before your Lordship, and in doing so, beg respectfully to state that I shall be glad to wait upon your Lordship in order to give the results of my calculations, should it please your Lordship to require me to do so.

Samuel Clegg, Jun.,
M. Inst. C.E., F.G.S.

11, *Buckingham-street, Strand*, 17*th July*, 1854.

## INFLUENCE OF EXTERNAL AGENTS ON THE DURABILITY OF BUILDING MATERIALS.

By George R. Burnell, C.E.

*[Paper read at the Royal Institute of British Architects, June 5th.]*

When the very imperfect state of that part of meteorology which treats of the constituent parts of the atmosphere is considered, it cannot be a matter of surprise that little is known to guide us to any definite conclusions as to the causes which affect the durability of building materials, and to their modes of action even under ordinary circumstances. Experience and tradition are the only authorities upon a subject of such importance; and the rules at present adopted in the selection and employment of the various classes of building materials can hardly be considered other than empirical. In the following article it will therefore be my object merely to state what is known and acted upon, and at the same time to call attention to some phenomena which require explanation.

The influence of the atmosphere upon building materials is of a complicated nature; it is chemical, mechanical, and *medial*, under which term are included all the various modifications produced by moisture, heat, and electricity.

The chemical influence, or, in other words, the decomposition determined by chemical affinity, depends of course upon the composition of the atmosphere itself, and this is known to vary in an extraordinary manner in different localities. The normal composition of atmospheric air is considered to consist principally of oxygen and nitrogen, in the proportions of 208 of the former to 792 of the latter; but there are also numerous other gases present, such as the carbonic acid, ammoniacal, hydrochloric, nitrous, and sulphuric with sulphuretted hydrogen; the proportions of all which are affected by local causes. Even in the same locality the composition varies with the elevation above the ground, and the application of some theoretical deductions have led to such signal failures as to justify us in dwelling on the necessity for examining carefully the actual conditions of each position.

It is to Messrs. Dumas and Boussingault that we are indebted for the analysis of the atmosphere quoted above, and from the researches of numerous other philosophers, it appears that the proportions of oxygen and azote are constant. Messrs Boussingault and Levy ascertained that the quantity of carbonic acid gas varied from 3·253 to 2·989 parts of gas (in volume) in 10,000 parts of air, the former result having been obtained at Paris, the latter at Andilly, near Montmorency; but Michael Levy states that the quantity of this gas in suspension varies between 4 and 6 in 10,000, the smaller quantity being that most frequently found in the open country. Carburetted hydrogen is found most abundantly in the neighbourhood of marshes; nitrous acid gas in districts which are subject to violent storms, and it is supposed to be generated by the decomposition of azote by electrical action. M. Fresenius (Ann. de Chim. 1849, p. 208) states that he found the proportion of ammonia in the air to be in 100,000 parts in volume, 0·133 ammonia, 0·205 oxide of ammonium, and 0·379 carbonate of ammonia. But M. Boussingault's observations upon the quantities of ammonia in rain-water show that it varies notably, according to the position, from 1 to 5·45. Under all circumstances, the air of the night is richer in ammonia than that of the day,—a fact which may be accounted for by the theory of the nutrition of plants, and the precipitation of ammonia by the early morning dews.

M. Chevalier (*Journal de Pharmacie*, 1835) found that the atmosphere of London contained sulphuric acid, generated, no doubt, by the combustion of coal. The same author also observed that the atmosphere of Paris contained the acetate and the hydrosulphate of ammonia, which are to be attributed to the exhalations from the numerous cesspools of that town. M. Vogel, of Munich, has the merit of having ascertained the presence of hydrochloric acid in the atmosphere surrounding the waters of the Baltic and the Mediterranean. The action of the sea breezes upon some building materials, to which I shall have occasion hereafter to refer, appears to prove that this gas is not confined to those seas. As it is furnished by the evaporation of the ocean, it necessarily varies in quantity according to the season; and we may also suspect that other deleterious gases are from time to time suspended in the atmosphere, though their existence can hardly be demonstrated on account of their minute proportions.

The meteorological conditions of the atmosphere are subject to periodical variations, and they have distinctly-marked phases of day and night, unless extraordinary phenomena occur. Thus, in clear weather, the atmosphere attains two maxima and two minima in its electrical state; the first maximum being between seven and nine in the morning, and the second between seven and nine in the evening; the first minimum about four in the morning, and the second between five and ten in the evening; but it must be observed, that its hygrometric state frequently modifies these periods. The intensity of the sun's light, and necessarily of its actinic influence, has its maximum rather before mid-day, and two minima corresponding nearly with the periods of twilight. A maximum occurs in the temperature about two o'clock in the afternoon upon the average of the year, but there is a slight irregularity according to the seasons; a minimum occurs, generally speaking, when the sun occupies a position about 14° 47′ below the horizon, according to M. Bouvard's observations in Paris; the period of mean temperature varies in the different months. The atmosphere is driest about mid-day, and contains the greatest amount of moisture at night; the deposition of dew takes place to the greatest extent between midnight and sunrise, on account of the greater cold which then prevails. In our latitudes the disturbances of the barometric action are not marked by any regularity; but there is a tendency to increase in the morning, when the barometer generally rises; it falls about mid-day, rises again about sunset, and falls once more about midnight. It may, in fact, be considered that the meteorological fluctuations of every day are affected by the relative positions of the sun and the earth, and that they correspond more or less closely with the cardinal positions of the former at rising and setting at mid-day and midnight.

The mean temperature of London throughout the year is 50° 50′, while that of the surrounding country is 48° 50′. The thermometer very rarely rises above 96°, and the greatest cold hitherto recorded in our metropolis is 5° below zero. The mean barometric range amounts only to 2·07 inches.

One of the most important conditions of the atmosphere depends upon the rate of evaporation, and the amount of humidity in suspension; and the intensity of these agents is greatest at directly opposite seasons of the year. Evaporation is greatest in summer and least in winter; the reverse takes place with respect to humidity. Mr. Daniell estimated the mean evaporation in the neighbourhood of London at 23·974 inches per annum, ranging in the various months from about $\frac{1}{2}$-inch in January and December to $3\frac{3}{4}$ inches in June, and $3\frac{1}{4}$ inches in July. Supposing the complete saturation of the atmosphere to be represented by 100, the humidity of the months of December, January, and February will then be expressed by 92. In the intervening months the humidity diminishes with tolerable regularity to the minimum of 78 at the end of June, except in the month of May, when a trifling irregularity occurs. It thus happens that the greatest amount of moisture is suspended in the air, to be absorbed by porous materials, precisely at the season of diminished temperature and exposure to the attacks of frost; while evaporation takes place at the period when the conditions of temperature are most favourable to the production and development of the salts by the previously-absorbed moisture acting on the earthy bases.

Such we may consider the general properties of the atmosphere likely to affect the conditions of building materials, and we may trace their influence under circumstances apparently very dissimilar.

The various external agents produce effects, either by the new combinations they superinduce between the earthy bases, the metals, and the metalloids of the different classes of building materials and the gases they contain, or by the solution and removal of the combinations previously existing. There are few, indeed we may almost say that there are no conditions either of organic or inorganic chemistry which can be considered permanent; and as the gradual decay of rocks is a law of nature everywhere, and inevitably, at work to renew the face of the world by apparent destruction, it is not be expected that the insignificant quantities we deal with can be exempt from similar laws. The consideration of the circumstances attending the formation of the new compounds of oxygen, hydrogen, carbonic, ammoniacal, and hydrochloric gases with the bases above mentioned, with the action of the fermentation of woody sap, would lead to a lengthened investigation of the most abstruse branches of chemistry. The importance, however, of these compounds cannot be too strongly insisted upon, nor can the attention of scientific men be too decidedly called to them. Sometimes they act to destroy, at others to consolidate; but in all their influence is very marked, and calls for serious consideration from the architect. Limes, cements, and some descriptions of building stones, when properly employed, gain in strength and durability by the slow, but sure, action of the air. When injudiciously employed they rapidly decay, through the decomposition to which that element gives rise, or the mechanical agents to which it serves as a medium, while the destruction of the metallic or the organised matters employed is equally occasioned by the same cause. I shall now proceed to point out the various phenomena exhibited by the respective classes of building materials usually employed in London, not attempting, however, more than a very general description of a subject so vast, and at the same time so complicated.

Granites present many varieties, differing greatly in their composition and the mechanical arrangement of their elements. Those from Devonshire and Cornwall contain a large proportion of schorl, and are frequently pervaded by masses of felspar, of such dimensions and so distinctly crystallised as to cause them to assume a porphyritic character. According to Sir H. De la Beche, the granites of Ireland are of the same character, but the schorl occurs in smaller proportions. The granites of Aberdeenshire are more decidedly micaceous, and schorl is rarely found in them; they also differ from those of England and Ireland in having their component parts more equal in volume and more evenly distributed. In some cases, hornblende takes the place of mica, and in others the quartz and the felspar are so much affected in colour by the presence, doubtless, of hydrous oxide of iron, as to give a general rosy hue to the whole mass. An instance of this is the well-known granite of Peterhead. The granites of Guernsey, Jersey, and the Isles Chausey, which are occasionally brought into the London market, resemble those of Cornwall; and, indeed, M'Culloch, in his 'Classification of Rocks,' states that they pass into the same variety. Their appearance is, however, sometimes diversified by the occurrence of large, imperfectly-shaped crystals of compact felspar, which give the whole mass either a greenish tinge, as in the case of the Guernsey, or a rosy one, as in that of the Jersey granite.

The decomposition of granites takes place from the action of the atmosphere upon their constituent particles. "The quartz is almost pure silicious earth, in a crystalline form. The felspar and mica are very compounded substances, both contain silica, alumina, and oxide of iron. In the felspar there is usually lime and potassa; in the mica, lime and magnesia. When a granitic rock of this kind has been long exposed to the influence of air and water, the lime and the potassa contained in its constituent parts are acted upon by water and carbonic acid; and the oxide of iron, which is almost always in its least oxidised state, or in that of the protoxide, tends to combine with more oxygen; the consequence is, that the felspar decomposes, and likewise the mica, but the first the more rapidly." Such are the words in which Sir H. Davy ('Agricultural Chemistry,' p. 189) describes the mode of decomposition of granites; and they may be taken to express the present state of science so far as the granites usually employed in England are concerned. But there appear to be different conditions in the combinations of the bases of felspar which give rise to some apparent anomalies. Thus the Egyptian porphyries, which contain a notable excess of rose-coloured felspar, resist the influence of the atmosphere in an extraordinary manner. Possibly this may be accounted for by the closeness of the grain (so to speak) which would to a certain extent prevent atmospheric moisture from communicating with anything beyond the immediate surface; or the more simple character of some of these porphyritic rocks may be favourable to their preservation; whereas the different rates of expansion of the ingredients must have a material mechanical influence in disintegrating rocks when they exist in considerable numbers. The difference between the rapid rate of decomposition of the porphyritic granites of Spain, Brittany, and Cornwall and that of the Egyptian specimens appears to justify the inference that the cause last suggested has great influence upon their durability. The former are, in fact, composed of a greater number of ingredients than the latter, in which both mica and hornblende are wanting.

Practically it is found that the uniform character of the Aberdeen granites resists atmospheric influences in our latitude better than the more easily worked stones of Devonshire and Cornwall.

It may perhaps be as well to call attention to the fact that the modern application of the term "porphyry" is in some cases inconsistent with its derivation; the *grey* granites of Devonshire, Cornwall, and the north-west of Spain being occasionally called porphyritic, as well as the *purple* felspathic rock of Egypt. The latter is almost entirely composed of felspar, with occasional crystals of amphibole and quartz; but the colour is entirely owing to the felspar, which is of a beautiful purple, occasioned by the presence of a large proportion of the hydrous oxide of iron. Ophite (green antique porphyry) and melaphyre (black porphyry) are instances of a similar disregard for the derivation of a generic name. A description of granite, known to mineralogists by the name Syenite, was also much used by the ancient Egyptians; it is remarkable for having the mica replaced by hornblendish amphibole, and is of a rose colour. The atmosphere does not appear to have much action upon this variety, at least in Egypt, if we may judge from the state of Pompey's Pillar and Cleopatra's Needle.

Whinstones or basalts become disintegrated unequally under the effects of exposure to the atmosphere, in consequence of the variable proportions of felspar they contain, and perhaps also of the particular combinations of alumina, lime, and magnesia, which, in connection with silica, constitute their base. If any potassa be present in combination with the silica in the shape of felspar, the action is more rapid than under ordinary circumstances, the humidity of the atmosphere decomposing the felspar into two substances, one of which is soluble, and easily removed by succeeding rains. Serpentines and the diallage rocks, which are silicates of magnesia combined with hydrates of that base, yield easily to the attacks of acids when the silicates are in certain proportions and alumina is present. The most beautiful varieties of these materials employed in the arts are obtained from the environs of Genoa, and from Zœblitz in Saxony; but it is much to be feared that the atmosphere of large towns, especially when containing sulphuric acid gas from the combustion of coal, renders the employment of even the best of these decorative materials very hazardous. It appears also, that in parting with their water of crystallisation upon exposure to the air, an unequal contraction takes place in the constituent parts of the serpentine obtained in certain localities, which in consequence breaks in an irregular manner.

The next description of building materials to be considered, in following the ascensional order of the geological series, are the slate rocks. Those worked for the supply of the London market are principally situated in North Wales, Cumberland, and Westmoreland, the former being a tolerably homogeneous clay slate, the latter much more chloritic. Exposed freely to the action of the atmosphere, both varieties appear to be tolerably durable; but Westmoreland slates decay very rapidly in damp positions when the air around them is not frequently renewed. They decay, in fact, in the covered parts, probably from the decomposition of the silicate of iron, to which they owe their peculiar colour. The combination of silica and alumina in the Welsh slates appears to be more stable than that which prevails in any other material of the same nature; for their powers of resistance to atmospheric influence are greater than those of any slates employed in Western Europe or North America. As a general rule, the denser the slate the more durable it will be; and the most important condition to be observed in its use is, that water should not be allowed to percolate between the edges of the strata. Practically, it is found that the smoother the surfaces of the slates, and the closer they lie, the greater is the pitch requisite to be given to the roof; because, under such circumstances, capillary action takes effect to a greater extent than when the slates present irregular and perceptibly large intervals.

The various sandstones, millstone grits, and conglomerates, are affected by the atmosphere, either through the decomposition of the material cementing their particles together, or by the mechanical effects of moisture. These last may consist either in the removal of the cementing material, or in the destruction of the cohesion of the particles by the expansion of the water in freezing. Many of the sandstones occur in regular layers, separated by thin films of a species of clay, as in the common Yorkshire flagstones, and when these films are sufficiently thick to offer an efficient resistance to the passage of water, to retain it, in fact, under the upper shale, the expansion during frost will almost inevitably destroy the stone. If the water should change its form from other causes, such as heat, the same effect will be produced; and it is therefore found that the Yorkshire stones of a very porous, and at the same time of a very fissile character, are unable to resist the extremes either of cold or heat. The best materials of this description are those of an homogeneous nature—such as the Park Spring, the Idle, and the Darley Dale stones, in all of which the minute subdivisions disappear, and the mass may be described as consisting of an assemblage of distinct molecules of similar nature, united by mechanical juxtaposition.

The sandstones, in which the silicious molecules are united by a calcareous cement, are far more susceptible of decomposition than those united by a silicious cement, for it appears that in the former cases the chemical combination is rarely effected between the lime and the silica; as the latter is not in the state known as free silica, nor such as can easily form combinations with other materials. In the case of some of the millstone grits, however, the cementing substance, which is silicious, forms so energetic a combination with the molecules it envelopes, that both resist the action of external causes in an equal manner, and the durability of the Bramley Fall Stone may fairly be compared even to that of granite itself. These remarks may be extended to the conglomerates—in all essential respects at least—because in fact, generally speaking, they differ from the millstone grits only in the size of their elements.

The crystalline marbles vary in such a very marked manner, both in the nature and the proportions of some of their constituents, and they have been so modified by the accidental circumstances of their geological position, that it is more than usually difficult to trace the laws of their decomposition under the action of atmospheric causes. In many instances they are traversed by veins filled in with more perfectly-defined crystals of the base of the rock, or the fissures caused by these veins are filled in with extraneous matters, such as clay, and sometimes even with minerals. Again, however regular the structure of the mass may seem, there is always a tendency in the more crystalline rocks to assume a distinct cleavage, which is often different from the direction of the planes of stratification. Under such circumstances the moisture furnished by the atmosphere either furnishes the elements necessary for the decomposition of the materials introduced into the veins, or by the mechanical effects it produces in consequence of the changes of temperature disintegrates the mass. The former class of phenomena may be most distinctly observed in the Breccias, or such marbles as the Brocatello and Oriental Jasper; the white marbles very frequently exhibit the cleavage above alluded to, and are most exposed to the injuries produced by the infiltration of water between the planes of division. It is to be observed that the species of false stratification indicated by the cleavage is most apparent in the rocks which, like the slate rocks, have been affected by proximity to igneous formations, and that the more crystalline the marble the more exposed it is to this inconvenience. At the same time it must be observed that the more perfectly crystallised carbonates of lime, under which denomination, in fact, nearly all the finer marbles may be included, resist the chemical influences of the atmosphere more successfully than similar substances where the forms are not so distinctly marked. It would appear as though the process of crystallisation were accompanied by the development of some chemical affinity between the ultimate particles, similar to that which is noticed with respect to the various forms of silica, and which enables them afterwards to resist more energetically external causes of decay. In some marbles the joints assume different directions from either the lines of stratigraphical deposition or from the planes of cleavage; but in the practical operations of building the consideration of this peculiarity may be neglected, because they are usually so distinctly marked as to place in reality the natural limits to the sizes of the blocks raised.

M. Durocher communicated to the Académie des Sciences a memoir "sur l'absorption de l'eau atmospherique par les substances minérales," which throws some light on the subject of the decomposition of silicated materials, or those containing metallic oxides. From his experiments, it appears that all substances of this description actually absorb water from the atmosphere, and undergo a commencement of hydration, which must necessarily facilitate the decomposition of mixed minerals, such as the silicates, and is apparently the commencement of that action. Messrs. Jamin and Bertrand have also shown that in porous bodies gases are condensed with remarkable facility, so that it is possible that the conditions of molecular aggregation influence the durability of mineral substances in the direct proportion of the facilities which are offered to the passage of air to the interior. From this we may infer that the existence of a crystalline structure is in itself a protection to the materials in which it may occur, because under such circumstances the porosity is usually less; or at any rate the intervals between the ultimate molecules are proportionally smaller than in the case of materials held together simply by aggregation without crystallisation. Sir H. De la Beche notices the universality of this law (Geol. Observer, ed. 1851, p. 8), but he does not attempt to account for it.

The magnesian, the oolitic, and the ordinary secondary and tertiary limestones, are liable to decay under the influence of the atmosphere with very various degrees of rapidity; and it is, moreover, to be noted, that the same formations yield materials varying singularly in their powers of resistance according to the position they occupied in the quarries, and the exposure of the building in which they are employed. The results obtained by the use of the Anston magnesian limestone, and the marked differences to be observed in the Bath, Caen, and Portland oolites, as well as in the several members of the tertiary series of the Paris basin, appears to show that no *a priori* laws can be laid down with respect to their durability when exposed to the air. All these classes of materials are supposed to have been deposited by waters containing their elements in solution, and if they were once in that state (*i. e.*, of solution) it must be evident that they are always susceptible of passing into it again, if the necessary conditions are presented, unless the deposition should have been effected by the introduction of some additional element, or such element should have been supplied at a later period. There is another chemical agent at work in many cases to hasten the decomposition of the sedimentary rocks unaffected by Plutonic action—namely, the animal matter which they so often contain; and as the distribution of this matter is not subject to any definite law, it necessarily produces irregular effects. Occasionally, also, the body of the stones is traversed by numerous fissures, which have been subsequently filled in by more crystalline materials of greater powers of resistance; and again, the chemical nature of these stones often varies, owing to the presence of more or less silica in combination with the ordinary bases. Every possible variety in the mode of disintegration may therefore be observed in these stones.

Experience has shown that the magnesian limestones are not more capable of resisting the effects of our London atmosphere than the carbonates of lime formerly used, when proper care has been exercised in the selection of the latter. Mr. Rogers, indeed, remarks (Brit. Assoc., 1849) that rain-water slightly carbonated takes up the carbonate of magnesia more rapidly than it does the carbonate of lime, and that the magnesian silicates are easily soluble, even in pure water. Forchhammer also observes, that water which contains carbonate of soda acts easily upon magnesian rocks. Now, it is very probable that the rain-water falling through the atmosphere of London should be charged at any rate with carbonic acid gas, and thus become extremely prejudicial to this class of materials; and it is possible that the rain may give rise to a catalytic action between the lime and magnesia contained in this class of stones, which would facilitate their decomposition. Every stone, as may be gathered from what has been said above, is exposed to decay in the precise ratio of its porosity, but in addition to this cause of disintegration, which acts principally by allowing water to exercise its natural mechanical powers, all the ordinary building stones are exposed to the peculiar process known by the name of nitrification, which, in consequence of the formation of the crystals of nitre, combined with a base, tends to disintegration of the surface. The magnesian limestones allow the development of this process as freely as the carbonates of lime, even if they do not offer extraordinary facilities for its action. The generally received opinion is, that the azote, furnished by the decomposition of the animal matters diffused through the rocks combines with the oxygen of the atmosphere to form nitrogen, which latter gas in its turn combines with the soda, existing in small quantities in all sedimentary deposits, to form the nitrate of soda or the saltpetre of commerce. Dumas says, that azote and oxygen combine most readily under the influence of electricity, but that the energetic bases, lime and magnesia, may suffice, especially when moisture is present, to replace that intermediate agent. At any rate, this chemical operation takes place in nearly all building stones of a porous nature; and it may confirm the common opinion, that of stones, of the same description geologically, the densest are the most likely to resist the action of the atmosphere.

The phenomena of the saltpetring of building materials are very little understood; but there are certain practical rules which may serve to guide the architect in his endeavours to avoid the inconvenience arising from it. They are—First, to employ, if possible, in damp positions, either granite, the millstone grits, the conglomerates of a purely silicious character, or sandstones free from animal matter and the sulphate of iron.

Secondly. If the cost of either of these classes of materials should render their employment impracticable, the use of any of the ordinary limestones should be avoided in positions where they are exposed to warm dampness, should it be desired to execute any coloured decorations upon the immediate surface of the walls. When from local considerations it may be advisable to employ these materials in basements or other damp positions, they must be separated from the upper structure by the interposition of a layer of some impermeable material, to intercept the passage of the water, which would otherwise be absorbed by the capillarity of the upper stonework.

Thirdly. Every precaution must be taken to prevent the saturation of the ordinary limestones by sea water, and the use of sea sand in the mortar to be employed with them must be carefully avoided, because sea water furnishes the salts of soda most likely to assist in the formation of the nitrates, and sea sand is also highly impregnated with the same salts. It is equally known that the atmosphere of the sea shore holds in suspension a notable quantity of the various salts which pass off by evaporation from the surface of the sea, and it is for this reason that stones which are exposed to nitrification suffer more rapidly in such positions than in the interior of the country.

Fourthly, to isolate decorative works effectually from the walls formed of materials in any way susceptible of saltpetring. Of late years attempts have been made in Paris and some other continental towns to revive the practice of mural decorations, but the results have generally been unfavourable, in consequence of the chemical action of the atmospheric moisture transmitted through the pores of the stones. So seriously has this cause been observed to affect internal decorations, that the architect of the new Hôtel du Ministère des Affaires Etrangères, M. Lacornée, has lined the inner surfaces of the walls destined to receive either silk panels or paintings with sheet lead, and has then battened out independently of them. In the new church of St. Vincent de Paul, the painting on the dome behind the high altar has begun to fade from the effects of the transmission of the moisture of the atmosphere through the stone vaulting. This work has not been executed more than about twelve months.

It must be observed, with respect both to the carbonates of lime and the magnesian limestones, that their principal elements exist only in the state of subcarbonates while the stones remain in the rock. They absorb carbonic acid from the atmosphere, and harden by exposure to the air; but as the hardening process will augment the cost of labour, and is moreover very slow in its action, it is rarely resorted to in practice. For many reasons, however, it would be desirable to quarry the stone required for an important building twelve months before it is to be employed, because the danger to be apprehended from frost would be avoided, and the carbonisation would be more perfect. Another very useful precaution is to cover the exposed surfaces with a wash of some description, able either to close their pores or to produce a chemical action on the stones themselves. The practice of some London masons of painting the stonework as it is carried up with a thick slime of stone dust and water acts in the former manner; the washing all exposed surfaces with an alkaline silicate acts in the latter, and it would be unquestionably preferable were it not that in some positions the addition of even the small quantity of soda, requisite to hold the silica in solution, might furnish the element of the saltpetre.

Of late years attempts have been made to cast doubts upon the correctness of the generally-received opinion, that it is essential to place stones on the same bed as they occupied in the quarry. With some few stones when in place, it may be true that the position of the layers is a matter of indifference; for the roche de St. Cloud and the Villebois stone of the neighbourhood of Lyons, amongst the secondary and tertiary limestones, have been employed without reference to the planes of bed for many centuries without inconvenience. But these cases are decidedly exceptional, and even in them the powers of the stone to resist a crushing weight are less when it is applied in a direction parallel to the beds than when it is applied transversely. In almost every other case it will be found that when stones are used the wrong way of the bed—to employ a workman's phrase—they disintegrate in parallel plates. Great care requires to be exercised to ascertain the precise direction of the natural beds, because many stones present the appearance of inclined planes of deposition, which cut the beds and joints under every modification of angle. When, from the stones having been worked in the quarry, it is difficult to ascertain the precise bed, it is possible that the mason may be misled by the greater facility with which they work in one direction, and may mistake this cleavage for the real bed. The only remedy appears to be to cause the stones exposed to this danger to be marked in the quarry, but fortunately the examples of its occurrence are rare.

The principal danger of exfoliation arises from the expansion of the moisture contained in the stone under the influence of frost, and a very elegant process was invented by M. Brard, for the purpose of ascertaining the probable extent due to this cause. M. Brard in his experiments upon the resistance of stones, caused them to be boiled for half an hour in a saturated solution of the sulphate of soda. They were then withdrawn and allowed to stand in a flat vessel, at the bottom of which was a small quantity of the same solution, the first efflorescences were washed off, and the degradation of the stones during the next five or six days, under the effects of the continued efflorescence, were taken as an indication of the probable extent to which they would be affected by frost. In the first volume of Rondelet's Art de Bâtir, p. 307 (ed. 1842, Paris), M. Brard's process is described in detail; but some very curious experiments recorded in vol. 7, 1re serie des Annales des Ponts et Chaussées by M. Minard, together with an article by M. Vicat, inserted in the same volume, throw very considerable doubts upon the exact amount of dependence to be placed on its indications. M. Vicat, indeed, very properly observes, that it still remains to be proved that the expansive action of water in freezing is identical with that of crystallisation, which can only produce energetic effect at temperatures between 68° and 86° Fahr. According to this very accurate observer, stones which are exposed to a southerly aspect, on the north of the equator, are more affected by frost than those exposed to the north; and the most efficient protection to materials of this description of a porous nature is a coating of oil paint, or any other fatty pigment which prevents moisture from being driven or absorbed into the stone. M. Minard recommends that stone should be quarried in the spring, and not employed in a building until it has been exposed to the effects of one winter at least.

In many varieties of the oolites, the fossil shells are to be observed left in high relief upon the surface by the decomposition of the materials in which they were embedded, and in Bath stone the veins of calcareous spar frequently become detached. It appears that the cause is the same in both cases, and that the shells and the veins protrude in consequence of the resisting powers of the more perfectly crystallised carbonate of lime, of which they are composed, exceeding those of the amorphous mass in which they are embedded. When nodules of flint or chert occur in the numerous varieties of carbonate of lime, the stone around them is usually more durable than the general mass of the rock, doubtless because it contains a portion of the silica in combination with the lime. It is known, indeed, that the application of a soluble solution of silica will at all times add much to the durability of the purer carbonates of lime; but it is very desirable that the conditions under which such a solution should be employed should be made the subject of close and careful experiments.

There are some varieties of arenaceous limestones and sandstones with calcareous cements, and a very remarkable silicious deposit, to be met with in the upper secondary and tertiary formations, which may eventually serve to throw light upon the chemical changes produced by the atmosphere in consequence of the very decided character they assume. For instance, the sandy beds of the Kentish rag perish in consequence of the mechanical removal of the sandy cement which binds together the particles of limestone. The grès or sandstones of Fontainebleau and Windsor forest as frequently decompose, in consequence of the removal of their calcareous cement by moisture, or by the action of the air; whilst the silicious beds of the lower chalk appear likely, from Mr. Way's experiments, to furnish materials of inestimable value to plastic art, and also affording a convenient and economical supply of the soluble silica required to compensate the deficiencies in other more generally employed materials.

With respect to the gypseous formations, it appears that where they occur in sufficient abundance to be used as ordinary building materials, they absorb moisture from the atmosphere with extraordinary facility; while they decompose with such rapidity that the municipal authorities of Paris have forbidden their being used for the walls of houses. Occasionally, however, rubble plaster stone is used for enclosure walls, but it rarely lasts more than from twenty to thirty years, when exposed to the weather near Paris. The cause of this rapid decay, according to Gmelin, is to be found in the fact that the sulphates with an earthy base (gypsum being a sulphate of lime) are soluble in water. It is also to be observed that many of the gypseous deposits, especially those found near Paris, are impregnated with an extraordinary proportion of organic matter; this decomposes on exposure to the air in warm and damp positions, and gives rise to the formation of nitrous salts to such an extent, that the saltpetre used by the French powder manufacturers, during the last war, was almost entirely obtained from cellars constructed of rubble masonry, set in plaster in the style usually adopted in France. It is possible that the gases which are present in rain water, or in the atmosphere, may give rise to a species of decomposition by relative affinity, in combination with the sulphuric acid of the gypsum.

Atmospheric influence upon bricks, tiles, and other building materials obtained by the burning of plastic clays, depends very much on the chemical composition of the clays, and on the degree of burning. Thus any distinct portions of limestone present in them would be converted into quicklime in the kiln, and when the bricks were thoroughly wetted would expand in such a manner as to disintegrate the mass. If the clay used is too poor,, that is to say, if it contains an excess of sand, the bricks will not become sufficiently fused, and upon exposure to the weather their constituent parts will separate. It is to be observed that in bricks, as in stones, decomposition does not take place with the greatest rapidity where constant moisture exists, but rather where, from the influence of capillarity, variable according to the moisture furnished by the atmosphere either directly or indirectly, a series of alternations of dryness and humidity prevail. The foundation walls of buildings do not in fact suffer so much in the parts immediately upon the ground, as they do in those at a height of from one to three feet, according to the permeability of the materials employed. When bricks made of clay containing free silica are laid in mortar, and moisture can pass freely from either one or the other, it may be observed that the edges in contact become harder than the body of the bricks. No doubt this arises from the formation of a silicate of lime and alumina, the lime being furnished by the passage of the water through the bed of mortar.

Upon limes and cements the effects of the atmosphere are very marked, although at present they are considered to be of far less importance than formerly. All the materials of this class, whether the hydraulic, or the rich limes, the cements, or the plasters properly so called, have a remarkable avidity for water, and abstracting it from the surrounding atmosphere assume the form of hydrates. If these occur in the conditions requisite to enable them to pass into the carbonates, or sulphates, a species of confused crystallisation, or aggregation, takes place. But it must be evident, from what was said in the commencement of this notice, that the quantity of carbonic acid gas the atmosphere is capable of furnishing within a moderate period is exceedingly small, and the theory that limes or cements harden originally by the absorption of that gas, and the consequent conversion of the lime into carbonate of lime, must be abandoned. There can be no doubt but that the conversion of the lime into the carbonate must increase its cohesion, but the rapid setting, to use a workman's phrase, cannot be accounted for in this manner. It appears, so far as we are able to judge in the actual state of applied chemistry, that mortars harden in consequence of the formation of an insoluble silicate of lime and alumina, the silica being either furnished by the limestone itself, or by the sand, pozzolano, or other ingredient mixed with the slacked lime. When the setting has been once effected, the absorption of carbonic acid gas from the atmosphere may tend to harden a thin external film; but the very perceptible character of this film militates against the supposition that the cause producing it can act upon the interior of the mass.

Nevertheless, the numerous classes of limes, cements, and plasters, exhibit very marked differences in their manner of resisting the action of the atmosphere. The purer carbonates of lime when used for the preparation of mortar, are excessively soluble in water; and if the mortar obtained from them be much exposed to the weather, or to the action of running water, it will be rapidly removed. The argillaceous limestones, on the contrary, furnish the elements necessary to form an insoluble double salt of lime with the silica and alumina; and if the mortars made from them be protected from running water during the period required for their setting, the action of either weather or running water subsequently will rather tend to increase their powers of resistance. The practical lesson to be drawn from these facts would appear to be, that none but the limes obtained from argillaceous limestones should be employed in damp situations. With respect to the use of plaster, the observations before made upon the gypseous stones will apply here perhaps with even greater force. Indeed the marked difference between the external aspects of the applied plaster and the natural stone, would show that in the process of calcination some element we are unable to ascertain must be driven off. It may be that the burnt plaster yields more readily on account of the absence of this very element; but certain it is that plaster of Paris very rapidly decays when exposed to the influence of the atmosphere.

Temperature appears to act in a distinct manner upon limes and cements, for if they are used in summer, without the adoption of any precautions to defend them from the sun, they invariably crack; and of course, if their water of crystallisation becomes frozen in winter, the whole mass will disintegrate. The more rapidly limes or cements solidify, the more they appear to be exposed to the danger and inconvenience of cracking in warm weather, and it would appear that the most favourable condition for their resistance is when a certain degree of uniform moderate dampness prevails. It must also be observed, that sea air has a marked influence upon the durability of some limes, because the minute particles of sea-water it contains hold in solution many salts with which free lime has more affinity than with silica.

The decay of wood superinduced by atmospheric action, is affected by a different class of phenomena from those which tend to destroy stones and metals, namely, those connected with organic chemistry; although at the same time the changes produced by inorganic elements are as powerful in the one case as the other. From the day when wood is felled to the day it is used, it requires care and attention, and when it is in place precautions should still be taken to ensure its durability. Currents of air which are either renewed with too great rapidity, or are too dry, a temperature too elevated, constant moisture at high temperatures, alternations of dryness and humidity, absence of ventilation producing wet rot, the accidental transport by the atmosphere of the seeds of certain cryptogamous plants producing dry rot, and the attacks of insects, together with the fermentation of the sap of the trees, may be cited amongst the numerous sources of danger from which it is necessary to secure wood either when in store or when employed.

When wood is exposed to frequent currents of air, especially at high temperatures, the moisture it contains evaporates too rapidly, and gives rise to cracks and fissures which either destroy the resistance of the material, or open a passage for the water contained at other times in the atmosphere to penetrate to the interior of the mass. If the temperature to which wood is exposed, whilst any sap remains in it, is too elevated, the vegetable fluids ferment, the tenacity is diminished, and when the action is carried to its full extent, the wood quickly becomes affected by the dry rot. Exposure to the atmosphere in positions where rain can lodge in quantity, contact with the ground, and application in damp situations deprived of air, will render wood liable to the wet rot; and however well seasoned it may have been previously to being brought within the influence of any of these causes, it will infallibly suffer. It is therefore of the highest importance, that whether in the merchants' stores, or subsequently when placed in a building, wood should be preserved from contact with the ground, and that air should have free access to it in every direction. The germs of destruction are often communicated whilst the wood is in store from neglect of these simple precautions; if they be once implanted, the progress of decay can never be subsequently arrested. It has been supposed that keeping wood in water tends to prevent the commencement of dry rot, because in that position the sap is washed out of the pores. If this theory is correct, it must be evident that the oftener the water is changed, the greater will be the probability of its producing the desired effect, because if it be allowed to stagnate it must become saturated with the sap in course of time, and unable to take up any additional quantity which may be present. Duhamel observed, that if wood were immersed immediately after it was felled, it would be less liable to decay than if put in water at a subsequent period; he also found that immersion tended to preserve the wood from the attacks of insects, and even to arrest the progress of some kinds of decay, but that a notable portion of the strength was lost. The drying and seasoning take place with greater rapidity after immersion, probably because the water displaces the sap, which does not evaporate so rapidly as the thinner fluid. Duhamel asserts that the process of charring the ends of posts, &c., built into the ground, is very inefficient, and that it is only of use to the extent of interposing an extraneous substance between the wood and the earth; in his opinion it would be better to enclose the lower ends in sand, stone, cinders, or other materials which would easily carry off the water supplied by the surrounding media.

When wood is converted and placed in a building, its durability may be greatly increased by covering it with a coating of paint, or other substance which will prevent the moisture of the atmosphere from obtaining access to it. But it is essential that the wood so covered should be free from sap or internal moisture, or the very perfection of the coating will be found to accelerate its decay. Care must be taken to prevent water from finding its way into the joints, and if the wood be exposed directly to the action of the sun, it should be painted of a colour able to reflect rather than to absorb heat. It is desirable that it should be planed before being painted, in order that the paint may be applied in an equal manner over the surface. It is important also to observe, that the moisture in the atmosphere not only affects the volume of the wood, but frequently alters the position of the fibres by producing a torsion analagous to that which may be observed in hygrometric cords.

Of late years the processes of Kyanizing, creosoting, and immersing, timber in solutions of mineral salts, have been applied with various success for preserving it from rot, and the attacks of worms or ants. Of these, Kyanizing, which employs a solution of deutochloride of mercury, appears to be most satisfactory; and among some striking illustrations of its results may be cited the fence of the Regent's Park; the posts of which were inserted in the ground, without being painted, at least 18 years since, and remain at the present day in very tolerable condition. For railways, and harbour works, English engineers appear to prefer the system of creosoting, or immersing the timber in the rough oil of tar, until it has absorbed at least 7 or 8 lb. per cubic foot. The difficulty of injecting so large a quantity of oil is overcome by exhausting the sap and moisture from the wood in vacuo, and then forcing in the oil under great pressure; a species of artificial drying is, however, frequently necessary, and indeed the success of this process appears to depend entirely upon the extent to which the original moisture is withdrawn. Both corrosive sublimate, and oil of tar, are capable of resisting the causes of decay communicated by the atmosphere, and the latter is said to be an effectual preservative against the attacks of boring animals; but it is to be feared that the ordinary manner of applying them does not ensure their penetration to a sufficient depth to attain the objects desired. The use of the sulphate of copper, and of the other metallic salts has hitherto been unsuccessful.

In the bent timber bridges which have been constructed on some of the recent lines of railway, although every ordinary precaution was taken in selecting the timber, immersing it in solutions of the metallic salts, and in painting it when in place, the wet rot has exhibited itself in so many instances as to render it almost necessary to abandon a system which appeared to have many recommendations. It is however, to be observed that these bridges decayed solely because their elasticity caused them to yield upon the passage of every train. The play thus produced caused the joints to open; and moisture, furnished by rain or the condensation of vapour, found its way into the interior of the beams. The failure of the bent timber ribs in such situations does not, therefore, in any manner affect the propriety of using that construction on more suitable occasions. A valuable lesson is, however, to be learnt from the above fact, viz., that it is difficult, if not impossible, to protect complicated systems of carpentry from the effects of the atmosphere, when exposed to the occasional action of heavy loads able to produce a disturbance of their main parts.

In the theatre at Munich a soluble glass was applied to the woodwork and scenery for the purpose of preserving, and, as far as possible, rendering them incombustible. This glass was in fact a solution of free silica in caustic alkali; and if the wood was properly seasoned, there can be no doubt of the value of the application, especially if it was injected under pressure. Professor Way's researches into the silica beds of the lower chalk prove that a solution of this nature could be obtained easily and economically; and the advantages it offers certainly render its application desirable.

The action of the atmosphere upon metals is even more complicated than that which takes place upon stones, because the electro-chemical changes are more efficient, and the metallic bases are susceptible of combining with a greater number of gases than the earthy bases or the metalloids. In building operations the metals commonly used are iron, lead, copper, tin, zinc, with the mixed metals, brass or bronze, and to them we will confine our attention.

Iron, whether cast or wrought, becomes rusted on exposure to the air or water under certain conditions; that is to say, the outer portions of the metal are converted into a hydrous oxide, and can be detached in scales, or flakes. Many systems have been proposed to obviate the danger and many substances applied to correct the evil arising from this cause, full information concerning which is contained in Mr. Robert Mallet's papers in the Transactions of the British Association for the Advancement of Science. His experiments appear to show that gas tar applied hot is the most efficacious for iron work exposed to cold water; and that a coating of caoutchouc varnish resists the longest in hot water; but that neither of them can be considered a durable defence. Cases cited by M. Vicat are within the knowledge of every architect who has examined this class of phenomena, which prove that in some waters, as in some positions in the open air, iron work, totally unprotected, will last an indefinite period. These exceptions are, nevertheless, so rare, and the destruction of iron unprotected is generally so rapid, both in air and in water, that constant care and attention are required to guard against the destructive tendencies of those agents. If iron work be exposed to the air in positions which render the renewal of the latter difficult, and at the same time retain it in a marked degree of dryness, the iron will become covered with a coat of rust, through which the atmosphere cannot penetrate to attack the metal beneath. If the water, in which iron is immersed, contains a very small portion of some of the earthy salts, the decomposition will take place slowly. But it is necessary to observe that these remarks only apply to iron of considerable dimensions: small wires decay rapidly on exposure to either of these causes of disintegration.

Should iron, however, be exposed to confined air in damp positions, the decay attains its maximum. Carbonic acid gas contributes much to this, for, under its influence, iron passes (to use the words of Vicat) into the state of the carbonate of protoxide, which, absorbing fresh doses of oxygen, transforms itself into a hydrated peroxide. It is indeed generally considered that oxidation cannot take place to a dangerous extent unless carbonic acid be present; and it is precisely for this reason that iron, bedded in fresh masonry or concrete, resists the action of the air, because either the mortar absorbs the carbonic gas, which has a greater affinity for lime than it has for iron, or the masonry is sufficiently dense to protect the iron from contact with the atmosphere. The investigations of the Commission in 1850, respecting the fall of the bridge over the Maine, at Angers (recorded in the Annales des Ponts et Chaussées, vol. 29, 2nd series, page 394) appear to prove that the preservative action of the lime depends upon its being in immediate contact with the iron, and that if a space, however small, be left between the two substances, moisture will insinuate itself, and in course of time produce active oxidation. Vicat, in a note inserted in the Annales des Ponts et Chaussées for May and June, 1853, appears to doubt the correctness of this conclusion, but even he admits that the preservative action of the lime depends upon its absorption of carbonic acid gas, and that directly its hardening ceases, it loses its power of resisting the action of the atmosphere on the iron.

M. Payen found that the addition of very small quantities of the sub-carbonate of potassa, or of sodium, to pure water, was sufficient to render it innocuous either to cast or wrought iron, and the same property existed in nearly all alkaline solutions; whilst, on the contrary, the addition of a small quantity of the chloride of sodium rendered the process of oxidation much more rapid than it usually is in pure water. It appears that grey cast iron is more susceptible of destruction by oxidation than either wrought-iron or white cast-iron; and that wrought-iron resists the action of sea water more effectually than cast. It is a peculiar fact connected with this subject, that iron, exposed to frequent displacements, shocks, or vibrations, is less affected by oxidation than when it remains constantly in one place, without disturbance. Thus, anchors in constant use are less exposed to rust than those preserved in the magazine; the rails of the main-lines of railroads are less corroded than those in the sidings; iron steamers rust less when in active service than when in dock. But the positions in which iron decomposes with the greatest rapidity, are those where it is fixed, and alternately exposed to the air and immersed in sea water. Ammoniacal and sulphuric acid gas exercise very serious effects upon the durability of cast and wrought iron. It is important, therefore, to prevent their use, either in urinals, roofs over gas works, or the engine sheds of railway stations. There appears also to be some danger in using iron in contact with sulphate of lime, or in fact under any circumstances where it is likely to take up sulphuric acid gas, for which it has great affinity.

The galvanisation of iron, which, as generally practised, consists in forming a superficial coating upon the metal by immersing it in melted zinc, appears to constitute an efficient protection, so long as the iron is covered. The contact with the zinc brings the iron into an electro-negative state, and it is known that, so long as the latter prevails, there is little tendency on the part of the iron to combine with oxygen. From a series of experiments made at Brest between the years 1842 and 1851, (see note by M. Dehargne, Annales des Ponts et Chaussées, 1851) it appears that the zincing process does not, in any sensible degree, affect the tenacity or the ductility of the iron; but it is important to secure the protected metal from any shocks, or friction, likely to remove the surface.

Zinc, when exposed to the atmosphere in its ordinary state, becomes rapidly covered by a whitish efflorescence, which adheres to the metal, and forms, as it were, a species of varnish, capable of arresting any further decay. This efflorescence is considered to be a carbonate of zinc; but if the atmosphere should contain any sulphuric or hydrochloric acid (as in London and in the immediate neighbourhood of the sea), compounds are formed of a nature to compromise the solidity of the metal. In the purer atmosphere of Paris, and other continental towns, where wood is the ordinary fuel, and to which the sea air does not reach, zinc is employed successfully for roofing purposes; in London, and on the sea shore, its durability is very limited; and at all times its combustibility must be a serious objection to its use externally.

Copper resists the action of the atmosphere very successfully, and the presence of some of the gases mentioned above does not seem to affect it in any material degree. A film of oxide, or carbonate of copper, is rapidly formed over the surface, and secures the metal from further decay. It is found, however, that a mixed metal or bronze, made of copper and zinc, resists the influence of the atmosphere, and sea water, more successfully than pure copper alone.

Lead undergoes little change upon exposure either to air or water, especially when the latter contains small proportions of the salts of lime. According to Brande, when lead is kept in distilled water, to which air has access, small crystalline scales of oxide of lead are formed, a portion of which dissolves in the water, and is again slowly precipitated in the form of a carbonate. Soft water also, or that without the salts of lime, appears to be more likely to attack lead than that containing lime. The use of lead for cisterns must, therefore, be regulated by the nature of the water to be preserved in them; for all roofing or analagous purposes, there do not appear to exist any philosophical reasons to object to the use of this metal, or to limit its application to any particular districts.

A very important remark with respect to the use of metals must be made; viz., that when two of them are used in contact in positions where moisture, in any form, has access to them, a species of galvanic action is established, which causes them to decay with great rapidity. Illustrations of this may be observed in iron railings, when the bars are secured to the stone curb with lead, and the decay is most evident when the iron is of the best and most malleable description. A similar phenomenon may also be observed when copper, or bronze, is in contact with iron in sea water; though the iron decays rapidly, it appears to exercise a protective influence upon the copper.

The laws of electricity developed by the contact of two metals with a liquid containing a solution of an alkaline salt, are treated at some length in vol. 1, 'Gmelin's Hand-book of Chemistry,' p. 364. From this authority it appears that zinc, tin, and iron, protect copper in sea water. Zinc protects iron and tin plate, but it is not so effective for the defence of iron in sea water if air be present, and it is itself rapidly corroded when used with iron in the sea. In that element tinned iron decays unequally, the iron oxidating whilst the tin remains intact; and it appears that the decay, superinduced by the contact with tin, is greater than that resulting from the contact with copper. The corrosion of copper may be considerably retarded by fastening to it at several points pieces of cast or wrought iron, or of zinc, when sulphuretted hydrogen is likely to be present. Water containing bicarbonate of lime will deposit the lime if placed in contact with zinc and copper, the deposit taking place upon the copper; and when water of this description flows through leaden pipes, the carbonate of lime is deposited at the solder joints (composed of an alloy of tin and lead), on the brass cocks, and on any piece of iron or silver which may be introduced. The inconvenience arising from the stoppage thus produced may be obviated by the use of a lateral pipe fitted to the main at intervals, and furnished with plugs of a metal likely to deposit the calcareous matter, which can thus be withdrawn from the main.

The class of atmospheric influences included under the term medial action in the early part of this paper acts more powerfully upon some of the metals than on other building materials. Thus the tenacity of the former increases or diminishes with the temperature, and the electrical state of the atmosphere frequently modifies their powers of resistance. The most elaborate observations which have been made on this subject have been exclusively connected with the changes superinduced in iron, perhaps on account of its more general employment. They are to be found in Mr. Fairbairn's 'Treatise on the Application of Cast and Wrought Iron,' and in a communication by M. Wertheim to the Annales des Chimie et Physique (3rd series, vol. 12) from both of which it appears that the coefficient of resistance of the metal diminishes with an increase of temperature in a more rapid proportion than the dilatation. Below and near the freezing point cast-iron becomes exceedingly brittle, but between about 40° and about 120° Fahr. there does not appear to be much change in its elastic powers. The lineal dilatation of metals, and indeed of all building materials, requires to be carefully attended to in all constructions. Very useful tables upon the subject are to be found in Weale's 'Engineers' and Contractors' Pocket-book for 1854,' and in the 'Annuaire du Bureau des Longitudes.'

Glass under certain circumstances is affected by the action of the atmosphere, for the potash and soda employed in its manufacture are susceptible of being decomposed and removed by the moisture, or the gases contained in it; and according to Gmelin the decomposition takes place with greater ease in proportion as the glass is richer in the above-named alkalies, and the temperature of the moisture or water is higher. Glass in which there is a deficiency of silica is exposed to this description of decay, which may often be distinctly perceived in window glass, the alkali from which is gradually attracted (Knapp's 'Applied Chemistry,' vol. 2, p. 8) by atmospheric moisture and washed away, whilst a thin layer of silica or silicate of lime remains upon the surface and exhibits a play of prismatic colours. An analagous decomposition takes place in the glass used in stables in consequence of the ammoniacal gases; and according to Knapp, glass containing oxide of lead is liable to blacken on exposure to air impregnated with sulphuretted hydrogen.

The chemical changes produced in oleaginous and metallic pigments by the gases contained in the atmosphere are subjects of the highest importance to the decorative artist, but as the examination of them would extend this paper too far beyond the usual limits, I must refer the architect who would investigate them to the researches of M. Chevreul in the Memoires de l'Acadèmie des Sciences, 1850 (vol. 22). I may, however, state that M. Chevreul attributes the solidification of paints to the oils they contain absorbing oxygen from the atmosphere, and states that the driers act by facilitating the power of absorption. The various substances introduced to communicate colour appear to affect the rate of absorption; and the surfaces upon which the paints are applied have an influence independent of their mere capacity of taking up moisture. The varieties in the rates of drying upon the several woods and metals, experimented upon by M. Chevreul, indicate some peculiar differences in this respect, which have not hitherto been sufficiently examined.

## APPARATUS FOR MEASURING AND GOVERNING THE FLOW OF WATER AND OTHER LIQUIDS.

THOMAS TAYLOR, *Patentee*, November 15, 1852.

(*With Engravings, Plate* XXX.)

THESE improvements consist, firstly, in admitting liquids to meters through an orifice or orifices capable of expansion and contraction, so as to possess varying areas, for the purpose of rendering the action of the measuring apparatus more sensitive when a comparatively small quantity of the fluid is drawn off. Secondly, in an arrangement and construction of valve for governing the flow of fluids,—one point of novelty of which consists in forming the valve of metal, covered with gutta-percha, and fitting it to its seat by applying the gutta-percha in a plastic state; and another peculiar feature is the method by which a valve is opened and closed.

In Plate XXX., fig. 1 is a plan, with the casing in section, of a meter; fig. 2, is a vertical section of the same; and fig. 3, is a detached view of one of the orifices by which the fluid is admitted,—the parts being shown in two positions. The principle by which the measurement is effected, is the rotation of a wheel provided with vanes, against which the fluid is caused to impinge, so as to effect its revolution. It is evident that, however accurate the construction, a force of fluid, beyond a certain amount, must impinge upon the vaned wheel, before a rotation can be effected, and consequently before a measurement will be indicated. Before this necessary action, therefore, can be obtained, a certain amount of fluid may be drawn off, without producing any effect; and although this quantity may be very small in reference to the construction of meter, it is yet desirable to reduce it; this is effected by causing the orifices to contract or expand by a self-acting process, according as less or more fluid is allowed to pass from the meter. In the figures above referred to, the rotatory drum or wheel *a*, is mounted upon a shaft within a casing *b*,—the fluid to be measured passing inwards through nozzles *c*, connected with passages; and to these nozzles the improved apparatus is attached. The passage *d*, by which the fluid enters, is provided with a valve or shutter *e*, turning upon a centre at *f*; and to this centre is attached a vane *g*, extending towards the centre of the drum *a*. The axle of the valve *e*, also carries an eccentric pulley *h*, to which is connected one end of an elastic band *i*,—its other extremity, after passing over a pulley *j*, being attached to an arm *k*, which also carries the pulley *j*. By the elastic force, therefore, of this band, the valve *e*, when not forced outward, is kept to its seat within the nozzle *c*, so as to close the aperture, with the exception of a small orifice formed by a pipe *l*; which pipe extends outwards so as to deliver a stream of fluid at a point almost in contact with the vanes of the drum *a*. Suppose the parts to be in the position shown at fig. 3, and that a small quantity of fluid be drawn from the meter,—to supply the place of this, a like quantity must pass therein; this will take place through the small orifice of the pipe *l*,—the valve being kept to its seat by the elastic band *i*; and as the pressure is thus concentrated, sufficient force will be exerted to turn the drum *a*, upon its axis, and consequently register the quantity of fluid used. The drum *a*, having been thus put in motion, and a more considerable quantity being now drawn off, a circular stream of the fluid will take place, and by acting against the blade *g*, will turn the valve *e*, upon its centre, so as to open the full area of the passage *d*, as shown in dots at fig. 3; and in order to provide for this motion, a slot *m*, is formed in the nozzle *c*, through which the pipe *l*, may pass.

The second improvement is shown as applied to a "stand-pipe," in the vertical section, fig. 4. To the upper part of the pipe is adapted a box *a*, within which is placed a valve *b*, turning upon a joint at *c*: this valve is formed of metal, to which a piece of gutta-percha *d*, is affixed, and having been made plastic by heat, is moulded into the seat *e*. To the metal plate of the valve is jointed a link *f*, connected to a short lever *g*, fixed to an axle *h*, one end of which passes through the box *a*, and is there provided with a handle *i*. By turning this, therefore, the valve will be lifted from its seat, and the fluid allowed to pass through the orifice *j*,—the pressure subsequently returning it to the closed position.

*Claims.*—First,—the adaptation of apparatus capable of contracting and enlarging the induction orifice or orifices by the action of the fluid to be measured. Second,—forming a valve by moulding gutta-percha in a plastic state on to the seat thereof.

## IMPROVED WATER FILTER.

(*With Engravings, Plate* XXX.)

THE filter that forms the subject of the present paper,—the original invention of Mr. James Forster of Liverpool,—consists of a small apparatus attached to the cock from which the supply of water is drawn, the water being passed through the filter at the time of discharge.

The construction of the filter is shown in Plate XXX., in which fig. 5 is a vertical, and fig. 6 a horizontal, section of a plate; the filtering material consists of a hollow stone cylinder A A, about 4 inches diameter, 7 inches long, and ¾-inch thick, with a rounded close end below, and cemented at top into a groove in the cast-iron cap B B. This cap has a brass delivery pipe C, communicating with the interior of the stone cylinder, and bent to prevent the escape of water when not required.

D D, is a cast-iron base into which the supply pipe and cock E, is fixed; and a cylindrical tin casing F F, is fixed in a groove in the cap and base, and is secured by the frame and screw G G, connected by two side pins to the base, and screwed down upon the centre of the cap, making the joints water-tight.

When the supply cock E, is opened, the water fills the outer casing, filters through the stone cylinder, and is discharged by the delivery pipe C; the stone being a fine-grained pure sandstone, suitable for the purpose, retains all the impurities of the water upon the outer surface, and delivers the water in a pure, clear stream. The action of the filter is an imitation of a pure spring, issuing from a sandstone rock, which may be considered as a natural pressure-filter.

There is an important advantage in filtering water immediately before using it, as its freshness is then insured; but this is liable to be impaired if the water is filtered previously, and stored up until drawn off for use. With the use of such a filter, whatever may be the state of the water in the mains, from the opening of them for repairs and other causes, a supply of pure water is always obtained for use.

The practical value of a filter is greatly influenced by the facility with which it can be kept clean; and in the present filter this object has been more particularly aimed at: the process of cleaning it is very simple, and can be effected by any person in a few minutes. The filter may work for some months before requiring to be cleaned; the general plan is to clean the filter when the water is found not to flow freely from it.

The top screw G, is then loosened and the frame turned on one side, which allows the iron cap with the stone cylinder attached to be lifted out of the casing; the outer surface of the stone being scrubbed with a piece of sandstone, and well washed, removes all the deposit, and leaves it as clean and ready for use as at first. Previous to loosening the top screw, the small screw-plug H, is opened at the bottom to let the water out of the casing; and the screw I, opened to let in air.

The deposit from impurities from the water is found to take place entirely on the outer surface of the stone, and penetrates only a very slight depth into the stone, so that it can be readily and completely cleaned by scrubbing the surface with sandstone.

When the water to be filtered is very dirty, the stone cylinder is encased in a flannel bag, which prevents the larger portion of the deposit from lodging on the stone, and saves trouble in cleaning, as well as enabling the filter to continue in action longer. In cases where the water is somewhat infected, by being exposed to any decaying organic matter, some animal charcoal is placed in a bag, or a flat perforated box, in the bottom of the filter, so that the water is purified by passing through the charcoal before entering the filtering stone.

These filters are applicable for general domestic use, as the pressure required for filtering is so small, that any house having water laid on from water-works, or even a rain-water cistern at a moderate height, would have sufficient pressure for working this filter; it is working at Lambeth, with a pressure of only 9 feet, and at the Board of Health, under about 15 feet head. The small size of the filter, and its convenience of application, make it suitable for any situation.

It appears also from experiment, that in the cases where the water is soft, and has become impregnated with carbonate of lead, from contact with leaden pipes or cisterns, this is entirely separated by the stone filter—an important sanitary advantage.

## APPARATUS FOR MEASURING GAS, WATER, AND OTHER FLUIDS.

George Hanson & David Chadwick, *Patentees*, March 31, 1853.

(*With Engravings, Plate* XXX.)

This invention consists in the use of a flexible tube or bag, into one end of which gas, water, or other fluid to be measured, enters from the main or other source, and there exerting its force against a roller or rollers placed upon the tube or bag, causes the said roller or rollers to revolve and discharge from the other end thereof the fluid which had previously entered. Each revolution, therefore, will represent a certain amount of fluid which has passed through the apparatus, and it may be registered by means of any ordinary count connected to the roller or rollers. If used for obtaining motive power, motion may be communicated in any ordinary manner.

In figs. 7 and 8 (Plate XXX.) *a*, represents a circular-flattened tube of india-rubber or other flexible material, the two ends *b*, *c*, being open; and upon this is placed a roller, so that the line *d e*, may represent that part of its periphery which rests upon the bag or tube, the said roller turning upon a centre at *f*. By such an arrangement two chambers A, B, will be formed, the one having an inlet at *b*, and the other an outlet at *c*. If a fluid be now passed through the orifice *b*, with sufficient pressure, the roller will be caused to revolve around the centre *f*, in the direction of the arrow, enlarging the chamber A, which will continue to be filled by the fluid. Upon the line *d e*, having arrived coincident with that of the aperture *c*, that orifice will be closed, and the whole tube be charged with fluid; but, the pressure being continued, the roller will be forced onward beyond the end *c*, of the tube, which will then be at liberty to open and discharge its contents, the roller passing onward to be propelled as before. One revolution has therefore represented the amount of fluid, or nearly so, necessary to fill the tube; and if such rotations, as they follow each other, be registered by any ordinary wheel-work, the quantity of fluid discharged may be ascertained.

The apparatus employed in practice as a water-meter is shown in fig. 9, a cross section of the meter, and fig. 10 a horizontal section thereof. The tube or bag, formed of india-rubber or other flexible material is shown at *a*, *a*, resting upon a metal plate *b*, which is slightly concave and cut from its outward circumbrance towards the centre; one end thus formed being bent upwards so as to constitute a spiral surface, the object of which is to bring the discharge end *c*, of the tube *a*, above that of the inlet end *d*; the former of these opens direct into a metal casing *e*, which incloses the whole apparatus. The metal plate *b*, rests upon a division-plate *f*, and its helical form is supported by occasional pieces situate between the two. The end of the tube *a*, at which the fluid enters, is closed water-tight, the passage for the fluid being formed by an orifice *g*, cut through the under fold of the bag or tube; through this orifice a metal socket passes, provided with a flange, which rests upon the interior surface of the tube, and upon which it is drawn down so as to make a tight joint by a hollow screw-nut *h*. The tube or bag is kept in its central position by a ring of metal *q*, screwed to the plate *b*. The roller which rests upon the tube is shown at *i*, provided with an axis placed within a slot formed in an upright shaft *j*. in which slot it is retained by two pins or screws, but remains at liberty to play up or down in the slot. The shaft *j*, turns on a stop *k*, at bottom, and within a cross rail *l*, at top; and upon it is mounted a circular disc *m*, the surface of which is forced upon the roller *i*, by a spiral spring *n*, the fixed abutment of which is against the cross-rail *l*. The object of this arrangement is to secure a pressure on the tube sufficient for preventing the fluid in the bag from passing under the roller. The fluid entering through the pipe *o*, passes into the lower chamber *e**, of the casing, and thence through a wire-gauze *r*, into the tube or bag *a*, through the orifice *g*, causing the roller, as before described in reference to figs. 7 and 8, to revolve, the water admitted at the previous revolution escaping by the open end *c*, into the casing *e*, from which it may be withdrawn by the pipe *p*. The revolutions of the shaft *j*, may be registered by any ordinary count; and as that part of the apparatus embraces no feature of novelty, it is not shown in the accompanying drawings.

The arrangement of the apparatus for measuring gas is the same as that of the water-meter, but of lighter construction, and formed of suitable materials for resisting the chemical action of the substance to be measured, the pressure of the gas being equalised by any known or suitable arrangement of regulating apparatus. In employing this apparatus as a motive-power engine, the only difference necessary will be to construct the machine of proper strength: motion, in this instance, may be taken from the shaft *j*, in any ordinary manner.

## THE PHŒNIX THEATRE AND BUILDINGS ON BROADWAY, NEW YORK.*

A walk up Broadway at the present time is replete with suggestion in regard to our city's growth. There is hardly a block between the Battery and Union-square that is not undergoing alterations of some kind or other. A man who should now walk it for the first time in five years would not recognise the street from anything in its former appearance which might still live in his memory. Old frame buildings have given way to marble halls, wider streets stretch out from it on every side, and the spirit of improvement is still borne onward with railroad speed. We will give a sketch of the various changes now being made along this street.

The first of importance is on the corner of Broadway and Cortlandt streets. This tract of ground, 55 by 100 feet, is being built upon by Mr. P. Gilsey. Upon it formerly stood small frame buildings, used as segar shops, card-engraving, and match and blacking stores. Mr. Gilsey, we understand, holds a lease upon this property for twenty years, at a rent of 8000 dols. per annum, for which he has refused 100,000 dols. The new building here is to be of iron, and is intended to be one of the finest ornaments in the city.

Progressing up, the next vacant space is the lot whereon stood the late store of W. T. Jennings and Co., destroyed by fire, well remembered on account of the sad calamity attending it. Upon this, we understand, is shortly to be erected a fine store.

On the corner of Warren-street is a new building just completed, built after the style of Stewart's dry goods store, and of the same material.

The next improvement is on the corner of Chambers-street, on the old site of Tiffany, Young, and Ellis. Here is to be erected an elegant structure for the Central Bank adjoining the Chemical. The size of this lot is 25 by 68 feet, and the new structure is to have a beautiful front of ornamented marble, and will cost not less than 100,000 dols. When this is completed, together with Stewart's, the Irving House, the Chemical Bank building, and the famous stores on Chambers-street, it will give to this part of the city an imposing appearance. The old building is already demolished, and the foundation of the new one is about being laid.

Now proceeding as high as Canal-street, our admiration is again taxed on behalf of the Brandreth building, standing on this corner, but not quite completed. The dimensions of these premises are 37 feet on Broadway, 128 feet on Canal, 126 feet on Lispenard, and 56 feet in the rear, giving the whole a triangular shape. It will be perceived that an architect upon such a shaped lot must work at a great disadvantage. Notwithstanding this, a splendid edifice has been erected here six stories high, having a brown stone exterior, and challenging competition with the finest of Broadway's decorations. It is owned by Dr. Brandreth, and will not cost short of 160,000 dols. It is intended for stores.

On the next block above, Mr. Dibblee is making great alterations. Two stores are being thrown into one, the building to be very neatly finished, and the premises inside to be gorgeously fitted up—in short, to be made a palace of mirrors for the hair-dressing business. Liberality in expenditure is to make this another of Broadway's richest attractions.

On the corner of Howard-street extensive improvements are being made on the former building, fitting it up for insurance companies and offices.

The next of the new buildings is the Institution for the Savings of the Merchants' Clerks, directly opposite the St. Nicholas. This bank started with rooms in the old Clinton Hall, on the corner of Beekman and Nassau, but the moving of the Mercantile Library Association compelled its directors to look for new quarters. A lot, 25 feet by 100, directly in front of the middle entrance of the St. Nicholas Hotel, was purchased, and upon it has just been completed a splendid white marble edifice, four stories high. Adjoining this, reaching to the corner of Spring-street, are five lots, which are now being cleared for the

* From the 'New York Herald.'

erection of some more giant buildings for stores. Upon these lots have heretofore stood small two-story brick houses, only a few years ago private residences, and very lately occupied as tailor shops and retail fancy stores. They are all now nearly levelled with the ground, and soon in their place, no doubt, will stand buildings worthy of association with the St. Nicholas.

Continuing our way upward, on the next block, and on the same side of the street with the the last-mentioned changes, stands, adjoining Dr. Chapin's church, a stately and highly-ornamental building, just finished for Tiffany, Young, and Co., at a cost of near 50,000 dols. This is of white marble, and five stories high. Adjoining this edifice, three lots are cleared away, the substance of the former buildings being piled along the sidewalk. Upon these, we understand, Captain French is about to erect two handsome marble stores, equal to anything that stands along this thoroughfare. The three great hotels, the Metropolitan, the Prescott, and the St. Nicholas, all within call of each other, associated with these great improvements when finished, will make this spot the great point of Broadway.

We are next intercepted in our walk on the succeeding block, at the corner of Houston-street. Here three new stores have been marked out, two of which are but just finished, and the other is now rapidly approaching completion. The first of these is a large brown stone building, six stories high, and that adjoining is of white marble, five stories high; the corner building is on a triangular piece of ground, of about half the dimensions of a lot cut diagonally. A brick building is going up here with window caps similar to those of the Prescott House. These give the premises a highly-ornamented appearance, and the three buildings, when completed, will be well worthy the association with their majestic and august neighbours.

On the corner of Bleecker-street, masons and carpenters are busily at work erecting two buildings for stores; both of these are to be of brick, and six stories high. They have already gone up two stories, and will soon be completed.

The next spot that courts our attention is the site of the late Metropolitan Hall and Lafarge Hotel, destroyed by fire last winter. But few of our citizens are aware that here is being built that which bids fair to rival all the other theatrical establishments in the metropolis. Mr. J. M. Trimble, the well-known architect, who designed and built the Broadway theatre (the Tripler Hall, as it was first called), and many others of the first buildings in the city, is now upon this spot, striving to outdo all his former triumphs. The friends of Wright, Lanier, and Co., the proprietors of the Lafarge House at the time of its destruction, failing to re-erect for them another hotel on the same spot, Mr. Lafarge, the owner of the property, resolved to raise on it a theatre and stores that should defy competition. This work was entrusted to Mr. Trimble, who is now energetically driving it on. The plan is, to build stores on the Broadway side, and the theatre on Mercer-street. One of the stores, six stories high, is now externally completed, with a white marble front. Five others are to be erected by the side of this, all of them of the same height and material. Each of these is 25 feet wide and 85 feet deep.

In the rear of these stores is building a new theatre, to be named the Phœnix Theatre, or the Metropolitan Opera House. This is the same dimensions as the old Metropolitan Hall, 100 by 150 feet, and when completed will be the largest establishment of the kind in the country. The rear of the theatre is where was the stage of the Metropolitan Hall, and the stage of the new establishment is in the place of the old entrance, reversing the former and the present building end for end. One of the important features of the new building is the many exits and entrances, by which the entire audience assembled within its walls, in case of fire, can be emptied into the streets at a moment's warning. The main entrance is from Broadway. One of the lots adjoining the Bond-street House has been reserved for this. On the Mercer-street side there are eight different doorways for egress, so that a sudden rush from the theatre would find no check till it reached the street. The parquette connects with the first tier of boxes similar to that of the Broadway Theatre when first built. The seats of the parquette have a gradual rise from the stage, and are so near the level of the stage that every action upon it can be seen by the entire audience. Above the parquette will be three tiers of boxes, each tier 15 feet above the other, and every tier to be finished and furnished in the neatest, strongest, and richest style. On each side of the stage rise two rows of private boxes, in all ten, and every one of them large, and having a full view of the stage. The lowest of these private boxes are on a level with the parquette, and at each end of the orchestra-seats, and are large enough to seat a party of thirty persons. They are intended for private parties who frequently wish to visit the theatre and sit by themselves. Here they are accommodated and have every portion of the stage before them.

This theatre, when completed, will seat comfortably 3500 people, and in case of any great attraction 4500 people can be accommodated. The height from parquette to dome is 64 feet. The stage, in keeping with the size of the house, is the largest in the country, the width of the drop curtain being 60 feet—20 feet wider than that of the Broadway Theatre.

On the second floor, or the first floor over the Broadway entrance, will be a large, sumptuous saloon for dinner parties, suppers, balls, or refreshments. These gorgeous halls will connect with the second circle of the theatre, and from almost every portion of them the stage can be seen. By this it is intended that in warm, sultry weather a party may, if they choose, sit at a table in the saloon, and, while enjoying their ice creams, at the same time witness all that takes place upon the stage. The inner wall of the theatre being on the second tier, wholly arched around the entire circle, opens the stage to view from the refreshment saloons, as we have just stated. These saloons, it is estimated, will be large enough to seat at a time about 1000 persons.

Between the inner and the outer walls of the theatre is a lobby 30 feet wide, making a grand place for a promenade between the plays and acts, or when one is tired of the performance. The orchestra box makes the entire circle of the stage in front of the parquette, and will be large enough to seat one hundred performers—about five times as large as the orchestra of any of our other theatres.

This theatre is to be painted and decorated by Guiseppe Guidicini, a well-known artist both in this country and Europe. As Mr. Trimble has spared no pains to make this building the first in the land, so Mr. Guidicini is resolved to make it surpass every other in the splendour of its decorations.

The theatre and the stores now being erected upon these premises will together cost something over 300,000 dols. It is intended to have them all finished by the 1st October next, and Mr. Trimble says the theatre will be ready to open by the 1st September next. At the present time one of the stores, as we have said, is externally completed, and the others and the theatre have been raised to the second story, and the work is going bravely on. This theatre, when completed, bids fair to be unlike other establishments of the kind that are now building or already in full blast, fit only for a picture gallery, or circus, pantomime, and rope dancing, but the Phœnix Theatre, while it will answer for all these purposes, will in addition to them be unequalled as a home for the drama, opera, or song.

This completes the list of the main improvements now going up in the Broadway. In addition to those we have enumerated, there are a few alterations in buildings taking place, but none of them calculated to have much effect in changing the appearance of this street.

## REVIEWS.

*Healthy Homes, and How to Make Them.* By WILLIAM BARDWELL, Architect.

It is a good sign of the times, that from all quarters a strenuous crusade is being waged against the crying sanitary evils of the day, whose name is legion, and whose malignant powers of spreading death and disease seem now, though somewhat tardily, to have aroused the lethargic energies of men, professional and in authority, as well as the masses of the public, who, in these matters, must ever be dependent upon those whose duty it ought to be to search out the pestilent defects of our social system, and provide the necessary remedies and means for their removal. The day would seem to have arrived when almost every nuisance has its own particular opponents determined to effect its annihilation. The vexed question of sewage and drainage is in a fair way to be solved, in spite of the contrariety of opinions respecting it, and the party warfare between the Board of Health and the Commissioners of Sewers. The suppression of intramural grave-yards may be expected after another visitation of cholera has revived the dying activity of corporations and parochial authorities. The squalid, ill-drained, ill-ventilated, and demoralising dwellings or styes of the labouring classes are fast disappearing in favour of well-built, salubrious lodging-houses and working-men's houses, erected by the Metropolitan Association and similar institutions in all parts of the country. The Smoke Act, it is to be hoped, will to a great extent prevent our lungs and buildings from being coated with a deposit of carbon. The waterwork companies are mostly endeavouring to supply a liquid less impregnated with mineral and animal impurities, by improved filtration, or by seeking purer sources of supply. Upon these and a host of minor evils, government commissions or private speculators sit almost daily; and though the axiom, "Trust not to partial care a general good," may be ordinarily the safest to follow, yet these questions may be safely left in the hands of those undertaking their solution, provided the public and the press continue their agitation until they are thoroughly and permanently disposed of.

Mr. Bardwell, despite the "crown of nobleness" which he plants upon his own head, and the self-commendation he lavishly bestows, has a fair title to be considered as by no means an idle agent in forwarding the successful accomplishment of a scheme of dwellings for labouring men, which meets most of the requirements of the case, and at the same time combines the advantages of efficiency and economy. If we still continue to build houses and cottages for the lower classes on the old plan of excluding as much air and light as possible, and carefully providing means to retain the vitiated gases and pernicious exhalations from crowded rooms and overflowing cesspools, it will not be because we are unavoidably ignorant of the necessary sanitary precautions and the laws that regulate the health of the human body (which will all be found in Mr. Bardwell's *brochure*), but because our wilful stupidity and inexcusable and mistaken mercenary calculations blind us from the real facts of the case.

Mr. Bardwell proves, without doubt, that it is as cheap almost in the first instance to erect houses, both small and great, in which the various and well-known evils of most structures of the day shall be avoided, and the poor man enabled to enjoy what are now wrongly-called "luxuries" of a comfortable dwelling, and learn to respect the abode he is compelled to select, instead of flying, as he not unwisely does, from the pestilential den the cupidity and short-sightedness of his landlord condemns him to inhabit. It is demonstrable that it would be more profitable to owners of land and builders, as well as a great benefit, even in a pecuniary sense, to the public in general, to provide clean, well-ventilated, properly-drained homes for working men; we are, therefore, not only robbing ourselves, but committing a great injustice to the lower classes by neglecting to do so. Our limited space will not allow us to do much more than glance at the mere index to contents of Mr. Bardwell's work, which professes to embrace every subject connected with social economy, whether it be the purification of the domestic atmosphere, the erection of fireproof buildings, or the destruction of the poor man's plague, a flea.

Mr. Bardwell, although he originates no novel Utopian sanitary system, or panacea for every evil that afflicts mankind, has taken the trouble to collect and practically apply the simple and common-sense remedies for them. With regard to the labours of the Society for Improving the Condition of the Labouring Classes, Mr. Bardwell says:—

"It is now become pretty well known, that to the larger buildings erected in various parts of the metropolis the superior artisans and their wives have many serious objections, greatly disliking the species of communism, and the apparent opportunity afforded to numerous parties of unkindly noticing their habits, or prying into their domestic economy. Their pride also revolts against the barrack-like appearance or character of these establishments, and they appear to consider themselves more at 'home' in the mean little dwellings of the back streets. So difficult is it to overcome long-established usages, or to engraft novelties upon national customs which have grown into necessities by the force of circumstances...... Hence it becomes a somewhat difficult matter to design the arrangement of sets of lodgings, to be let at a low rent, combining the means of cleanliness, decency, privacy, and comfort, with such an adequate amount of interest as will induce the capitalist to embark his money in the erection of these dwelllings."

In consideration of these excusable antipathies of labouring men, and the extension of the feeling that the amelioration of the condition of the working classes is the great economic question of the future, the idea of separate dwellings for every family found many supporters, amongst whom may be named His Royal Highness Prince Albert, and an association of gentlemen calling themselves the "Labourer's Friend Society." These last, some years ago, erected at Shooter's-hill a number of cottages from designs by Mr. Bardwell, in which the following principles were strictly adhered to:—

"That every dwellinghouse, on the floor containing its living-rooms, should be raised at least 18 inches above the general surface of the ground; that the chimneys should be placed in the interior walls; that a porch is indispensable; that the exterior walls should be hollow, so that the rooms might be cool in summer and warm in winter; that the roof should project, so as to throw off the rain-water from the walls; that there should be no valleys in the roof, to bring on decay; that the practicability of the economical application of fuel,—of the collecting, filtering, and preserving the water which falls on the roofs,—and of the collecting and economising the liquid and other manure produced in and about the dwelling,—should all be kept in view; that the smallest possible quantity of materials should be introduced, consistent with the durability and the accommodation required; and, as a consequence, that improved dwellings might be erected at a remunerative cost."

These cottages were erected at a cost of 115*l.* per pair; the outhouses 10*l.* per house; and the land (an acre and a quarter per house) 50*l.* an acre; and have paid an excellent per-centage on the first outlay.

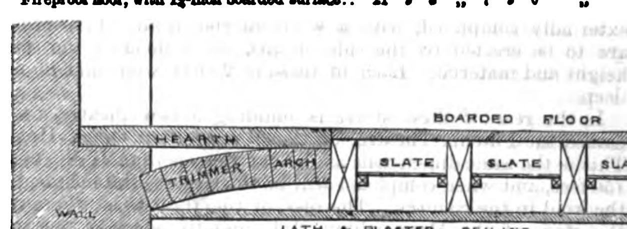
The French government has wisely employed legislative interference in the erection of "healthy homes" for workmen, and a sum of 10,000,000 francs has been devoted to their erection; of which 3,892,082 francs have been granted in subventions to contractors, for which accommodation has been provided for 5300 unmarried people and 800 married workmen in Paris, for 150 unmarried men at Marseilles, and for 300 couples at Mulhouse.

Mr. Bardwell illustrates the beneficial effects resulting from the application of the Lodging Houses Act in Wolverhampton, and the efficacy of sanitary provisions in preventing the recurrence of epidemic diseases, as exhibited in the recent improvements in Lambeth-square, in conformity with the measures set forth in the Health of Towns Act. He further advocates the somewhat impracticable idea of converting the house-tops of London into "cultivated gardens," filling the air with perfumes, and wafting health in every breeze. This he would do by making all roofs flat and fireproof, as exemplified in the flat roofs placed upon Buckingham Palace by George IV., and the plans of Mr. Frost and others; but this hygienic improvement was negatived by what Mr. Bardwell calls the "twaddle about mediæval architecture," which, he says, has caused us to retrograde to the "principles and practices of the dark ages."

With regard to fireproof floors, Mr. Bardwell estimates the difference in cost between an ordinary timber and plank flooring and one rendered fireproof by the adoption of Messrs. Fox and Barrett's (or similar) plans, to be nearly as under:—

Room, 18 feet long, 16 feet wide:—

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Timber floor, of the *commonest* description.... | £15 | 5 | 7 | or £5 | 6 | 0 | per square |
| Timber floor, of a superior description ...... | 20 | 9 | 1 | ,, 7 | 2 | 0 | ,, |
| Fireproof floor, with cement surface ........ | 17 | 3 | 0 | ,, 5 | 19 | 0 | ,, |
| Fireproof floor, with 1-inch boarded surface.. | 20 | 9 | 3 | ,, 7 | 2 | 0 | ,, |
| Fireproof floor, with 1½-inch boarded surface.. | 21 | 9 | 5 | ,, 7 | 9 | 0 | ,, |



The variations in length of cast-iron girders from alterations in the temperatures of rooms is so infinitesimally small that they need not be considered in practice. Where, however, the use of iron girders is impracticable, Mr. Bardwell has shown in the annexed engraving a method to be substituted for Hartley's patented plan of interposing sheet-iron or copper or tin between the flooring-boards and the joists. Mr. Bardwell proposes to place slates resting upon fillets between the timber flooring joists, laying them with putty or Johns' liquid cement, thus forming a close joint, and preventing all upward currents of air. When the fillets and slates are placed immediately beneath the boarded floor, and jointed in the same manner, a perfectly fireproof flooring is formed on the same principle as Hartley's fire-plates.

Mr. Bardwell shows a method of forming a fireproof quarter partition by fixing slates to the quarters by screws, one screw taking one corner of four slates. They may then be covered with paper in the usual way, or ornamental styles may be run in cement, or metal, or leather; and for splendid rooms the slates may be enamelled in the Japanese manner.

This work contains woodcuts, but no description, of a domestic fire-grate, invented by Mr. Quarm, clerk of the works to the Houses of Parliament, which Mr. Bardwell pronounces to be "simple, effective, scientific, and beautiful," and by which "nine-tenths of the smoke is consumed, and a saving of 50 per cent. in the cost of fuel is effected." This is no unimportant matter; but without having seen this stove in actual work, we should doubt, from its construction, the realisation of the grand results Mr. Bardwell anticipates. The grate is formed without any passage for the escape of smoke, except at the back, which opening rises no higher than the level of the top of the coals, so that it appears to us to be very liable to be choked up at the top by fresh fuel, in which event there is no exit for the smoke, excepting into the room. However, should our doubts not be correct, Mr. Bardwell, with rather unnecessary confidence in the stove, remarks, that "our legislators may therefore, at the expiration of one or two years, with the strictest justice, cause every householder in the metropolis to be fined from whose chimney opaque smoke is seen to issue. We wish we could concur in these observations; the abolition of the smoke nuisance from private dwellings would be a great benefit, but the means of so doing are still wanting.

There will be found appended to this work a specification and drawings entailed in the erection of a pair of "third-rate" dwellinghouses, estimated to cost 1000*l*., which, if generally followed, Mr. Bardwell (for a reason we cannot discover) imagines would entitle such masses of buildings to be called "gardens" in lieu of streets or lanes. But we must leave our readers to judge of the merits or demerits of this specification for themselves, and close our remarks by observing, that many useful, though not altogether new, means of ameliorating the numerous sanitary evils will be found scattered up and down through this somewhat rambling book.

---

*Electro-Magnetic Telegraph, with an Historical Account of its Rise, Progress, and Present Condition, &c.* By LAURENCE TURNBULL, M.D. Philadelphia. 1853.

The modes of facilitating the means of communicating between different places have, during the last century, engrossed the earnest attention of the most eminent scientific men of all countries;—the extension of commerce, the requirements of science, and the increased rapidity of locomotion, imperatively demanded more ready conveyance of intelligence. The old and defective system of telegraphing by semaphores had long proved totally inadequate to the growing necessities of the last more active generations. At an early period the more diffused and intimate knowledge of the phenomena and laws of electricity suggested its employment in the transmission of communications. Its rapidity of transit, its power of decomposing chemical combinations and of deflecting electronometers, offered facilities for signalising that were not neglected by electricians, whose laborious researches and carefully-conducted experiments have at last elaborated that triumphant achievement of genius, the Electro-Magnetic Telegraph, which stretches in numberless ramifications, like a vast nervous system, over the greater portion of the civilised globe. By slow and and almost imperceptible steps has this discovery advanced; since the commencement of the 18th century philosophers have occupied themselves with the fascinating idea of rendering the electric current subservient as a means of inter-communication.

Dr. Turnbull, in his valuable work, has carefully traced the earliest indications of this extraordinary invention, and followed its progress to its present perfection, and we recommend it to the attention of all interested in the science of electro-magnetic telegraphing, as well as to the general reader. It contains very clear descriptions, illustrated with plates and engravings of every variety of electro-magnetic telegraph, together with abstracts of most of the patents relating to this subject, arranged in chronological order.

As early as the year 1729, the instantaneous transit of electricity through great lengths of wire was observed, and in 1746 numerous experiments were made in Leipsic and Paris by Winckler and N. Lemonnier, on the transmission of electricity through wire, earth, &c.; in one case more than two miles in length of wire were employed. These experiments were repeated by Dr. Watson and others in 1747, when shocks were transmitted across the Thames, and through two miles of wire and two miles of earth at Shooter's Hill; and also in 1748, by Franklin, across the Schuylkill, at Philadelphia; and in 1749, by De Luc, across the Lake of Geneva.

The nature and capabilities of the telegraphs in which electricity has been employed have naturally been varied and improved according to the progress of electric discovery. During the period from 1745 to 1800, the electric telegraph in which simple frictional electricity was employed, was alone used; from 1800 to 1825, the galvanic, where voltaic electricity was employed; and from 1825 to the present time, the electro-magnetic, combining the agencies of electricity and magnetism.

The first electric telegraph appears to have been that of Lesage, established at Geneva in 1774, consisting of twenty-four metallic wires, each in communication with an electrometer formed of a ball of elder suspended by a wire, the repulsions of which, when acted upon by a current of electricity, indicated a certain letter of the alphabet. A. Young, in his 'Travels in France,' in 1757, describes a similar contrivance, the invention of Lomond. Reusser, of Geneva, in a letter to *Voigt's Magazine* for 1794, described an electric telegraph, in which sparks, emanating from strips of tinfoil fastened on a glass, indicated preconcerted signals. Professor Boeckman proposed as signals the combination of sparks, at intervals, transmitted through but two wires.

In 1796, Prince de la Paix presented to the King and Court at Madrid an electric telegraph, the invention of M. D. F. Salva, and two years after the Infanta Don Antonio constructed a more complete telegraph under the instructions of Salva, upon the principle of which Humboldt asserts that a telegraph of twenty-six miles in length was established between Madrid and Aranjuez; other writers affirm that M. Betancourt connected these places, in 1787, by a telegraph worked by frictional electricity. In 1816, F. Ronalds constructed a telegraph of eight miles in length, employing frictional electricity. The apparatus consisted of a paper disc at each terminus, caused to rotate by a clock, and on which were marked words and signs. The discs were covered by perforated plates, disclosing but one letter at a time, consequently the transmission of a current of electricity at the required moment would indicate at both places the signal conveyed by the word or number apparent at that time. H. G. Dyer, an American, in 1827, constructed a telegraph on Long Island, and supported his wires in glass insulators on poles and trees. The difference of time between sparks acting on litmus paper and producing a red mark, indicated different letters and signs. The current of electricty was returned through the ground.

The profound researches of Volta, of Parma, on the development of electricity on surfaces in contact, of different metals when subjected to the action of acids or other aqueous solutions, or decomposed substances, between their plates, led inevitably to the abandonment of all preceding abortive attempts at electric telegraphing. Frictional electricity was too easily dissipated, and devoid of the continuous action of galvanic electricity, to be of essential service; the chemical force generated in the galvanic battery being pre-eminently more manageable, of greater constancy, and of less tendency to escape, than that produced by mechanical means.

Dr. Turnbull gives an epitome of the various batteries employed in generating galvanic electricity, describing minutely those of Daniell, Grove, and Bunsen, accompanied by the results of Faraday's experimental researches.

The first application of galvanism to telegraphing was by Sömmering, of Munich, in 1809. He employed a number of glass test-tubes, reversed in a reservoir of water, and connected by wires from a battery situated at the transmitting station. Each glass tube was marked with one of the twenty-five letters of the German alphabet and ten numerals. By the action of the battery the water was decomposed in the requisite tube, the evolution of the gaseous constituents of the water in which indicated the signal to be conveyed. The next in order of those depending on the galvanic principle solely, was the physiological telegraph of Voezleman De Haer, in 1839, which was not calculated to succeed, being based on the property of galvanism to produce physiological effects on the nerves and muscles, which sensations are found to become extinct in the operator after a short time, as is proved in the gutta-percha manufactory of Fonropert and Pruckner at Berlin, where the workmen engaged in proving insulated tubes lose sensibility in their hands and fore-arms after a day's work.

In this telegraph the signals were recorded upon a piece of calico saturated with a solution of ferro-cyanate of potass, to which had been added a few drops of nitric acid, and caused to move over rollers. The action of the voltaic current (transmitted through an indicator touching the calico), when rapidly formed and broken, produced a blue mark by the electric fluid decomposing the ferro-cyanate of potass, and forming cyanate of iron.

"The species of battery which is best adapted for producing the electro-chemical indications, consists of forty repetitions of charcoal and zinc plates; the charcoal plates being composed of three parts of pulverised charcoal, two of pulverised coke, and one of wheaten flour, mixed together with water; when formed, the plates are dried and placed in an earthen crucible, in the lid of which is an aperture for the escape of gases; in this they are heated to redness. This battery will keep up an uniform and energetic current for a considerable time, the cells being merely filled with water; the only attention which it requires subsequently being to wash off any oxide which may be deposited on the plates, and supply fresh water. The battery employed for the electro-magnetic telegraph is a calorimeter or single circle. The electricity generated by this battery has a tendency to weaken in its progress, so that the defect must necessarily be provided for by batteries at different distances, according to the desired amount of power; this objection is completely removed in the voltaic apparatus. Experiment has proved that the electric energy from the intensity battery, in producing the electro-chemical effects, increases instead of diminishes in regard to distance. Faraday ascertained that the quantity of electricity required to decompose a single drop of water is equal to that of a powerful flash of lightning, while from the largest single circuit ever constructed, not the slightest chemical effect can be exhibited. On the other hand, a small single circle, composed only of a few square inches of copper and zinc, will temporarily magnetise a large bar of iron, while a powerful voltaic trough will not magnetise a lady's sewing-needle. Throughout the whole of the practical details of the electro-magnetic apparatus a far greater amount of carefulness of workmanship is required than in those of the voltaic one. Thus the whole of the joinings of the conducting-wires require to be in perfect metallic contact and carefully isolated, whilst the electro-chemical communications may be transmitted through the medium of a wire fence," as was proved in an experiment in which the communicator and indicator were attached to the contrary extremities of an iron fence 1868 yards in length, when a number of signals were transmitted with great facility.

The next in chronological series was the instrument of Alexander Bain, depending for its efficiency on electro-chemical action, and consisting of a transmitting apparatus at one end of the line, and a recipient one at the other terminus. In the specification of his patent, 1846, Mr. Bain remarked that he had "rejected magnetism altogether, and caused the pulsations of the electric current to be transmitted through groups of perforations, forming signs, which are recorded at the receiving-station by pulsations of the electric current acting on chemically-prepared paper; so that the circuit is completed and interrupted without the electric current having to produce any mechanical motion, and without any manipulation of the operator in forming the intermittent pulsation of the electric current, thereby effecting the transmission of a communication to one or a plurality of distant receiving-stations with far greater rapidity than by any other mode."

Dr. Turnbull remarks that "this may be true in theory, but it will require more time than the simple passage of the current in practice; for in every case decomposition of the fluid will take place, and time is required for the operator to see the mark. If the paper should become dry, as it is known to do, the mark then becomes very indistinct, from the want of proper conducting material; and as the wire is not of platinum, by becoming oxidised it prevents the proper metallic contact, so that it will require an intense and constant current, which cannot be produced and kept up in the form of battery described by Mr. Bain—viz., zinc and copper battery. There is also the inconvenience arising from the fumes from the chemicals employed in preparing the paper."

In 1849, Mr. S. F. B. Morse patented in America an electro-chemical telegraph, but which was never practically used. The peculiar novelties of this telegraph were, the employment of a single circuit of conductors for marking telegraphic signs, by means of the decomposing, colouring, or bleaching effects of electricity acting upon any known salts that leave a mark upon paper, cloth, or metals; and also a combination of machinery, by which any two metallic points, as platina discs, or other known conducting substances, having the chemically-prepared material in contact with and between them, may be employed for marking telegraphic characters.

Messrs. Bain and Smith obtained a patent in 1849, having for its object the better construction and arrangement of marking instruments, keys, wires, and batteries of electro-chemical telegraphs, whereby copies of messages transmitted from any one station can be marked upon chemically-prepared paper or other fabric at one or any desired number of stations in communication therewith, and also, if required, at the transmitting station, without requiring the use of any secondary current.

Bain's system, as is well known, consists in punching the letters of an alphabet, composed of dots and lines, upon a narrow strip of paper, which is wound upon a roller, over which are four springs communicating with the conducting-wire of the telegraph line. When the springs rest on the covered parts of the paper, the circuit is not formed, but as soon as an empty space is presented to them, they touch the metallic roller on which the paper is wound, and which is in connection with the battery, and thereby complete the electric circuit. The current is then transmitted to any one or all of the stations on the line, and there recorded upon similar strips of paper chemically prepared by being dipped first into a solution of sulphuric acid, and then into a solution of prussiate of potash, by means of a small style attached to the conducting-wire of the line. The electric current is completed afterwards through the earth. In forty-five seconds the 1200 letters, composing a page or entire strip, are neatly drawn on the chemical paper.

Bain's telegraph is in operation on the North-Western from London to Manchester, and from thence to Liverpool, an extent of 186½ miles, and in America on a line of 1242½ miles.

The last electro-chemical telegraph we can notice is that of Messrs. Westbrook and Rogers, of America, the peculiarity of which is the employment of metallic surfaces to receive the signals and messages, instead of chemical paper. The metallic recording surface, after being filled and transferred, is cleaned by a sponge saturated with acidulated water.

As most of these electro-chemical telegraphs have proved hitherto unsuccessful, and, with the exception of Bain's, have not been extensively used, we will at once pass on to the consideration of the electro-magnetic system, which is now, generally-speaking, in universal operation. The present forms of this telegraph depend on the power of the electric current to deflect a magnetic needle or impart temporary magnetism to iron, or to produce electric currents by magnetic induction. Professor Œrsted, of Copenhagen, was the first to deduce any important results from experiments on the magnetising properties of electricity. He ascertained, in 1819, that when a wire-conducting electricity is placed parallel to a magnetic needle properly suspended, the needle will deviate from its natural position. And further, that this deviation follows a regular law, which he stated in four general rules—1, if the needle is above the conducting wire, and the electricity passes from right to left, the north pole of the needle will be moved from the operator; 2, if the needle is below the wire and the electricity passes as before, the north pole of the needle will be turned towards the observer; 3, if the needle is put in the same horizontal plane with the wire, and is between the observer and the wire, the north pole will be elevated; 4, if the needle is in like manner placed on the opposite side, the north pole will be depressed. To exhibit these effects, the needle must be very near to the wire. Other important facts were discovered by Ampère and Arago in France, Davy and Faraday in England; and Professor Henry and others in America. Ampère's hypothesis, which referred all observed phenomena to the laws which govern the mutual actions of electrical currents, was, that magnetism consists in electrical currents, revolving around the minute particles of a magnet, in planes perpendicular to its axis.

"The laws of electro-dynamical attraction and repulsion, experimentally established by Ampère, which serve to explain all known phenomena, are contained in the following propositions: —1, Parallel currents flowing in the same direction attract each other, and mutually repel, when their directions are opposite; 2, Two currents attract each other when they both flow towards or from a certain point, if they are not in the same plane, and repel each other when one current approaches and the other recedes from that point; 3, The attractive forces vary in their intensity in the inverse ratio of the square of the distance, their force diminishing as the distance increases; 4, The attraction or repulsion exerted by a current passing through a tortuous or helical conductor is exactly equal to that which is produced by the same current when it follows in a straight line from the same points." The magnetic needle not only acts as a galvanoscope by which the existence and direction of an electric current can be detected, but will serve as a galvanometer, and, from the degree of deflection, will indicate the exact measure of its force. It is from these qualities that the needle forms the basis of all present magnetic telegraphs.

Dr. Turnbull's work contains some interesting particulars of the discoveries and experiments of Arago, Sturgeon, Henry, Faraday, and others, in connection with the subject of electro-magnetism, but we must confine ourselves to the history of the telegraph, and at once continue the series of improvements in the apparatus and methods employed in transmitting signs and messages by means of electricity.

After Œrsted's discovery that feeble electric currents would produce a variety of magnetic actions, a fresh impulse was given to electric telegraphing, and modifications and contrivances were speedily introduced to render available these newly-disclosed electro-magnetic properties. Ampère, in 1820, was the first to devise a telegraph in which the deflection of the magnetic needle was employed. His plan consisted of as many needles as letters of the alphabet, which were actuated by electric currents passed through metallic conductors, communicating respectively with the battery by means of keys, depressed at pleasure. In 1825, P. Barlow, F.R.S., suggested an instantaneous telegraph by means of conducting wires and compasses. In 1828, St. Amand proposed to connect Paris and Brussels by a metallic wire coated with silk, and inclosed in glass tubes hermetically sealed. A galvanic battery imparted electricity to this conducting wire, which at the opposite end was to be in connection with an electroscope sensible to the slightest influence, the signals conveyed by the deflections of which were to be determined at pleasure. In 1832 and 1833, Baron Schilling, a Russian Counsellor of State, devised a needle telegraph, consisting of a number of platinum wires insulated and united in a cord of silk, which actuated by keys thirty-six magnetic needles, each placed vertically over the centre of a multiplier.

An improved form of Schilling's instrument was exhibited by Dr. Munke in 1835, in which light discs of cardboard, attached to magnetic needles inclosed in galvanic coils, were moved by the magneto-electric current. Five similar magnets, arranged so that the round discs of cardboard were presented to view edgewise, were connected by wires with the distant battery; according to the direction in which the current was sent, the magnets were deflected to the right or left, showing to the observer in the one case one side, and in the other the reverse side of the cardboard discs, thus indicating, according to an established code, different telegraphic signals.

Between the years 1833-35, Counsellor Gauss and Professor Weber, two of the most illustrious philosophers of Germany, established telegraphic communication between the Astronomical and Magnetic Observatories of Gottingen, consisting of a double line of wires carried over the house-tops. It was erected principally to investigate the laws of the force of galvanic currents under different circumstances. The greatest length of circuit was 15,000 feet, part of which was reeled. They first employed galvanic electricity by using small-sized plates, and found that the action was much increased by adding to their number. The main apparatus was a magneto-electric machine, to which Gauss adapted a commutator, by which the direction of the current could be reversed by a single pressure of the finger, with which the two ends (called inductors) of the reel were in connection, and also the two conducting wires of the telegraph. When the inductors were suddenly drawn off the magnet-bars on which they rested, and immediately replaced, two induction currents of short duration were produced, one directly after the other, in opposite directions, which were transmitted through the conducting wires. The observing apparatus at the opposite station consisted of a strong multiplicator, or square copper frame, round which an insulated wire was coiled, having its two ends in connection with the conducting wires from the other station, thus forming together a single closed wire circuit.

In the coils of the mutiplicator, a magnetic bar of about four pounds weight was suspended by 200 parallel silk threads, easily moveable in the strip carrying the bar, which could be raised or lowered by a wooden screw, to which the upper ends of the threads were attached. On a brass rod passing through the copper frame was fixed a vertical mirror, which turned with the magnet, and was so directed towards a cypher-scale fastened at the foot of a spy-glass, that the reflection of the scale could be seen through the glass. In a state of rest the null point of the scale was visible through the glass, but as by the slightest movement of the magnet the mirror was also moved, a different portion of the scale was presented to view. In this manner the signs indicated upon the cypher-scale were made to convey certain conventional letters and words.

In the year 1836, Messrs Taquin and Ettieyhausen experimented with a line over two streets in Vienna, the wires passing through the air and under the ground of the Botanical Garden.

In 1835, Mr. J. B. Morse constructed an electro-magnetic telegraph, upon which have been founded most subsequent instruments of the like character. In 1836, Mr. Morse was joined by Mr. L. D. Gale, who suggested many useful improvements. The apparatus consisted of a train of clock-wheels giving motion to a strip of paper passed round two cylinders. A wooden triangular pendulum was suspended over the paper, and vibrated at right angles to the length of the paper. At the lower end of the pendulum was fixed a pencil, kept in contact with the strip by a weight. An electro-magnet was supported above the paper, and attracted an armature attached to the pendulum; one of the conductors of the magnet helix passed to a single-plate galvanic battery, and the other to a cup of mercury attached to a port rule; the other pole of the battery was connected to a second cup of mercury. A rule or composing-stick carrying the type, the tops of which projected above the sides of the rule, was supported and moveable upon rollers attached to the port rule, at one end of which was suspended a lever, having at one end a key or tooth, which was acted upon by the type in the rule, and at the other a forked wire, which, when the opposite end of the lever was raised by the type, connected the two cups of mercury, and consequently completed the circuit, which had the effect of causing the pendulum to make one vibration for every single type, thereby causing the pendulum pencil to make a V-shaped mark upon the paper; a combination of these marks and spaces represented certain numerals, which again were typical of certain letters or words. In 1837, Mr. Morse, finding that this instrument was useless for great distances, adopted a receiving-magnet and a relay or repeating circuit. This telegraph, having been modified and improved, was tried on the line between Baltimore and Washington, in America. In the instruments thereon employed a signal lever-key was substituted for the port rule, and a lever in the register in place of the pendulum; and it was further provided with a "local circuit" and register, a receiving-magnet and adjuster, self-regulating break, and metal points were employed in place of the lead pencil to indent the signals instead of marking them on the paper.

The chief improvements on the Morse telegraph, now in almost general use in the United States, are the spring lever-key, by means of which the local circuit may be closed to allow communications to be sent through the office to stations on either side of it; keeping the main circuit continuous, it also acts as the transmitting apparatus. On merely depressing the long end of the lever, a point is made at the receiving-station, whilst, if retained down, a line is marked of a length proportionate to the time of such retention. The receiving-magnet, which is an intensity one, surrounded by a helix of fine wire 3000 feet in length, is of the horse-shoe form, and fixed in a horizontal position. The main circuit passes through this helix unbroken, by the action of a self-acting apparatus, consisting of an armature fixed to a vertical moveable standard opposite the poles of the magnet, in such manner that when the current flows through the main circuit the receiving magnet attracts the armature and closes the local circuit.

The self-acting winding apparatus, attached to the register, secures an uniformity of motion through any number of messages. It consists of an extra magnet placed in the register, causing a lever to vibrate; this lever has a click at its end, which causes a ratchet-wheel to revolve and transmit its motion to the shaft of the spring which actuates the registering apparatus. An arrangement is also made by which two points come into contact and cut off the current from the winding magnet, and consequently prevent the further winding up of the spring when powerful enough to give motion to the register, the revolutions of which, in its turn, cause the points to separate, when the current again flows through the magnet, and the winding of the spring is once more effected. The batteries usually employed are those of Grove, thirty cups being necessary in a space of 150 miles, which may be either collected or distributed at intervals along the line. Only one wire is now used on the main line, the earth affording the return circuit. On the Baltimore and Philadelphia line the daily performance of one of Morse's machines is to transmit from 8000 to 9000 letters per hour. The best proof of the efficiency and economy of Morse's system is the fact, that it is employed on no fewer than fifty-six different railway lines in America, and extends over a length of 19,963 miles, or nearly nine times the whole extent of the English telegraphs of all descriptions.

The next electro-magnetic telegraph, as regards date of publication, was that of Professor Wheatstone. In 1834, he published the results of a series of experiments on the velocity of electricity, and in 1836 repeated his experiments at King's College, in which he employed an insulated circuit of copper wire, about four miles in length. In 1837, Professor Wheatstone, in conjunction with Mr. W. F. Cooke,, patented a telegraph, the principle of which was founded upon the discovery of Œrsted, of the deflecting influence of an electric current upon a magnetic needle; and consisted of a combination of several peculiarly-constructed galvanometer needles. Without troubling our readers with the descriptions of the first imperfect attempts of Wheatstone and Cooke, we will briefly explain their system as at present in use. Their transmitting instrument consists of a horizontal brass wheel, divided and marked on its upper surface like the disc of the telegraph, with which it exactly corresponds. The circumference of this wheel is cut away in twelve places, into which small pieces of ivory are let. A metallic spring in connection with the battery pressing against the circumference of the wheel when the wheel is turned round, is alternately in contact with the brass of which the wheel is composed and the ivory pieces, by which means the electric circuit is alternately completed and broken. Iron pins are inserted in the wheel corresponding to each letter, by which the wheel is caused to revolve to any extent required. Another modification of this instrument consists in connecting concentrically to the brass wheel having iron pins or handles, a toothed wheel, which gears into a small pinion, on the axis of which is affixed an armature of soft iron, surrounded with coils of copper wire. A strong spring, acting upon clockwork, imparts motion to the disc or index, the attraction of the armature being used to regulate the escapement, every current releasing a single tooth, and so advancing the disc one letter.

The receiving instrument consists of a similar arrangement of clockwork giving motion to a disc, on which the letters of the alphabet or other signals are marked. The escapement is also acted upon by the keeper or armature in a manner corresponding to that of the transmitting instrument. Thus every movement given to the brass wheel at the transmitting station is instantly repeated at the receiving station, thereby enabling messages to be conveyed with great rapidity, one letter only of the telegraphic disc being exposed to view at a time.

Cooke and Wheatstone's patents were purchased by the Electric Telegraph Company in 1846. The average number of words transmitted by their double-needle telegraph is about seventeen per minute, which is slow in comparison with either Morse's or the House telegraphs, which are capable of forwarding from thirty to thirty-five words per minute.

The next electro-magnetic telegraph in point of date was that of Professor Steinheil, a notice of which was published in 1836. His apparatus was adopted by the Bavarian government, and in operation in 1837. This was the the first telegraph in which the earth was employed as half the circuit. At Bogenhausen, the Royal Academy is connected to the Royal Observatory by a double-copper wire, the total length of which amounts to 32,506 feet, weighing 260 lb. In this instrument the deflection of the two magnetic bars or armatures is made to produce sound from metal or glass bells, whose notes differ about a sixth. To the north pole of one magnet and the south pole of the other are affixed little cups, with fine perforated beaks, that contain printing ink. In front of these beaks a flat surface of paper is kept moving. On the deflection of either of the magnetic bars, the beak of its cup, from which issues by capillary attraction a minute quantity of ink, is caused to touch the paper, and leaves thereon a round black dot. Different arrangements of four of those dots are ingeniously contrived to represent all the letters of the German alphabet most commonly used.

After Steinheil's came Alfred Vail's printing telegraph, which was proposed in 1837. It consisted of a type-wheel, having on its surface the twenty-four letters of the alphabet; on the side of this wheel were a corresponding number of holes. The type-wheel was caused to revolve by a spring, that caused an electro-magnetic key to advance; at each interruption and return of the current the paper was made to move under the type-wheel by means of clockwork. But as the precision of this instrument was dependent on the exact correspondence of the receiving with the transmitting instrument, and it was necessary that the type-wheel should present the same letter at both stations, this system was never put into execution.

A little time after Vail's telegraph was published, Alexander proposed a method of indicating signals by letters arranged systematically, and covered by small light screens, to each of which was attached a magnetic needle, connected to the battery by a separate wire. An electric current passed through one of these wires caused its needle to be deflected, which moved the screen and disclosed the particular letter it covered. This was also a complicated and non-efficient instrument, and accordingly has been little or never used.

After Alexander, Davy produced an ingenious contrivance, by means of which the electric current, acting upon a series of keys, eight of which were marked with three letters of the alphabet, caused slides or magnetic bars to be withdrawn from over any particular set of letters, which appeared illuminated to the spectator by a lamp properly arranged for that purpose. Three strokes on a bell drew the attention of the observer, and one stroke indicated the termination of each word, which was copied down by the observer just as represented.

In 1837, Professor Masson, of Caen, described, in a letter to the French Academy, the results of several trials he had made with a magneto-electric telegraph for a distance of 1800 feet. He employed the machine of Pixii to develope the currents that deflected magnetic needles placed at the extremities of the circuits. In 1838, Masson, together with Bréquet, experimented with this instrument, but failed to produce any satisfactory result.

Amyot, in 1838, addressed a letter to the Academy of Science at Paris, proposing to write on paper with mathematical precision by means of a single circuit and needle. The message was to be transmitted by a simple wheel, on which points or pins were adjusted, in a manner similar to those of a barrel organ; but this was only another abortive attempt at mechanical telegraphing.

In 1838, Edward Davy patented a method of employing the decomposing action of the galvanic current to produce marks upon chemically-prepared calico, treated to a solution of the iodide of potassium and muriate of lime. A local battery produced the telegraphic signs by chemical decomposition, and operated an electro-magnet, whose armature regulated a receiving instrument similar in principle to that of Cooke and Wheatstone, with the exception that the circuit was closed by the contact of metals instead of mercury, in the same manner as the Morse instrument. The main circuit was opened and closed by finger-keys; when closed the needle was deflected, which closed the short circuit; but when interrupted, the needle opened the short circuit by returning to. its original position. The prepared calico was drawn between a metallic cylinder and a series of platinum rings surrounding a wooden cylinder; by these rings the current from a local battery passed through the calico to the cylinder beneath, producing signs consisting of simple dashes, arranged in six rows,—the calico was caused by clockwork to move in proportion to the number of signs transmitted. The platinum rings could be connected at will with the other poles of the battery, but were insulated from each other. Three telegraphic wires, by means of a commutator, connected the local battery with either of the six platinum rings. An exceedingly ingenious escapement regulated the movement of the paper, but we must refer our readers to the work of Dr. Turnbull for a description of it.—We shall continue our history of telegraphing and review in our next Number.

*Railway Wheels.*—Mr. W. B. Adams, C.E., has patented an improvement in railway wheels, which consists in constructing them with a disc body of timber, formed of wedge-shaped pieces dowelled or tongued-and-grooved together and turned down in a lathe, so that the wheel is made thinner at its edge than at its centre.

## AMERICAN RIVER AND CANAL NAVIGATION.*

Immediately after the acknowledgment of the independence of the American colonies by England in 1783, several companies were formed in the two principal states of the Union, those of New York and Pennsylvania, for the purpose of constructing a system of canals. These enterprises were accordingly commenced, but on a scale too limited for the attainment of the ultimate objects; and as the United States advanced in commercial prosperity, more extensive plans were adopted. In 1807, the senate charged the Secretary of State, Mr. Galatin, to prepare a project for a general system of intercommunication by canals, based upon the geographical character of the territory of the Union. A system of artificial water-communication was accordingly projected, which, with some modifications, was at a later period adopted and carried into execution. These projects, however, suffered an interruption from the renewal of the war in 1812; and it was not until five years later that the vast works were commenced, the result of which has been a system of inland navigation which is without a rival in any country in the world.

On the anniversary of the declaration of independence celebrated the 4th July, 1817, the commencement of the great line of canal connecting the Hudson with the Lake Erie was inaugurated. The river Hudson presented a navigable communication for vessels of a large class from New York to Albany. The object of this line of canal was to open a water-communication between Albany and the northern lakes, so as to connect, by continuous water-communication, the North-western States with the Atlantic. In less than eight years this work was accomplished by the state of New York, with its exclusive resources. That state alone executed and brought into operation the largest canal in the world. As first constructed, the Erie canal, with its branches, cost 2,600,000*l*. sterling; but its magnitude and proportions being still found inadequate to the exigencies of a continually increasing traffic, its enlargement was decided upon in 1835, and it was finally completed, at a cost of upwards of 5,000,000*l*. sterling. The total length of this canal is 363 miles, and its cost of construction per mile was therefore about 13,700*l*.

Meanwhile, the other states of the Union did not remain inactive. Pennsylvania especially rivalled New York in these enterprises, and became intersected with canals in all directions. In short, these works were undertaken to a greater or less extent, in most of the Atlantic and some of the Western States; and the American Union now possesses a system of internal artificial water-communication amounting to nearly 4500 miles, executed with a degree of skill and perfection rarely surpassed by any similar works constructed in the states of Europe.

According to M. Michel Chevalier, whose work on this subject supplies most voluminous and valuable details, the extent of canals which were in operation in the United States on January, 1, 1843, was 4333 miles. There was a further extent projected, but not executed, amounting to 2359 miles. The total cost of executing the canals which were completed was, according the M. Chevalier, 27,870,964*l*. being at the average rate of 6432*l*. per mile.

Since the date of these returns considerable extension has been given to the system of canal navigation by the opening of new lines and the increased length of former ones, and it is probable that the actual extent of artificial water communication now in use in the United States considerably exceeds 5000 miles. The average cost of executing this prodigious system of water-roads was at the rate of 6432*l*. per mile, so that 5000 miles would have absorded a capital of above 32,000,000*l*.

This extent of canal transport, compared with the population, exhibits in a striking point of view the activity and enterprise which characterise the American people. In the United States there is a mile of canal navigation for every 5000 inhabitants, while in England the proportion is a mile to every 9000 inhabitants, and in France a mile to every 13,000. The ratio, therefore, of this instrument of intercommunication in the United States is greater than in the United Kingdom, in proportion to the population, as 9 to 5, and greater than in France in the ratio of 13 to 5.

The river navigation of the United States is on a scale commensurate with the extent of their territory. The division of the country east of the Alleghanies, forming the Atlantic States, is drained by a vast number of rivers, of the first and second class, all navigable for vessels of considerable burthen, the principal of which are the Hudson, the Delaware, the Susquehanna, the Connecticut, the Potomac, the James, the Roanoke, the Savannah, and, to the southwards, the Atamala, and the Alabama.

The steam navigation of the Hudson is entitled to attention, not only because of the immense traffic of which it is the vehicle, but because it forms a sort of model for most of the rivers of the Atlantic States. This navigation is conducted, as will be seen, in a manner and on a principle altogether different from that which prevails on the Mississippi and its tributaries.

In the steam-vessels used on these rivers, no other strength or stability is required than is sufficient to enable them to float and bear a progressive motion through the water. Not having to encounter the agitated surface of an open sea, they are supplied with neither rigging nor sails, and are built exclusively with a view to speed. Compared with sea-going steamers, they are slender and weak in their structure, with great length in proportion to their beam, and a very small draught of water.

The position and form of the machinery are affected by these circumstances. Without the necessity of being protected from a rough sea, the engines are placed on the deck in a comparatively elevated situation. The cylinders of large diameter and short stroke, almost invariably used in sea-going ships, are rejected in these river boats, and the proportions are reversed,—a comparatively small diameter and a stroke of great length being adopted. It is but rarely that two engines are used. A single engine, placed in the centre of the deck, drives a crank placed on the axis of the enormous paddle-wheels. The great magnitude of these latter, and the velocity imparted to them, enable them to perform the office of fly-wheels, and to carry the engine through its dead points with but little perceptible inequality of motion. The length of stroke adopted in these engines supplies the means of using the expansive principle with great effect.

The new and largest class of steamers are capable of running from twenty to twenty-two miles an hour, and make, on an average, eighteen miles an hour. These extraordinary speeds are obtained usually by rendering the boilers capable of carrying steam from forty to fifty pounds pressure above the atmosphere, and by urging the fires with fanners, worked by an independent engine, by which the furnaces can be forced to any desired extent.

It is right to observe here that this extreme increase of speed is obtained at a disproportionately increased consumption of fuel. When the speed is increased, the space through which the vessel must be propelled per minute is increased in the same proportion: and, at the same time, the resistance which the moving power has to overcome is augmented in the proportion of the square of the speed. Hence, the effect to be produced by the moving power per minute, is increased by two causes; first, the actual resistance which it has to overcome is augmented in the ratio of the square of the speed; and, secondly, the space through which the moving power has to act against this resistance in each minute is increased in the ratio of the speed. Thus, the total expenditure of moving power per minute will be augmented in the proportion of the cube of the speed. It is found in some cases that the increase of three or four miles an hour on eighteen miles will cause nearly triple the consumption of fuel.

Much of the efficiency of these engines arises from the application of the expansive principle; but to this there has been hitherto a limit, owing to the inequality of the action of the piston when urged by expanding steam on the crank. When the steam is cut off at less than half-stroke, the force of the piston is diminished before the termination of the stroke to less than one half its original amount. This inequality is aggravated by the relative position of the crank and connecting-rod, the leverage diminishing in nearly the same proportion as the power of the piston diminishes. On this account it has not been found generally practicable to cut off the steam at less than half-stroke.

The steam is universally worked with expansion, the valves for its admission and emission being moved independently of each other. A separate engine is genenerally provided for driving the blowers, and a cylindrical fan-blower is employed for each boiler. Some of these blowers are 10 feet in diameter, being driven by a crank placed on their axle, which receives its motion from the small independent engine.

The great power developed by these river engines is due not so much to the magnitude of their cylinders, as the pressure of steam used in them. Some of the most recently constructed boats have cylinders 76 inches in diameter, and 15 feet stroke. The steam has 40 lb. pressure in the boiler, and is cut off at half-

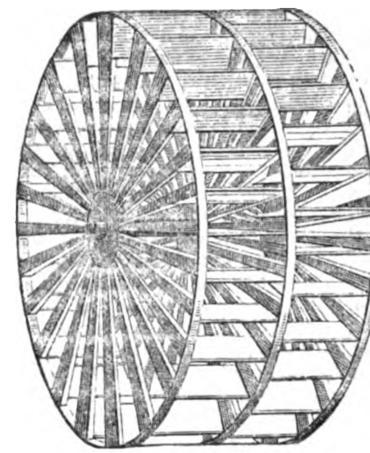

Fig. 3.

stroke. The wheels, which are 45 feet in diameter, make sixteen revolutions per minute. The speed of the circumference of the wheel will therefore be twenty-five miles an hour; so that if the speed of the boat be twenty miles an hour, we have the difference, five miles, giving the relative movement of the edge of the paddle-boards through the water.

The increase of the dimensions of these vessels and of their machinery has been attended with a greatly augmented economy of fuel; while practical evidence of economy is also supplied by the fact that the proprietors of the Hudson steamboats reduced their tariff for passengers, as well as for freight, as they increased the size of their vessels.

The ease with which these vessels of extraordinary length and beam and small draught move through the water is very remarkable. The results of their performance show that the resistance per square foot of immersed midship section is not perceptibly increased by the increased length of the vessel, and the consequently augmented surface and friction. This anomaly has not been explained, but it is certain that the increased length does not diminish the effect of the moving power in any perceptible degree.

The form and structure of these river-steamers will be more easily understood by fig. 1 of the annexed engravings, which represents a side elevation of one of the Hudson steamers, and fig. 2 is a cross section of the hull with one-half of the platform, which is placed upon it, and which supports the upper cabins and saloons. This hull is constructed with a perfectly flat bottom and perpendicular sides, and is rounded at the angles. At the bow or cutwater they are made very sharp.

The split paddle-wheel, which until very lately was exclusively used in these boats, is represented in fig. 3, and is formed as if by the combination of two or more common paddle-wheels, placed one outside the other, on the same axle, but so that the paddle-boards of each may have an intermediate position between those of the adjacent one, as represented in fig. 2.

The spokes, which are bolted to cast-iron flanges, are of wood. These flanges, to which they are so bolted, are keyed upon the paddle-shaft. The outer extremities of the spokes are attached to circular bands or hoops of iron, surrounding the wheel, and the paddle-boards, which are formed of hard wood, are bolted to the spokes. The wheels thus constructed, sometimes consist of three, and not unfrequently four, independent circles of paddle-boards, placed one beside the other, and so adjusted in their position that the boards of no two divisions shall correspond.

The other class of steamers used for towing the commerce of the rivers corresponds to the goods trains on railways. No spectacle can be more remarkable than these locomotive machines, dragging their enormous load up the Hudson. They may be seen in the midst of this vast stream, surrounded by a cluster of twenty or thirty loaded craft of various magnitudes. Three or four tiers are lashed to them at each side, and as many more at their bow and at their stern. The steamer is almost lost to the eye in the midst of this crowd of vessels which cling around it, and the moving mass is seen to proceed up the river, no apparent agent of propulsion being visible, for the steamer and its propellers are literally buried in the midst of the cluster which clings to it and floats round and near it.

As this *water goods train*, for so it may be called, ascends the Hudson, it drops off its load, vessel by vessel, at the towns which it passes. One or two are left at Newburgh, another at Powkeepsie, two or three more at Hudson, one or two at Fishkill, and, in fine, the tug arrives with a residuum of some half-dozen vessels at Albany.

## ON THE ROTATION OF THE PENDULUM.

By Alfred Day.

Having been one of the parties who, in an early stage of the inquiry, proposed a simple original solution of this phenomenon of the rotation of the pendulum, which is now commonly adopted without acknowledgment, and which has been again and again repeated both here and in America, I am desirous of correcting some unsatisfactory representations which still find their way into print in works of a respectable class. I refer to the account given of the problem in a manual of the physical sciences by Dr. Golding Bird and Mr. Brooke, where the correct explanation is also given, being exactly the same as my own, even to the form in which the trigonometrical relation is expressed, the same fraction, $\frac{\cos.\ \lambda}{\cot.\ \lambda}$, occurring in both. But this explanation is accompanied, or rather prefaced, by some remarks, which represent the problem, first, as having excited much more attention than it deserved; next, that the rotation of the pendulum is not an immediate effect of the earth's rotation; and thirdly, that the rotation of the pendulum is only an *apparent* rotation. Now on this I cannot help remarking, that the problem would have been most interesting, and deserving all the scientific examination it received, if only as a purely speculative or abstract one; and it was remarkable that the precise case had never been discussed. As it was, it took mathematicians by surprise, baffled not a few respectable professors of the science, and was wrongly apprehended by several analysts of considerable eminence. None of the analytical solutions, if such they can be termed, that have from time to time appeared in this country, have established

* From the 'Philosophical Magazine.'

anything more than is done with far greater clearness and simplicity by the explanation given in the work referred to; and the whole thing, notwithstanding its great interest and novelty, has sunk into temporary contempt and neglect, as if the scientific republic was rather ashamed of having allowed so much discussion and so much algebra to be wasted on a thing so readily demonstrable by a person tolerably conversant with Euclid only, or, to say the least, with Euclid and the first elements of plane trigonometry. By way of retaliation, there is no glory to be got out of it, the problem is now never mentioned, and a large body of people at this moment look upon the whole thing as tacitly given up, notwithstanding that the exact experiments of Mr. Bunt, certainly undertaken with no bias in favour of bringing out the precise result, have proved it, in a great variety of trials, to be true in practice, which is by no means necessary to establish the truth of theoretic reasoning. It is not, however, as a speculative case that the problem is of the highest interest, but as an immediate proof of the earth's motion round its axis; and the discovery was hailed as important chiefly on this ground by the members of the French Institute. It is true you do not see the earth's rotation any more than before, nor does the pendulum move away at a rate necessarily corresponding with that in which the former is performed. I may state the real value of the illustration thus. It is only within a comparatively recent period of the world's history that the apparent motion of the heavens has been finally reconciled with the supposition of a motion in the spectator on the earth's surface, and not in them; and while no objection can be raised against adequacy of this supposition to account for what is witnessed, there are a hundred reasons why it should be adopted implicitly, without one to be urged on behalf of the ancient hypothesis which makes the earth stand still. We have heard indeed of incredulity on this point, but it must be confined to those who, with their systems of philosophy or theology, stand as still as the earth on their theory; and to offer a serious refutation would be loss of time, without the hope of bettering the state of their convictions. Notwithstanding, however, that the mass of men are fully agreed on this question, and that the great conspiracy of arguments tends to render the conclusion in the highest degree probable, and to the philosopher certain, it cannot be denied that a diurnal rotation of the heavens would produce effects such as those ordinarily observed, and that the reasons which lie against it are not those which can be easily understood by persons unskilled in physical demonstration. We are glad then of a new fact, which, though it does not really make the rotation of the earth more a sensible phenomenon than before, shows that a relative motion exists between the earth and other independent planes, in which the same positions do not necessarily recur after twenty-four hours, and which are in no way affected by any rotation of the sidereal heavens, and yet are wholly explicable on the hypothesis of the earth's rotation round its axis in twenty-four hours, and on no other. To a person who views the pendulum experiment, the rotation of the plane of its vibration is readily and speedily manifest; and because this may be shown to depend on the rotation of the earth, it is not unnaturally designated a making the earth's rotation visible. We do not, however, apart from reasoning, attribute the effect observed to the motion of the earth, any more than we do the motion of the stars about us to that cause; for what we appear to see is strictly a motion of the plane of vibration round the zenith as a pole. It may suit the purpose of popular explanation to say that the plane of the pendulum's vibration remains unchanged while the earth rotates under it; but a little consideration shows that this is not strictly true, and the conception of what does take place becomes more difficult than in the case of the apparent motion of the heavens, since the pendulum being carried at its point of suspension with the earth, appears to be one with it. But though the earth's diurnal rotation is less directly proveable in this way, it is far more conclusively so than it is by the motion of the stars. In these last, the motion having existed from the commencement of all things, might have been originally impressed as well as that of the earth; but with the pendulum set in motion by human agency, and continuing to vibrate without solicitation to the right hand or left, on the supposition of the earth being at rest, no such apparent rotation could be brought about on any known physical law. It is, therefore, the earth that moves, not at the rate of the pendulum nor round the pendulum-wire when at rest as an axis, though this it might do if this were consistent with the observed motion of the stars; but round another axis pointing to another star, and at a rate coinciding with the apparent rate of the sidereal revolutions. It is therefore a sensible proof of another kind than any previously known to exist, and of directly sensible proofs measured by the eye in short intervals of time, the most conclusive in its kind.

The value of the whole argument may be thus stated. Either the heavens or the earth rotate once in twenty-four hours, or both move by a joint motion away from each other equivalent to this in amount; and either of these conditions is abstractedly possible, so that no conclusion can be drawn. In this latitude the pendulum rotates in about thirty hours, or the earth in twenty-four; and as there can be no assignable reason why the former should do this without a cause, the rotation of the earth in twenty-four is a fact for the rational being, since it is clear that no supposition of the observed motion being partly in the earth and partly in the heavens will fulfil the second set of conditions. The experiment of the pendulum is, therefore, very correctly designated as a making visible the earth's rotation, though hardly in the sense popularly attached to it: its importance cannot, we think, be overrated. So much then for the second objection; and I shall now proceed to show that the rotation is to all intents and purposes real, and not merely apparent on the part of the vibrating plane. I have elsewhere, in a published diagram, shown that the pendulum's actual rotation is the resultant of two sets of continually-exerted forces, one tending to keep the pendulum swaying parallel to itself, the other to make its point of suspension and the line which the pendulum would occupy if at rest rotate obliquely to the axis of the two circles described by the point of suspension and the ball at the mean of the oscillation. Shortly after the publication in question, I constructed a simple mode of illustrating the fact. Cut out two circular discs of card, and make an equal number of cogs or teeth in the rim of each. Paste one of these on a larger circular disc and concentric with it, and cut both through along any radius from the circumference to the centre. If now we draw a diameter on the other toothed disc, and cause it travel round by placing the teeth of the two discs in one another in the manner of ordinary wheels when acting on each other, but so that the larger disc shall remain motionless, we shall find that this line will have rotated once for one entire revolution of the moving wheel round the circumference of the fixed one. If now we coil up the large disc with its attached rack into the shape of a cone, so as to hide some of the teeth, our index-line will not rotate once during the revolution of its disc over the entire surface of the rack on the conical surface; and the more acute the cone is, the smaller the amount of rotation. This is not only analogous to the case of the pendulum, but it is exactly the same in amount, when the plane sectional angle of the cone is altered proportionally to the latitude of the place where the pendulum is set swinging.

Great confusion has arisen in many minds with reference to this problem from not separating two things, a free and a constrained and conditioned motion, and not distinguishing what is real from what is apparent. Thus, if a cone be set revolving on its axis, a fixed straight line on the surface of the cone will, after one entire revolution, be in the same spot, and we say of it that it has not rotated round any point in itself; but yet if a plane be conceived to pass through the line in its first position and the axis of the cone, and the projection of the line after a quarter revolution falling perpendicular on this plane be drawn, the two lines will cut one another at an angle equal to half the plane sectional angle of the apex of the cone, and in half a revolution this angle will be doubled. The partial rotation, however, in the first half of its course, which reaches its maximum in half a revolution of the cone, is in fact retrograde during the second half, and at the completion of the whole period all things are as they were. The whole of this is a constrained motion, during which every point in the line moves in a circle, but every point with a velocity different from that of its neighbour and in a different circle. This is totally different from the case of a line occupying at each infinitesimally-consecutive instant a position parallel to itself, and thus having all its points moving uniformly in equal circles, or constrained to keep to the surface of the revolving cone, so as to cross always a given point on it, or, in other words, moving at the same rate as the cone. It has been sufficiently and irrefragably demonstrated, that while the cone continues to revolve in the same direction, the line so circumstanced would constantly rotate in one direction round that point which it always crosses; and that though this result is obtained by the tendency of the line to keep parallel to itself, coupled with the constraint applied to it, it will not, after a complete revolution of the cone on its axis, bring the line into parallelism with its first position, but only after the lapse of a longer period. Hence the rotation is real, not merely *apparent*; and were there no apparent rotation, there must have been a real retrograde force of rotation applied to the plane of oscillation, so as to have obliterated all the advance we actually see in practice. I have met with other gentlemen of mathematical education and reputation, who have persisted in calling this rotation an apparent one, which it certainly is, and something more.* When we talk of the apparent rotation of the heavens, we mean that they do not revolve, but only the earth, in twenty-four hours, all things being replaced. If the earth really revolves in twenty-four hours, it is certain that the oscillation of the pendulum is not in the same direction; and consequently it has rotated; unless any one is absurd enough to maintain that the rotation of the earth itself varies its period at different latitudes.

* There is no rotatory tendency in the plane of oscillation, excepting in so far as this is produced as a result of the earth's constraint on the point of suspension; in other words the rotatory effect is due to the earth. In this sense it is the earth's rotation made visible, though the angular motion is slower than that of the earth; and the case may be compared to the motion of the box containing the main-spring of a watch, as evidenced by the motion of the hands.

## ON DR. STENHOUSE'S CHARCOAL RESPIRATOR.

By Dr. G. Wilson.

[*Paper read at the Royal Scottish Society of Arts, June 19th* 1854.]

Dr. Wilson commenced by stating, that having read with much interest the account of Dr. Stenhouse's researches on the deodorising and disinfectant properties of charcaal, and the application of these to the construction of a new and important kind of respirator, he had requested that accomplished chemist to send one of his instruments for exhibition to the Society, which he had kindly done. Two of the instruments were now on the table, differing, however, so slightly in construction that it would be sufficient to explain the arrangement of one of them. Externally, it had the appearance of a small fencing-mask of wire-gauze, covering the face, from the chin upwards to the bridge of the nose, but leaving the eyes and forehead free. It consisted, essentially, of two plates of wire-gauze, separated from each other by a space of about $\frac{1}{4}$ or $\frac{1}{8}$-inch, so as to form a cage filled with small fragments of charcoal. The frame of the cage was of copper, but the edges were made of soft lead, and were lined with velvet, so as to admit of their being made to fit the checks tightly, and enclose the mouth and nostrils. By this arrangement no air could enter the lungs without passing through the wire-gauze, and traversing the charcoal. An aperture is provided with a screw or sliding valve, for the removal and replenishment of the contents of the cage, which consists of the siftings or riddlings of the lighter kinds of wood-charcoal. The apparatus is attached to the face by an elastic band passing over the crown of the head, and strings tying behind, as in the case of the ordinary respirator.

The important agent in this instrument is the charcoal, which has so remarkable a power of absorbing and destroying irritating and otherwise irrespirable and poisonous gases or vapours that, armed with the respirator, spirits of hartshorn, sulphuretted hydrogen, hydrosulphuret of ammonia and chlorine, may be breathed through it with impunity, though but slightly diluted with air. This result, first obtained by Dr. Stenhouse, has been verified by those who have repeated the trial, among others by Dr. Wilson, who has tried the vapours named above on himself and four of his pupils, who have breathed them with impunity. The explanation of this remarkable property of charcoal is twofold. It has long been known to possess the power of condensing into its pores gases and vapours, so that if freshly prepared and exposed to these, it absorbs and retains them. But it has scarcely been suspected till recently, when Dr. Stenhouse pointed out the fact, that if charcoal be allowed to absorb simultaneously such gases as sulphuretted hydrogen and air, the oxygen of this absorbed and condensed air rapidly oxidises and destroys the accompanying gas. So marked is this action, that if dead animals be embedded in a layer of charcoal a few inches deep, instead of being prevented from decaying, as it has been hitherto supposed they would be by the supposed antiseptic powers of the charcoal, they are found by Dr. Stenhouse to decay much faster, whilst at the same time no offensive effluvia are evolved. The deodorising powers of charcoal are thus established in a way they have never been before; but at the same time it is shown that the addition of charcoal to sewage-refuse lessens its agricultural value contemporaneously with the lessening of odour. From these observations, which have been fully verified, it appears that by strewing charcoal coarsely powdered, to the extent of a few inches, over churchyards, or placing it inside the coffins of the dead, the escape of noisome and poisonous exhalations may be totally prevented. The charcoal respirator embodies this important discovery. It is certain that many of the miasmata, malaria, and infectious matters which propagate disease in the human subject, enter the body by the lungs, and impregnating the blood there, are carried with it throughout the entire body which they thus poison. These *miasms* are either gases and vapours, or bodies which, like fine light dust, are readily carried through the air; moreover, they are readily destroyed by oxidising agents, which convert them into harmless, or at least non-poisonous, substances, such as water, carbonic acid, and nitrogen. There is every reason, therefore, for believing that charcoal will oxidise and destroy such miasmata, as effectually as it does sulphuretted hydrogen or hydrosulphuret of ammonia, and thus prevent their reaching and poisoning the blood. The intention accordingly is, that those who are exposed to noxious vapours or compelled to breathe infected atmospheres, shall wear the charcoal respirator, with a view to arrest and destroy the volatile poisons contained in these.

Some of the more obvious applications of the respirator were then referred to:—1. Certain of the large chemical manufacturers in London are now supplying their workmen with the charcoal-respirators as a protection against the more irritating vapours to which they are exposed. 2. Many deaths have occurred among those employed to explore the large drains and sewers of London, from exposure to sulphuretted hydrogen, &c. It may with confidence be asserted that fatal results from exposure to drainage-gases will cease as soon as the respirator is brought into use. 3. In districts such as the Campagna of Rome, where malaria prevails, and to travel during night, or to sleep in which, is almost certainly followed by an attack of dangerous and often fatal ague, the wearing of the respirator for even a few hours may be expected to render harmless the marsh poison. 4. Those who, as clergymen, physicans, or legal advisers, have to attend the sickbeds of sufferers from infectious disorders, may, on occasion, avail themselves of the protection afforded by Dr. Stenhouse's instrument during their intercourse wlth the sick. 5. The longing for a short and decisive war has led to the invention of "a suffocating bomb-shell," which, on bursting, spreads far and wide an irrespirable or poisonous vapour; one of the liquids proposed for the shell is the strongest ammonia, and against this it is believed that the charcoal-respirator may defend our soldiers. As likely to serve this end, it is at present before the Board of Ordnance.

Dr. Wilson stated, in conclusion, that Dr. Stenhouse had no interest but a scientific one in the success of the respirators. He had declined to patent them, and desired only to apply his remarkable discoveries to the abatement of disease and death. Charcoal had long been used in filters, to render wholesome poisonous water; it was now to be employed to filter poisonous air.

## SUB-ARCH TUNNELS

We have received a letter from Mr. Austin, respecting his plans of drainage, &c., drawings of which he exhibited at the meeting of the Institute of British Architects, in which he states that the idea of sub-archways was one entirely original with himself, and that he had no previous knowledge of any similar proposition.

This may be very true, as is the case with many other ideas; yet still the individual who first publicly makes known any scheme or invention has the *jus priores* to be considered as its originator.

We wish not to detract from the credit due to Mr. Austin for his proposition, which is not only practicable, but can be demonstrated to be in the end cheaper than the present imperfect patchwork system of drainage, &c.

He wishes us to correct the dimensions given of his tunnel, which, instead of being proposed to be 26 feet in height by 18 feet in width, should be 26 feet by 24 feet. We may probably notice Mr. Austin's scheme next month.

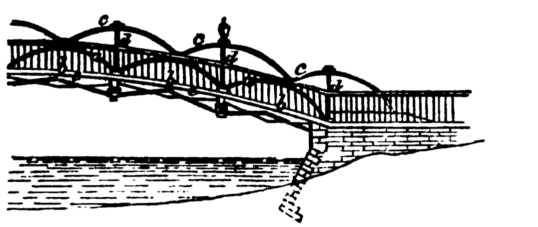
## CONSTRUCTION OF BRIDGES AND VIADUCTS.

JOHN MACINTOSH, *Patentee*, August 3, 1853.

THIS novel method of constructing bridges and other similar structures consists in combining a series of bow and string arches into one girder or beam, in such manner that each bow or arch springs from the crowns of the two bows or arches to which it is connected. And in constructing and repairing arches, particularly in rivers and waterways, in place of having piers and foundations, and springing the arches from and supporting the arches by such piers, inverted metal arches are used to support the arches above.

Fig. 1 of the annexed engravings is the side elevation of a bridge constructed in accordance with this invention. *a, a, a,* are a series of bows having their extremities tied in by rods *b, b,* as shown. *c, c, c,* is an upper tier of bows having their bearing upon the crowns of the arches or bows *a, a,* to which they are firmly fixed in such manner as to form a strong girder; the roadway *e,* is suspended by rods *d, d,* or otherwise to the bows *a, a, c, c,* as shown.

FIG. 1.



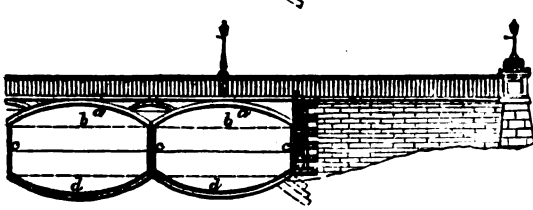


FIG. 2.

Fig. 2, is a side elevation of another form of bridge. The bows *a, a,* having strings *b, b,* are connected together and to vertical supports *c, c,* and the roadway *e, e,* is supported or laid on the crowns of the bows *a, a*; the vertical supports *c, c,* are at their lower ends connected together by inverts *d, d,* which lie at the bottom or bed of the river or other stream suitably prepared to receive them. By this means bridges can be constructed without the necessity of forming cofferdams; and the inverts may be temporarily tied with strings *b, b,* similar to those of the bows *a, a,* and the ends closed water-tight so as to float the parts to their destination, and then to remove the water-tight ends and sink the parts to the bed or bottom of the river or other channel over which the bridge is to be constructed. The several portions of the bridge each being formed of the parts *a, b, c, d,* are, after being sunken to the bed of the river and properly set in position, firmly secured together, after which the roadway and side railing are placed and affixed as usual, and the strings *b,* of the bows *a,* and inverts *d,* may then be removed so as to allow of the full dimensions of the arch formed by the bows *a,* and the inverts *d,* being clear for the passage of traffic.

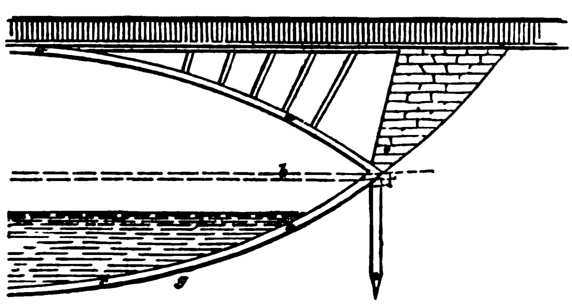

FIG. 3.

Fig. 3 shows a side view of another description of bridge. Instead of employing bows *a, a,* alone, as shown in fig. 1, the bows are connected, the one being inverted to the other, firmly united together at their ends, and strings or tie-rods placed across to stiffen the parts during the floating of them to their destination, after which and the filling in of the masonry, &c., at *e, f,* and the bed of the river at *g,* will be then sufficient to prevent the bows *a,* and inverts *c,* from becoming displaced.

The materials to be used in the construction of the bows and inverts and supports, may be of iron or wood or iron and wood combined, according as the dimensions or span of the bridge require.

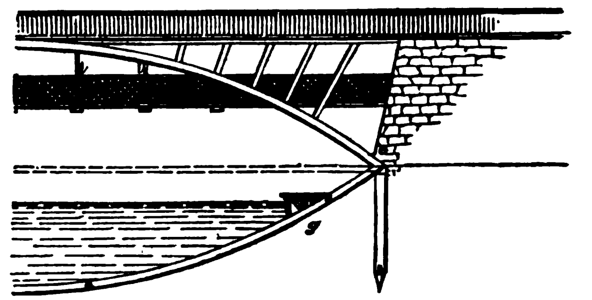

FIG. 4.

Fig. 4 shows a side view of a bridge of somewhat different form to either of the above described, in which the rods *i, i,* from the bows *a, a,* are made to sustain a road or footway bridge, in which case the bridge above at *h,* may be a railway bridge or suitable for any other purpose, and the bridge below being suspended therefrom by rods *i, i,* as shown, may be a roadway or footway bridge, or both, as desired.

*Claim.*—The modes of constructing bridges by forming and connecting bow and string arches into girders or beams. Also, the constructing and repairing arches without the ordinary abutments by using inverts, as herein explained.

## STEAM ENGINES.

GEORGE LEEDHAM FULLER, *Patentee*, August 17, 1853.

IN the ordinary form of compound engines, commonly known as double-cylinder condensing engines, the steam is allowed to expand from the first supply cylinder into one or more working conjointly with it, as regards the times or periods of stroke (as in Woolf's, MacNaught's, or Miller's patents), thus forming only, in effect, a single engine, with but small advantages over the plan of expansion in a single cylinder, and being considerably more costly in construction.

The novelty of this invention consists in an arrangement for expanding into and supplying two or more cylinders connected with a condenser and air pump, or condensers and air-pumps, in the usual ways, from one or more cylinders, supplied direct from the boiler, such supply and exhaust cylinders respectively not, as heretofore, having their pistons arriving at the top and bottom of their strokes conjointly, but being so arranged as regards their times and periods of action as to form together a complete rotary power.

Three cylinders will be found most economical, both as regards first cost and working, and for facility of arrangement. They are arranged in line, or at any convenient angle, as required, and are so adapted that one cylinder shall be in course of being supplied and two exhausted, and *vice versâ*.

For marine purposes, also, such engines afford peculiar advantages for provision in case of accidents to either of the cylinders or their respective parts, since a simple provision for cutting off the connection between the cylinders, and of connecting instead the exhaust passages and the ports of the supply cylinder, and the steam passages and the ports of the exhaust cylinders respectively, at once renders each cylinder an independent engine as regards its working, to which might also be added, if required, the provision of a second keyway to the crank, so as to give the power of placing the cranks of either two cylinders at any time at the usual working angle as regards each other, should the remaining cylinder become disabled.

The relative positions of the cylinders, the angles at which the cranks are placed, the proportion of areas of the cylinders to one another, the number and description of steam cylinders employed, whether direct action, side lever, beam, or vibrating, may be varied at pleasure. Nor does the inventor fix any particular times of the respective strokes for cutting off, which may or may not be made different for each cylinder, and such supply may or may not be continued to the end of the stroke, or may be variable by means of an expansion-valve in the ordinary way, at pleasure. Neither to any particular form of valve for such engine, or to the entrance and exit ports of the cylinders being the same or separate; but claims as new all and every arrangement and form of steam-engine, wherein steam being supplied to one or more cylinders, passes from it or them into two or more other cylinders, discharging into a condenser in the usual or any other manner, and so arranged in connection with the said supply cylinder or cylinders, as regards their times of action, that the whole cause a continuous rotary motion to a common driving-shaft, instead of having only, as in the present arrangement of such compound engines, the effect of a single engine, thus combining all the economical advantages of an unlimited power of expansion with the effect obtained by two or more separate engines.

The second part of this invention relates to the valves of vibrating engines. The steamways are continued through one of the trunnions, formed with a division in it, to separate the top and bottom steam-way respectively; on an enlargement of the trunnion are formed valve faces and ports, on which a segmental slide-valve can be worked for the purposes of lead and expansion, as in ordinary engines; thus substituting for the present method of having a steam-chest fixed on to and moving with the vibrating cylinder, and supplied and discharged through the two trunnions respectively—both of which require consequently to be furnished with stuffing-glands at their junctions with steam and exit pipes respectively, and so add greatly to the friction—a fixed steam-chest with passages through only one trunnion, and no absolute necessity (except sufficient to provide for any chance leakage of the valves) for any stuffing-glands at all; while at the same time the valve gearing, instead of being, as at present in such engines, comparatively complicated and expensive, is rendered as simple as that for ordinary fixed cylinder-engines. And moreover, by the motion of the cylinder being rendered available, the entrance and exit of the steam through the ports is quickened considerably while the required motion or throw of the valve need only be sufficient for the purpose of expansion and lead.

Under this second head, the inventor claims any arrangement whereby, by means of ports and faces formed on an enlargement of the trunnions of vibrating engines (whether such engines be condensing, non-condensing, or compound, and working within or against a properly-formed seat), steam is obtained from fixed steam-pipes, through a fixed steam-chest or valve-box, and let out in a similar manner; and to which faces and seats also segmental slide-valves, formed as herein described, can be applied and moved for the purposes of giving lead or cutting off steam, reversing, &c., in the same manner and with the same facility as the slide-valves of ordinary fixed cylinders.

## NOTES OF THE MONTH.

*Mr. Christopher.*—We regret to announce the death of Mr. James Charles Christopher, architect, on the 14th ult. It appears that the deceased, after partaking of an entertainment given to the Committee of the District Surveyor's Association, by Mr. Gutch, at Greenwich, proceeded to join his brother to witness the embarkation of the French troops at Calais destined for the Baltic. While his brother's vessel, the *Lizard*, was nearing the *Algiers* line of battle ship, her topmast got foul of the yards of the *Algiers*, and snapped, and the falling spar, in its descent on deck, struck the back part of deceased's head, and caused his instantaneous death. He was a member of the firm of Garland and Christopher, and was district surveyor of the parish of Hammersmith, which office he had held from the date of its first creation.

*Paper from Peat.* — A French chemist, J. Lallemand, has recently patented a method of manufacturing paper from peat or turf. The process consists in first thoroughly separating, by washing, all the earthy from the fibrous portions of the peat. The fibres are then placed in a bath of caustic ley. After a lapse of twenty-four hours, the fibres are removed to a bath acidulated with hydrochloric acid, in which they are agitated for about four hours. The fibres are next washed in clear water, and then again bathed in water containing a small quantity of alum. They are then bleached in a chlorine vat, and mixed with from five to ten per cent. of rag pulp, which mixture is placed in an ordinary pulping engine, and undergoes the processes usually adopted in the manufacture of paper.

*Spurious Coin Detector.*—An ingenious apparatus for detecting genuine from counterfeit coin has been proposed by a Mr. G. Davis, which, although simple, we are afraid will not come into very general use, as in these matters tradesmen and others mostly prefer relying on their own shrewdness, to employing mechanism liable to derangement. The apparatus in question consists of a gauge-plate let into the counter, having slots cut in it exactly corresponding to the diameter and thickness of the different varieties of coins. Beneath each slot is suspended a balance or lever, with an arm immediately under the opening, and exactly weighted to the precise weight of the coin. It is thus evident that this arrangement will readily pass genuine coins of the precise size and weight, whilst those that are not of standard weight will be unable to depress the lever, and those of greater diameter, which is generally the case with spurious coin, cannot be passed through the slot. The apparatus is best adapted for gold, as most of the silver currency is deficient in weight, yet perfectly genuine.

*Sydney Royal Mint.*—The whole of the machinery for the Sydney Royal Mint, consisting of two condensing steam-engines, rolling mills, machine for adjusting the thickness of metals, the cutting-out presses, coining presses, bars, furnaces, &c., have been shipped to Sydney. About eight months ago, the order for the machinery was awarded to Mr. Joseph Taylor, engineer, of Broad-street, Liverpool, by whom the whole has been completed to the entire satisfaction of the government. The cutting-out presses, and milling machines, are from new designs by Mr. J. Taylor, and have been successfully in work at the Royal Copper Mint, in that town, for some weeks.

*Railway Adaptation.*—Among the materialism carried by rail, *water* has come to take a place. The *Scottish Railway Gazette* observes, that the trains of the Morayshire Railway actually convey the pure fluid from Elgin to Lossiemouth to accommodate the summer visitors to that place. The fact is suggestive, trivial though it may seem. By means of interchanging commodities, or bringing commodities to a quarter where they are required, and where a money price may be had for the articles, a traffic of considerable value is obtained. This however, may to some extent, if not wholly, depend on the interposition of local railway officials, for it is to be recollected that to be profitable the railway system must not only secure the traffic already existing in a district, or that traffic to a great extent, but create more. By good management, by attending to diversified wants throughout districts and by suggesting the means of supplying these, a trade is likely to be got up which may bear on final results in a very favourable way.

*Soapstone.*—A new building material is coming into notice in New York which promises to supersede everything else. This is steatite or soapstone, either in its purest state or in combination with other rocks. Its common qualities are perfectly familiar. It is so soft that it can be cut with a chisel, planed, bored, sawed, or turned in a lathe. Yet it resists pressure very well indeed, particularly when mixed with the harder ingredients, such as hornblende or serpentine. In beauty it is often found equal to marble, with even a greater variety of appearance. It bears an excellent polish, and, if broken, can easily be mended, by using its own powder as cement, so nicely as to be detected only by a critical examination. A house of this material was built at Northampton in 1807, and it is said to be still standing fresh and clear, to all appearance as if it had encountered only the rains of our last watery spring. The stone may be heated to a white heat, and then gradually cooled, or plunged into cold water at the option of the experimenter—and in either case it does not shell off nor crumble. Wet granite, as we all saw at the burning of the Custom-house, positively explodes in the heat—the flutings of the pillars, for instance, leaping off two or three feet. If, therefore, soapstone should be employed for floorings as well as for walls (and there is no reason against it), a perfectly fireproof building would be the result. So if the assertions of all the chymists turn out to be correct, we have at last found out the very perfection of building materials. But they are testing the matter in New York, and we shall soon hear.—*American Paper.*

## COPPER, TIN, AND ZINC IMPORTS AND EXPORTS.

A Parliamentary paper has just appeared, containing returns of the quantities of copper, tin, and zinc imported and exported for the year ending on the 5th of January 1854. The total amount of copper ore imported into the United Kingdom within that period was 45,285 tons 19 cwt. 1 qr. 7 lb.—of which 29,049 tons 5 cwt. 0 qr. 19 lb. were imported into Swansea, 13,246 tons 8 cwt. 2 qr. 16lb. into Liverpool, and 2873 tons 1 cwt. 2 qr. 13 lb. into London. Of the entire amount, 14,606 tons 19 cwt. 2 qr. were imported from Cuba, 13,342 tons 3 cwt. 2 qr. 12 lb. from Chili, 4759 tons 5 cwt. 0 qr. 12 lb. from Spain, 3373 tons 10 cwt. 1 qr. 17 lb. from Peru, 2676 tons 15 cwt. 2 qr. 8 lb. from South Australia, 1322 tons 10 cwt. 3 qr. 25 lb. from New Zealand, 540 tons 0 cwt. 1 qr. 12 lb. from Van Dieman's Land; from the British North American Colonies 949 tons 4 cwt. 1 qr. 19 lb., and from the British West Indies and British Guiana 561 tons 15 cwt. 2 qr. 25 lb. The total quantity of British copper exported from the United Kingdom within the same period was 15,632 tons 7 cwt.; of which 6721 tons 12 cwt. were from the port of London, 6539 tons 17 cwt. from the port of Liverpool, and 1301 tons 11 cwt. from that of Swansea. Of this quantity 3799 tons 5 cwt. were exported to the United States of America, 3039 tons 16 cwt. to France, 1409 tons 10 cwt. to Holland, 940 tons 9 cwt. to the Hanseatic towns, 707 tons 14 cwt. to Belgium, 803 tons 0 cwt. 1 qr. to Italy, and 1815 tons 10 cwt. to the British possessions in India.

The entire quantity of tin imported into the United Kingdom in the same year was 2487 tons 0 cwt. 1 qr. 4 lb., besides 156 tons 14 cwt. 1 qr. 25 lb. of tin ore and regulus. Of tin, we received from Holland 587 tons 14 cwt. 1 qr. 11 lb., from the British territories in the East Indies, exclusive of Singapore and Ceylon, 548 tons 13 cwt. 2 qr., and from Singapore, 1155 tons 15 cwt. 3 qr. 15 lb. The quantity of tin exported from the United Kingdom within the same period was—British, 1277 tons; foreign, 1072 tons 10 cwt.

The quantity of zinc and zinc ore imported into the United Kingdom was 20,418 tons 19 cwt. 0 qr. 21 lb. of zinc, and 342 tons 6 cwt. 3 qr. 18 lb. of oxide of zinc, of which we received from Prussia 11,429 tons 0 cwt. 2 qr. 14 lb. of zinc, from the Hanseatic towns 7497 tons 14 cwt. 3 qr. 16 lb., and from Belgium 4011 tons 14 cwt. 3 qr. 4 lb.; and during the same period we exported from the United Kingdom 3181 tons 18 cwt. of British, and 9461 tons 4 cwt. of foreign zinc and zinc ore. In the foregoing abstract we have only given the most important places, the returns from others being, in many instances, very inconsiderable.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated January 12, 1854.*

77. J. Serf, Paris—Improvements in seats or chairs for advertising

*Dated April 10.*

835. L. M. Trouble, Paris—Improvements in stamping-apparatus or autoperitype.

*Dated April 15.*

874. C. B. Goodrick, Old Kent-road—Improved artizan's tool, which may be used as a measuring-rule, straight edge, set square, T square, bevil, and plumb-rule

*Dated May 2.*

979. T. Jackson, Commercial-road, Pimlico—Improvements in the manufacture of paper from flax, hemp, jute, Indian grass, and other fibrous vegetable substances, or the tow produced from such fibrous substances.

*Dated May 10.*

1041. J. W. Hoby, Renfrew, and J. Milner, Stanley-street, Pimlico—Improvements in steam-engines

*Dated May 11.*

1049. H. Tylor, Queen-street—Improvements in chair-bedsteads

*Dated May 18.*

1106. T. C. Hine, Regent-street, Nottingham—New method of applying glass in the ornamentation of chandeliers and other fittings required for gas, candle, oil or other artificial light

*Dated May 29.*

1190. A. E. Sablons, South-street, Finsbury—Improvements in the construction of trunks, travelling-boxes, portmanteaus, and other similar receptacles

*Dated May 30.*

1194. A. E. L. Bellford, Castle-street, Holborn—Improvements in machinery for making bags of paper or other suitable material. (A communication)

*Dated May 31.*

1203. T. Harrison and E. Harrison, Blackburn, Lancaster—Improvements in looms for weaving

1205. G. A. De Penning, Calcutta—Appendage to screw-propellers

1207. A. Rogers, Beeston Royds, near Leeds—Improvements in the mode of ventilating mines, sewers, and other subterranean works, and likewise for the warming and ventilating of all kinds of public buildings

1210. L. I. Molinos and C. Pronnier—Improvements in locomotive steam-engines

1211. A. V. Newton, Chancery-lane—Improved mode of manufacturing soluble silicates. (A communication)

*Dated June 1.*

1213. J. Whitaker and J. Pickles, Todmorden, York—Improvements in machinery or apparatus for opening, cleaning, and preparing cotton, wool, or other fibrous substances

1215. C. King and E. S. Benfield, Chenies-street—Improved machinery for cutting and carving wood, stone, and other materials

1217. J. T. Chance, Birmingham—Improvements in machinery for roughing or preparing the surfaces of glass. (A communication)

1219. J. Robinson, Denton-mill, Carlisle—Improvements in apparatus for mixing wheat and other grain and matters

1221. G. K. Geyelin, Camden-town—Improvements in furnaces and fireplaces for facilitating the consumption of smoke

*Dated June 2.*

1223. C. Maschwitz, Birmingham—New or improved instrument for paring and slicing apples, potatoes, and other fruits and roots. (A communication)

1225. E. O. W. Whitehouse, Brighton—Improvements in effecting telegraphic communications

1227. E. Websky, Wustewaltersdorf, Prussia—Improvements in bleaching. (Partly a communication)

1229. J. Mason and L. C. Koeffler, Rochdale, Lancaster—Improvements in scouring and in washing wool, hairs, and yarns, and in machinery or apparatus for effecting the same

*Dated June 3.*

1231. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improved fuel. (A communication)

1233. T. Lenox, Pigott-street, Limehouse—Novel mode of reefing topsails, jibs, and other sails from the decks of ships while at sea

1235. A. H. Leplay, Douvrin, France—Improvements in extracting and manufacturing the alcohol of beetroot, and of other sweet matters or tubers

1237. W. E. Newton, Chancery-lane—Improvements in breech-loading fire-arms. (A communication)

1239. A. F. Goodnow, New York—Improvement in scythe snaths, or in the manufacture thereof. (A communication)

1241. A. G. Barham, Bridgewater, Somerset—Apparatus for damping or moistening the adhesive surfaces of stamps or labels.

*Dated June 5.*

1243. R. A. Brooman, Fleet-street—Improvement in screw-propellers. (A communication)

1245. G. Garbert, Port Louis, Mauritius — Improvements in the construction of buildings

1247. N. Neron, Rue St. Lazare, Paris—Improvements in muskets, carbines, fowling-pieces, and other fire-arms. (A communication)

1249. A. Spottiswoode, New-street, St. Bride's—Improvements in the manufacture of fuel

1251. T. Spiller, Red Lion-square, Holborn—Improvements in propelling carriages when atmospheric air is used

*Dated June 6.*

1253. W. J. Baillie, Southwark—Improved mode of propelling ships and other floating vessels

1255. J. Nicholson, Blackwall—Improved ratchet-screwing and drilling-stock, which may also be used as a spanner

*Dated June 7.*

1258. J. Mansfield, Stoke Stafford—Improvement or improvements in steam-boilers

1259. C. A. Perpigna, Paris—Improved apparatus for effecting the combustion of smoke in fireplaces. (A communication)

1260. W. E. Newton, Chancery-lane—Improved manufacture of bonnets and other coverings for the head. (A communication)

1261. P. Hindle, Ramsbottom, Lancaster—Improvements in power-looms for weaving

*Dated June 8.*

1262. J. Wilson, Albert-place, Stratford—Improved pump applicable to mines, wells, ships, fountains, and domestic purposes, and raising melted metals in foundries, so constructed that it cannot lose water, draw grit, draw air, or freeze

1263. J. Kaye, Beeston, near Leeds—Improvements in machinery or apparatus for slubbing, roving, spinning, and doubling wool and other fibrous materials

1264. W. Aldritt, Belfast—Improvements in lighting and ventilating

1265. M. Scott, Great George-street, Westminster—Improvements in roofing or covering reservoirs or holders for liquids

1266. J. Leadbetter, W. Wight, and T. Davis, Halifax—Improvements in machinery or apparatus for raising water and other fluids

1267. J. Skertchly, jun., Kingsland—Improvements in the manufacture of gates, hurdles, and fencing; in vehicles, wagons, carts, and trucks, for common roads and railways; and in facias, entablatures, window-headings, parapet, and other mouldings projecting from the brickwork of buildings

1268. P. Journet, Rue de Belzunce, Paris—Improvements in chucks for lathes

1269. B. Blackburn, Clapham-common—Improvements in the manufacture of pipes when applying slate for such purposes

1270. T. Richardson, Portland-place, Newcastle-upon-Tyne — Improvements in the manufacture of alum

*Dated June 9.*

1271. J. B. M. Erard, Paris—Improvements in the preparation of paint

1272. F. Marguritte, Paris—Improvements in wet gas-meters

1273. R. A. Brooman, Fleet-street—Improvements in machinery for cutting brads, lath-nails, and others of similar character. (A communication)

1274. T. Bramwell, Enfield House, Durham—Improvements in the manufacture of the carbonates and prussiates of potash and soda

1275. J. Nelson and D. Boyd, Selby, York—Improvements in preparing and scutching flax, hemp, and other substances

1276. J. L. Hancock, Neath, Glamorgan—Improvement in cutting, hay, straw, and other fibrous articles and substances

1277. J. Currie and R. Young, Glasgow—Improvements in the treatment and grinding of grain, and the products thereof

1278. B. Cook, Birmingham—Improved means of ornamenting metallic bedsteads, chairs, and couches, which said improvement is also applicable for ornamenting standards for glass frames, tables, and fire-screens, cornice-poles, and other articles of furniture

1280. G. A. Buchholz, Hammersmith—Improved machinery applicable to the hulling or cleaning of grain, seeds, and other vegetable produce

*Dated June 10.*

1282. A. L. Dawson, Southwark—Improvements in machinery for cutting and shaping wood

1283. A. Barclay and J. Barclay, Kilmarnock—Improvements in printing textile fabrics and other surfaces

1284. L. Bois, Paris—Improvements in looms

1285. J. Whitehead, Preston—Machine for weaving wire-netting of iron, brass, or other material. (A communication)

1286. E. P. Alexander, Lincoln's-inn—Improvements in moulding. (A communication from M. De Louvrie, St. Marc, France)

1287. F. Puls, Whitechapel-road—Improvements in electro-galvanic apparatus for medical purposes; parts of which improvements are also applicable to other electro-galvanic apparatus

*Dated June 12.*

1288. J. Young, Wolverhampton—Improvements in locks and latches
1289. R. A. Brooman, Fleet-street—Method of producing plans in relievo. (A communication)
1290. R. A. Brooman, Fleet-street—Improvement in or addition to sugar-basins. (A communication)

*Dated June 13.*

1291. A. L. Péter, Lyons, France—Improvements in treating a certain kind of indigo
1292. C. H. Compton, Bloomsbury—Improved railway-break
1293. W. Southall, Swan-lane—Improvements in machinery or apparatus for cultivating and pulverising land

*Dated June 14.*

1294. J. Barlow, Accrington, Lancaster—Improvements in the mode or method of extracting gluten, and preparing the same for sizing purposes
1295. J. Pickup, Liverpool—Improvements in steering apparatus
1296. J. Hargrove, Kirkstall—Improved machinery for washing, scouring, and felting or fulling

*Dated June 15.*

1297. J. Edwards, Camberwell—Improved knife-cleaner
1298. F. Martini, Mumford-court, Milk-street — Improvement in working steam-engines
1299. T. Wilson and J. Hadley, Birmingham—New or improved method of constructing certain kinds of rolls or cylinders and dies or surfaces
1300. J. Kite, Princes-street, Lambeth—Improvements in machinery and apparatus for expressing moisture from substances
1301. J. Gedge, Wellington-street South—Improvements in the construction of locks and latches, spindles and knobs, applicable to doors and other similar purposes
1302. S. Varley, Stamford, Lincoln—Improved construction of haymaking-machine
1303. J. D. M. Stirling, Blackgrange, Scotland—Improvements in the manufacture of iron. (Partly a communication from M. L. Talabot)

*Dated June 16.*

1304. J. E. Piper, New-road, St. Pancras—Improvements in the preparation of linen, cotton, and other fabrics, to produce a factitious leather
1305. W. Brindley, Moorgate-street—Improvements in applying steam for offensive and defensive purposes
1306. R. Hornsby, Grantham, Lincoln—Improvements in portable thrashing-machines
1307. T. M. Fell, King William-street, and W. Cooke, Curzon-street, Hanover-square—Improvements in ventilators
1308. W. Cooke, Curzon-street, Hanover-square—Improvements in boots and shoes
1309. C. Hargrove, Birmingham—Improvement or improvements in the manufacture of certain kinds of iron
1310. W. Evans, St. Leonard's-terrace, Chelsea—Improved tap for drawing off liquids
1311. F. Martini, Mumford-court, Milk-street — New or improved construction of steam-engines
1312. J. Macnee, jun., Glasgow—Improvements in caps, hats, and other coverings for the head
1313. F. J. Julyan, Gerrard-street, Soho-square—Improved method of producing musical sounds
1314. W. G. Pidduck, Camberwell—Improvements in the construction of vent-pegs
1315. H. Hughes, Aldersgate-street—Improved machinery for cutting and embossing, either separately or simultaneously
1316. T. Parramore, Castle-street, Southwark—Improvement in the manufacture of air-tight seats, beds, and other articles required to be inflated and air-tight
1317. D. Lowe, Leicester—Improvements in knitting machinery

*Dated June 17.*

1318. G. J. Hinde, Wolverhampton, Stafford—New or improved combination of materials to be used for the manufacture of pipes or tubes for drains, or such purposes as the same is or may be applicable to
1319. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in treating bitumen. (A communication)
1320. J. Aspinall, Tavistock-square—Improved means of creating a vacuum or partial vacuum for evaporative purposes
1321. J. Foudrinier, Sherborne-street, Islington — Improvements in machinery for washing, boiling, cleaning, and bleaching rags, fibrous, and textile substances
1322. A. V. Newton, Chancery-lane—Improvements in machinery for block-printing. (A communication)
1323. J. Rawe, jun., Haverstock-hill—Improvements applicable to stoves, stove-grates, or fireplaces for domestic use
1324. G. Holloway, Stroud, Gloucester—Improvements in sewing and embroidering machines
1325. J. A. Williams, Baydon, Wilts—Improvements in machinery or apparatus for ploughing and cultivating land
1326. A. E. L. Bellford, Castle-street, Holborn—Improvements in water-mill machinery (A communication)

*Dated June 19.*

1327. L. A. Henry, Metz, France—Improvements in constructing railroads
1329. Sir J. C. Anderson, Fermoy, Cork—Economical railway for the conveyance of passengers, goods, and letters
1330. G. Mears, Whitechapel-road—Improvements in machinery or apparatus for obtaining sounds
1331. J. Westlake, Newton Abbott, Devon—Improvements in treating the pulverised solution obtained from machines used for crushing ores, gossans, earths, and rocks
1332. J. V. Weber, Orchard-street, St. Luke's—Improvements applicable to chronometers and other mechanism requiring a steady spring power
1333. W. Baur, Munich, Bavaria—Improvements in propelling vessels
1334. P. G. Dartiguenave, Regent-street—Improvements in aërial navigation
1335. J W. Schlesinger, London-wall—Means of readily discovering any street, road, river, locality, or place, on maps, charts, and plans. (A communication)
1336. S. Riley, Oldham, Lancaster—Improvements in pocket-books, bill-cases, or other such depositories
1337. J. Oliver, Wapping—Improved construction of signal lantern
1338. D. Bogue, Fleet-street—Improved apparatus for facilitating the attachment of adhesive stamps. (A communication)

*Dated June 20.*

1339. H. Worrall, Staley-bridge, Chester—Improvements in machinery or apparatus for carding cotton, wool, or other fibrous materials
1340. W. Brunton, Camborne, Cornwall—Improvements in metallic pistons
1341. J. Acland, Langley-cottage, South Lambeth—Improvements in the manufacture of paper
1342. T. L. Holt, Warwick-square, and W. C. Forster, Hatton-garden—Making paper
1343. C. Reeves, Birmingham, and W. Wells, Sutton Coldfield, Warwick—A new or improved method of manufacturing certain kinds of metallic tubes
1344. J. Day, Birmingham—Improvement or improvements in certain kinds of candle-sticks
1345. A. Stephen and A. Pernie, Kelvinaugh, Glasgow—Improvements in the application of materials for and in the arrangement of and method of applying apparatus to be used as templates for ascertaining and marking the proper positions for the rivet and bolt-holes required in the plates, frames, and other pieces or portions of the materials used in the construction or manufacture of iron ships or vessels, boilers, tanks, masts, spars, and other similar articles
1346. J. E. Jesson, Paris—Improved barometer, called "Hydrographer Barometer"
1347. N. Clayton and J. Shuttleworth, Lincoln—Improvements in portable and fixed combined, thrashing, shaking, and winnowing machines
1348. W. T. Monzani, St. James's-terrace, Bermondsey—Improvement in brushes and brooms
1350. F. Braithwaite, Gower-street, Bedford-square—Improvements in constructing suspension-bridges, roofs, and coverings
1351. G. R. Chittenden, Wood-street—Improvements in sewing-machines. (A communication)
1352. A. McLaine, jun., Belfast—Improved mode of constructing and fitting gun-boats
1353. W. E. Newton, Chancery-lane—Improved manufacture of pigments or colouring matters. (A communication)
1354. G. H. Byerley, Brompton—Improvements in machinery for the manufacture of bricks, tiles, quarries, tubes, and other such like articles

*Dated June 21.*

1355. W. Donald and W. Heginbotham, Carlisle, Cumberland — Improvements in looms
1356. J. McInnis, Liverpool—Improved composition for coating the bottoms of iron ships to prevent their fouling, and other useful purposes
1357. H. V. Physick, North-bank, Regent's-park—Electric telegraphs, and apparatus connected therewith
1359. O. R. Chase, Cornhill—Improvements in machinery for manufacturing lozenges, and for other purposes
1360. J. W. Shaw, Birmingham—Improvements in apparatus or machinery for producing motive power. (A communication from Don M. M. J. T. Miciano y-Contillo, Cadiz, Spain)
1361. W. E. Newton, Chancery-lane—Improvements in apparatus for generating and utilising steam. (A communication)
1362. T. Rhoads, Vine-street, America-square—Improved method of framing school-slates. (A communication)
1363. W. Stableford, Worcester—Improvements in railway-breaks
1364. W. Parsons, Paradise-street, Lambeth—Improvements in rotatory engines
1365. J. F. Heather, Woolwich—Improvements in apparatus for regulating the flow of gas

*Dated June 22.*

1366. W. Stidolph, Wintoun-place, Greenwich—Transferable book-marker
1367. T. C. Yates, Bolton-le-Moors, Lancaster—Improvements in wickets for the game of cricket
1368. G. Simpson, Union-buildings, Leather-lane—Improvements in furnaces
1369. J. M. Blashfield, Millwall, Poplar—Improvements in the manufacture of china, pottery, bricks, and other articles manufactured for the most part of clay
1370. W. H. Brown, Sheffield—Improvements in the construction of furnaces for the melting of steel and other metals requiring a crucible in the melting thereof
1371. C. Cowper, Southampton-buildings—Improvements in machinery for combing cotton, wool, flax, tow, silk waste, and other fibrous substances. (A communication)
1372. A. E. L. Bellford, Castle-street, Holborn—Improvements in machinery for forging or hammering iron, which may be also applicable to the hammering of other materials. (A communication)
1373. E. Smith, Carlisle-street—Improved watch-key
1374. A. E. L. Bellford, Castle-street, Holborn—Improvements in grate-bars and certain appliances to the same, for the purpose of preventing them from warping or twisting by heat. (A communication)
1375. G. F. Logan, Glasgow—Improvement in portable winches
1376. A. P. Price, Margate—Improvements in the treatment of certain alloys of tin
1377. A. P. Price, Margate—Improvements in the purification of tin, and in obtaining useful products arising from such purification
1378. G. Ermen, Manchester—Improvements in machinery or apparatus for winding yarns or threads
1379. I. Farrell, Dublin—Improvements in fireproof flooring and roofing, which improvements are also applicable to the construction of walls and bridges, and other like structures

*Dated June 23.*

1380. C. Phillips, Offchurch, Warwick—Improvement of apparatus or machinery for reaping
1381. D. C. Knab, Rue Rosini, Paris—Improvements in the production of carburets of hydrogen
1382. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in machinery for the manufacture of nails. (A communication)
1383. A. E. L. Bellford, Castle-street, Holborn—Improvement in propelling vessels in water. (A communication)
1384. S. Dreyfus-Werth and P. Meunier, Sainte Marie-aux-mines (Haut Rhin), France—New or improved system of applying designs to all kinds of fabrics, and of surfaces of wood, marble, and stone
1385. A. E. L. Bellford, Castle-street, Holborn — Improvements in machinery for picking or opening cotton and other fibrous materials, and all kind of waste rags and old materials, to prepare the same for the operation of carding, or for other operations. (A communication)
1386. T. Rudd, Pimlico—Improvements in stands for casks or barrels
1387. J. Weild, Glasgow—Improvements in preventing the drainage waste of cargoes on ship-board
1388. J. Keyse, Apollo-buildings, Walworth—Improved method of loading muskets, rifles, carbines, pistols, and all descriptions of small arms with cartridge, without applying the cartridge to the mouth
1389. T. L. Dimsdale, Hadley—Improvement in the manufacture of gas for lighting and heating purposes
1390. W. E. Osborn, Milton, New York—Improvements in breech-loading guns or cannon
1391. R. Garrett, jun., Leiston Works, near Saxmundham, Suffolk—Improved arrangement of valves for working steam expansively
1392. R. M. Letchford, Whitechapel—Match-stand and holder for holding matches while being ignited

*Dated June 24.*

1393. H. Lightbown, Pendleton, Lancaster—Improvements in drying pulp in the manufacture of paper, also paperhangings and printed textile fabrics
1394. T. Skelton, Plaistow, Essex—Improvement in or addition to tillers or yokes
1395. R. A. Brooman, Fleet-street—New or improved projectile for ordnance and small arms, and a sabot or plug to be employed therewith, which sabot or plug may also be used with other projectiles. (A communication from W. A. Holwell, Quebec)
1396. D. L. Williams, Cannon-street, and J. W. Neale, Stepney—Improvements in furnaces
1397. R. A. Brooman, Fleet-street—Improved mill for grinding and pulverising paints and various vegetable and mineral substances. (A communication)
1398. J. Davies, Bristol—Improvements in propelling vessels
1399. J. Thomson, Newton-le-Willows, Lancashire—Improvements in centrifugal apparatus used in the manufacture of sugar
1400. J. Kenworthy and T. Rigby, Preston, Lancaster—Improvements in waterclosets

1401. R. Bottomley, Rochdale, D. Schofield, Oldham, and H. Spencer, Rochdale, Lancaster—Improvements in machinery or apparatus for spinning and doubling cotton and other fibrous materials
1402. J. Revell, Newark, Nottingham—Improvements in horse-shoes

*Dated June 26.*

1403. E. Hubner, Mulhouse, France—Improvements in machinery for preparing wool, cotton, silk-waste, tow, and other fibrous materials
1404. A. Bain, Queen's-row, Camberwell—Improvements in fire-arms and the apparatus connected therewith
1406. J. Brown, Haddington, Scotland—Improvements in the manufacture of metal spouts or troughs
1407. W. Palmer, Sutton-street, Clerkenwell—Improvements in candle-lamps
1408. C. Beale and J. Latchmore, Leicester—Improvements in the manufacture of knitted shirts
1409. T. H. Bakewell, Wellford-road, Leicester—Improvements in the manufacture of gloves
1410. W. Yates, Mary-street Bromley—Improvements in furnaces

*Dated June 27.*

1411. W. Brindley, Moorgate-street—Improvements in the construction of life-boats
1412. A. Smith, Princes-street—Improvements in the manufacture of certain kinds or descriptions of wire and other ropes and strands
1413. C. H. Collette, Lincoln's-Inn-fields—Improvements in the manufacture of beer. (A communication)
1415. R. L. Antrobus, Birmingham—New or improved method of printing oil-cloth for floor and table covers, paperhangings, and other surfaces
1416. W. Morgan, Birmingham—Improvements in machines for cutting paper, card, and millboards, woollens, veneers, and materials used in making paper; parts of which improvements are applicable to other machines where quick and slow motions are used, and where machinery is required to be thrown into and out of gear
1417. C. Iles, Birmingham—Improvements in metal bedsteads
1418. W. Coltman, High-street, Leicester—Improvement in knitting-frames
1419. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in apparatus for producing aerated waters. (A communication)

*Dated June 28.*

1420. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in the construction of axle-boxes. (A communication)
1421. J. Brunlees, Manchester—Improvements in drawbridges applicable to rail and other roadways
1422. H. S. Edwards, Cranbourne-street—Improvements in preparing textile fabrics or materials, for the purpose of their better retaining colours applied to them. (A communication)
1423. E. Cockshutt, Preston, Lancaster—Improvements in bungs or adjustable stopper apparatus for casks and other vessels
1424. J. Morison, Paisley, Renfrew—Improvements in the treatment or manufacture of ornamental fabrics
1425. T. Schlœsing, Paris—Improvements in the manufacture of carbonates of soda
1426. J. G. Jones, Roscommon-street, Liverpool — Improvements in apparatus for teaching addition

*Dated June 29.*

1427. W. J. Biesecker, Birmingham—New or improved method of labelling bottles and such other vessels or articles as require or may require labelling
1428. C. S. Sperry, Connecticut, U. S.—Improved knitting-machine. (A communication from W. M. Chase, Boston, U. S.)
1429. T. Markland, Hyde, Chester—Improvements in machinery or apparatus for warping, dressing, and weaving textile materials
1430. W. Smith and W. B. Hayes, Manchester—Improvements in power-looms for weaving

*Dated June 30.*

1431. E. J. Hughes, Manchester—Improvements in sewing-machines. (A communication)
1432. J. Edwards, Manchester—Improvements in railway-chairs
1433. D. Shears, Bankside, Southwark—Improvements in curing or separating moisture from sugar and other substances. (A communication)
1434. L. F. Izart, France—New mode of removing organic vegetable substances from woollen fabrics
1435. W. T. Monzani, St. James's-terrace, Bermondsey—Improvements in the manufacture of folding chairs, stools and other articles to sit or recline upon
1436. N. Thompson, jun., New York—Improvements in regulating the supply of steam from steam-boilers
1437. H. G. Gray, Commercial Wharf, Mile-end-road—Improvements in preserving potatoes, roots, plants, grain, and seeds
1439. T. Slater, Somers-place West, St. Pancras, and J. Tall, Crawford-street, Marylebone—Improvements in the construction of planes, and in cutting-apparatus, and in the machinery employed therein
1440. J. H. Johnson, Lincoln's-inn-fields—Improvements in machinery or apparatus for winding thread or yarns. (A communication from L. J. N. Carpentier)

*Dated July 1.*

1441. R. L. Jones, Chester—Improvements in locks and keys
1442. J. Hulme, Manchester—Improvements in steam-engines, and in valves; parts of which improvements are applicable for diminishing friction in other engines
1444. J. H. Johnson, Lincoln's-inn-fields—Improvements in submarine navigation. (A communication from Messrs. Payerne and Lamiral)
1445. J. H. Johnson, Lincoln's-inn-fields—Improvements in stoppers for bottles and other vessels, and in apparatus connected therewith. (A communication from H. Bordet)
1446. G. Hutchison, Glasgow—Improvement or improvements in the manufacture of soap
1447. J. Wilder, Reading,—Improvements in agricultural rollers and clod-crushers

*Dated July 3.*

1448. J. K. Milne, Edinburgh—Improved means of holding letters, documents, or other similar articles
1449. B. Walters, Wolverhampton—Improvements in spindles for locks and latches, and in the means of adjusting knobs to the same, to suit any thickness of door
1450. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in stopping bottles, and in drawing off aerated or other liquids contained therein. (A communication)
1451. W. Greenshields, Edinburgh—Improvements in chenille fabrics
1452. W. Balk, Ipswich—Improved friction dynamometer
1453. A. V. Newton, Chancery-lane—Improvement in the construction and arrangement of marine steam-engines. (A communication)
1454. J. Hopkinson, jun., Huddersfield—Improvements in steam-boilers and furnaces, and in apparatus connected therewith
1455. E. A. D. Guichard, Paris—Improvements in ornamenting the surfaces of various articles and fabrics
1456. U. Chauveau and C. d'Epinois, Paris—Improved means or apparatus for preventing collisions on railways

*Dated July 4.*

1457. J. Sunter, Derby—New or improved drilling-machinery
1459. C. T. Tiffany, Leeds—Improvement in the manufacture of brushes used in gig-mills and machinery for brushing piled fabrics
1460. T. Haimes, Melbourne, near Derby—Improvements in the manufacture of gloves and mits by warp machinery
1461. J. McGaffin, Liverpool—Improvements in corrugated cast-iron
1462. J. A. C. N. Delpech, Castres, France—Improved lift and force pump, called "Castraise Pump"
1463. J. Newman, Birmingham—Improvements in the manufacture of metallic rods, rails, and bars
1464. J. M. Bardet and F. Collette, Paris—Improvement in the construction of matches
1465. R. Garrett and R. Garrett, jun., Leiston Works, near Saxmundham, Suffolk—Improvements in machinery for drilling seed and manure
1466. G. D. Bishopp, Inverness-terrace—Improvements in the construction and arrangement of engines to be driven by steam, air, gas, or water
1467. T. Elliott, Manchester—Improvements in safety-valves, and apparatus connected therewith, which valves may also be used as steam-valves
1468. H. Heycock, Manchester—Improvements in hydraulic presses employed for packing or pressing cotton, silk, flax, wool, or other fibrous materials
1469. D. Bowlas, Reddish, Lancaster—Improvements in machinery or apparatus for knitting or manufacturing healds or harness used in looms for weaving
1470. J. H. Johnson, Lincoln's-inn-fields—Improvements in obtaining motive power. (A communication from J. E. Armengaud, Paris)
1471. J. H. Johnson, Lincoln's-inn-fields—Improved system or mode of coating iron with copper. (A communication from E. Bocquet, Corbehem, France)

*Dated July 5.*

1472. L. J. Cheval, Raismes, France—Improvements in beer-engines
1473. J. Burch, Crag-hall, near Macclesfield—Improvements in marine and other steam-engines
1475. T. Restell, Strand—Apparatus or holder for holding parcels of gloves and other goods and papers
1476. W. Symes, Pimlico—Improvement in tills

*Dated July 6.*

1480. J. Glasgow, Manchester—Improvements in machinery or apparatus for cutting, compressing, punching, shearing, and shaping metals
1482. O. Avery, Castle-street—Improvements in sewing and stitching-machines
1484. J. Lamb, Newcastle-under-Lyne — Improvements applicable to machines for cutting paper
1486. J. Radcliffe, Stockport—Improvements in power-looms for weaving
1488. J. H. Johnson, Lincoln's-inn-fields—Improvements in electro-magnetic engines. (A communication from T. C. Avery, New York)
1492. J. Petrie, jun., Rochdale, Lancaster—Improvements in machinery or apparatus for washing or scouring wool

## PATENTS APPLIED FOR WITH COMPLETE SPECIFICATION.

1414. S. Shipley, Stoke Newington—Improvements in fittings, suitable for dressing-cases, and for other purposes of elegance and utility.—June 27.
1458. A. S. Stocker, Hall-street, City-road—Improvements appertaining to match-boxes, and in the fitting, stoppering, and covering of tubes and other vessels of glass, porcelain, and other materials.—July 4.
1513. P. F. Aerts, Brussels—Improvements in constructing parts of railway rolling-stock, and in the lubrication thereof.—July 11
1515. T. Henley, Brompton—Improvements in the preparation of certain colouring materials.—July 11
1520. W. Eassie, Gloucester—Improvements in trucks used on railways.—July 12.

### NOTICES OF APPLICATION FOR LEAVE TO ENTER DISCLAIMERS.

A petition has been presented to the Attorney-General for leave to enter a disclaimer or memorandum of alteration of the specification of the invention for which letters patent were granted to Charles Hancock, gentleman, on the 29th day of July 1848, bearing the title, "Improvements in apparatus and machinery for giving shape and configuration to plastic substances." The parts of the specification which the petitioner desires to disclaim are from the word "firstly" to the word "fourthly," from the word "lastly" to the word "harden" (with the drawings there referred to) and the first, second, third, and sixth claims.

A petition has also been presented by William Seed, of Preston, Lancashire, machine-maker, for leave to disclaim a portion of the specification of his patent for "Certain Improvements in machinery or apparatus for preparing, slubbing, and roving cotton and other fibrous substances," dated July 14, 1846.

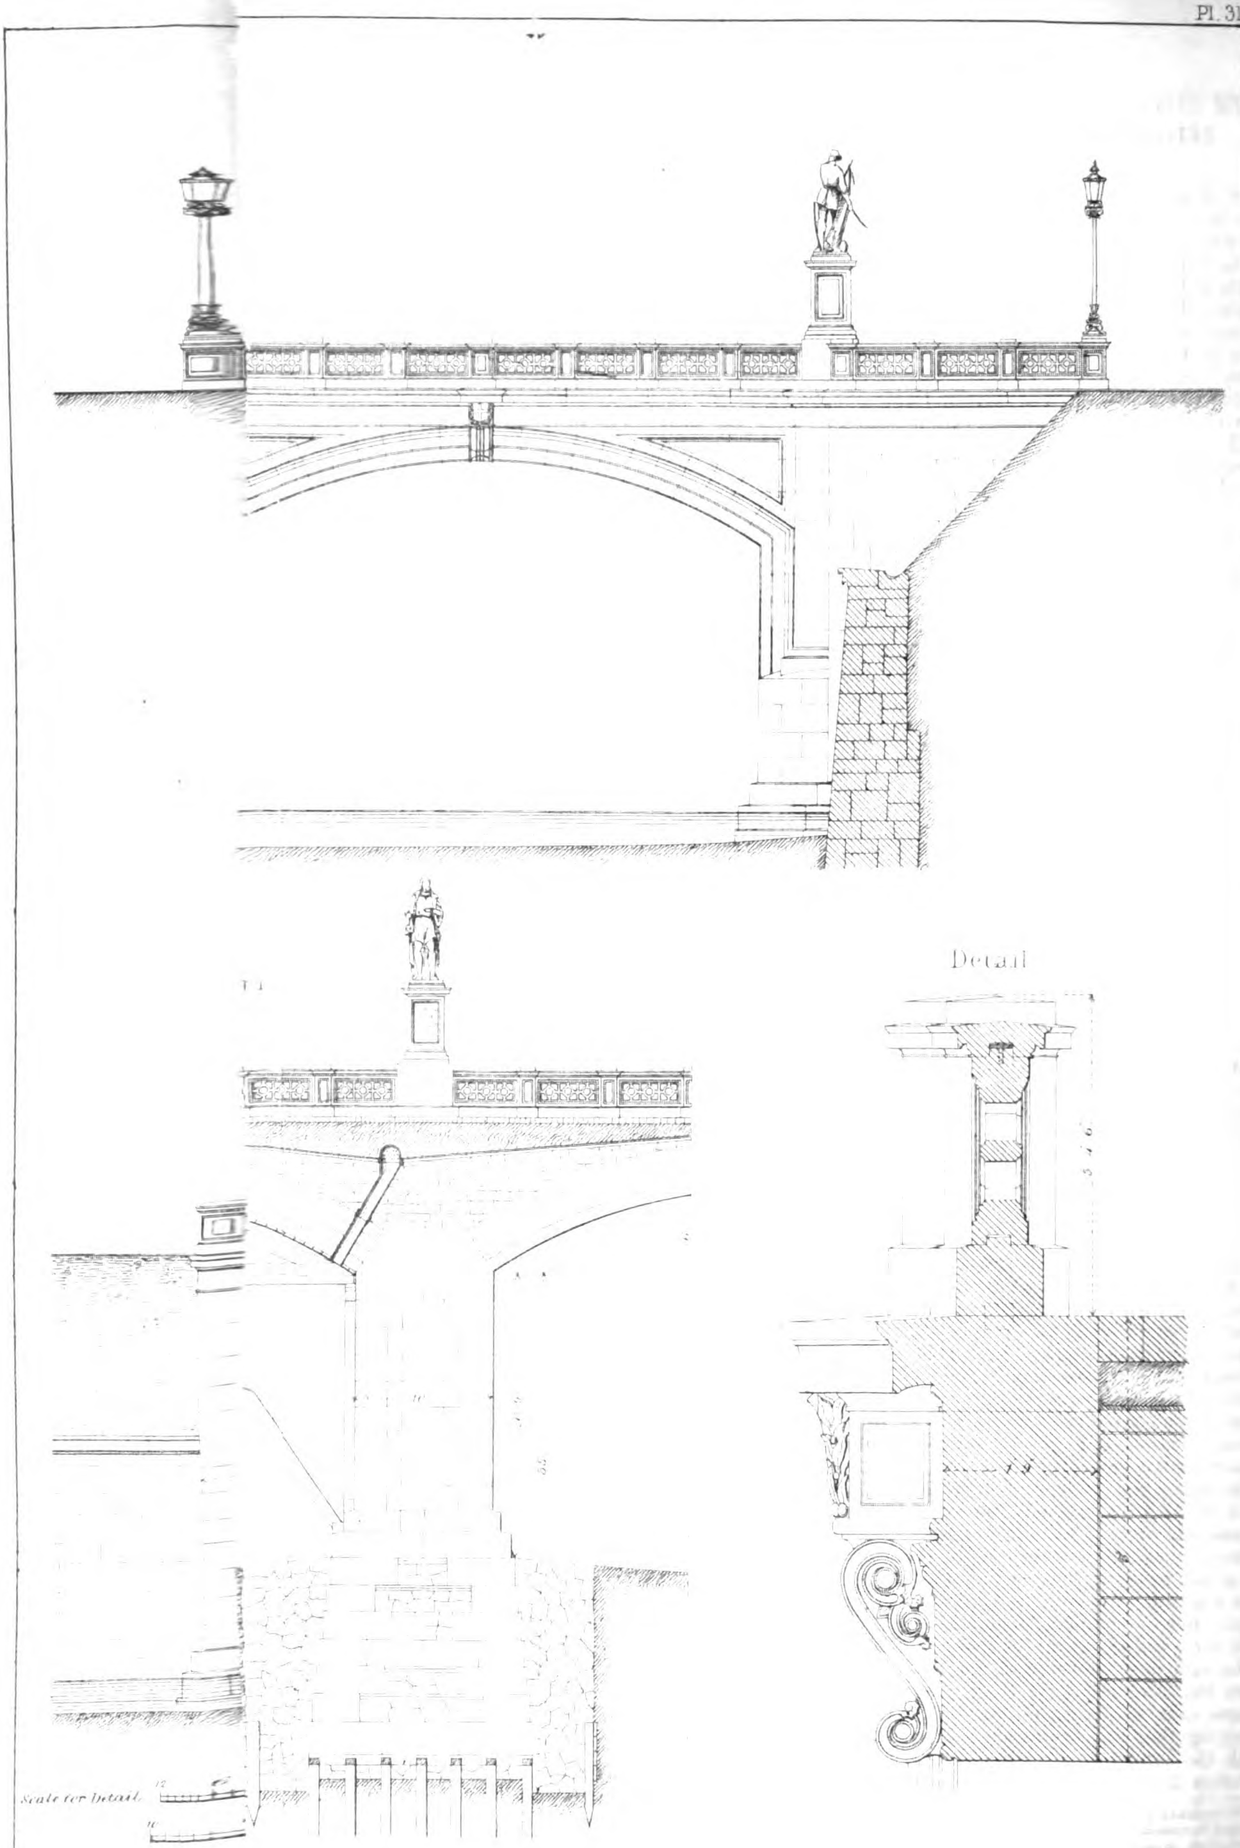
A petition has been presented to the Attorney-General for leave to disclaim a portion of and amend the title and specification of letters patent granted to Peter Fairbairn, of Leeds, Yorkshire, machine-maker, for "Improvements in machinery for heckling, carding, drawing, roving, and spinning flax, hemp, tow, silk, and other fibrous substances." Dated October 26, 1848.

### NOTICES OF APPLICATION FOR PROLONGATION OF PATENTS.

A petition will be presented to her Majesty in Council by Edward Foard, late of Queen's Head-lane, Islington, in the county of Middlesex, now of 39, Nicholas-street, Hoxton, in the said county, machinist, praying her Majesty to grant a prolongation of the several letters patents granted to him for England, dated 16th January 1841; for Scotland, dated 16th July 1841; and for Ireland, dated 28th August 1841; for "An improved method or improved methods of supplying fuel to the fireplaces or grates of steam-engine boilers, brewers' coppers, and other furnaces, as well also to the fireplaces employed in domestic purposes, and generally to the supplying of fuel to furnaces or fireplaces in such manner as to consume the smoke generally produced in such furnaces or fireplaces." On the 14th August (or on the next day of sitting of the Judicial Committee of her Majesty's Privy Council, if it do not sit on the day mentioned) an application will be made to that Committee to fix an early day for the hearing of the matters contained in the said petition; and any person desirous of being heard in opposition, must enter a caveat to that effect in the Privy Council Office on or before that date

A petition will also be presented by Edward Godson, of Aldersgate-street, in the City of London, ironmonger, as assignee of the above-mentioned several letters patent granted to Edward Foard, for a prolongation of their several terms; and on the 16th of August (or on the next day of sitting of the Judicial Committee of her Majesty's Privy Council, if it do not sit on the day mentioned), an application will be made to that Committee to fix an early day for the hearing of the matters contained in the said petition; and any person desirous of being heard in opposition, must enter a caveat to that effect in the Privy Council Office on or before that date.

A petition will be presented to Her Majesty in Council by Mary Honiball, of St John's-Wood, widow, praying her Majesty to confirm the letters patent granted to her on the 9th February, 1853, for "Improvements in Anchors," or to grant new letters patent for the same invention, for which William Henry Porter, of Russia-row, Milk-street, Cheapside, in the City of London, warehouseman, obtained letters patent on the 15th August, 1838. An application will be made on the 29th August next to the Judicial Committee of the Privy Council (or so soon after as their lordships shall be sitting) to fix a day for hearing the matters contained in the said petition; and all persons desirous of being heard in opposition, must enter a caveat to that effect in the Privy Council Office on or before that date.

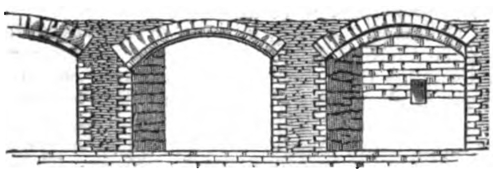


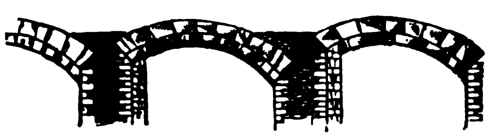
J. R. Jobbins

## THE OLD AND NEW BRIDGES OVER THE WIEN, BEFORE THE KÄRTHNER-GATE, VIENNA.

(*With an Engraving, Plate* XXXI.)

M. Förster, the able conductor of the *Allgemeine Bauzeitung*, has been appointed by the municipal authorities of Vienna to construct the new bridge over the Wien, one of great importance to the traffic of the Austrian capital. The above-named journal contains the following particulars relating to the subject. It appears that the old bridge was already standing in the 13th century, and, on its being demolished, M. Niernsee, the engineer, thus speaks of it. Amongst the most curious features are the oblique arches, which were constructed of square blocks, between which rubble and masonry formed the complement. As this, however, would not have been sufficiently strong for the heavy traffic, an arch of bricks, one foot thick, was added on the part towards the flow of water. The piers consisted of an irregular dressing of square blocks, and rested on a bed of concrete, fat lime, river sand, and large and small rubble, 6 feet in thickness, which was laid on oak piles irregularly placed. From the indications shown, it would appear marvellous that the bridge had not long since crumbled to pieces.





The old bridge was closed for traffic in September 1850, but when the floods of the spring of 1851 had carried away another bridge then building, the question was raised, whether the plan of M. Förster should be abandoned altogether. Still, the new building was begun in the summer of 1851, the precaution being adopted of making the foundations 5 feet deeper than originally proposed, since which time the new Vienna bridge has advanced favourably towards its completion.

## PROPOSED ADDITIONAL CATHEDRALS.*

The subject which has occasioned the pamphlet before us is one which, from various causes, has of late attracted much public attention. With an ever-growing population, the serious responsibility of its rulers is of no little moment, and the need of providing and maintaining ample as well as suitable means to supply its religious wants, becomes imperative. It is the especial distinction of this nation, that every one is free to perform his sacred duties in the way his conscience best approves; but, with this toleration to all, it is wisely understood that *one* form shall be exclusively recognised by the law of the land.

The origin and history of cathedral churches is a matter on which so little is generally known, that it may be acceptable to our readers, while it will form an appropriate introduction to the question immediately before us, to string together such information as can be gleaned, so as to present a comprehensive idea of what was contemplated and what has been accomplished by their establishment. Historic documents on the subject are comparatively rare, and therefore the more valuable and instructive.

The cathedral churches of England and Wales which existed before the Conquest, had their origin in the early missionary colleges, each consisting of a bishop, with his associated clergy (living together and maintained by common funds), by means of which the inhabitants of this country were converted to the Christian faith.

* 'Additional Cathedrals: a Letter, written at the request of a Member of the Cathedral Commission, on the question of what existing Churches would be available as Cathedrals, in case of the erection of Additional Sees.' By George Gilbert Scott, Architect. London: J. H. Parker. 1854.

The four bishoprics in Wales claim the highest antiquity, they having been founded chiefly in the earlier part of the sixth century, and belonging to the ancient British Church. The churches in England coeval with these were ruined by foreign invasions and some of them refounded by the Roman missionaries in the time of the Saxon heptarchy. There were then no parochial ministers; the bishop and his clergy resided at the cathedral church, where public worship was maintained, the word of God preached, and schools of Christian education established. Many of the English bishops received their education in the "*Monasteria*," places of retirement wherein persons might be brought up in a way of devotion and learning, to fit them for further service. Yet, antecedent to the Conquest, it would appear (*Dugdale:* Canterbury, York, &c.), that, as a result of these labours, a parochial clergy had been organised, each ministering in his own church, with a definite cure of souls.

In the next period, dating from the Conquest, we find the cathedral institutions assuming a form required by the altered circumstances of the Church. The dioceses were divided into parishes, having each its own minister and a separate endowment, the whole being under a still more marked administration. Besides the bishop, there was a dean, a precentor, a chancellor, and a treasurer; with archdeacons, canons, prebends, and a chapter council.

While the organisation above described was introduced into the nine English cathedral churches known by the title of the Old Foundation (viz., York, St. Paul's, Chichester, Exeter, Hereford, Lichfield, Lincoln, Salisbury, and Wells), the substitution of monks for the secular clergy was effected in three other cathedrals, Canterbury (1080), Durham (1083), and Rochester (1089), as had previously occurred at Winchester and Worcester.

During this period the stately fabrics of the cathedrals which now exist, and the greater part of our parochial churches, were built.

The collegiate church of Manchester was founded, in 1422, for a warden and eight fellows; and the royal chapel of Windsor, in 1483, consisting of a dean and twelve canons.

It may be observed here, that, by the Regulations of the Province of Canterbury, the bishops are considered as forming a cathedral chapter, of which the primate is the bishop; the Bishop of London, dean; the Bishop of Salisbury, precentor; the Bishop of Lincoln, chancellor; and the Bishop of Winchester, sub-dean.

About the time of the Reformation, many alterations inevitably took place. There had previously existed thirteen cathedral churches of the Old Foundation, the nine in England already specified, four in Wales (St. Asaph, Bangor, Llandaff, St. David's), and eight conventual churches attached to bishoprics (Winchester, Worcester, Canterbury, Durham, Rochester, Norwich, Ely, and Carlisle). The changes alluded to as now occurring were not so much materially affecting the constitution of those bodies, as modifications to suit the doctrine and ritual of the Reformed Church of England.

In the era we are now discussing, Henry VIII. founded five new bishoprics, associating with each a dean, and chapter of canons,—viz., Bristol, Chester, Gloucester, Oxford, and Peterborough, endowed wholly or in part out of the possessions of the respective monasteries in those places.

To the subsequent changes which have taken place it will be needless to make more than a general allusion, as they are chiefly on points of subdivision and discipline, although in their working the aspect of affairs took many phases. The statute of Henry VIII., having been framed before the Reformation was completely carried into effect, and in some cases not having been promulgated with due form and authority, it was found necessary to grant amended statutes to several of the collegiate churches, and this was done by royal authority, by virtue of the power reserved to the crown. The laws of patronage have also been re-adjusted.

The present state of the several cathedrals, with reference to the operation of the above acts, shows as follows. It appears that there are in the

| | |
|---|---|
| Patronage of the Crown ........................ | 27 gifts |
| „ of the Lord Chancellor ......... | 12 „ |
| „ of the Bishops ..................... | 90 „ |
| „ of the Universities or Colleges | 5 „ |

The whole number of Deaneries is thirty; of residentiary canonries, according to the provisions of 3 & 4 Vict. c. 113, one hundred and thirty-four. The whole number of clergy in England and Wales is about 18,000.

We must not, however, forget Ripon, and Manchester; which, from *collegiate* churches, are now made *cathedrals*, and annexed to newly-founded bishoprics.

*Collegiate Churches.*—A few words may be added regarding these, and exhibiting the distinction between them and cathedrals. The cathedral contains the *cathedra*, *sedes*, or *see* of the bishop; and the city in which the cathedral is situate gives a name to the diocese in which it is placed. A collegiate church has no such character; but, to speak strictly, has a *collegium* or capitular corporation, and in some cases a collegiate institution, for the purposes of education, attached to it. In some instances, also, the collegiate church is exempt from episcopal jurisdiction, a condition of things originally introduced under the Papacy, but which has been consideraby modified since the Reformation, and particularly in recent times.

The following churches in England and Wales are commonly called *collegiate*, though some of them have now lost that character, and have been made *parochial*:—

| | |
|---|---|
| Westminster. | Wolverhampton. |
| Windsor. | Southwell. |
| Middleham. | Brecon. |

Statistics give thus much respecting the ecclesiastical history of bishoprics; we will now subjoin a short statement of what has been done and is doing in the maintenance and repairs of some of the fabrics themselves, as collected from the answers of the several chapters on this branch of inquiry.

Two-thirds of the cathedral and collegiate fabrics are represented as being in sound and good repair as regards safety; though in many cases it is stated, that owing to the perishable nature of the stone and other causes, the ornamental parts of the exterior are much decayed, and that a large outlay is continually required. But a few churches are described as being in a bad state, especially Carlisle, on which, as a special case, the Ecclesiastical Commissioners have agreed to expend forthwith 15,000*l.* In several cathedrals very extensive restorations and improvements, substantial and decorative, have been carried out, partly by means of capitular funds and contributions from individual members of chapter, and partly by the aid of public subscriptions.

At Canterbury the amount expended in thirty years is estimated at nearly 100,000*l*; a gradual restoration of the whole fabric, outside and in, having been in progress from 1823 to the present time. The north-west or Lanfranc's Tower was rebuilt at a cost of 25,000*l.* At York, the restorations consequent on the two calamitous fires of 1829 and 1840, have been effected at a cost of 106,500*l*; of which 71,590*l.* was derived from public subscription. An additional sum of 5000*l.* has been laid out on the chapter-house and the peal of bells. Hereford has been in process of restoration since 1841, and is still far from complete, although nearly 30,000*l.* has been expended on it. At Ely, the beautiful south-west transept has been rescued from a state of desecration, thoroughly repaired, and opened to the church; the ruined chapel adjoining it has been rebuilt from the ground on its original plan; the eastern portion of the church restored to its former beauty; and a new choir formed. The outlay has been about 17,000*l*; and, with donations for special works, the funds contributed swell to a total of about 30,000*l.*, inclusive of the late Bishop Sparke's gift of 15,000*l.* for the east window of the choir. At Wells, also, the choir has been restored, and other works executed, at a cost of nearly 13,000*l.* The Cathedral at Llandaff, having suffered great injury in 1722, was partially rebuilt in a style quite at variance with its original character. In the year 1844 this was resumed on a more correct system, which is still in progress, the expense of which has amounted to 6275*l.*, of which about two-thirds was derived by public subscriptions.

In several other cases smaller restorations have been carried out, which partake of the general spirit of improvement which has prevailed during the present century.

There are not more than a *third* of the cathedrals which have any fabric fund, and most of such belong to the Old Foundation; often among these the fund is very small! Where there is no special fabric fund, the repairs are provided for out of the general capitular revenues; in most cases by the setting aside of certain portions of income derivable from woods, reserved rents, &c., with additions from the general funds in cases of emergency.

The total amount expended on the twenty-eight cathedrals and the two churches of Westminster and Windsor, during the last fourteen years, has been about 370,000*l.*, derived as follows:—

| | |
|---|---|
| From chapter funds and individual contribution of members | £250,000 |
| From public subscriptions | 120,000 |

When it is remembered that for many years previous to those to which the above calculations refer, large sums had been annually devoted frequently to the same object, it may be anticipated that the future requirements, for substantial works at least, will for a time be diminishing.

It is matter for congratulation that so large an amount has been available to the purpose within so comparatively short a period, and for still greater satisfaction that it has been expended in an age when the respect due to the founders of noble edifices had been observed, and the conservative rather than the destructive principle had been cherished. The Vandalisms committed during the last century under the name of repair or restoration are irretrievable. Certain it is, that while for very much of this may be pleaded unwitting ignorance, still more must be imputed to wilful caprice. Sir Christopher Wren has the credit of setting an example in his avowed dislike to Gothic architecture, and his consequently clothing it in classic detail when compelled to employ—we can hardly say imitate—it. Yet even he is too often misjudged. It is with architecture as with other things; that for which we have earliest conceived a predilection, or which chance has thrown in our way when shaping our education, will ever retain its influence; and devotedness to any particular study, or to the various developments of that study, is sure to engender feelings and prejudices, which can be strengthened, but can with difficulty be effaced. A story in point, though almost incredible, is told of the celebrated Brindley, the canal engineer, who when twitted about his favourite hobby, and asked what he thought was the use of rivers, is said to have replied, in sober earnestness,—*to feed canals!* This affords some palliation for the grievous errors which the said Sir Christopher has committed in Westminster Abbey, especially in its west front. There are few who demur to the propriety of the two towers, and it is evident they were originally contemplated; nor do many find fault with the grouping or outline, when seen from a distance; this seems to indicate that the architect had studied as usual the general effect of his composition, but, for want of that thorough knowledge which long and careful examination of good models is alone capable of imparting, he has lamentably failed in the "making-up" of his parts. This, we say, was a case of unwitting ignorance, as proved by his own words in writing to the Bshop of Rochester, on the subject of these very works: "I shall," says he, "speedily prepare proper draughts and models, such as I conceive proper to agree with the original scheme of the architect, without any modern mixtures to show my own inventions." But, in speaking of Wren and the Abbey, it may be well to remark that the modernisings of this building must be laid to the door of others besides our great architect. What does a pompous marble against the south wall of the adjoining cloister record? It is to the memory "Edvardi Tufnell, architecti, qui latera hujusce augustissimæ ædis Australe et Orientale magnâ ex parte refecit et exornavit; et inde sibi * * * perennius extruxit monumentum. Obiit 2° Septembris A.D. 1719." We are not aware that writers on the history of the Abbey have ever noticed this account, which, thanks to the *filii* who originally *posuerunt* the tablet, and to the authorities who have lately made clearer its hieroglyphics, is thus plainly set forth, as if to win the admiring gaze of the passer-by.

The disfigurements our cathedrals sustained during the first half of the past century we may charitably characterise as short-comings; in the second and more disastrous half, as sheer, wanton conceits. One scarce can bear to read of the wholesale destructions which then were rife; of some of which architects were the perpetrators, and others in which the so-called conservators of the respective edifices were either principals or knowingly connived. To allude to the freaks in which but one individual was permitted to indulge at three of these noble structures. James Wyatt,—"transcendantly distinguished in his profession," as his memorial slab at Westminster, one could almost think derisively, tells us—at Salisbury swept away the old altar screen; also the Beauchamp and Hungerford Chapels (whose discordant fragments were jumbled together to compose a new organ screen); and in the process destroyed numberless tombs, thus altering the whole internal plan; and then, by way of finish, he "white-washed" the walls (as probably he did himself too, in true Pecksniffian style); and hastened to make himself equally famous at Lichfield. There, after repeating the same dose, he was guilty of the enormity of blocking, or fairly building up the arches between the choir and the aisles, making a sort of chancel 200 feet in length, without side openings to give it breadth or relief. Another scene of his exploits is Durham; and here, by paring and scraping alone, he is said have removed full 1100 tons weight of stone. He took down the parvise over the north porch, substituting a tricky pediment. He actually purposed clearing away the noble galilee, because it stood in the way of a convenient carriage-drive contemplated between the castle and the west door of the cathedral! This was in 1796, and the dean, Lord Cornwallis, coming down for his "summer residence," found its destruction already commenced, but was in time to save it; posting to town, we are informed, to protest his ignorance of what had been going forward, although the very person most responsible, as he should be most interested, for the condition of the building.

We mention these instances in self-gratulation that better times have since dawned. Ignorance and inattention are no longer venial; deans and chapters are not quite such snug bodies as they were, nor can architects let loose their vagaries with impunity. There is little now that escapes the ordeal of public criticism, and this has a tendency to put or preserve things on their right footing. Church disputes are of course subjects on which we do not touch: but who, while he laments the ill-savoured truths which are too often brought to light, can doubt that inquiries such as have been instituted at Rochester, Guildford, St. Cross, Dulwich, and Stoke Pogis, will tend in the issue greatly to strengthen the efficiency and maintain the purity of the Establishment? Revelations like those we just hinted at have had their share in provoking the legislature to active operations, and to the appointment of committees and convocations to take the whole question of ecclesiastical affairs into deliberate consideration. Among these commissions is one by Royal authority in 1852, deputing certain bishops, clergy, and their legal functionaries, with two noblemen (in all numbering twenty), to inquire into the state and condition of the several cathedral and collegiate churches in England and Wales, "with a view," (among other things,) "to the suggestion of such measures as may make the said cathedral and collegiate churches, and the revenues thereof, available in aid of the erection of new sees, or of other arrangements for the discharge of episcopal duties." From what has transpired of their proceedings, we may judge that they are strongly in favour of the proposed alterations. They state that many places once were sees which are now deprived. Thus, at the Reformation twenty new ones were to be erected: and, among these Westminster, which was elected to a bishopric, but only lasted nine years. Again, sees have not unfrequently been transferred from one city to another, and Bishop Godwin, in his catalogue of bishops, enumerates fifty-two places in the two provinces of Canterbury and York, which at different times were episcopal sees. Coventry was once a bishopric by itself, but an agreement was subsequently made between this city and Lichfield that they should choose their bishops alternately, and make one chapter: so that the Bishop of Coventry was styled Bishop of Coventry and Lichfield, which title was preserved till the time of the Dissolution. This order was afterwards reversed, and "Lichfield and Coventry" is the designation familiar to most of our ears; yet, recently, by a strange perverseness, it has been stripped wholly of the privilege, and annexed to the diocese of Worcester.

In 1852 the bishops and clergy of the province of Canterbury, assembled in convocation, observed in their address, that "although the population of England and Wales has been doubled in the last half-century, the number of English and Welsh bishops remains nearly the same as it was three centuries ago."

Now, to meet these exigencies, it has been thought advisable to scan the several districts of England, so as to ascertain with tolerable correctness the population of each, with the provision for their religious wants, and to note in the survey such localities as either have historical claims or other recommendations to become the centres of new spheres; and it is in connection with this inquiry that the little work which has called forth this article, was originated. "Intended only as a private communication in reply to individual inquiries," as the preface states, "it has been suggested that it might be convenient that the reply should be printed;" and, though it is presented in the humble form of "A Letter," there is a mine of information comprised which cannot fail to be of deep historical and archæological interest. Perhaps there is no person better acquainted with the architectural remains in our land, especially its ecclesiastical resources, and their bearing on the subject in question, than the author of this pamphlet. He discusses the facilities as well as requirements of each county, *seriatim*, in a way that shows him well qualified to give an opinion; and if only as a text reference for architects, the mass of careful information is surprising. The uniformly practical nature of the treatise fits it more for study than extract, but we may be permitted to transcribe the author's recapitulation of districts which have struck him as appearing the best suited to form new dioceses, with the towns and churches which in such case would appear suited to become their episcopal seats:—

| | |
|---|---|
| "1. Northumberland | Hexham. A very noble church |
| 2. Westmoreland and Furness | Kendal or Cartmel. Good churches; the latter an ancient priory church |
| 3. Part of the North Riding of Yorkshire | Qy. Whitby? Ruined abbey |
| 4. The East Riding | Beverley with Hull. The minster at Beverley perfect, and a noble church at Hull |
| 5. Part of West Riding | Qy. Leeds? Using Kirkstall Abbey |
| 6. Western Lancashire | Liverpool. No cathedral |
| 7. Qy. Derbyshire? | Derby. No cathedral |
| 8. Nottinghamshire | Southwell. Minster perfect |
| 9. Shropshire | Shrewsbury. Nave of abbey church |
| 10. Qy. Leicestershire? | Qy. Leicester? Perhaps St. Margaret's. (No church really suitable) |
| 11. Warwickshire | Coventry. St. Michael's |
| 12. Hertfordshire | St. Alban's. The abbey church |
| 13. Essex | Colchester. (No cathedral) |
| 14. Qy. Part of Middlesex? | Qy. Westminster? The abbey church |
| 15. Berkshire | Qy. Windsor or Reading? |
| 16. Cornwall | Bodmin or St. German's |
| 17. Dorsetshire | Sherborne. The minster |
| 18. Somersetshire | Bath. The abbey |
| 19. Surrey | Southwark. St. Saviour's |
| 20. Suffolk | Bury St. Edmund's. St. Mary's |
| 21. Wales, counties of Brecknock and Radnor | Brecon. The priory church |
| 22. The Channel Islands | St. Peter's, Guernsey, or St. Helier's Jersey. (The latter I believe not a good church)." |

Prefixed is a reference map of England and Wales, in counties, showing also the extent of the several dioceses, which are clearly defined by the different tints. It needs but a glance at this interesting sheet to be convinced of the imperfectness of the present arrangements, and the consequent urgency of some such changes as are under consideration, and which must doubtless be set on foot ere long.

## THE NEW TOWN HALL, BURSLEM.

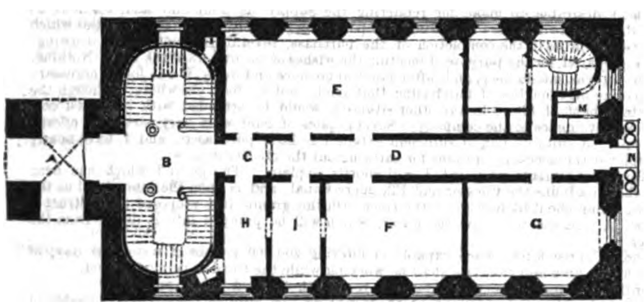
THAT the present age is essentially one of progress and improvement, is a remark which is corroborated by the events of our daily history. We continually hear of the edifices and institutions of byegone times being swept away and superseded by others of more modern date, and more in accordance with the spirit of the age. This progressive movement is everywhere observable, from the great metropolis itself to smaller and less distinguished localities. In few places, perhaps, has the march of improvement been more defined and remarkable than in the Potteries during the last few years, the aspect of the district having been greatly changed for the better in that period by the erection of beautiful churches and chapels, public institutions, extensive manufactories, handsome shops and houses, and other edifices. The town of Burslem, which has been not inaptly styled "the parent of the Potteries," has not been behind-hand in these respects with its younger offspring; and it is at length succeeding in effecting an object which has long been contemplated, and which has become necessary to meet the requirements of the increasing importance and population of the neighbourhood—namely, the erection of a more commodious Town Hall.

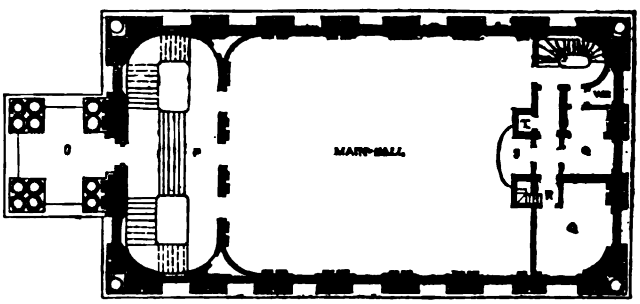
The demolition of the old building was determined on some months ago, and that determination having been carried into effect a short time since, active measures were taken to replace it without delay with an edifice more worthy of the town; and on the 24th May the laying of the corner stone was celebrated by a grand procession, composed of several thousands of persons, and extending fully a mile and a half, and afterwards by a public dinner.

The form of the ground being an irregular triangle, necessarily limits the size of any regular rectangular figure placed within it, and for this reason, the architect, though at first inclined to adopt an irregular figure for the plan of the building has, on mature consideration, chosen a regular parallelogram, as being more simple in arrangement, and producing an elevation of more grandeur and boldness of effect than could be obtained by a broken and irregular outline.

In fixing the dimensions and site of the building, due regard has been had to the thoroughfare and traffic in the different streets; that on the south side will be 60 feet wide, the same width as it now is; the street on the north side will be 30 feet wide at the narrowest part, and a clear space of 50 to 60 feet will be left between the Town Hall and the Market Hall; and the building being thus completely isolated, will have an importance and nobleness of aspect suitable to its purpose.

PLAN OF GROUND FLOOR.





PLAN OF PRINCIPAL FLOOR.

In the basement there is to be a room for the warming apparatus, a coal-store, a kitchen provided with a lift to a room on the principal floor, a pantry, a store-room and cellar, with a rolling way from the street. All the rooms in the basement will be well lighted by windows into an open area on the north side.

We now come to the ground floor, the figure of which, as we stated, and as shown in the annexed plans, is a regular parallelogram, 109 feet long, 58 feet wide outside the walls. At the west end there will be a projecting porch A, sufficiently wide to admit carriages to pass through, so that the occupants may alight protected from the weather. From this porch a large doorway will open to the entrance hall B, from which two handsome staircases will lead to the main hall on the principal floor.

At the east end there will be another entrance N, by a wide and airy corridor to the several rooms, the first of which on the left is intended for the news-room G, containing an area of about 560 superficial feet; adjoining the news-room will be a board-room F, of 600 feet area; with two retiring rooms H, I, connected therewith, which may be used as offices. On the north side of the corridor is the magistrates'-room E, extending nearly the whole length of the building, and containing an area of about 900 feet. The magistrates'-room will serve for lectures and other purposes, for which the main-hall would be too large. The bench for the magistrates is to be placed at the east end of the room, and communicate with the corridor and the retiring rooms adjoining, on the north side of the corridor; and nearer the entrance will be the passage leading to the hallkeeper's residence, and also private stairs to the orchestra, the stairs to the basement, watercloset, and lavatory. The height of the rooms on this floor will be 15 feet.

The principal floor will be mainly occupied by the great hall, which will contain a floor area of 3350 feet, exclusive of the orchestra or platform S, at the east end, occupying a space of 800 feet. The two staircases before mentioned are to be united into one spacious and imposing flight of steps, leading at their point of junction to a large open portico O, from whence popular assemblages in the open air may be addressed, and which will be sufficiently spacious to accomodate the speakers and a considerable number of their supporters. From this point in the stairs, five steps P, 16 feet long, lead to three large doors by which access is gained to, or egress from, the principal hall.

A private staircase R, will lead to the orchestra, forming a private entrance for performers, and also for the principal speakers and others at times of public meetings in the hall. Under the orchestra or platform there will be a number of private rooms in one of which will be the lift or hoist T, from the basement, by which all the viands, dishes, &c., required at the time of a public dinner may be sent up direct from the kitchen to the hall, without delay of risk or chill, and avoiding the confusion of running up and down stairs by the attendants.

At the back of the orchestra there will be another small staircase, by which chorus-singers and others at the rear may retire without crowding upon those in front. These stairs will also lead upwards into the roof for access to the clock chamber, and also to the valves for ventilation.

The architect has chosen the style usually called the Cinque-cento-Italian, or that employed by Michael Angelo, Raffaele, Palladio, and others in Italy, in the 15th and 16th centuries, and afterwards in our own country by Inigo Jones and Sir Christopher Wren. He has been induced to employ this style, not more from their example than from its complete applicability to the purpose, and in which a greater amount of light can be admitted and more architectural decoration obtained at the least expense of space and money. It will also better harmonise with the architecture of the adjoining Market Hall.

The principal features of the elevation will consist of a bold, rusticated, battering basement, relieved by large windows, the jambs and arches of which are to be deeply coved. Surmounting this will be a double-pilastered façade of the Corinthian order. In the intercolumniations will be wide, arched windows, with moulded archivolts.

The roof will be covered with Italian tiles of the local manufacture, producing a pleasing effect from an essentially structural feature.

The west elevation will have for its principal feature the entrance porch, surmounted by the portico before mentioned. Over this is the clock chamber, and the clock and bell turret, with four faces sufficiently elevated to be seen from all parts of the surrounding neighbourhood.

The east elevation is the same as three bays of the south side, having in the centre the doorway leading to the rooms on the ground-floor, and decorated with a suitable portico.

The north elevation will be the same as the south.

With respect to the architectural decorations of the great hall, we may mention that the interior will be similar in character to the exterior, consisting of a pilastraded wall, with a coved and panelled cornice and deeply-trabeated ceiling. We understand that in arranging the dimensions and proportions of the hall, due attention has been paid to acoustic effect therein; and though the proportions may appear wanting in height, this has been purposely done to aid the effect of sound, both vocal and instrumental, and to prevent the great reverberation and echo invariably heard in lofty and apparently well-proportioned rooms.

The building is intended to be heated by a hot-water apparatus, fixed in the basement, and pipes carried through each of the rooms, and has been undertaken by Mr. Whitehead, of Preston.

The architect is G. T. Robinson, Esq., of Leamington, and formerly of Wolverhampton; and the builder is Mr. Young, of Burslem. Mr. R. Hales, Surveyor to the Local Board of Health, as town surveyor, is carrying out the design, under the architect.

## CHESTER WATERWORKS.

A controversy of some interest is going on in Chester, relative to the water supply of that ancient city. The present waterworks, which have been established about twenty-six years, have supplied the town very inefficiently for a long time past, pumping the water, with an old ricketty engine, directly from the river into the cisterns of the consumers, without filtration, and distributing even that very partially on the intermittent system of supply.

In the autumn of last year, the Corporation determined that the public of Chester should no longer be subjected to the sanitary evil of an impure and inefficient water supply, and they gave notice of their intention to go to Parliament for a new bill to supply the town with pure filtered water, and on the system of constant supply under high pressure.

Accordingly, Messrs Rammell and Lester were instructed to lay down a scheme of water supply for the town, and they proposed taking it from the neighbourhood of Delamere Forest (which district Mr. Bateman, in a letter to Lord Shaftesbury, stated was capable of supplying even Liverpool). The estimated cost of this scheme was 32,000*l.*

The Waterworks Company, finding the Corporation were determined to proceed with their bill, came forward and pledged themselves to the town, at a public meeting, that they would so improve and extend their works that there should be a constant supply of water under high-pressure, ample in quantity, and that it should be properly filtered; which pledge the Corporation was disposed to receive, and the Wat works Company instructed Mr. Bateman to prepare such a plan of water supply that would carry out the suggestions of the Company and the general wishes of the town.

The proposed plans of Mr. Bateman are as follows:—There are to be three pumping-engines, two at the side of the River Dee, and one under the service tank, which is about 300 yards from the river. There is to be *one* subsiding reservoir to hold 400,000 gallons, into which the water will be pumped from the river; from thence it is to be passed through filters, of which there are to be three, of the following dimensions: two 63 feet by 50 ft. 8 in., and one 40 feet by 50 ft. 8 in., area 8576 feet, which are stated to be capable of filtering and purifying 960,000 gallons daily.

From the filter it will flow into a pure-water tank of 400,000 gallons capacity, and from thence the water is to be pumped into an elevated service-tank on a tower 60 feet high above the ground. The tank is to be 70 feet diameter and 14 feet deep through the centre of the tank; the engine-chimney will be carried 158 feet above the surface of the ground.

These several works are shadowed forth in the report of Mr. Bateman, which we have annexed; but it appears that the Corporation and the Company are at issue (see Borough Engineer's report, also annexed) as to whether the plans proposed will afford a constant supply under high pressure, *in the full acceptation of that term*; and whether, from the very impure character of the Dee water after heavy rains, it will be pure at all times, and fit for human consumption;—whether the mains of the Company, which have been laid down now some twenty-six years, very close to the surface of the streets, very much broken and patched, some of which are wood and lead, are suitable for a high-pressure supply;—and also, whether the fire-plugs, which are upon the old spigot-and-faucet principle, should be retained (the liability of the repairs of which the Water Company repudiate!), while the wants of the town demand hydrants of an improved construction. It is also argued that the quantity of pure water these works are capable of supplying is insufficient, there being only *one* store reservoir, capable of holding only 400,000 gallons for 30,000 inhabitants—two-thirds of a day's supply! Surely the gentleman who is to give so copious a supply to Manchester (45,000,000 million gallons for 316,213 inhabitants, with reservoirs amounting to 344A. 0R. 39P., and capable of holding 507,906,831 cubic feet), will not, in these days of sanitary reform, deal out on the other hand such a stinted measure of water supply for an increasing population like Chester. We now give the reports as they have reached us, without further comment, and express a hope, which is generally felt throughout the country, that in devising schemes for the future water supply of towns, that supply may be copious and cheap, so that the humblest cottager may realise the full benefit of an ample quantity, at a low rate, of that necessary of life.

[Copy.]

TO THE CHAIRMAN AND DIRECTORS OF THE CHESTER WATERWORKS.

You wish me to state the various steps which have been taken for the purpose of improving the supply of water to the city.

In the spring of 1849 I had first the honour of receiving your instructions to take the supply of water into consideration, and to advise you as to the best course to be pursued, with a view to its proper and perfect filtration.

After examining various situations closely adjoining or continuous to your pumping establishment, on which filters might be constructed, and that there existed considerable difficulty in obtaining a suitable site, I recommended you to sink into the red sandstone rock, which forms the bed of the River Dee, to a sufficient depth by the side of the river to enable you to pass under it, as near to the bottom of the river as could be done with safety, in the hope that the water of the river would pass through the rock into the tunnel in a perfectly filtered state, and in a sufficient quantity to meet the demands of the city.

The best situation for filters appears to be on the opposite side of the river; and it was a recommendation in favour of the scheme of tunnelling proposed, that should we be disappointed in obtaining a supply of filtered soft water by percolation from the river, the tunnel would afford a communication by means of which the water of the river, after having been artificially filtered on the opposite side, could be conducted to the pumps of the company, and forced from thence into the town for use. In case of success, it was intended to tunnel or chamber under the bed of the river to such extent as might be found necessary for obtaining the requisite supply. The water of the River Dee was analysed, and was found to be exceedingly good and very soft. The only objection to its use without filtration being the occasional turbidness caused by heavy rains and floods. The water issuing in springs from the red stone, and found in the course of sinking the shaft alluded to, was bright and beautiful to look at, and pleasant to drink; but *very* hard, and consequently unfit for general domestic use. This is the common characteristic of water from the new red sandstone formation.

The operations recommended were commenced in the course of the summer or autumn of 1849, and extended over a considerable period. They were, however, comparatively unproductive of good water, and after some time it was deemed advisable to abandon them. The tunnel had been driven to the opposite bank of the river, and negotiations were entered into for the purchase of the requisite land for the construction of filters. This land *was supposed to have been purchased* now twelve months ago; and I then received instructions for laying out the necessary works, not only for the perfect filtration of the water, but for such other improvements in the supply as it might be deemed desirable to make for rendering the supply as abundant and efficient as possible. Drawings were accordingly prepared, and in consequence of difficulties which afterwards arose in the completion of the purchase, several different sets of drawings were prepared, for the purpose of meeting the wishes of the owners of the land. Nothing, however, was satisfactory, and, after much annoyance and delay, it was found necessary to give up all thoughts of purchasing that land, and to look elsewhere; although the establishment of filters in any other situation would be attended with increased cost and inconvenience to the company. Several plots of land were suggested and offered for sale. A suitable plot of sufficient extent has been purchased, and I have nearly completed the necessary designs for carrying out the objects in view.

The arrangements proposed I will shortly explain. The ground which has been purchased adjoins the Chester and Ellesmere Canal, and is upon the same level as the canal, being about 65 feet above the river. On this ground it is proposed to construct—

1st. A reservoir to receive the water, which will be pumped into it direct from the river.

2ndly. Three filters, each capable of filtering 300,000 gallons of water per day, of which it is proposed that two shall be working while the third is being cleansed.

3rdly. A covered reservoir or tank, to receive the filtered water; and

4thly. An elevated tank, about 65 feet above the level of the ground, capable of holding about 200,000 gallons, into which the filtered water will be pumped, and from which the city will be supplied *constantly*, and at a pressure sufficient to allow the water to rise freely to the highest floor of the highest house in the city.

It is also proposed to put down additional pumping engines; to lay down new mains to the city, and to extend and enlarge the piping generally.

The contract drawings are nearly ready, and the works may be completed in about six or eight months after being commenced: probably, if great exertion be made, in a somewhat shorter period. When finished, the city will be supplied in as perfect a manner as possible, and with water of most excellent quality.

Your very obedient servant,

*Manchester, November 19th* 1853. J. F. BATEMAN.

N.B. The costs of these works are estimated at 12,000*l.*

[Copy.]

WATER SUPPLY COMMITTEE.

The following report was read:—

The deputy town clerk having laid before the committee certain plans of the works proposed to be carried out by the Waterworks Company, and the following report of the surveyor having been read:—

"*Chester, August* 7, 1854.

"Gentlemen—The drawings you have submitted to me are further detailed plans of the proposed improvements of the Chester Waterworks; but these, in my opinion, will not supply your committee with the necessary information that you may pronounce an opinion upon them; they are mere details of parts of the works. What your committee require are full and comprehensive plans of the whole works, showing where and how the supply of water is going to be obtained; the nature and power of the machinery intended to be used; the means and extent of storage; the system of purification and mode of supply; and the plan to be adopted in distributing the water, whether for domestic use or for other purposes.

"This is necessary preliminary information that must, I presume, be in possession of the Waterworks Company previous to the commencement of works that are to cost, they say, 12,000*l.*

"In the absence of that information, I may observe, on the information I possess, it is well known that the present source of supply of water to the city is very impure, being immediately below the point where the drainage of the eastern part of the town discharges itself into the River Dee. Surely it is intended to remedy this evil by taking the water at a higher and purer source.

"Again, it is stated that the Company intend to give a constant supply of water under high pressure; if that is the case, it is necessary that the pumping engines should be in duplicate at both pumping stations, viz., by the river side and in the Spital Field, *as is usual in all modern waterworks*; instead of that, I understand they intend erecting only two new engines, so they will have two at the river side and one in the Spital Field. In case of accident to the engine in the Spital Field, the supply of water must cease (with the exception of the small quantity in the service tank) until that accident is repaired.

"I think, also, the subsiding reservoir too small for a population like Chester; its contents, according to the plans, are to be 400,000 gallons, or less than one day's supply. (Chester requires 600,000 gallons, according to the usual calculation, on the number of the population, as a daily supply) so that for the supply to be continuous the water must be pumped daily, whatever may be the state of the river; and this I think objectionable, as it is well known that the river water after heavy rains is filthy and discoloured for days together, and which no process of subsidence or filtration will purify under two or three days. This, I understand, is the experience derived at the Eaton Waterworks (where Mr. Simpson was the engineer). Under these circumstances there should be two storage reservoirs, which should contain at least two million gallons, one million gallons in each reservoir; so that while one was supplying the town, the water in the other might be subsiding and depositing its muddy sediment after the reservoir was filled. I presume it is also intended to relay and amend the distributing pipes in the town, which are generally in a defective state, as well as introduce improved hydrants. Neither the pipes nor the hydrants (which latter are upon the worst possible principle of construction) will withstand the hydraulic head of the proposed high pressure supply of water; and to attempt to introduce the high pressure supply until those defects are remedied, appears to me to be a very impolitic step, if not an impossibility.

I am, &c.

"The Water Supply Committee." B. BAYLIS, C.E., A.I.C.E.

"*Resolved*—That the drawings which have been submitted to the committee do not afford sufficient information to enable the committee to understand the exact nature and extent of the works intended to be constructed, but from the details which have been supplied, it is evident that they will be incapable of insuring such a continuous supply of pure water as the city requires, and as was promised when the guarantee of the company was given to the council in December last.

"That the plans are not only imperfect, but the Company has not afforded any information as to the pecuniary means at their command for carrying them into effect.

"That the required extension of the mains to various parts of the city and suburbs is not stated; and that no allusion is made to the prices which it is intended to charge the public, but that the committee infer from certain published notices of the Company that a considerable increase in the rates is contemplated; that the present objectionable source from whence the supply is taken appears to be retained, and that the delay which has taken place in proceeding to fulfil the pledges given to the council and the public last year is unreasonable and censurable.

"The committee, therefore, in discharge of the duty intrusted to them, cannot recommend the council to give their sanction to the plans which have been submitted; and express their dissatisfaction that at a time when the committee was led to expect an improved supply of water, nothing effectual has been done to remedy the present unsatisfactory state of the works.

## SUPPLY OF WATER TO THE METROPOLIS.

*An Abstract Return of the average number of gallons of water supplied daily by each of the several Metropolitan Water Companies, during the twelve months ending the 31st day of December 1853, and stating whether the supply can be increased, or is in course of being increased; and a statement of the number of houses, manufactories, and public establishments supplied with water by each Company.*—[By order of the House of Commons, June 1, 1854.]

*New River.*

The average number of gallons of water supplied daily by the New River Company in the year 1853 was 17,537,396, and this quantity is capable of being increased to 29,000,000.

The houses, manufactories, and public establishments were as under: viz. Houses, 90,510; Manufactories, 223; Public Establishments, 191; Total, 90,924.

FREDERICK INGLIS,
*June* 16, 1854. *Clerk.*

*East London Waterworks.*

The average quantity of water supplied daily by the company, during twelve months ending 31st December 1853, was 11,990,989 gallons.

The number of dwelling-houses supplied by the company during 1853 was 63,142.

The number of manufactories and public establishments supplied by the company during 1853 was 463.

This supply, which is capable of increase to any extent proportionate to the requirements of the district, is in course of increase accordingly.

J. CECIL,
*June* 15, 1854. *Secretary.*

*West Middlesex Waterworks.*

The average quantity of water supplied daily by the West Middlesex Waterworks, for seven days in the week, during the twelve months ending the 31st December 1853, was 5,000,606 gallons.

An additional main, 30 inches diameter, has recently been laid from the works at Hammersmith into London; which is enlarged to a 36-inch main from Bayswater to the company's reservoir at Barrow Hill, adjoining Primrose Hill. Also another powerful engine is now being erected at their pumping establishment at Hammersmith; by which means this company will be enabled to increase their supply of water by about 6,000,000 gallons per diem.

The number of houses supplied by this company (exclusive of stables) is 24,376.

The number of manufactories, comprising also breweries, dye-houses, steam-saw mills, &c., is 28.

The number of public establishments, comprising hospitals, workhouses, baths and wash-houses, theatres, barracks, bazaars, botanic gardens, markets, &c., is 23.

The above enumeration of manufactories and public establishments does not, however, include several other trade supplies, such as livery stables, omnibus establishments, cow-yards, nursery grounds, &c., or charity-schools, almshouses, dispensaries, &c.

W. H. WHIFFIN,
*June* 20, 1854. *Secretary.*

*Grand Junction Waterworks.*

The average quantity of water actually pumped daily for six days in each week, from the 1st of January to the 31st of December 1853, amounted to 5,968,288 imperial gallons, equivalent to a daily supply delivered for each of the 365 days during the year, of 5,115,675 imperial gallons.

The number of houses, manufactories, and public establishments supplied with water to the same period, amounts to 16,019. Upon the completion of the company's new works, they will have the power of very largely increasing their supply, as the engines at Hampton and the trunk main will be capable of delivering above 20,000,000 imperial gallons per diem.

Since the period to which the above return has reference, the number of houses supplied, and the average daily quantity of water delivered, have considerably increased. For the twelve months ending the 1st of April last, the water delivered daily for seven days in the week, amounted to 5,518,343 imperial gallons, and the number of houses, &c., supplied, to 16,417.

E. O. COX.
*June* 1854. *Assistant Secretary.*

*Southwark and Vauxhall Water Company.*

Quantity of water supplied by the company, from the 1st January 1853 to the 31st December 1853.

| | |
|---|---|
| | Gallons. |
| Total quantity pumped in the year ...................... | 2,652,573,277 |
| Being an average per week of ........................... | 51,011,024 |
| Or an average per day (for six days in the week)...... | 8,501,837 |
| 40,046 Houses supplied, averaging per day, 175 galls. | 7,001,837 gallons. |
| 634 Consumers, namely, railways, distilleries, road-watering, fires, flushing sewers, and trades generally, averaging per day 2366 gallons.......................................... | 1,500,000 gallons. |
| 40,680 tenants, averaging per day 209 gallons ...... | 8,501,837 gallons. |

This supply can be more than doubled if required; the 36-inch main, with the engine-power provided at Hampton, will deliver at Battersea 20,000,000 gallons in the twenty-four hours.

JAMES ROSSITER,
*June* 29, 1854. *Secretary.*

*Lambeth Waterworks.*

The average quantity of water delivered daily by the Lambeth Waterworks Company, in the twelve months ending 31st December 1853, was 5,603,000 gallons per diem.

The supply can be increased from the existing works of this company at Seething Wells to upwards of 10,000,000 gallons per diem, and by the erection of additional works on lands acquired by the company, under the Lambeth Waterworks Act, 1848, the supply of water may be carried to the utmost extent that can ever possibly be required.

The number of houses at present supplied by the company is 25,583, and the manufactories and public establishments 524 in number.

W. S. PHIPPS,
*July* 20, 1854. *Secretary.*

*Chelsea Waterworks.*

The average daily supply of water by the Chelsea Waterworks Company, during the twelve months ending 31st December 1853, was 5,632,000 imperial gallons.

The supply of water can be increased about 15 per cent. from the present works, and new works are in course of construction above Kingston-on-Thames, under the Chelsea Waterworks Act, 1852, which will enable the company to double the quantity, and the supply may be still further augmented when required, the company having possessed themselves of land for the purpose.

The number of houses supplied with water was 22,725, and the number of manufactories and public establishments 2004.

ALBERT GILL,
*July* 21, 1854. *Secretary.*

*Kent Waterworks.*

The total quantity of water delivered during the twelve months ending the 31st day of December 1853, was 671,942,164 gallons.

The average daily supply of six days per week was 2,146,780 gallons.

The foregoing is the year's and average daily supply delivered by the company's engines during 1853; but in estimating the power of supply of a waterworks, it should be taken at the highest day's demand. In the course of last summer this has risen frequently at these works to near 4,000,000 gallons, and could without any inconvenience be increased to any quantity required by the district.

The number of houses in supply on the 31st December 1853 was 14,573.

The number of public establishments and manufactories supplied by this company are as follows:

The supply and constant protection from fire of the Government naval and military establishments at Deptford and Woolwich, and Greenwich Hospital.

The public baths and wash-houses.

Seventeen manufactories, bleachers, gasworks, railways, and steam-engines.

Water was also supplied for flushing sewers, and road and street watering.

W. R. MORRIS,
*June* 14, 1854. *Engineer to the Company.*

*Hampstead Waterworks.*

During the year 1853, the number of houses supplied by the Hampstead Waterworks Company was 5454.

The average daily supply of water was 607,368 gallons; of this quantity about 3000 gallons a day were for manufacturing purposes.

During the six months, from March to October, an additional quantity, averaging 45,000 gallons a day, was supplied for the purpose of watering streets and roads.

There is no public establishment in the district supplied by these works.

For the purpose of increasing and improving their resources, this company are boring through the chalk at their works in Kentish-town, in the expectation of deriving an abundant supply of pure water from the greensand. The depth of the boring is now 940 feet. The work is prosecuted with all possible speed, and the directors have every reason to think it will soon be brought to a successful issue. Meantime arrangements have been made with the New River and West Middlesex Waterworks, and the mains connected, so as to furnish any quantity of water which may be required in the district.

THOMAS HAKEWILL,
*Secretary.*

*June* 16, 1854.

## FORMING SHEETS OR PLATES FROM SLAGS.

GEORGE ROBINSON, *Patentee*, August 27, 1853.

THIS invention consists in the conversion of the molten slag (formed in the various processes of manufacturing, puddling, and refining iron and other metals) into sheets or plates, by pouring it upon an iron or other table artificially heated, whereon it may, by means of rolling or pressing, be reduced to any requisite thickness, according to the purpose for which it is intended to be used. The plates thus formed are afterwards annealed by being allowed to cool gradually in any suitable furnace; and may be employed for roofing and other useful purposes for which they may be considered applicable.

The slags best adapted for the formation of sheets or plates by the processes about to be described, are those of a metallic appearance, and which are more or less crystalline in structure, and contain iron or other metals in various proportions, combined with silica and other earthy substances. They are variously termed, but may be easily recognised by the above description.

These slags or refuse matters are to be used while in a fluid state; that fluidity being derived either from the heat of the furnace in which they are first formed, or from their being afterwards remelted in any convenient manner. In order to form from these refuse matters the sheets or plates required, the molten slag is poured upon an iron or other table, artificially heated, and is pressed or rolled out thereon, by suitable machinery, to any requisite thickness, after the manner used in manufacturing plate-glass, or by any other suitable mechanical arrangements which will readily suggest themselves to any intelligent mechanic. The sheets or plates thus formed are at once to be transferred to a suitable annealing furnace, previously heated, and there allowed to cool gradually for from six to eight days, or even less. When cold, the sheets may be employed for roofing buildings, covering walls, and for many other useful purposes.

The sheets or plates, while in a plastic state, may likewise be cut, perforated, and ornamented by means of suitable elevations and depressions on the rollers by which they are formed. For instance, rough sheets of suitable thickness having been obtained on the table, slabs with mouldings or other ornaments thereon may be produced, by causing dies or engraved or ornamented rollers to press on the upper surface of the sheets, and produce any impression that may be required. These slabs must of course be annealed in the same way as the thin sheets above mentioned.

The patentee remarks that he is aware that slags have heretofore been cast into blocks in moulds, and have been employed for paving and such like purposes; he does not therefore intend to claim the application of blocks cast in moulds, nor does he intend to confine himself to any particular mechanical contrivances for forming the sheets or slabs as above mentioned; but he claims—first, the formation of sheets, plates, or slabs, of various thicknesses, from the slabs or refuse matters obtained during the manufacture of metals, by rolling or otherwise pressing the molten slag on tables artificially heated; and secondly, the application of the sheets, plates, or slabs thus formed to roofing and other useful purposes.

## EDUCATIONAL EXHIBITION.

### *Abstract of Lectures, Papers, and Discussions.**

*On Models and Diagrams.* By THOMAS SOPWITH, F.R.S.

THE lecturer commenced by stating that his present object was to speak of models and diagrams as applicable to ordinary use in schools. Of these, models were, he considered, the more valuable, inasmuch as they are a representation of the solid form of an object, and can be viewed in any direction, whereas a diagram, even in its most pictorial form, only presents one aspect of the object, and if different portions of the same object are required to be shown they are necessarily separated. The portability and cheapness of diagrams as compared with models, renders them better adapted for extensive use in schools, and the disadvantage of presenting only one face of an object becomes a means of instruction, inasmuch as all the practical applications of drawing depend on a right appreciation of the laws under which solid forms can be represented on a plane surface.

The real use of the model is to carry the mind from the actual observation of a small object presented to the eye to the comprehension of a large object, not presented to view; and in doing this, the mind is necessarily employed in a study of relative dimensions, and of corresponding forms. Excellent models of geometrical forms, as the cube, &c., are to be had at a small cost; but in the smallest village school, unprovided with funds for the purchase of expensive models, much may be done at a very small cost; as for example, the construction of a cube may be explained by a piece of pasteboard, and so of the other simple geometrical figures; and the mode of construction is indirectly an explanation of geometrical conditions, as for example, that the tetrahedron is bounded by 4 surfaces—the cube by 6. The gonigraph may be easily made by a country carpenter, or even by a skilful lad, and is well represented by the ordinary scales or rules used in France. It affords a ready model of various geometrical figures.

In astronomy it is desirable that all scholars should learn something of the motions, and magnitudes, and distances of the heavenly bodies. The most rapid motion which can be readily comprehended by boys is about 20 miles an hour, or one mile in three minutes. It is about double the quickest speed they see in road vehicles, and is a usual rate on railways; but it will be brought still nearer to their comprehension within the walls of the school-room, by a white ball fastened to a string of about 3 feet in length, and whirled round at the rate of two revolutions, nearly 40 feet in each second, and by graduating the length of the string, and timing the revolutions to 120 in each minute; the length of a mile may be described by the ball in 3 minutes, and if this were continued an hour we should have 20 miles of space passed over by the ball. When once the minds of children are directed to a palpable illustration of this kind, they have obtained as it were the seeds of knowledge—they have a foundation on which to rest all future researches of a like kind, and without some such solid, distinct, clear, and palpable exhibition of the rate of motion, no definite ideas will be afforded by the most skilful and elaborate study of mere figures unapplied to some such datum. Very few persons have clear conceptions about space and motion. If we ask a child the meaning of a sentence which it has read, we probably find that no solid or distinct ideas of the meaning of the sentence have been formed, and so it is with children of a larger growth. With men, and even with able and accomplished men, propositions involving large conditions of space and motion are read by them, and stated by them as truths, without even attempting to resolve them into tangible considerations. What, for example, is so common as to hear it said of Archimedes, that if he had a fulcrum on which to rest, the power of a lever would enable him to move the world; and so it is taken for granted that by an enormous lever the weight of Archimedes, exerted at the extremity of its enormous arm, would suffice to move the world. In theory this is true, but how few have an idea how far it is from all practical value. If Archimedes had machinery free from friction, and in perfect equilibrium, so that his whole power could be made available, it would require him, at 16 hours a day, and using his whole power, more than *seven millions of years* to move the earth through the *one-hundred millionth part of an inch.*

Mr. Sopwith then proceeded to explain various other kinds of models, which were capable of being simply constructed in paper and cardboard as geological models—models of local districts—models of school-rooms, and others.

He referred to the lectures of Richard Dalton, as an example of the great utility of models, illustrating mechanics, hydraulics, hydrostatics, optics, astronomy; and spoke of several other mechanical models. He considered that collections of models should be made in every large town, and that government should offer premiums for their production.

Under the head of diagrams, the lecturer spoke as to—1, the principles of construction; 2, the objects capable of illustration; 3, the materials to be employed; and 4, the special advantages they afford in promoting education. A diagram being the representation of one or more objects on a plane surface, due regard must be paid to the exhibi-

* From the 'Journal of the Society of Arts.'

tion of it in such a form as to convey a clear idea to the mind. An uninstructed person, who, for the first time, attempts to make a diagram of a cylinder, is disposed to make a circle for the top, and then continue lines to represent the length of the cylinder. Again, an inexperienced draughtsman, wishing to represent the shaft of a mine, with two roads at the top, one running direct north and the other east, and with two drifts, or galleries at the bottom, one going south and the other west, would in the first instance, represent the roads the same as on an ordinary ground plan, with the top of the pit (or hollow cylinder) at the point of intersection. He would proceed to lay down the shaft in a perpendicular line, and the south and west drifts in their relative position to the north and east roads. The fallacy of this figure must be apparent to every person. We perceive, then, that every diagram must be designed in a certain relation to the truth, in order to convey correct ideas to others. The methods of effecting this are,—first, by a ground plan; secondly, by a sectional plan; thirdly, by an isometric projection; and, fourthly, by a parallel projection. If the object to be designed or explained only has relation to one uniform plane surface, then the first of these modes is all that is required; but in every solid object the representation must depend on one or other of these methods of projection, unless perspective delineation is necessary. Diagrams require a close adherence to geometrical accuracy, and, for the most part, are capable of being delineated by projection by parallel rays. The first and second of these modes are especially meant to represent one surface only. When solid forms are to be delineated, we may have recourse to the third method, which is best explained by reference to a cube, with a house and tower upon it. The fourth plan is based on the theory of shadows, by which a principle is afforded for a mode of delineation of great practical value.

Of the objects capable of illustration, Mr. Sopwith first adverted to number, which might be represented by a space of length, and its relation to other numbers by lines of comparative length; thus we had a method of teaching addition, subtraction, multiplication, and division, which ought to be in use in *every* school. The next general application of diagrams is to represent space, in relation to area, for as to mere extension, that is only the repetition of number. In areas we have to deal with a different mode of progression, and the *line* 3 times the length of another, is the index to an *area*, if square, of 9 times. And we may proceed, from the relative size of the school-room, one square mile, one hundred square miles, England, Scotland, and Ireland, Europe, and finally the globe; and so by a series of well-studied diagrams, the mind may be carried from magnitudes easily understood, to those vast distances which can only be comprehended by patient study; but which process is equally required in every department of art and science.

This subject is one which is scarcely at all known in hundreds—nay, in fact, in the great majority of the humbler class of schools. The few examples adduced would serve to show the useful aid which they afford to the teacher, the animation they impart to otherwise dry and uninteresting lessons, the awakening of *new* ideas in the mind, and the formation of correct habits of thought. All these show forth the value of such means of illustration in the school, but *here* their value only begins, for they establish in the eye of the youthful student an exact habit of observation; which will be of the greatest use in every stage of life; whether it be in the recreations of travel, in the pursuit of science, in the following industrial occupation of any kind, however humble, scarcely a day can pass without affording some opportunity of applying the kind of knowledge which has been imparted; in every department, from the complicated details of finance, or other difficult statistical conditions, which claim the mind of the statesman, down to the humblest artisan, well-constructed diagrams may be made the means of presenting, as in were in one field of view, combinations and relations of numbers, value, or space, in relation to time, or other conditions, in a way which cannot be done by means of figures or descriptions.

---

*On Teaching Crystallography.* By Rev. Walter Mitchell, M.A.

The lecturer commenced by stating that few geometrical forms had been greater favourites with the ancient geometers, than those regular solids known by the name of the Platonic bodies. It had been stated that Plato and his followers had affirmed that the greatest secrets of nature were contained in them. So far as we are aware of, they were unacquainted with the fact that three out of the five Platonic solids are found in nature, formed by the action of the molecular forces of matter with a precision and accuracy defying the imitation of art. After the prophetic vision of the scientific value of these forms had slumbered for many ages, the genius of Haüy gave the first glimpses of their practical application to a revelation of some of the most recondite mysteries of nature. A natural crystal of chrome alum, in the form of a perfect octahedron, one of the Platonic bodies, whose edges were about an inch in length, was exhibited. The fact that fluor spar occurs frequently in perfect cubes was mentioned, and that this mineral possesses the property of cleaving or splitting readily in such directions as to enable us with great ease to cut out a perfect octahedron from the cube.

By means of models it was shown how a cube of fluor spar afforded a demonstration of the last proposition but one of Euclid's Elements—the 3rd proposition of the 15th Book—"How to inscribe an octahedron in a given cube." The cube of fluor spar would readily split in such directions as to present the form of an octahedron or a tetrahedron, and thus afford accurate models of three out of the five Platonic bodies, while it could not be broken so as to present clean smooth surfaces in any other directions. Many other bodies in nature, of which the diamond was one, possessed the same properties in this respect as fluor spar.

The ready way in which some minerals cleave was illustrated by breaking some portions of calcareous spar, the fragments invariably presenting the edges and inclinations of a geometrical solid known by the name of the obtuse rhomboid, the angles of which were always similar. White marble, reduced to the finest powder, presented under the microscope no rough fragments, but sharp and defined rhomboids.

The accidental discovery of the cleavage of calcareous spar by Haüy, enabled him to classify the most innumerable and exceedingly complex forms of crystalline minerals in a system remarkable for its simplicity, while it affords what might justly be considered a model of a classificatory science. This presents an instance that no one should despair because a subject had presented almost insuperable difficulties to the greatest minds. Linnæus, who carefully studied the external forms of crystals, although so successful in other domains of nature, failed to discover a key to unravel the complicated forms of the mineral kingdom. The same substance which revealed, by a happy accident, to Haüy, the property of cleavage, had been carefully investigated by Newton. In his "Optics" he mentions this property, and even gives the measurement of its angles, though he failed to make the application of the fact, which brings nearly the whole range of inorganic nature within the sphere of geometry.

To give an idea of the nature of Haüy's labours, it was shown that the Comte de Bournon, in his treatise on Carbonate of Lime, had described between six and seven hundred crystals of the same substance, all differing from one another, some of the most complex presenting 40 or 50 different faces. All these were shown by measurement to possess the simplest geometrical relations to the rhomboid obtained by cleavage.

Mr. Mitchell then demonstrated, by a series of models of the cubical system of crystallography, the nature of these geometrical relations, and how bodies, at first sight apparently most dissimilar, possessed relations in common with one another. The property that all the simple bodies of the cubical system can be inscribed in the cube, and their relations to that body, as well as the process by which one body may be conceived to pass into the form of another, was shown in a variety of ways by a number of models.

A number of instances, showing the value of crystallography, not only as a means of mental discipline of the highest order, but also as of the greater practical importance to the chemist, the mineralogist, the medical man, and the manufacturer, were then mentioned. The next question was, could this subject be taught so as to bring it within the range of our elementary schools? The lecturer maintained that it could, and practically demonstrated how, by a few sheets of cardboard and a few pieces of wire, amusement might not only be afforded to children, but they might easily be brought to apprehend truths which even a mature and practised intellect would have great difficulty in comprehending from drawings on a plane surface.

A few circles of wire were combined together in such a manner as to demonstrate some of the most complicated theorems of crystallography. The opportunity was taken of impressing on the educators of youth how easily they might thus for a few pence construct instrumental aids for education, which would make many of the most difficult problems of astronomy, geography, spherical trigonometry, and solid geometry, clearly understood.

Having acquired a knowledge of the simpler forms of bodies by pasteboard models and wire-work skeletons, it was shown how readily a knowledge of their complicated combinations might be acquired by coloured diagrams and models, care being taken that the planes of the same simple form should be represented of the same colour throughout the representations of all the combinations.

---

*The Swansea Docks.*—The centre, or great point stone, of the entrance-gates of these important works was laid, with some formality, but without demonstration, on the 22nd ult., by the Mayor of Swansea. The stone, a noble specimen from the Craigleith quarries, Edinburgh, weighing 7 tons, was placed in the slings of the goliah, and having been carefully adjusted, was finally set in its appointed place. Within a recess, his worship placed the various current coins of the realm, which had been expressly obtained from the Bank of England; and plans and detailed statement of the works, of its promoters, officers, &c., were likewise inclosed. The contractor, Mr. Pickering, and resident engineer, Mr. Neill, having finally proved the levels to be correct, the worthy Mayor took the mallet, and giving the stone the customary three knocks, declared the foundation-stone duly laid.

## THE GREAT GANGES CANAL.

It is not long since, when, in the course of our comments on a pamphlet on the public works of India, published by the Indian Reform Association, we had occasion to observe that the works executed by the East India Company were not of a character to call for much notice, from those to whom the extraordinary feats of engineering skill daily exhibited in this country, were familiar. We were not, however, then aware that the completion of the great work to which we would now direct attention, was so near at hand. We had been given to understand that the Great Ganges Canal, the work to which we allude, was still in so incomplete a state as to require a much longer period to elapse than has yet taken place, ere it would be in a condition to be of any value to the district it is intended to benefit. Advices from India, however, have since informed us of its having been opened amid much rejoicing and ceremony. It is now three months since the event took place, and the nature of the works have now been tested in some degree, so that we feel ourselves at liberty to lay before our readers some account of the work—an undertaking of which it is difficult to find a parallel either in ancient or modern times, and which in its future effect on India can hardly be fairly estimated.

It is not merely a canal for the purpose of navigation and commerce, but the chief end proposed in its construction is the irrigation of a tract of country which has for centuries been doomed to aridity and waste. No work of the famous Sesostris, to whom Egypt was indebted for its numerous canals, can be compared in point of extent to the vastness of the subject of our article. Even the most famous canal of antiquity—that which baffled the skill of Sesostris, exhausted the immense resources of Darius, the Persian, and finally required all the Greek talent and Egyptian ability at the command of Ptolemy Philadelphus to complete,—the canal connecting the Nile with the Red Sea, was but 1000 stadii, or 125 English miles, in length; while the one to which we advert has a channel, navigable throughout, nearly 890 miles long, extending through a country of a nature quite as difficult, in an engineering point of view, as the one through which the great Egyptian work passed. All the difficulties presented by the country, the climate, the people, and many others not easy to define or enumerate, have been, however, overcome by the energy and skill of Lieutenant-Colonel Cautley and the engineer-officers under his command. It is no easy matter to fix the amount of credit to which they are entitled, and those who are at all acquainted with the nature of what Lieutenant-Colonel Cautley has done, will agree with us in thinking that the dignity of K.C.B. lately bestowed upon him is but a very inadequate reward for the services he has performed. With a small staff of military engineers, Colonel Cautley had to educate the whole of his subordinates, who, without exception we believe, were drawn from the rank and file of the Indian army, and such natives, as he could find suited for the employment. With such means and such assistance, has been constructed the Great Ganges Canal, which we will now attempt to describe; to do which we shall have frequent occasion to quote the pamphlet which has been published on the subject by the East Indian Government.

The River Ganges, rising among the snows of the Himalayas, leaves its mountain channel above Hurdwar, and at that point breaks through the Sewalic Hills as a pure and plentiful stream, flowing over a bed of great stones, and separating into several branches, one of which passes Pyree Ghat, the most sacred of the bathing-places of the Hindoos. The main branch turns off a little to the eastward, and flowing past Khunkhul, receives again, immediately below that town, the Pyree branch. It is through this latter channel, that the supply for the canal is brought to Myapoor, where the regular excavation commences. At Myapoor, a very extensive and complete series of works have been constructed for regulating the admission of water into the canal-bed. They consist of a great dam of masonry, 517 feet in length, across the Pyree Ghat branch of the Ganges, and a regulating bridge of ten arches, each 20 feet wide, across the channel of the canal, with gates and all the necessary machinery for regulating the admission of water, according to the wants of the cultivators on the banks of the Canal. The left flank of this bridge is connected with the dam by a line of wall, which protects the earthen bank against the action of the water, and on the right bank there are long lines of deep steps, stretching from the bridge to the branch, down which natives may come, who wish to bathe in the sacred waters. Between the Myapoor regulating bridge, and the high land on which Roorkee is situated, the most formidable obstacles have been found. They consist principally of slopes, to regulate which, four falls of 9 feet in depth have been required between Hurdwar and Roorkee, which delivers the channel on the edge of the valley of the Solani River at Mahawur, 27½ feet above the level of the lowest part of the valley. The continuation of the channel is then provided for by an earthen aqueduct, called the Solani Aqueduct, about three miles in length, protected throughout with masonry walls, having steps on their water-faces for the convenience of the natives. The Solani River is then crossed by a masonry aqueduct of fifteen arches, each having a span of 50 feet, giving a clear waterway of 750 feet for the passage of the floods of the river, which is one of the great drains of the Sewalic Hills. On this aqueduct—one of the largest in the world—the Indian Government have expended a sum of not less than thirty lacs of rupees (300,000*l.* sterling). It is founded on an elaborate series of blocks of masonry, sunk 20 feet deep below the bed of the stream, each of which measures 20 feet square. Piles and other devices for resisting the action of the stream have also been used.

Up to Roorkee, the head-quarters of the engineers and work-people employed in the construction of the works—where a college for their education was some years since founded by the late Lieutenant-Governor Thomason—the canal has cost about 700,000*l.* It thence proceeds southwards in a single line to Nanoon, a distance of 180 miles. The slopes being regulated by masonry where falls were necessary, round each of which a navigable channel with a lock is carried, for the purpose of transit. Bridges for cross communication are built at intervals not greater than three miles, and to each bridge there is attached a main irrigating channel, whereby the water is carried to the adjoining villages. The length in a straight line, as we said before, from the canal-head to Nanoon, is 180 miles; the breadth at bottom 140 feet, diminishing gradually as it reaches Nanoon to 80 feet. Between Roorkee and Nanoon, are three great branches, one leading to Futtehghur, leaving the main line at fifty miles from the head; the second to Bolundshahr, leaving at the 110th mile; and the third to Koel, leaving at the 152nd mile. The two last ultimately unite, and form one branch, used for irrigating the great district of Hatrass.

At Nanoon, the canal branches into two separate lines, directed respectively on the Ganges at Cawnpore, and the Jumna below Etawah. The total length of channel navigable throughout, including the trunk and terminal lines, with the great branches, is nearly 890 miles; along which are distributed 17 dams or escapes, with waterways, varying from 800 feet to 18 feet; 902 bridges for the purposes of regulation and cross-communication, with waterways varying from 200 feet to 20 feet; 297 inlets for local or minor drainage; 16 falls for regulating the slopes; 31 locks and navigable channels for navigation; 282 heads for irrigation; an aggregate length of not less than ten miles of steps for bathing, for the use of the natives; 170 buildings for the shelter of the establishment; 6 workshops for supplying the various wants of the canal works: all which has cost about 700,000*l.* sterling, and has been executed within the last eight years. But to quote the words of Captain Baird Smith: "The visible results are far from being a true measure of the amount of labour which has been expended. It is the work of the hand in construction only, that is seen on the surface of the country; to estimate the extent of mental and manual labour of other kinds that are here required for pure constructive purposes, the records of the office must be examined; and there will be found proofs of the thoughtful care and immense toil with which every part of the great design has been elaborated by those concerned in working it out. Nor should those who execute works of civil engineering in countries overflowing with every resource that mechanical skill and individual enterprise can supply, overlook those peculiar difficulties which beset the engineer's path in India, where his resources are chiefly in himself, and where he must not only be the designer of works, but the head mason, the head carpenter, the head brick and lime burner; in fact, the man of all detail work or of all general design."

This vast undertaking being entirely the work of government, the results, of course, constitute a portion of the public revenue, and are estimated to amount, on the gross average, to the sum of 145,000*l.* per annum. The water-rent, from the cultivators, who will use the canal for irrigating their lands, is estimated to produce about 130,000*l.* per annum, while the transit duties and other items of revenue are reckoned at 15,000*l.* The annual charge for maintenance is estimated at 40,000*l.*, and when the various contingent works are completed, the total capital sunk will be about a million and a half, on which the net income will amount to 125,000*l.*, just seven per cent. on the outlay.

But it is not merely as a stupendous work of engineering, or as a profitable investment of capital, that the Ganges Canal is most worthy of our notice, remarkable though it be in both respects: but as a boon to the countries through which it passes. As an instance of what may be done in India by the judicious expenditure of capital, its construction constitutes one of the most remarkable events that have taken place during the present age. It has been the means of bringing into regular cultivation millions of acres which for ages have lain almost waste, and only cropped in those years when the rains have been more than usually abundant; it has removed thousands beyond the dread of famine, and rendered unnecessary those periodical migrations which have hitherto characterised the habits of the people of those regions.

Although we have before given the estimated direct return of revenue from the canal, it is impossible to give any idea of what amount of increased land revenue may be indirectly realised by the government, by the construction of this great work enabling the cultivators to raise crops on those lands which before had lain waste: and not only the increased revenue, but the increased production, adding to the wealth of the country, raises the estimate to a higher figure than we would venture to name. The construction of the Ganges Canal is, in a word, the most profitable acquisition that has been made by the British empire since the conquest of Bengal, and affords a convincing proof that, as a field for the employment of capital, India is not behind the rest of the world; though, to judge by recent transactions on the London Exchange, when Indian speculations have been the subject of traffic, such would not appear to be the opinion of the commercial world generally. Another word, and we have done. It was at one time said, and perhaps truly then, that if the English were expelled from India, they would leave no traces of their sojourn behind them, but a few gaols and empty bottles. Now, however, the joke may pass harmless. The Ganges Canal is the standing answer to the sarcasm.

## MATERIALS FOR PAPER MAKING PROCURABLE FROM INDIA.

Paper, it is well-known, is in Europe made chiefly from linen or cotton rags, but also from the refuse and sweepings of cotton and flax mills, as also of the coverings of our cotton bales and of worn-out ropes. But paper is also made from the stems and leaves of many grasses, as from rice-straw and from the bamboo by the Chinese, and of late from common straw in this country, and even from wood shavings. The fibrous part of many lily and aloe leaved plants have been converted into excellent paper in India, where the fibres of tiliaceous, malvaceous, and leguminous plants are employed for the same purpose. As in the Himalayas, one of the lace-bark tribe is similarly employed, and in China one of the mulberry tribe, and the nettle in Holland. I mention these various sources, because plants belonging to the same families as the above abound in India and other warm countries, and are capable of yielding a very abundant and never-failing supply of sufficiently cheap and very excellent materials for paper-making of all kinds. Some may be used without any further process of bleaching, but all are capable of having any colour they may possess destroyed by chemical means, as I would not even except the jute canvas or gunny bagging, because I have seen specimens of jute of a beautiful silky white, both plain and manufactured into fabrics for furniture, &c., as shown by the late Colonel Calvert at the East-India House. As the Chinese make paper of rice-straw, and of the young shoots of the bamboo, while the Hindoos make ropes of different grasses (such as Saccharum munja and Saccharum sara), strong enough for their Persian wheels as well as for towing-lines, it is evident that these, and probably many others, contain a sufficiency of fibrous material for paper-making. The cultivated cereals cannot well be turned to much account, for their straw forms the chief food for cattle; but as the country abounds with grass jungles, which are in the autumn of every year burnt down in order that the young blades may spring up and afford pasturage for cattle, it is evident that there are many situations where a sufficiency might be cut down before it has become perfectly dried up, and converted into *half-stuff* for paper-makers.

Of the sedges also some are employed in India for making ropes, as the Bhabhur or Eriophorum cannabinum, for making rope bridges for crossing some of the hill torrents. The papyrus, we know, was used by the Egyptians for making their paper, but this was by cutting the material into thin slices and making them adhere together under pressure. But others of the genus, as the Cyperus tegetum, is used in India for mat-making. As these plants as well as rushes grow together in large quantities, it would be quite possible in many places to turn them to profitable account.

Many parts of the world abound in the lily and aloe-leaved plants which have been alluded to above, and of which the leaves contain much easily separable fibrous materials. These belong to the genera Agave, Aloe, Yucca, Sausevieras, Bromelia, and others; all of which abound in white-coloured fibres, applicable to various useful purposes, and of which the tow might be used for paper-making, and considerable supplies obtained. Paper used to be made from the Sausevieras in Trichinopoly, and some made of the unbleached Agave alone, and also mixed with old gunny bags.

Among cultivated plants there is probably nothing so well calculated to yield a large supply of material fit for making paper of almost every quality as the plantain (*Musa paradisiaca*), so extensively cultivated in all tropical countries on account of its fruit, of which the fibre-yielding stems are applied to no useful purpose. The plant, as every one acquainted with tropical countries knows, is common near the poorest huts and in the largest gardens, and is considered to yield by far the largest quantity of nutritious matter. Its fruit in many places supplying the place of bread, and in composition and nutritious value approaching most nearly to the potatoe, may, if produced in too large a quantity, be preserved in the same way as figs, or the meal may be separated, as it resembles rice most nearly in composition. Each root-stock throws up from six to eight or ten stems, each of which must be yearly cut down, and will yield from three to four pounds of the fibre fit for textile fabrics, for rope-making, or for the manufacture of paper. As the fruit already pays the expenses of the culture, this fibre could be afforded at a cheap rate, as from the nature of the plant, consisting almost only of water and fibre, the latter might easily be separated. One planter calculates that it could be afforded for 9*l.* 13*s.* 4*d.* per ton. Some very useful and tough kinds of paper have been made from the plantain, and some of finer quality from the same material in France.

All the plants which have been already mentioned are devoid of true bark, and are called endogenous in structure. Simple pressure between rollers, and washing, would appear to be sufficient for the separation of the fibres of most of them. But the following families of plants are all possessed of true bark, which requires to be stripped off usually after the stems have been steeped in water, before their respective fibres can be separated from the rest of the vegetable matter.

The flax plant abounds in fibre, but this is too valuable to be converted into paper. India, however, grows immense quantities of the plant on account of its seed (linseed), which is both consumed in the country and exported in enormous quantities, but nowhere is the fibre turned to any account. This is no doubt owing to the climate not favouring the formation of soft and flexible fibre; but the short fibre which is formed, and might be easily separated, would be valuable for paper-making, and might add to the agriculturists' profits without much additional outlay.

So some valvaceous plants are cultivated on account of their fruits, being used as articles of diet, as the Okhro (*Hibiscus esculentus*) of the West Indies and of the United States. The *Ram-turai* of India is closely allied to it, and is cultivated for the same purposes. Both plants abound in fine flexible fibre, which is not, but might be easily, separated, and afford a considerable supply, especially if the cultivation was extended in the neighbourhood of towns. Paper is made from a species of Hibiscus in Japan, and *Hibiscus Sabdariffa* is cultivated in India on account of its jelly-yielding calyxes. Numerous other species of Hibiscus, of Sida, and of other genera of this family abound in warm climates; several are cultivated in different countries; as *Hibiscus Canabinus* in India, and *Sida Tiliaefolia* in China; more might be so. They grow quickly and to a large size, and abound in fibrous material of a fine, soft, flexible quality, on which account they might be cultivated with profit, and the tow be useful to the paper-maker.

The Tiliaceæ are likewise remarkable for the abundance and fine quality of fibre which many of them contain. *Tilia Europea* produces the enormous quantities of bast exported from Russia. *Corchorus olitorius* and *Corchorus Capsularis*, the leaves of both of which are used as a vegetable, yield the large supply of jute imported into this country, as well as the gunny cloth and bags exported even to America. Several species of Grewia yield edible fruit, on which account they are cultivated. Others abound in the jungles, and most would yield a valuable fibre, as some of them already do, for commercial purposes. Some paper is made from gunny bags. Some of the Leguminosæ also abound in valuable fibre. *Crotalaria juncea* yields the common sunn of India. *Sesbania Cannabina* yields the dhanchi of Bengal; while *Bauhinea Racemosa* is used in making rope bridges in the Himalayas. The fibre of *Parkinsonia aculeata* was sent to the Exhibition in 1851 expressly as being fitted for paper-making; though colourless it wants strength.

Several plants produce large quantities of a silky, cotton-like substance, not applied to any use, such as the silk-cotton tree, the mudar of India, &c., several species of Saccharum, which might be collected where labour is cheap, and would no doubt be well fitted for conversion into pulp for paper.

Among the nettle, the mulberry, and bread-fruit tribes of plants, there are many which seem well calculated to yield material for paper-making. The Chinese, we know, employ the inner bark of morus, now *Broussonetia papyrifera*. This, no doubt, produces some of the Chinese paper, which is remarkable for toughness; I believe that the refuse cuttings of the bush cultivation of the mulberry in Bengal might be turned to profitable account. The barks of many stinging (*Urtica*) and of stingless (*Bohemeria*) nettles abound in fibres remarkable for strength; the tow of these might be converted into paper stuff if not required for mixing with wool.

The weeds of tropical countries, which grow in such luxuriance, and among which are species of sida, of grewia, of corchorus, of triumfetta, and of many other genera, might all yield an abunddance of fibrous material if the refuse of the above cultivated plants was found not to be sufficient. Some simple machinery for separating the fibre would greatly facilitate operations, while the expenses of freight might be diminished by compression, or, as suggested, by packing the material as dunnage; and the cheapness of labour, as of everything else in many of these countries, would enable material for paper-making to be brought here in great abundance, and at a sufficiently cheap rate, if ordinary pains were taken by the consumers in Europe to encourage the planter or colonists of a distant region.

J. Forbes Royle.

*East India House, May* 3, 1854.

## ON THE RAW MATERIAL FOR THE MANUFACTURE OF PAPER.

It is unquestionably true that there is a great and increasing scarcity of the raw material used in paper-making. The cause of this scarcity, in spite of an increased demand, would appear to depend on the circumstance that the raw material of papermaking is in reality the product of the wear and tear of a substance of very advanced manufacture, and depending for its quantity on the collateral causes which produce a greater or less activity in the latter. Hence the stoppage or partial suspension of linen and cotton manufacturers is sufficient to account for occasional and especially for local scarcity. Thus the paper-mills have been influenced by the lock-outs of Wigan and Preston, and the half-time working of Belfast and the surrounding districts.

It would appear, also, that apart from occasional depressions of the manufactures, or the wear and tear of which the raw material of paper chiefly depends, the demands of the paper-makers have been greater than can be supplied by the *less* increased rate of consumption of the manufactured products. While this has been the case, other consumers of the raw material have come into existence, railways and steam-boats now exhausting a very large quantity of cotton and other waste for wiping machinery. But the most important of all new competitors have been undoubtedly the Americans, who have purchased not only largely in our own markets, but also in those foreign parts which are open for the sale of rags. It may be mentioned also, that the rag trade is in the hands of only a few capitalists, who buy from small collectors and import from abroad, and that this limitation of the trade enables them readily for a time to influence the market, both as to supply and price, by withholding their stocks, but these influences can only be temporary, and cannot be persevered in for long periods.

The disadvantage of the *raw material* of paper-making being dependent upon manufactures having no immediate relation to its supply and demand, and the fact, also, that the growing thirst for literature is at a greater rate than the increase in the manufacture of cotton and flax, seem to furnish adequate reasons why the supply of rags does not meet the increased demand.

Many attempts have been made to furnish new raw materials for paper, but hitherto with only partial success. The failure generally results from one or more of three causes. (*a*) Some fibres require so much cost to bring them to the state in which they are offered to paper-makers, in the form of rags or cotton waste, that in point of economy they cannot enter into competition with the latter. (*b*) Certain fibres lose so much weight in bringing them to this state that they cease to be economical. (*c*) Certain fibres, which are well adapted on account of their texture for the paper trade, present so many difficulties in bleaching them as to render them unfit for white paper. The Surat bass in which cotton has of late years been imported into this country, offers an example of this difficulty.

The price which is mentioned in the Treasury letter, of 2*d.* to 2½*d.* per lb. for a partially-prepared pulp is generally considered by most makers to be too high, and they think that materials to be of benefit should be looked for at the price of 1*d.* to 1½*d.* per lb. The latter price refers to *roughly*-prepared pulp, but should the pulp be offered in a bleached state, or in as far an advanced state with regard to colour and texture as cotton or linen rag, then 2½*d.* to 4*d.* per lb. might be obtained. The quantity of any promising material sent home for experiment should not be less than half a ton in weight.

In considering this subject, it appears that very little is known of the statistics of the consumption of various materials used in the manufacture of paper, and that an inquiry on this subject would be useful.

Lyon Playfair.

To Sir J. E. Tennent, Board of Trade.

## CONDITION OF THE THAMES MARSHES.

*The Select Committee appointed by the House of Commons to inquire into the Sanitary and Agricultural State of the Marshes on the Sides of the Thames, the Means for their Improvement, the existing Legal Powers for the Purpose, and the Necessity for further Legislation thereon—Have agreed to the following Report, dated July 17th:*

The terms of the order of reference to the Committee would have admitted of a more extended investigation; but the committee have felt justified, at the present period of the session, in confining their inquiry to the condition of the Marshes on the banks of the Thames below London Bridge, which it appears extend over 32,000 acres, and are under six distinct commissions of sewers.

It appears from the evidence of highly intelligent and eminent gentlemen of the medical profession residing in the neighbourhood of the marshes on both sides of the Thames below London Bridge, that the diseases prevalent in those districts are highly indicative of malarious influence, ague and fever being very prevalent; and that the sickness and mortality is greatest in those localities which adjoin imperfectly drained lands, and far exceed the usual average; and that ague and allied disorders frequently extend to the high grounds in the vicinity. In those districts where a partial improvement in the drainage has been effected, a corresponding improvement in the health of the inhabitants is perceptible.

The Committee have inquired more particularly into the state of the marshes adjoining the Royal Arsenal at Woolwich, which they had reason to believe gave a fair representation of the state of the other marshes.

The mortality of Woolwich, particularly East Woolwich, is much higher than the average. Woolwich adjoins the Plumstead and Erith marshes, where the water is frequently dammed up, which increases the quantity of decaying vegetation and malaria, and the description of ague from which people suffer in that neighbourhood is stated to be very distressing, and to produce many complications of disease.

It appears also, that in the neighbourhood of Woolwich and Charlton, many houses have been built, and are building, whose drainage empties itself into the marsh ditches; this seems to your Committee a new source of miasma of dangerous character, and one likely to increase.

To remove such evils is an object obviously deserving the attention not merely of the landowners and residents in the district, but of the legislature, and it is most satisfactory to find, from the evidence before your Committee, that there is good reason to believe that the increased value given to the lands by improved drainage would be such as amply to remunerate the proprietors for the necessary cost attending such works.

And with regard to the means to be employed, it was proved that no engineering difficulties exist.

The existing legal powers of the Commissioners of Sewers are inadequate to effect these objects. The authority of the Commissioners enables them to maintain existing works, but they cannot interfere with the private ditches, nor can they construct any new works without the previous consent of three-fourths of the owners and occupiers.

It appears, however, that any plan of effective drainage would require an amount to be expended in a single year, which, in justice to all interests, should be raised by loan, and repaid by annual instalments, spread over a period of years.

In order to carry out the improvements which the Committee consider to be indispensable, it will be necessary to provide some means for ascertaining the due proportion of interests in the lands to be dealt with, which shall be sufficient to bind the minority. The Committee suggest, that the poor's rate assessment offers, at the present time, the best criterion for ascertaining the proportionate interests.

The Committee recommend that additional powers be given by the legislature to the Commissioners of Sewers to enable them to carry out a more effective system of drainage, which would be beneficial alike in a sanitary and agricultural point of view. The Committee further suggest that the number of the Commissioners should be diminished, and that an alteration might be advantageously made in the mode of their appointment by the introduction of the elective principle.

---

*Estimate of the Expense of Draining the Marshes or low lands between Woolwich and Erith.*

TO THE COMMISSIONERS OF SEWERS OF DARTFORD AND OTHER LEVELS.

GENTLEMEN—Having received instructions from your clerk, Mr. Hayward, to make a report and estimate of the expense of effectually draining the marshes or low lands between Woolwich and Erith, I have caused the levels to be taken, to ascertain the heights of the present sluices above low-water mark, and collected other information that will enable me to comply with the instructions.

I find that low-water mark on the 1st and 2d instant, was about—4 feet below the Green Level Sluice; 6 ft. 2 in. below the Great Breach Sluice; 3 ft. 8 in. below the Abbey Level; 6 ft. 6 in. below the Old Corn Marsh; 5 ft. 6 in. below the Crab Tree.

The land in Green Level being higher than that in the other levels, it can be drained through the present sluice.

I should recommend a new sluice to be placed in Great Breach Level, about five feet lower than the present one.

In Abbey Level I should fix a new sluice, about two feet, or two feet six inches lower than the present one.

A new sluice should also be placed in Old Corn Marsh Level, five feet lower than the present one, and through this I would drain most of Church Level, a small portion of Abbey Level, which is very low and near the sluice, and also that part of Crab Tree Level east of the Griffin Manor-way.

By placing the sluices in this way, and diverting a portion of the drainage from Abbey Level, it will be seen that the water would be taken to the Thames, from the uplands, by a shorter route than if allowed to pass through Abbey Level, as it now does.

The putting down of the three new sluices, and sinking the whole of the main drains to a proper level, to admit of thorough draining being adopted in all the levels, I estimate at 1680*l*.

I should recommend that the whole of the private ditches, except those that can be filled up, be sunk to an average depth of two feet below their present level, which could be done at a cost of about 1560*l*.; and I am of opinion that it would be much to the interest of both landlords and tenants if a proper arrangement were made, and these ditches taken into commission, because they could then be kept clean and a proper supply of fresh water given for cattle, without the interference of any of the occupiers.

The fresh water must be supplied, I find, in a similar manner to what I recommended in my report, dated December 1847, but at two feet lower level, and this alteration I estimate at 160*l*.

The alteration made in the level of the fresh water in the ditches would involve the necessity of making drinking places for the cattle, and I am of opinion that 200*l*. would make all that would be wanted.

If the whole of these works were to be carried out, the cost, per acre, for all the levels would be under 25*s*., the total amount being 3600*l*., and the number of rateable acres 2923.

I have measured the length of the ditches in the levels, as shown on the plans, and find them to amount to 141,980 lineal yards; and, taking them at an average width of seven feet, the area would be equal to 68¼ acres, and of this extent I find we could stop up 12¾ acres without any exchange of property. But if the whole of the levels were the property of one landowner, a very much larger number of ditches could be done away with.

I was glad to learn, while collecting information for making this report, that ague had very much diminished since you carried out the works recommended in my report of December 1847, for lowering the main sewers, and for improving the supply of fresh water to the levels.

Should the plan here suggested be carried out the whole of the levels could be thorough drained, which would not only improve the district in a sanitary point of view, but would, I am confident, from my experience in thorough draining, pay the landlord and tenant together from 10 to 15 per cent. for the money expended.

There is one other subject to which I must beg to draw your attention, viz., the sewage and drainage of the new town now growing up between Plumstead Common and the railway, which is now taken along the railway into the Crab Tree Level. This is but very little, if any, nuisance at this time, but it will become worse every year, as the town increases; and therefore I think it right to draw your attention to it, the more particularly as I am not certain at whose expense it ought to be conveyed into the Thames without going into the level, which could be done at a cost of from 1600*l*. to 1700*l*.

I think, however, that you ought not to be called upon to do it, and, therefore, the question would rest between the North-Kent Railway Company and the proprietor of the land on which the town in question is growing up.

(Signed) JAMES EASTON, for Self and Partner.

*Grove, Southwark, December* 8, 1853.

---

Upon this report a meeting was called; a circular was sent to each landowner and each land-occupier, giving notice that a meeting of the Commissioners of Sewers would be holden very shortly after that date at Dartford, at which they would present before them a system of drainage throughout the district from Woolwich to Erith, and that they would be solicited to give their assent. The meeting was attended numerously. Mr. Easton was there, and he produced his plan, and explained the mode he had of doing this drainage; it resulted in the consent being signed by five persons as owners, two of them being commissioners themselves, and one occupier: there the matter has remained, and there have been no active steps taken since that meeting.

---

## OBTAINING LIQUID CEMENT, AND PIGMENTS OR PAINTS.

GEORGE BELL, *Patentee*, May 11, 1853.

THIS invention relates to combinations of lime with certain other matters in the production of liquid cements, pigments, and and paints.

In carrying out this invention, when it is required to produce a liquid cement suitable for outside walls and other like situations, the following matters are mixed in the proportions given: viz., six bushels of slacked lime, one pound of sulphate of iron or zinc, one quarter of a pound of sal-ammoniac, ground in a little water; six pounds, or thereabouts, of ochre, and six pounds, or thereabouts, of umber, being added thereto to give the required tint to the mixture. If the mixture, when ground, is not sufficiently fluid for use, the same may be rendered so by the admixture therewith of water to the extent desired.

To produce a liquid cement or colour, having a more adhesive character, and suitable for inside walls and other situations, six pounds weight of gum-arabic and one-and-a-half pounds of bees'-wax are added to and dissolved and mixed with the above.

To produce a black paint for common purposes, the following matters are combined in the proportions given:—Two pounds of slacked lime in powder, two pounds of sulphuric acid diluted in one gallon of water, and ten gallons of gas tar. These are mixed together in any suitable stirring apparatus, and are then fit for use.

An elastic paint, suitable especially for damp walls, but applicable for other purposes, is produced by combining one hundred-weight of oxichloride of lead or oxide of zinc, twenty-eight pounds of slacked lime, dry, and one gallon of a solution of india-rubber, diluted with one part of linseed-oil and two parts of spirits of turpentine. In obtaining this latter combination, the oxide of zinc or oxichloride of lead is first mixed with linseed-oil by grinding, and then the other matters are added as may be desired.

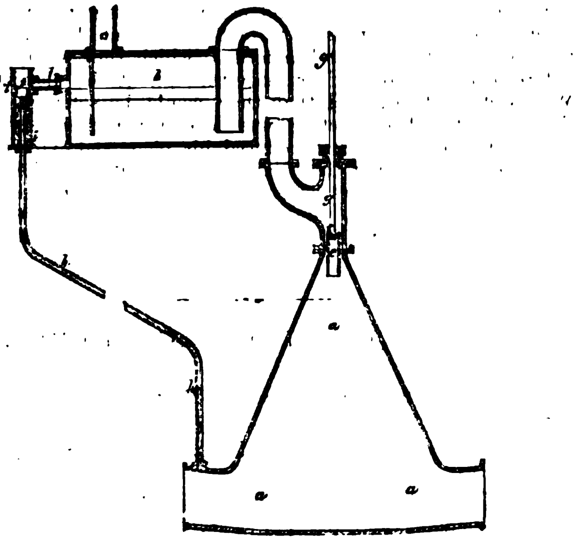
An oil suitable to be used for thinning the last-mentioned combination, of elastic paint may be obtained by combining one gallon of spirits of turpentine, half a gallon of turpentine varnish, one pint of linseed-oil, and one pint of rosin-oil.

Each of the above combinations may be applied by brushes in the ordinary manner of applying paint.

## MANUFACTURE OF GAS.

RICHARD HOLME, *Patentee*, August 1, 1853.

THIS invention consists of constructing retorts with enlargements or chambers at the upper parts, so that the gas as it is evolved, in place of passing away out of the retorts by the rising pipes, as heretofore, is received into the upper parts or gas chambers of the retorts, where there is constantly a quantity of gas, and it is from these chambers the gas is conveyed to be purified, and then to the gasometer. The retorts are each made either with one or two mouth-pieces, and the bottom of the retort rises towards the mouth-piece or mouth-pieces, so that the fluid flows towards the most heated part of the retort, and is converted into gas. And when the retorts are used for making gas from oils or fluids, they are supplied by means of a tube rising into a cylinder closed at bottom, and over such tube there is an inverted vessel, by which there is at all times a fluid joint found, opposing the passage of gas through the hole in the tube, by which the fluid passes into the retort.



The engraving shows a vertical longitudinal section of a retort constructed according to this invention. It may be made with doors at each end, or at one end only, and the ends of the retort rise from the central portion, whereby any fluid therein will flow towards the hottest part of the retort. The retort is made with a conical chamber over the central portion, as shown, into which the gas rises as it is evolved. The retort *a*, is to be set in such manner that the bottom may be heated the hottest, and the upper parts of the retort are also to be heated; the heating of these retorts, as with others, is to be according to the materials which are being distilled, which is well understood by gas engineers. The gas passes off at the upper part of the conical chamber of the retort into the hydraulic main *b*, as shown, and it passes from the main by the outlet-pipe *c*. In the hydraulic main there is a partition to prevent the gas getting away at the outlet *d*, where the tar is allowed to flow off; *e*, is a tube suspended on the plate or disc *f*, fixed to the rod *g*, which passes through a stuffing-box. This apparatus partly stops up the passage at the top of the retort, and carbon accumulates therein, and the same is to be cleared out by pressing down the rod *g*, when the lower end of the tube *e*, coming down on the contents of the retort, the disc will be forced down, and remove any matters which may have accumulated in the tube *e*. The tar accumulating on the water in the hydraulic main is allowed to flow away, there being a small opening in the partition for that purpose just above the water. The tar returns to the retort *a*, by the tube *h*, which enters the vessel *i*, and is covered by the inverted vessel *j*, there being openings for the passage of the tar under the inverted vessel *j*. The retort may be used for distilling from coal or other matters, and when fluids be used, such as resin or other oils, they are supplied to the retort by an apparatus, such as is used for conveying back the tar to the retort.

The patentee does not confine his invention to the use of the precise form of retort shown, as it may be somewhat varied, without departing from its peculiar character.

*Claim.*—The construction of gas retorts with upper chambers, wherein there will, when at work, be constantly an accumulation of gas.

## FORMING DESIGNS ON PAPIER-MACHE.

CHARLES BREESE, *Patentee*, July 19, 1853.

THIS invention consists in first producing a pattern or design upon paper by printing from stone or other surface in some adhesive material or composition, which is transferred to the surface intended to be ornamented. The paper is removed, and the pattern has applied thereon some material or composition in a finely-pulverised state, which will resist the action of acids or other agents employed to act upon that part of the surface not covered by the pattern. Or instead of the pattern being so treated only after being transferred, in some cases it is submitted to the like treatment on the paper, then transferred, the paper removed, and the process proceeded with as above described. When required to ornament glass and metal surfaces with vitrifiable colours or with metals, the process known in the trade as burning-in is employed. The vitrifiable colours or metals (in the state of powder or leaf) are rubbed into, mixed with, or applied on the pattern produced in the resinous or other material or composition aforesaid. When not required for burning-in, and for the purpose of producing designs and patterns in colours or in gold, silver, or other metal, the pattern is produced in an adhesive composition as aforesaid, and has applied thereon the gold, silver, or other metal in the state of powder or leaf; the superfluous metal being wiped away or removed from those parts where the adhesive composition has not been applied. Or the whole surface is covered with gold or silver leaf, and the pattern, produced in an adhesive composition and sprinkled with a resinous powder, is applied thereon. The gold or silver leaf is removed from those parts which the pattern does not cover by biting with acid or by simple rubbing. The resinous composition is next washed off with spirits of turpentine or other solvent, and the pattern appears in bright gold or silver.

In carrying out this invention, the pattern is first drawn or otherwise produced upon stone, copperplate, or other surface, or in type, in the usual way, and an impression in an adhesive matter or composition is obtained upon paper or other suitable fabric. A good adhesive composition for the purposes of this invention may be formed as follows:—Linseed-oil boiled till it assumes the consistence of putty, and thinned to the required consistence for printing with, that is, about that of ordinary printing-ink, by the addition of gold size, to which is afterwards added a portion of pitch. The pattern is transferred to the glass intended to be ornamented, whether plain or coloured (supposing the pattern to be produced on glass), and the paper moistened (when necessary) and drawn off. Some material or composition which will resist the action of acids or other agents, such as finely-powdered asphaltum or anthracite coal reduced to fine powder is then applied; or in some cases metal or other leaf, which adheres to the pattern only, and renders it impenetrable to the acid or agent to be afterwards employed, is used. In some cases heat is applied, or time is allowed with or without exposure to the vapour of spirit or oil, to enable the resinous or other material or composition employed to incorporate itself with the impression; and then fluoric acid (or other material having similar properties) is applied in the usual way on the face of the glass. Th will bite away from every part of the glass where the pattern does not extend, and will leave the pattern untouched.

In some cases the resinous or other powder is applied before as well as after transferring the pattern, and the operation is then proceeded with as follows:—Supposing the pattern to have been produced upon paper in the ink usually employed in lithographic printing, while the ink is still wet or damp a resin or resinous composition reduced to powder is applied thereon. The paper is exposed to the vapour of turpentine in order to cause the resin and oil in the lithographic ink to combine and form a varnish. Or, instead of exposing it to the vapour of turpentine, it may be exposed to heat or even allowed to remain a certain time, when the matters will of themselves combine and form a varnish. The pattern is then transferred on to the article to be ornamented, and the paper on which the pattern had been produced and treated as aforesaid is either stripped or washed off. In some cases an adhesive composition of a watery character is used for obtaining the impressions for the purpose of transferring. Gum or other suitable substance, in a state of powder, is then applied to the printed parts of the impression, either before or after transferring, or both before and after; and the process is proceeded with in other respects as before described. For the purpose of dissolving the gum applied as aforesaid, the surface is exposed to the vapour of water, or left for a short time exposed to a damp atmosphere, instead of using the vapour of oil or spirit and heat, as directed in the case of the resinous composition. When it is desired to obtain an impression of a very adhesive character, a lithographic stone or metal plate is employed, having those parts of the surface on which the pattern is produced in relief, or raised above the other parts of the surface of the stone or plate.

For forming designs in vitrifiable or fusible colours or metals on glass, china, and other suitable substances, the pattern produced by printing in an adhesive material is first taken, with or without the addition of the resinous composition, and transferred as before; and the colouring medium is then rubbed into the pattern; or if metal, it may be applied in the state of powder or leaf. The article is next subjected to heat, when the composition will disappear, and the colour or metal will adhere by fusion to the surface of the article. In some cases the colouring medium may be mixed with the adhesive composition before obtaining the impression, or it may be applied to the impression before transferring it to the surface of the article.

For producing patterns in dead gold, silver, and metal leaf or bronze powder, upon hard or bright surfaces (such, for instance, as japanned iron, papier-maché, oil-cloth, &c.), the pattern is first obtained in an adhesive composition as aforesaid, and transferred to the surface; the leaf or powder is then applied, and wiped off from those parts where the pattern does not extend. When necessary, the article may be subjected to the usual after-processes of stoving, varnishing, polishing, &c.

For producing designs and patterns in burnished gold or silver, gold or silver leaf is first applied by means of the ordinary gilding water, or in such manner as to cause it to adhere sufficiently to the surface of the ~~article to be~~ ornamented. A pattern or design produced in some adhesive composition, sprinkled with a resinous or other powder as aforesaid, is applied thereto, and the gold or silver leaf is removed from all parts which the pattern does not cover by means of an acid or by simply rubbing it off. The material or composition is next washed off, and the pattern is covered with spirit of turpentine or other solvent, when it will appear in bright gold or silver.

This process is also applicable to ornamenting metallic surfaces covered with gold or silver by what is known as the amalgamation process. In this case an impression is obtained in a resinous composition as aforesaid, and transferred to the surface to be ornamented; and acid or other agent is then used to bite away or remove the gold or silver from those parts not protected by the transferred impression. The resinous composition is finally removed by washing with spirit or other solvent.

For the purpose of ornamenting marble, wood, &c., impressions, obtained as aforesaid, are transferred to the surfaces thereof (those in watery compositions are, however, preferred), and dyes, pigments, or varnishes, or any required colour, are then applied to the surface; after which the transferred impression is removed, and the pattern of the original colour is left, surrounded by a ground of the colour produced by the dye, pigment, or varnish.

The patentee claims the method of forming designs and patterns upon papier-maché, japanned iron, glass, metal, and other surfaces, by printing any required design or pattern in an adhesive matter or composition; which design or pattern, so produced, is transferred to the surface to be ornamented, and has applied thereon, either before or after transferring, or both before and after transferring, a substance or composition possessing the properties hereinbefore described, whether employed to stop out the action of acids or other agents applied to those parts of the surface not protected by the pattern; whether vitrifiable colours or metals in the state of leaf or powder for burning-in are rubbed into or applied on it; whether colours in the state of powder, or metallic powder, or metal leaf are applied thereon or mixed therewith; or finally, whether employed to protect a surface of gold or silver leaf, all as hereinbefore described.

## ELECTRIC CONDUCTORS.

THOMAS ALLAN, *Patentee*, August 12, 1853.

THE engineering as well as the electrical difficulties to the laying down and working submarine telegraphs of any great length, extending much beyond what has already been accomplished upon the plans at present known, have led to the belief that other means were requisite, and that a different mode of applying known principles and materials would be necessary to obtain not only the greatest length of rope at the smallest amount of weight consistent with sufficient strength, but also the fullest amount of electrical conduction.

The invention consists in forming the electrical conductors of submarine and subterranean telegraphs of iron rods, wires, or strands of wires, insulated or otherwise, in lieu of copper as now used.

For submarine telegraphs, the patentee substitutes for the insulated copper wire conductors protected with iron, a stout iron wire or rod, or, what is preferable, a rope or strand of wires, which thus forms not only the conducting medium, but also the rope itself. When insulated, the iron need not be galvanised, thereby maintaining the full strength of the iron, besides effecting a great saving in cost.

The insulating medium requires to be of a material differing from that now used for the insulation of copper wires, and what is employed for the purpose is a compound of caoutchouc, sulphur, and coal-tar, or other similar substance, baked hard, and resembling in appearance the material manufactured according to the invention of Mr. Goodyear, for which letters patent for England were granted to Moses Poole, the 18th September 1852, and which itself might be employed with or without certain modifications. By these means a submarine rope will be produced of the required weight, with the greatest amount of strength that can be obtained from iron of the best quality, whilst the conducting medium will be considerably better, and give less resistance than the copper wire now used for such purpose, besides which many other electrical difficulties will be overcome which it is not requisite to enter upon here.

The patentee further adapts and substitutes iron wire or strands of small wires, insulated or otherwise, in lieu of copper, for underground electric conductors, and this, with an insulating material of the nature before mentioned, will effect a great saving of cost.

In some cases for the above purposes strands of wire of two different metals are used, that is, six or more iron wires with a centre core or wire of copper or zinc; by this means, according to circumstances, a better conductor can be obtained than by the use of iron alone, and such conductors may be used for overground telegraphs and suspended by means of posts, as well as for underground and submarine telegraphs. Under certain circumstances the patentee would employ the before-described conductors without insulation at all.

The second part of this invention consists in a cheap and efficient mode of insulating electric conductors of copper, iron, or other metals (for subterranean telegraphs, but which may also be used for submarine purposes). The conductors are insulated in the aggregate, that is, several at a time, by means of a die or dies of the form or construction hereafter described, by means of which a larger amount of the insulating material is saved, whatever that may be composed of.

The object is not merely to coat or cover the wire with two or more coatings of any insulating substance at one operation, but especially to cover three, five, or seven, or any number of wires all at one operation, and all conjoined in one rope. For this purpose, in the die-piece are placed two or three hollow mandrils (according to the number of coatings), the one behind the other; the first one at the back where the wire enters having the smallest aperture, the second being larger, and the last the full size to which the wire is to be covered, there being sufficient space between each to allow the insulating material to come freely in contact with the wire after each successive coating. To perform the same operation in the aggregate (say on seven wires), seven such series of hollow mandrils will be required, and worked in similar manner as if they were but one; and if required to be formed into one rope the die will require an extra mouth-piece, so that the seven wires, when twice or thrice covered separately, may be again covered and conjoined all into one rope.

*Claims.*—1. The adaptation of iron rods, wires, or strands of wires, or of strands of wires of different metals (insulated or otherwise) for submarine and subterranean telegraphs; 2. The mode of insulating several wires at one operation, as hereinbefore described.

## BORING ROCKS FOR BLASTING.

HENRY KRAUT, *Patentee*, September 15, 1853.

THIS invention consists in an improved tool or borer for cutting out a chamber at the bottom of the hole made by the common jumper generally used for blasting; which chamber is intended to receive the powder or other explosive agent.

In the annexed engravings, fig. 1 represents an improved borer for cutting out chambers in holes of larger diameter, with part of the rock in section, showing a portion of the hole made by the common jumper, as well as part of the chamber; and fig. 2, is a ground plan of the same. Fig. 3, is an improved borer for holes of smaller diameter, with part of the rock in section, showing a portion of the hole and chamber; and fig. 4, is a cross section of the same.

FIG. 1.

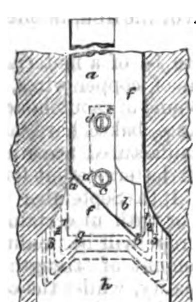


FIG. 2.

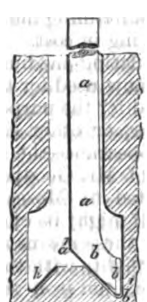

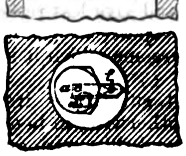

FIG. 3.

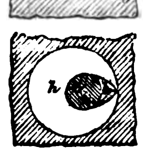

FIG. 4.

*a*, is a bar of iron, at the lower end of which a steel blade *b*, is inserted into a groove *c*, and secured by pins or sets screws *d*. From the side opposite the cutting-edge *x*, of the blade *b*, the bar *a*, and blade *b*, are tapered off, so as to form an inclined plane *a'*, *b'*, of any desired angle. *f*, represents the hole made by the common jumper reaching down to the dotted line *g*. After the common jumper is withdrawn from the hole *f*, the improved borer *a*, is introduced into it, and brought to act upon the rock in the same manner as the ordinary jumper, either by means of hammers or by the process usually called "churning,"—one man guiding and turning it round. It is evident that every time the borer is made to descend, the incline plane will force the edge *x*, of the blade *b*, laterally into the rock; whilst the bottom part of the blade will, to some extent, cut the rock in a vertical direction; and thus a chamber *h*, will be formed progressively in a manner similar to that indicated by the dotted lines 1, 2, 3, &c. From the time the chamber has been widened by twice the distance the blade *b*, projects beyond the bar *a*, or thereabouts, the continued action of the borer will increase its depth only. The conical elevations $1^1$, $2^1$, $3^1$, &c., which are formed during the process of boring, will, in some instances, have to be removed with the ordinary jumper; the loose stone and sand being scooped out, from time to time, by means of the scraper, in the usual way.

In the borer shown at fig. 3, the part *b*, *b*, is of solid steel, and welded on to the iron rod *a*; it is represented as arrived at the bottom of the chamber *h*. The length of the cutting-edge *x*, in figs. 1, and 3, varies according to the hardness of the substance to be cut. For hard stone, the cutting-edge has to be made as short as or shorter than that shown in fig. 3; and, for soft stone, it may be made as long as or longer than in fig. 1. In determining this length, however, the operator must be guided by experience.

This method of blasting effects a great saving in time. It is well known that three men will bore a hole of $1\frac{3}{4}$ inch diameter to a given depth, in one-third of the time required for a 3-inch hole. And as a chamber of 3-inch diameter at the bottom of a bore of $1\frac{3}{4}$ inch diameter, answers the same purpose as a uniform hole of 3-inch diameter made by the common jumper, it is evident that, making a liberal allowance for the time required to form a chamber, the economy of labour must amount to at least 40 or 50 per cent. And, in the second place, it is clear that a given quantity of powder deposited in a chamber formed as described, must produce a far better effect than if it were placed in a hole of uniform diameter.

The patentee does not confine himself to the particular shapes of the borers shown and described; but he claims, firstly,—the projecting part or blade *b*, of the borer; and, secondly,—the inclined plane *a'*, *b'*, at the lower end of the borer, for the purposes hereinbefore described.

## RAILWAY AND OTHER BREAKS.

JOHN JENNINGS, Jun., *Patentee*, February 11, 1854.

THIS invention relates to an improved construction of self-acting break for railway carriages, trucks, and other conveyances, and consists in attaching a spring to a break in connection with the buffers of the train, so that when the steam is shut off the momentum of the carriages behind the engine acts upon the buffers and springs, and the breaks are thereby caused to press upon the wheels, gradually stopping the train without inconvenience to the passengers. One of these breaks is applied to every wheel, or as many as may be required to stop the train in case of sudden danger. In applying the break to common road carriages, the backing action of the horse in descending a hill causes the break to bear upon the wheels, thereby tending in a great measure to retard the motion of the vehicle. In conveyances of two wheels, a slide will be employed in addition to the break, which will allow the body of the vehicle to move back on the axle in descending a hill, thereby lessening the weight on the back of the horse when a backward pressure is exerted. In ascending a hill, the body of the vehicle is moved forward over the axle, to bring the weight more over the back of the horse.

## ARTIFICIAL STONE.

FREDERICK RANSOME, *Patentee*, July 13, 1853.

IN the manufacture of artificial stone and such like wares by the use of soluble silicate, difficulty has been found in obtaining soda free from impurities, particularly from sulphuric acid, which is apt to produce an efflorescence from the stone under variations of the atmosphere. This invention consists of employing baryta, or salts of baryta, or any of the salts of lead, to neutralise such impurities, and the patentee finds such artificial stone considerably improved by exposing it, when moulded, to a bright red heat in a suitable muffle or kiln.

In the specification of a patent granted to him on the 22nd of October, 1844, the patentee described means of manufacturing artificial stone by employing a solution of silica, and he explained how he prepared soluble silica for such purposes. According to his present invention he carries on the manufacture of artificial stone as formerly described; but, in order to prevent efflorescence in such artificial stone after it is manufactured, he causes the solution of caustic soda used in preparing soluble silica to be first deprived of its impurities by applying a solution of baryta, and this is done by adding the solution of baryta to the solution of caustic soda, till no further precipitate is caused by such addition.

The solution of caustic soda is then separated or drawn off from the precipitate, and employed as formerly described in the manufacture of artificial stone. Although the patentee prefers to use a solution of baryta for the purpose of removing impurities from the solution of caustic soda used in the manufacture of artificial stone, he does not confine himself thereto, as a solution of a salt of baryta may be employed, or any salt of lead may be used in a similar manner. The articles of artificial stone manufactured according to the invention, after they are well dried, are then raised to a bright red heat in a suitable muffle or kiln, and are then allowed to cool slowly.

*Claim.*—The employment of a caustic solution of soda, deprived of its impurities, in the manufacture of artificial stone; and also the subjecting articles of artificial stone, made as described, to a red heat.

## NEW TRUSS BRIDGE.*

G. W. Thayer, *Patentee*, U.S., April 11, 1854.

Fig. 1.

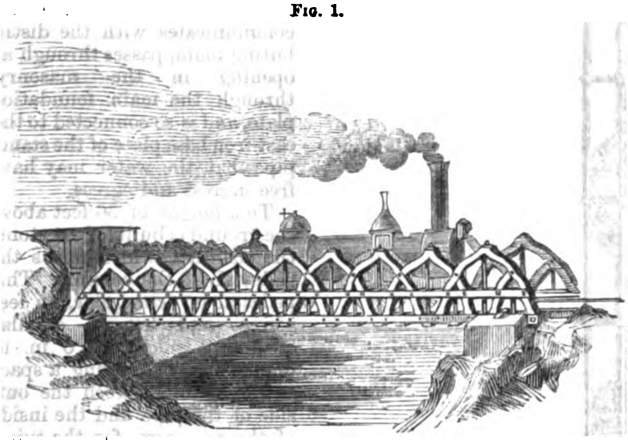

Fig. 2.

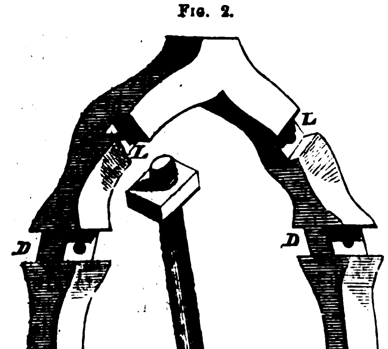

Fig. 3.

Fig. 1 represents a perspective view of the truss as applied to a railroad bridge; fig. 2 is a view of one of the gothic-arch braces detached; and fig. 3 represents two of the vertical rods with their straining blocks, their nuts and screws, the longer one extending from the bottom of the lower chords to the top of the gothic-arch braces, and the shorter one extends from the bottom of the lower chords to the top of the upper ones. The same letters refer to like parts. Each two of the gothic-arch braces are locked together at L, and secured by screw bolts. The lower chords of the bridge are applied to the tenons and shoulders P, P, at the bottom of the gothic-arch braces—one on each side, and secured thereto by bolts. The upper chords of the bridge are applied to the daps and shoulders at D, near the middle of the braces, and are secured by bolts. The longer rods E, pass through straining blocks beneath the lower chords, or through straining cross-beams beneath them, and extend upwards between the chords and through the top of the gothic-arch braces, where they are secured by nuts and screws. The shorter rods F, pass through straining blocks beneath the lower chords, extend upwards, and are secured at the top of the upper chords by straining blocks, nuts, and screws.

The advantages of this truss over others of a different construction are stated to be, first, "that it is not so liable to be affected by expansion and contraction from heat and cold; second, not liable to be increased in length by cambering; third, there is no thrust strain on the chords, but the greater the pressure on the truss, the nearer the parts are brought together, and the closer becomes the joints; fourth, every piece supports a part of the whole structure, and there is no dead-weight of iron or useless material."

* From the 'Scientific American.'

## TRACES OF MODERN ARCHITECTURE AND ART IN RUSSIA.

The first traces of the introduction of modern art in Russia are due to the Grand Duke of Russia, Ivan III. Wassiljewitsch, who reigned from 1462 to 1505. When he intended to erect, in 1473, a splendid church of the Ascension of the Virgin, in Moscow, he obtained from Plescow a person who had been instructed by German masons, and sent to Italy to obtain an able architect at any cost. Such a one was found in the person of a Greek of the name of Aristoteles, who had been previously employed by Mohammed II., at Constantinople, in the building of a palace, and at Venice had erected a splendid portal and a church. His wages were two pounds of silver (then ten roubles) a month, and he was the person who introduced the new Italian style into Russia, where before only the Byzantine-Gothic had been cultivated. Ivan III. also built for himself the first stone mansion, whereas all former Grand Dukes had lived in wooden houses. It was called the Hewn Palace (*granatowitaja palata*), and it was intended to be used on festive occasions, for the reception of ambassadors, &c. The latter, however, was built by an Italian architect, called Marco the Italian, who had for his assistant another of his countrymen, named Peter Antonio, who built the house during the period from 1487 to 1491. Another palace, built on the Jaroslaw Place, was burnt in the great fire of 1493. Ivan III. caused the erection of a more extensive building by the Milanese architect Aloysio, which was called Dworez Teremnyi, and is yet standing. He also surrounded the Kremlin with splendid walls and turrets. The whole fortress was surrounded by high and strong walls and ditches, and for obtaining an open space around it, houses and even churches were demolished. He sent also to Italy for silversmiths and founders. The latter established the first cannon foundry in Moscow in 1488, and also cast bells. To them, also, belonged the architect Aristoteles, whose name is to be found on Russian coins of that time. It was by Greek, Italian, and German artists that the first coins were struck in Russia, who had been brought thither by Ivan's wife, Sophia, and it was in her honour that the first gold coin was struck in Moscow in 1497.

For the sake of encouraging the opening of mines, and as the Russians were not able to drive shafts, Ivan availed himself of the amity of Mathias Corvinus, of Hungary, and obtained miners and engineers from thence, as well as from the Emperor of Germany, Maximilian I., and was constantly endeavouring to entice architects to his kingdom, for the erection of new palaces, churches, and entire towns — tendencies which again exploded during the reign of his ignorant and sanguinary successors.

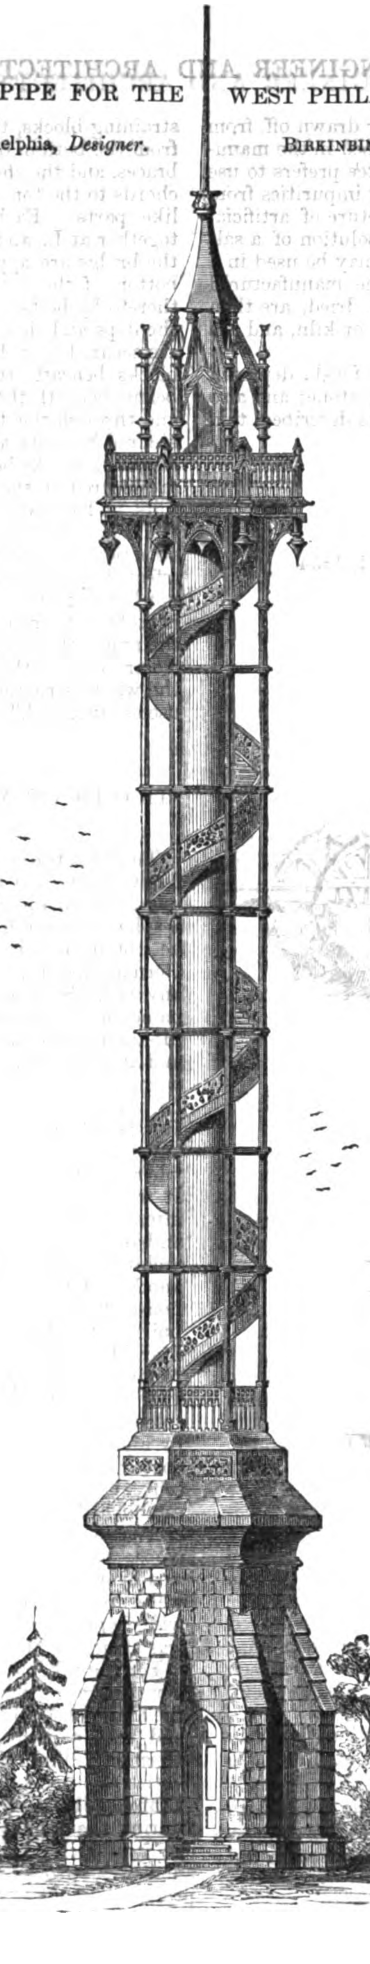
# ORNAMENTAL STAND-PIPE FOR THE WEST PHILADELPHIA WATERWORKS.

H. Howson, C.E., Philadelphia, *Designer*. Birkinbine and Trotter, *Contractors*.

Perhaps no city in the world is more profusely supplied with wholesome water than Philadelphia. Since the completion of the justly celebrated waterworks at Fairmount, what might formerly be termed the suburbs of Philadelphia have increased so rapidly and extensively, that it has been found necessary to construct additional works to supply the increased demand. Philadelphia, which, by a recent act of consolidation, now comprises both the old city proper and all the surrounding districts, is now plentifully furnished with water from three large works, namely, those of Fairmount, Spring Garden, and Kensington; the two former receiving their water from the river Schuylkill, and the latter from the Delaware.

On the banks of the Schuylkill, and directly opposite the old city, is the district of West Philadelphia, now also incorporated with the new consolidated city. This district has, on account of its elevated and healthy position, as well as its proximity to the business portion of the city, become a favourite locality with the mercantile and wealthier portion of the community. Its situation, too, with regard to the river, particularly adapts it to the establishment of manufactories, which of late years have rapidly accumulated.

To obtain an efficient supply of water for this flourishing district from the works already established on the opposite banks of the river, would have been attended with considerable difficulties; the enterprising commissioners therefore determined to erect substantial works on the spot. It was deemed advisable, in order to procure a sufficient head of water, to make use of a standpipe similar to that at the East London Waterworks. A plain pipe, however, erected in so elevated and prominent a position, would evidently have been a great eyesore to the whole neighbourhood. To obviate this, Messrs. Birkinbine and Trotter, to whom the contract for the whole works was awarded, proposed to erect a tower which should combine the two qualities of utility and ornament. With this object in view, these gentlemen applied to Mr. H. Howson, who furnished them with the original design and working drawings from which the structure of which we give an illustration was built.



The central portion of the tower, which comprises the pipe or tank into which the water is forced, is 5 feet in diameter and 130 feet high, and is made of plate-iron varying in thickness from $\frac{5}{8}$-inch at the bottom to $\frac{1}{2}$-inch at the top. The bottom of the pipe is riveted to a circular flanch on a thick cast-iron base plate, which is secured by substantial bolts and keys to the main foundation plate. The latter rests on a foundation of heavy masonry, to which it is permanently attached by strong anchor-bolts. A branch pipe, 12 inches in diameter, which communicates with the distributing main, passes through an opening in the masonry, through the main foundation plate, and is so connected to the cast-iron base plate of the stand-pipe that the water may have free ingress and egress.

To a height of 36 feet above the ground is built (of cut stone) the masonry, which forms the pedestal of the column. This pedestal is octangular, 15 feet across, and has a circular opening inside 9 ft. 6 in. in diameter, thus leaving a space of 2 ft. 3 in. between the outside of the pipe and the inside of the masonry, for the spiral stairs. Radiating from the centre of the pipe, and passing across this space at suitable intervals, are a number of wrought-iron bars which (one end being bolted to the pipe and the other let into the stonework) serve the double purpose of connecting the ironwork and masonry together, and act as supports for the cast-iron steps. At each of the eight corners of the pedestal are built buttresses 24 inches thick, and 22 feet measuring diagonally across the corners of the pedestal. The projecting cornice at the upper portion of the masonry is 20 feet across; above this, and into each of the eight sides, are let cast-iron panels ornamented with Gothic tracery. Access is obtained to the interior of the pedestal through a Gothic doorway, 8 feet high and 3 feet wide.

Screwed to the top of the masonry by means of strong anchor-bolts, are eight cast-iron plates firmly tied together so as to form a ring. To these plates are attached iron pedestals, which are connected together by Gothic railings, and which support the eight rows of cluster columns; the latter being carried upwards in lengths of 10 feet, form the exterior of the shaft. Rings of cast-iron, into which the ends of the cluster columns are packed, serve to keep them at the required distance from each other. Spiral winding pieces, also of cast-iron, are bolted to the outside of the pipe, and similar winding pieces to the inside of the cluster columns; both have a number of flanches projecting from their sides, to which the steps are separately bolted. To the exterior winding piece, and between the cluster columns, are secured a series of castings, which are so carved as to represent a continuous Gothic scroll railing. These pieces are further confined to their places by a suitable hand-rail, which is also bolted to the inside of the columns.

It will be seen that the spiral winding pieces and hand-rails, secured in this manner, serve as diagonal braces for the cluster columns. The stairway terminates at an octangular landing 17 feet across, which is composed of plates laid on radiating cast-iron beams, one end of the latter being fastened to the pipe, and the other to the corners of the entablature, and the whole further supported by the cluster columns and ornamental brackets securely bolted to both the columns and the entablature. Surrounding the platform or landing is a Gothic railing, of the same pattern as that already referred to.

The cluster columns are carried upwards through the platform, above which they are connected together by arched pieces, and to the pipe by flying buttresses, and terminate in suitable pinnacles. To the top of the pipe, or rather to the top of cast-iron pilasters attached to the pipe, is secured the plate-iron spire 9 ft. 6 in. high, surmounted with a flag staff.

The whole height of the tower from the ground to the top of the spire is 140 feet, and to the landing 114 ft. 8 in., the latter being reached by a flight of 172 steps. This altitude, together with the fact of the whole structure being erected on one of the most elevated points in the neighbourhood, will afford from the platform a prospect of the most extensive and varied description.

The engines of the West Philadephia Waterworks, which will be completed in the autumn of this year, are on the direct-action Cornish principle, and are furnished with Birkinbine's patent supplementary-valve apparatus (see *Journal, ante* p. 148), together with a modified and simple valve gearing arranged by Mr. Howson, of Stockton House, Philadelphia, the designer of the Stand-Pipe.

## ON THE MOTION OF WATER THROUGH PIPES.*

By Henry Hennessy, M.R.I.A.

A very elaborate series of experiments have been recently made at Paris, on the motion of water through pipes, by M. Darcy, director of the public waterworks of that city. A memoir detailing the methods of experiment, and the results obtained, having been submitted to the Academy of Sciences, a commission of inquiry was appointed, from which has emanated an extremely valuable report, drawn up by M. Morin, and published in the number of the Comptes Rendus which has been just received.

The utility of economising and properly regulating the supply of water to towns and manufactories, is now so fully recognised —the industrial and social importance of any practical conclusions that may be drawn from well-conducted hydraulic experiments, so completely admitted—that it appears desirable to give the utmost publicity to these investigations.

The experimental and mathematical researches which have hitherto formed the basis for engineering calculations, have generally afforded but little information as to the influence of the condition of the interior surfaces of the pipes on the resistance to the flow of water. Partly resulting from this cause is the fact not unfrequently observed in connection with great water works, that while the volume of water actually discharged through new cast-iron pipes is generally greater than that deduced from scientific rules, as soon as the pipes have been some time in use, and that deposits have been formed in them, the state of things is entirely reversed.

One of the chief objects of M. Darcy's investigations being to clear up practical difficulties of this kind, he proceeded to make a series of experiments, in order to determine—

1. The influences of the state of the surfaces on the discharge.
2. The influence of the diameters of the pipes on the resistance.

He used pipes varying in diameter from the smallest ever used for practical purposes, to half a metre, or a little more than 1 ft. 7½ in. The pipes were also of different materials, some of drawn iron or lead, and some of iron coated with pitch, or of smooth glass, also cast-iron pipes, some of them quite new, some old with deposits, and some old without deposits.

The experimental arrangements were such that the observer was able to measure the pressure or effectual head of water in the iron pipes at the origin of movement and at distances of 50 and 100 metres [164 and 328 feet] farther on. The difference would give the measure of the loss occasioned by the resistance of the surfaces.

The leaden pipes, which were 50 metres long, or more than twelve hundred times the diameter of the thickest employed, had the pressures measured at a distance of 25 metres. A similar arrangement was made in the glass tubes, which had nearly the same dimensions. The mean velocities obtained in these experiments varied from 0·03 metres to 5 or 6 metres per second; that is, from 1·18 inch to 16 ft. 5 in., or 19 ft. 8½ in. nearly, thus going even beyond the limits used in practice. The inclinations and diameters of the several pipes were carefully measured by the most approved methods.

The most important general result deduced from these experiments is, that the nature and state of the interior of the pipes exercise a considerable influence on the discharge.

It appears, for example, that compared with the formulæ of M. Prony, iron pipes coated with pitch give discharges greater than the calculated results in the proportion of nearly 4 to 3; that glass gives similar results; but that in cast-iron pipes, whose diameter had been only very slightly diminished by deposits, the velocities, and therefore the effective discharges, were decidedly less than the theoretical indications, while after a thorough scouring a perfect agreement became manifest.

The diameters of the pipes seemed also to exercise a more decided influence on the discharge than what had been hitherto assigned to them; for with small diameters the results were less than by the formulæ, while they were greater for large diameters. This influence of the diameters was probably overlooked, as suggested by M. Darcy, from the fortuitous compensation established between the resistance in very thin but smooth pipes, and those of considerable thickness but encumbered by deposits.

From a discussion of his experimental results, it follows that the law of resistance is generally expressed by the usual formula:

$$v^2 B + v A = R I$$

R being the mean radius or hydraulic mean depth, I the inclination of the tube due to the resistance, $v$ the velocity of efflux, and A and B constants. But an exception to this law holds in the case of very thin tubes and low velocities, in which case the term B disappears, and the resistance is proportioned to the velocity simply. As might be expected, therefore, the diameter and the substances composing the different pipes have been found to influence the values of A and B, for these have been found to differ in tubes of the same dimensions but of different degrees of internal smoothness, and also in those which were equally smooth but with unequal radii.

In pipes containing much deposited matter, which is usual in those that have been some time in service, it appears from M. Darcy's experiments that the resistance (as admitted by several engineers) could be safely considered as simply proportional to the square of the velocity, thus simplifying practical calculations. These experiments being made with pressures so varied and so considerable, an admirable opportunity was afforded for testing the long-admitted principle, that the resistance presented by the sides of a tube to the liquid passing through is independent of the pressure of that liquid. It was found, for example, that where the head of water varied in the ratio of from about 55 ft. 9 in. to 85 ft. 4 in., and again from about 72 feet to 131 feet, between the two parts of the pipe submitted to observation, the differences or losses of head have remained the same for both parts. Such decisive results completely comfirm the important hydraulic principle just mentioned.

In order to determine the numerical values of the constants A and B in the formula

$$v^2 B + v A = R I,$$

M. Morin objects very properly to the use of the method of least squares, as not only requiring very troublesome calculations, but also introducing into the results the influence of mere accidental anomalies, which such experiments sometimes present. He prefers a graphical representation of the actual results of experi-

* From the 'Dublin Monthly Journal of Industrial Progress.'

ment, as being more expeditious, and capable of rendering more palpable such accidental circumstances as may deviate from the usual law. M. Darcy has employed this method simultaneously with that of least squares, and has thus in a great measure obviated the imperfections of the latter. Observers in every department of physical science might profit by the hint of M. Morin as to the successive employment of the two methods, by which, we presume, he means the application, first of the graphical method, so as to detect the accidental anomalies, and then, on their elimination, the application of the method of least squares to the purified results.

After determining the values of the constant coefficients for tubes of different materials and dimensions, M. Darcy has estimated, by the aid of his formulæ, the velocities corresponding to the different inclinations, and has compared them with the observed velocities. This comparison shows, that for all kinds of pipes, and for every diameter, as soon as the velocities attain a few décimètres,* the formula of resistance may be changed to

$$v^2 B_1 = R I,$$

and this will be especially correct for pipes containing deposits; that is, for working pipes in their usual condition.

A comparison of the values obtained for the coefficient which determines the resistance in tubes differing but slightly in thickness, has shown that their different degrees of smoothness, and general condition of their internal surfaces, exercise very remarkable effects on the amount of that resistance. Thus, tubes of thin sheet-iron coated with pitch, of clean cast-iron, and of cast-iron covered with deposits, each having in inches respectively the diameters, 7·717, 7·401, and 9·567, gave for $B_1$ values which varied proportionally from 1 to 1·5 and 3. This result shows, that in estimating the action of a series of pipes for water-works, they should be always supposed to have arrived at the normal condition of being coated with more or less deposit, no matter how comparatively smooth they may be at the time of laying them down.

Having found by experiment that the resistance diminishes with an increase of diameter, M. Darcy sought the law of variation as some simple function of the diameter, and he has shown that $B_1$ in the formula last given, may be represented by two terms, one constant, and the other varying inversely with the diameter of the tube. The law thus becomes

$$R I = v^2 \left(a + \frac{b}{R}\right)$$

Or if L represent the length of the pipe and H the height due to the resistance,

$$H = v^2 \frac{L}{R} \left(a + \frac{b}{R}\right).$$

From a series of eight experiments with tubes of drawn and cast-iron, sensibly of the same degree of smoothness, and with diameters varying from half a metre down to 0·122 metre M. Darcy has obtained the following numerical values:—

$$a = \cdot0000507, \quad b = \cdot00000647.$$

When the values of R, L, and $v$ are given in English feet—

$$a = \cdot0000507, \quad b = \cdot00002122.$$

The expression generally recognised among hydraulic engineers as equivalent to the foregoing, is given by Mr. Neville in the form,†

$$R I = v^2 \left(a + \frac{b}{v^{\frac{1}{2}}}\right)$$

Where

$$a = \cdot00005585, \quad b = \cdot00006859.$$

On making use of these results a very satisfactory agreement was found with observation, so that it was possible to safely calculate the values of $B_1$ in the formula of $v^2 B_1 = R I$, for all diameters, for every centimetre from the first up to 50, or half a metre, and also for every 5 centimetres up to a metre. By simple transformations of the preceding formulæ, which will readily occur to scientific readers, it is possible to obtain rules for calculating the inclination required for obtaining a given velocity with a certain diameter of pipe, or the converse problem of finding the velocity corresponding to a given inclination.

The variation of the coefficient of resistance, which must be taken into account for narrow pipes, is much less perceptible in those with diameters greater than from about 5 to 6 inches, and it may be considered, without inconvenience, as constant for all those of greater diameter.

M. Darcy has also turned his attention to another question connected with the motion of fluids in pipes, which, although comparatively unimportant for practical purposes, possesses much scientific interest. The point referred to is the law of variation of velocity of the particles of fluid from the axis of a pipe where it is a maximum, to the surface where it is a minimum. With the aid of a small and very slender Pitot tube, of which one branch could be placed parallel to the axis of the pipe at different distances from that axis, and of a manometer giving the pressure exercised on the surface, he has determined the excess of pressure observed at the Pitot tube over that on the manometer, and by a special process, the velocity of the fluid acting on this tube, or some quantity proportional to the velocity. Comparing in this way, for different inclinations, the excess of velocities in the axis over the velocities at different distances therefrom with the square roots of the inclinations, it followed:—

1. That the ratio of this excess to the inclinations was constant.

2. That the ratio of this excess to the $\frac{3}{2}$ power of the distance of a moving particle from the axis was constant for the same inclination.

3. That the ratio K of the same excess to the product $r^{\frac{3}{2}} \sqrt{I}$, constant for the same pipe, varies from one pipe to another inversely as the radius, so that $\frac{K}{R}$ is constant.

It is hence easy to infer that the relation between the velocity V, of the particles situated in the axis of a pipe, with the velocity $v$, of those situated at a distance $r$, from the axis, is represented by

$$V - v = \frac{K r^{\frac{3}{2}} \sqrt{I}}{R}$$

Whence, if $w$ represent the velocity of a particle at the surface of the pipe,

$$w = V - K \sqrt{R I}; \quad \text{or, } K \sqrt{I} = \frac{V - w}{\sqrt{R}}$$

Whence substituting, we obtain,

$$v = V - (V - w) \frac{r}{R} \sqrt{\frac{r}{R}}$$

From which the velocity of any particle may be obtained if the velocities in the axis and at the surface are known.

It finally appears that for the mean velocity $u$, M. Darcy has deduced the expression,

$$u = \frac{3v + 4w}{7}.$$

By comparing the results of experiments made with different pipes, M. Darcy has been led to conclude, that although the degree of smoothness of the interior of a pipe must influence the resistance, and consequently the mean velocity of the fluid, it does not affect the law of variation of velocities from the axis to the surface, which appears to depend on the viscosity or molecular condition of the liquid.

It seems that the conclusions at which M. Darcy has arrived relative to the coefficient of contraction have not been considered quite satisfactory. It appears from the theory established by M. Poncelet, that the coefficient in question is a function of that at the opening of the tube, which varies with the head of water, the dimensions of the orifices, and the velocity. It follows, therefore, that the coefficient of contraction at the origin of the pipes ought itself to vary with these quantities; but M. Darcy has obtained a constant coefficient, such as is generally admitted, and this only by a compensation of differences. We have very little doubt that a more correct result would have been obtained if he had employed in the discussion of his experiments, the graphical method in the peculiar way to which attention has been already directed.

Here we must conclude our account of these important researches, which we are glad to learn will be publised in detail by the Academy of Sciences, in the 'Mémoires des Savants Etrangers.'

* One décimètre = 3·93708 inches, not much less than 4 inches.

† See 'Hydraulic Tables, Coefficients, and Formulæ,' by John Neville, C.E., M.R.I.A., County Surveyor of Louth.

## THE USE OF COAL IN LOCOMOTIVE ENGINES.

REPORT *of* Messrs. WOODS *and* MARSHALL *to the London and North-Western Railway Company, on the Burning of Coal in Locomotive Engines.*

Under the following resolution of the general locomotive committee of the 9th July, we have made a series of experiments on some of the engines of the southern division, with a view to report to you upon the questions submitted to us:

"Resolved,—That Messrs. Woods and Marshall be instructed to make trial of the various sorts of coal in the engines of the southern division, and to report to the next meeting of this committee whether coal can be efficiently and satisfactorily used, in what proportion, and at what cost, as compared with coke."

After conferring with Mr. M'Connell, and with a view to completing our report within the specified time, we judged it expedient to limit our experiments to the trial of two kinds of coal, and to a comparison of the performances of an engine of the class known as Mr. M'Connell's patent, with those of an engine of the "Bloomer" class.

The Hawksbury coal seemed to be most eligible for use on the southern division; on account of its being procurable at a comparatively low price, in consequence of the proximity of the pits to the main line of the southern division.

The pits are situate on the Coventry and Nuneaton branch, about four miles from Coventry, and yield a coal of hard quality, free from any excess of bituminous matter; and, in other respects (as, for instance, in freedom from clinker) favourable for combustion in engine furnaces.

Two qualities of this coal have been submitted by us to trial, viz:—Main coal, which is delivered in large blocks free from small coal, and the coal termed "screenings," or "cobbles," which is delivered in small lumps, but free from dust or slack. The prices, as given to us by Mr. M'Connell, are—

Main coal, delivered in contractor's wagons at Rugby .................. 9*s.* 7½*d.* per ton.
Cobbles, ditto........................... 7*s.* 8¼*d.* ditto.

The cobbles are not so hard as the main coal, and break into smaller fragments when struck by the hammer.

The cobbles can only be supplied in limited quantity.

For the purpose of comparison of the cost of working, it was important to obtain the exact duty of the engine with coke as well as with coal, and our series, therefore, includes the results of several days' work with the best coke we could obtain—viz., Pease's West coke.

The engine worked alternate days with coke and coal, performing each day 164¼ miles, the double journey between Rugby and London.

The performances of the first two days are not here recorded, and may be considered as preliminary. The weather on one of these days was very stormy, and rendered the results of an exceptional character; and the men had not then acquired the knowledge of the management of a coal fire, which a little further experience gave them.

For six consecutive days (the Sunday excepted) the passenger engine No. 303, Mr. M'Connell's patent, worked the 12·55 p.m. up express train, and the 5·45 p.m. down train, three days with Pease's West coke, and three with the Hawksbury main coal; these two trains being nearly equal in weight, and presenting little variation during the period.

The details of these, and the subsequent experiments, will be found in the table appended, but the following are the general results:—

*No.* 303 *Engine.*

| Series. | Description of Fuel. | Miles run. | Average Load Carriages. | Average Speed per Hour. | Fuel consumed per mile. | Water Evaporated per lb. fuel. |
|---|---|---|---|---|---|---|
| | | | | Miles. | lb. | lb. |
| A | Coke ...... | 492¾ | 14·1 | 31·62 | 25·34 | 8·59 |
| B | Coal ...... | 492¾ | 13·2 | 33·26 | 35·59 | 5·78 |

Deeming it necessary to ascertain the practicability of using coal with heavier trains, we caused the same engine, No. 303, to work the 6·30 a.m. down train and the 11·46 a.m. up train over the same ground. We had one day's experiment with coke, one day with Hawksbury Main coal, and one day with cobbles. The following are the results:—

*No.* 303 *Engine.*

| Series. | Description of Fuel. | Miles run. | Average Load Carriages. | Average Speed per Hour. | Fuel consumed per mile. | Water Evaporated per lb. fuel. |
|---|---|---|---|---|---|---|
| | | | | Miles. | lb. | lb. |
| C | Coke ...... | 164¼ | 19·2 | 29·41 | 26·80 | 8·82 |
| D | Main coal | 164¼ | 20·6 | 28·96 | 41·66 | 5·86 |
| E | Cobbles ... | 164¼ | 29·3 | 27·76 | 51·49 | 5·97 |

The remaining experiment we have to record is with one of the largest class of the ordinary engines, No. 293, working the 12·55 p.m. up, and 5·45 p.m. down trains, with Hawksbury Main coal. The engine has a large fire-box with a longitudinal midfeather and two fire-doors.

*No.* 293 *Engine.*

| Series. | Description of Fuel. | Miles run. | Average Load Carriages. | Average Speed per Hour. | Fuel consumed per mile. | Water Evaporated per lb. fuel. |
|---|---|---|---|---|---|---|
| | | | | Miles. | lb. | lb. |
| F | Main coal | 164¼ | 14·1 | 32·96 | 47·75 | 4·52 |

I. The question of the practicability of burning coal in such locomotives must be answered in the affirmative. The engines had no difficulty in maintaining the required pressure of steam and speed with the trains assigned to them.

II. Taking a general view of all the performances of the engine No. 303 with coal, the consumption, or rather non-production of smoke, was very completely attained.

In the majority of cases, both in travelling and standing, the engine was practically free from smoke, the trace being so slight as to be imperceptible without close examination, and we did not observe in any instance that the smoke emitted could be accounted a nuisance.

From these remarks we of course exclude the period of lighting the fire and getting up the steam, when the combustion is incomplete, and the production of smoke cannot be avoided.

The non-production of smoke, whilst the engine is working, no doubt depends very much upon the individual skill and care of the engineman and fireman, and demand very close and watchful attention on their parts.

The conditions under which the results related were obtained are as follows:—

1. Working with a very thin fire on a large area of grate, and with fire-bars laid much closer together than is necessary for coke. By the large area of grate and thin fire, a large volume of air is enabled to pass through the ignited fuel under a moderate draught.

2. Frequent firing in small quantities to equalise the disengagement of the gases, and thereby prevent the production of a larger quantity at one time than can be saturated by the air passing through a grate or fire-door. This frequency of firing involves much greater care and labour on the part of the fireman. It was found in the trials, that, on an average, the fireman fired four or five times more frequently with a coal than with a coke fire. Say once in every two or three miles, instead of once in 10 or 12 miles.

In throwing on the fuel the fireman has carefully to observe the state of the fire, that he may throw the fresh coal so as to maintain a uniform covering of the grate; the thickness of fuel ranged from about 4 to 6 inches.

3. *Alternate Firing.*—The fire-box, divided longitudinally by midfeather into two separate compartments, each provided with a fire-door, gives the means of firing alternately, and thus keeping a bright fire in one box, whilst the other is damped by the addition of black coal.

4. The combustion chamber allows of the mixture of the gaseous products of the two fires with the quantity of free oxygen needful to effect their due saturation, affording space for combustion to take place before the gases pass into the tubes. This arrangement, combined with the double box, renders Mr. M'Connell's engine a more perfect "smoke-consumer" than the common engine.

5. *Quality of the Coal.*—The coals were in lumps of moderate size, to prevent obstruction to the draught, and sudden generation of a large volume of gas, which ensues upon throwing small coal or dust into a bright fire. Hardness in the coal is a quality which tends to diminish the proportion of dust from breakage. The coal should contain as little bituminous matter as may be, and burn with little ash or clinker.

6. Damper, to regulate admission of air to the grate, must be capable of being closed, wholly or partially, otherwise smoke will be emitted, and fuel wasted at the stations.

It must be understood that the above were the conditions observed, and apparently required, in working the engine No. 303 efficiently and satisfactorily with coal; but we do not assert that these are invariable conditions as applicable to other engines, the different construction of which might adapt them to burn coal in another way.

The experiment with No. 293 engine did not give so good a result in point of smoke burning; a brownish tint of smoke was pretty constantly observable, but though sometimes very light, was frequently decidedly objectionable.

On the other hand, it is fair to state that the man who drove it had not had much experience in burning coal, which, as may be inferred from our foregoing remarks, requires a management of the fire altogether different from that of a coke fire.

We believe, however, that general experience shows that the ordinary engine is not well adapted for smoke burning, and it is certain that in the case of No. 293, the smoke-box became overheated by a large accumulation of coal-dust partly ignited.

These effects were altogether absent in No. 303 engine, owing, doubtless, to the large receptacle in front of the tubes, which served to arrest and detain in the fire-box the smaller particles of coal which otherwise would have passed through the tubes.

III. Relative powers of coke and coal.

The comparison of series A with series B indicates a consumption of coal 40 per cent. greater than that of coke in working similar trains, the average loads and speeds being nearly the same; but the work, as indicated by the consumption of water, being slightly less on the occasions when coal was used.

The comparison of series C and D, with a heavier and slower description of train, gives a consumption of coal 55 per cent. greater than with coke.

Taking the quantity of water as probably the most correct approximate measure of the several resistances, we find the mean duties to be as follows:—

1 lb. coke to 8·65 lb. water; | 1 lb. coal to 5·83 lb. water;

which show a proportion of 100 lb. coke as equivalent to 148 lb. coal, as consumed in No. 303 engine.

We shall, therefore, assume 48 per cent. increase in estimating the relative cost of coal as compared with coke.

The more imperfect performance of No. 293 engine gives a much greater difference, being no less than 90 per cent.

The consumption of coke observed in these experiments accords very closely with the results of the experiments made under similar circumstances, and detailed in our former reports.

From the great excess in the quantity of coal consumed over coke, we are strongly disposed to think there must be something disadvantageous in the construction of the above engines, or in the mode of working them, as regards their applicability for the use of coal as a fuel.

This view is confirmed by the results of some experiments made at Wolverton, in the fixed-engine boiler there, with the same qualities of coal and coke, wherein the difference of heating or evaporative power appears to be only 20 per cent., the evaporation being 7·99 lb. of water per lb. of coke, and 6·77 lb. of ditto per lb. of coal.

IV. Relative economy in cost of fuel.

The price of the Hawksbury Main coal being assumed at 9*s*. 7½*d*. per ton, and the price of Pease's West coke at 21*s*. 9*d*. per ton, which is the contract price for the same delivered at Rugby in the contractor's wagons, we may estimate that the cost of a quantity of coal, equivalent to one ton of coke, will be 14*s*. 3*d*., being 9*s*. 7½*d*. increased by 48 per cent.

Out of the 21*s*. 9*d*. paid for the above coke, we are informed that your Company receive back from the Midland Railway Company, under a special agreement, an allowance of 9*d*. per ton. This reduces the cost to Company to 21*s*. per ton.

The saving by use of coal would then be 6*s*. 9*d*. per ton, or the difference between 21*s*. and 14*s*. 3*d*.

Upon an annual total consumption of, say 74,000 tons on the southern division, the saving to locomotive power would be 24,975*l*. from this cause.

This, however, assumes that all the engines are of a kind suitable for burning coal, and that no other fuel is used.

As far as our present experience goes, the large engines of the No. 303 class are the only engines on the line in which coal can be practically used without occasioning a nuisance, and these constitute at present but a small proportion of the entire stock.

The expediency of increasing the stock of such engines, for the purpose of effecting, wholly or partially, the saving in cost of fuel which we have indicated, is a question which your Directors will probably not consider within our province at present to discuss, involving as it does so many collateral considerations; also having reference to the general economy of the Company's expenditure—such as cost of engines and the general working expenses.

If the question be entertained as a general one for the whole line, the additional weight of fuel to be transported from place to place—whether in the wagons or on the tenders—and the additional number of hands necessary for emptying the wagons and distributing the coal, will occasion expenses which we have not taken into account.

Although we consider the experiments made with No. 303 engine satisfactory in point of smoke burning, we cannot resist the belief that the consumption of coal is in excess of what it ought to be, and that there is room for considerable improvement in this respect by means which shall tend to utilise the heat which is at present wasted.

## THE TWO TUNNEL SEWERS FOR THE ARTERIAL DRAINAGE OF THE METROPOLIS.

TO THE RIGHT HON. VISCOUNT PALMERSTON, G.C.B., M.P.

MY LORD—I have been duly honoured with the acknowledgement of the receipt of my printed letter on the subject of the Great London Drainage Plan.

Seventy millions of gallons of water are daily raised to the surface of a densely-inhabited valley, and there converted into sewage, stagnating in the low-lying districts of the metropolis, and, daily polluting the atmosphere and the Thames, they urgently demand an efficient outfall.

The Metropolitan Commission of Sewers do not propose the removal of the injury resulting to the inhabitants, but to spend 1,050,000*l*. in covering over a naturally-formed rivulet, meandering through open fields, "the Hackney Brook," and in diverting similar rural drainage into the populous locality of Deptford.

These works have been strongly opposed by public meetings and circulars, by deputations to the Home Office and Greek-street, and also by petitions to Parliament; and it is respectfully submitted that no money should be devoted to their construction.

The Great London Drainage Plan of two tunnel sewers running through the most populous localities, extending from Chelsea and Vauxhall respectively to the marshes east of the metropolis, would be capable of removing not only 70 millions, but 270 millions of gallons of sewage daily, and would cost 1,000,000*l*.

These tunnel sewers were very favourably entertained by the government in 1845-6; were approved by the officers of the Westminster Improvement and Commission of Sewers in 1847; were not opposed by a resolution of the City Commission, February 29, 1848; and subsequently received assurance of support, March 21, 1848; their comprehensive character being acknowledged by the Metropolitan Commission, by resolutions, March 7, 1848, by report to Parliament, February 24, 1851, and by the resignation of the Commissioners when they were unable to carry them into execution, June 23, 1852.

This plan rests upon actual surveys and levels, confirmed estimates, borings, and data collected during a series of years. Its having been prosecuted through the agency of Commercial enterprise, as the only means available to private individuals, and its having been twice submitted to the scrutiny of a Select Committee, is respectfully urged in its behalf.

Your lordship directed the attention of the House to this arterial drainage of the metropolis on the 4th and 9th March, 1853, and subsequently.

S. S. MOREWOOD.

*Islington, July 21st, 1854.*

## HINTS ON THE NEW STEAM FRIGATES FOR THE UNITED STATES.*

By J. M. Roebling, C.E., Niagara.

It is announced that Chief Engineer Martin is going to Europe to examine naval machinery, with a view of introducing useful improvements in the construction of the new steam frigates ordered to be built. This move appears to indicate a determination on the part of our naval authorities to produce something excellent, and to do justice to the progressive spirit of the age. The following remarks are respectfully submitted to the consideration of those who will be charged with the planning of the machinery and boilers.

The great success of the Collins' steamers appears to be principally owing to the great evaporative power of the boilers, and to the excellent model of the hull—two points in which the Cunard steamers are inferior. The general plan of engines is the same in both lines, and I believe the expansive action of steam is made use of to nearly the same extent. Nor is there a material difference in the pressure of steam carried; the consumption of coal of the Cunard line I have not been able to ascertain. The power of the *Arctic*, with 95-inch cylinders, 10 feet stroke, cut-off at 4 ft. 4 in., 30 lb. pressure in the boiler, 28 lb. in the cylinders, 4 lb. vacuum, 14 revolutions per minute, may be rated at 1645 effective horse-power, one horse-power equal to 33,000 lb. raised one foot per minute. The average speed of this vessel during six voyages, according to Mr. Isherwood, was $12\frac{4}{10}$ miles (statute), consumption of coal per voyage 946 tons, and per hour 7980 lb. This makes the consumption of 1-horse power per hour 4·85 lb. really a very creditable result. The average evaporative power of the boiler is stated at $7\frac{1}{2}$ lb. of water of 110° by 1 lb. of anthracite. Looking at these facts, there appears to be left but little room for improvements in the way of efficiency and economy. And this is the opinion of many professional men, *such* men as would never have achieved the above results had *they* been the performers.

It is to be regretted that the old clumsy mode of feeding sea-water was adopted in the Collins' line, while such an excellent apparatus as Pirsson's Condenser could have been applied. This condenser is bound to work if properly constructed. Here, then, is one opening for a very essential and highly important improvement in our new steam frigates.

I shall now suggest another, but promise nothing new; I only desire to draw attention to the old, well-established, and well-known fact of the great economy produced by the expansive action of steam. I wish to see the principle of the Cornish engine successfully carried out in these new frigates. I propose to carry steam of 60 lb. pressure, or say 45 lb. above the atmosphere in place of $15\frac{1}{2}$ lb., the practice of the Collins' line, and to cut-off at one-eighth part of the stroke in place of half-stroke. And in order to produce a *uniform* rotary motion, and to keep down the size of cylinders, I propose three cylinders in place of two, to work three cranks set at an angle of 120°, in place of two cranks set at an angle of 90°. This plan contemplates a radical change in the old mode of construction; it may appear rash and venturesome to the timid and to the *let-good-enough-alone*. But nothing short of a radical change in the plan of engines and boilers will produce a *material* advance upon the great success of the Collins' steamers. I do not discuss the model, because I am not a competent judge on that point. Steam-engines and boilers are my province, where I may venture an opinion. I feel satisfied that, aside from the model, the above plan, if well carried out, will, in connection with my new boilers, bring steam navigation to perfection at once. I flatter myself that this opinion will be concurred in by all those who will candidly examine the question, and who have made themselves competent by study and experience. It is only recently that the Cornish engine has attracted much attention outside of the small district where it has been an established fact for many years. The astonishing labour so economically performed by that great pumping-engine which is draining the Haarlem Lake in Holland has been the result of expansion.

The rule for calculating the effect of expansive action is, divide the length of stroke by the length of the cut-off, the hyperbolic logarithm of that quotient, added to 1, will represent the effect of the whole expansive action, the force of the full stroke at full pressure being represented by the quotient. I propose to cut-off at one-eighth part of the stroke. Now let us examine the relative effect of the expansive action at one-half, one-quarter and one-eighth of the stroke:—

| | |
|---|---|
| The hyperbolic logarithm of 2 is | 0·693 |
| " " 4 is | 1·386 |
| " " 8 is | 2·079 |
| This gives the effect of half-stroke | 1·693 |
| The full stroke being represented by | 2·000000 |
| The effect of quarter stroke is | 2·386 |
| " full stroke being | 4·000000 |
| " cutting off at one-eighth | 3·079 |
| " full stroke being | 8·000000 |
| Now let us represent the effect of full stroke with full pressure by | 1·000000 |
| The effect of half-stroke will be | 0·846 |
| " quarter stroke | 0·596 |
| " cut off at one-eighth | 0·385 |
| And also, if one ton of coal at full stroke produces an effect represented by | 1·000000 |
| Ditto cutting off at one-half | 1·690 |
| Ditto " one-quarter | 2·386 |
| Ditto " one-eighth | 3·079 |
| And further, if a voyage to Liverpool, using steam without expansion, will consume | 1200 tons |
| The consumption at half-stroke will be | 700 tons |
| " quarter-stroke | 500 tons |
| " one-eighth stroke | 400 tons |

In round numbers, therefore, by cutting off at one-eighth part of the stroke, we will make this voyage with 400 tons, while we should consume 500 tons at quarter-stroke, 700 tons at half-stroke, and 1200 tons at whole-stroke. Here, then, is a wide field open—very wide indeed! I hazard very little when I predict, that in less than ten years our voyage to Liverpool in vessels of 3000 tons burthen will be made inside of ten days, and with less than 400 tons of good anthracite coal, and this will be achieved alone by expansive action, by three cylinders, and by my superior mode of combustion and generating steam, independent of improvements which may result from greater capacity and superior model, and perhaps a superior mode of propulsion.

The above figures show the theoretical effect of expansion, which of course will suffer a reduction in practice. Short stroke comparatively, say not exceeding 10 feet, but wide cylinders, well encased by three or four layers of felt, which will keep them warm, and prevent the reduction of the expanded steam, will bring us nearer to the theoretical result. But the whole of that result can be made good by a superior combustion and evaporation.

The application of three cylinders and three cranks will insure a more uniform rotary motion than is now obtained by two cylinders cutting off at half stroke.

Objections will be raised, on the score of safety, to carrying steam of 45 lb. above the atmosphere. These, however, can be fully answered. I should prefer a higher pressure, if the great increase in the weight of the boiler would not balance, to some extent, the increased economy resulting from the use of higher steam. The difficulty of securing tight joints and preventing leakage and waste is also another weighty argument against high-pressure, such as 100 lb. and more. As regards safety, if we take a common-sense and practical view of the matter, it will certainly be plain enough to every person, that if I provide a strength three times the ordinary allowance for sea-boilers carrying 13 lb. above the atmosphere, I shall be just as safe carrying 45 lb. pressure above the atmosphere. But can this be done, and safely and well? No one will deny it who is a practical worker in iron, and who is at all familiar with steam-boilers. Our steam-boat men in the West laugh at the idea of 45 lb. being called high-pressure. They have frequent explosions, and are altogether reckless in the management of steam; but there are also to be found intelligent and careful men who are conscious of the great danger, and who keep within the bounds of safety. The packets on the Ohio river have uniformly carried, before the new law came in force, 180 lb. per square inch upon the safety-valve in boilers of 42 inches diameter, of $\frac{1}{4}$-inch iron, when new. This is equivalent to an absolute force of 15,120 lb. per square inch section of iron, or scarcely one-third of the ultimate strength of good boiler iron, allowing for riveting. The contemplation of this fact, when travelling on those boats is well calculated to

* From the 'Scientific American.'

cause a little uneasiness. The fact that boilers made of good iron and well managed have run on the Ohio river for years, without accident, only shows how much good iron may be depended on. In marine boilers a very large allowance of strength is absolutely necessary; none but the best material should be used, and double riveted throughout.

If great power and economy are all important in a commercial steamer, they are still more so in a vessel of war. Long cruises cannot be undertaken with a propelling apparatus that wastes the fuel; strict economy is of paramount importance, In ordinary running, expansive action should be made use of to the fullest extent; the fuel should be saved to enable the vessel to keep the sea or to meet a superior enemy and beat him successfully. In place of cutting off at one-eighth of the stroke, cut off at half stroke in time of an action, this will more than double the power. The boilers, of course, should have capacity enough to keep up a supply of steam for a short time. A few rapid movements, which will give the steamer a decided advantage over his slow-moving enemy, may decide the whole action.

In case of an accident to one of the engines, the chances are in favour of three cylinders. The damaged one can be thrown out of gear, while the voyage is continued with the other two cylinders, which will give a more uniform motion than one single cylinder.

The cylinders of the *Arctic* have 95-inch bore and 10-feet stroke; this makes the area of the piston 7088 superficial inches, and the pressure at 19 lb. mean pressure per inch 134,672 lb., and the momentum of a 10-feet stroke 1,346,720 lb. Assuming the pressure of 52 lb. effective per inch, we find the momentum of one superficial inch of piston, acting at full pressure throughout the stroke of 10 feet, $52 \times 10 = 520$. To produce the effect of one of the *Arctic's* cylinders, an area of piston will be needed equal to $1,346,720 \div 520 = 2667$ superficial inches. And in order to cut off at one-eighth of the stroke, the enlarged size of the piston will be found $2667 : x :: 0·385 : 1000$, or $x = 6927$ superficial inches. Or a piston of 6927 superficial inches, equal to 94 inch diameter, carrying 52 lb. effective pressure at the commencement of stroke, and cutting off at one-eighth of the stroke, will produce the same effect, theoretically, as a cylinder of 95 inches diameter, with a pressure of 28 lb. at the commencement of the stroke, and cutting off at 4 ft. 4 in.

Using three cylinders in place of two, we shall find the required size of the pistons to be $6927 \div \frac{3}{2} = 4618$ superficial inches, or $76\frac{3}{4}$ inches diameter and 10 feet stroke. The strength of cylinders and balance of machinery must be increased over that of the *Arctic* to meet the greater pressure of the steam when admitted.

## ON MARINE BOILERS.*

By J. A. Roebling, C.E., Niagara.

The furnace of a boiler should be so constructed as to render combustion as perfect as possible, but it can do no more than produce carbonic acid. If only one-half of the oxygen necessary to form carbonic acid combines with carbon, the result will be carbonic oxide, a product of imperfect combustion. A certain supply of atmospheric air, therefore, is necessary. But this supply may be too copious or too scant, it may enter the furnace too rapidly or too slow, but it cannot be too high for rapid combustion. It is also evident that the quality of the fuel must have a controlling influence upon these various conditions. Wood as fuel for marine boilers is out of the question; we can only consider mineral coals—anthracite and bituminous—as fit for ocean steaming. It is not my intention here to analyse these varieties; I only notice them in so far as their peculiar qualities require peculiar mechanical arrangements for good combustion.

Soft or bituminous coal requires more time to be consumed, economically, than hard coal. The large bulk of hydrogenic and bituminous compounds, mixed up with floating particles of carbon, which result from the burning of soft coal, require to be thoroughly mixed with heated air before perfect combustion can take place. The mechanical arrangements to effect this are of great importance, but may be overlooked when hard or anthracite coal is consumed. This fuel admits of a much more rapid consumption and of a powerful blast, while the draught of a soft coal furnace should not be very strong.

Experience has not yet settled the most economical speed of consumption of mineral coals. Watt's rule was to allow one superficial foot of grate surface for every ten superficial feet of heating surface, and this rule produces good results with natural draught. The boilers of the Collins' steamers are undoubtedly the most efficient and best constructed boilers now in use either here or in Europe. According to Mr. Isherwood, those of the *Arctic* contain 0·357 feet of grate for 11·84 feet of heating surface for every effective horse-power, or 33 feet of heating surface for 1 foot of grate.

According to the same author, whose account of the performance of the *Arctic*, published in the 'Journal of the Franklin Institute,' appears to be reliable, the average consumption of anthracite during six trips was 7980 lb. per hour. The aggregate grate surface of the four boilers of that steamer is 588 feet, which gives 13·57 lb. of coal per hour for each foot of grate. In boilers of ordinary construction with natural draught, half the weight of soft coal would be a fair consumption.

Chemists who have examined the evaporative power of various fuels agree that 1 lb. of good mineral coal, perfectly consumed, will evaporate over 11 lb. of boiling water. Experiments on a larger scale will seldom evaporate more than 9 lb. to 10 lb. The boilers of the *Arctic*, during those six trips, evaporated $7\frac{1}{2}$ lb. of steam from water of 110° by 1 lb. of anthracite, and this is one of the highest results that has been obtained in the regular working of marine boilers. It is evident therefore, that there is room left for improvements. There is still a waste of fuel in the Collins' steamers, which arises from imperfect combustion, the result in part of a faulty construction, and no doubt in part is attributable to imperfect stoking. Much of course depends upon the mode of firing, nor is it always practicable, to carry on this important part of the service according to the best rules.

In attempting to improve the construction of boilers, we may receive good hints from an examination of the condition and working of other furnaces, in which good combustion and a high degree of heat are important objects. Furnaces used in the manufacture of iron, such as blast, puddling, heating, and annealing furnaces, may be referred to.

Perfect combustion can only take place under such circumstances as are favourable to the development of intense flame and heat. Aside from the necessary quantity of air supplied at a certain rule, and heated if possible, there are other contingencies upon which success depends; a very important one is the nature of the material which surrounds the furnace, forms its walls and roof, and comes into immediate contact with the fire. The question, then, at once arises, can the process of combustion be successfully carried on in a narrow furnace, surrounded by iron walls and roof, in contact with water, which absorbs the heat at a rapid rate? Most certainly not. Who would undertake to heat and puddle iron in a furnace built of iron plate in contact with water? Iron water-boshes are sometimes resorted to, but they have a tendency to retard the process, and should be avoided if possible. Such furnaces are constructed of good fire-brick, which is a slow-absorbing and slow-conducting material, and after being glazed over by the strong heat will strongly reflect it. By this strong reflection and non-absorption, the process of combustion is supported in an eminent degree, so much so, that a degree of heat is obtained far exceeding the temperature of any boiler furnace. As little heat as possible should be absorbed by the walls or roof of a boiler furnace; every endeavour should be made to reflect and concentrate the fire. Imperfect combustion in any furnace most generally arises from the fact that the heat is not allowed to accumulate and concentrate. The sole object of a boiler furnace should be to favour combustion, and to develope flame and blaze, and this can only be accomplished under the influence of a highly concentrated and excited action. The caloric stream thus fully elaborated, on leaving the furnace is then allowed to expand itself, and to be absorbed by the interior surface of the boiler.

I may remark here, by way of general comment upon furnaces for heating houses, that the whole tribe of *Patent Furnaces* with which the country is blessed, have all, more or less, grown out of erroneous notions, and are the offspring of profound ignorance of the laws of combustion and of heat. Aside from the vitiated air they supply, they are all wasting fuel at an enormous rate. This subject is better understood in the north of Europe, where long winters and scarcity of fuel have taught men to build furnaces on correct principles.

The temperature of a puddling or heating furnace has to be raised to about 3000°; this can only be accomplished under the reflecting and reverberatory action of the walls and roof. A con-

* From the 'Scientific American.'

centrated blast may produce a greater heat at a certain point, but it will not be diffused. Under the above circumstances, and by means of a strong blast, from three to four times as much fuel may be consumed on the same surface of grate in one unit of time as can be accomplished in a common boiler furnace. In a well-constructed heating furnace at my rolling-mill at Trenton, N. J., 8000 lb. of anthracite are consumed in ten hours for the heating of 18,000 lb. of charcoal hammered blooms, on a grate of 20 superficial feet, which is equivalent to 40 lb. per hour on 1 foot of grate. This cannot be accomplished in the furnaces of the Collins' steamers, which consume 13½ lb. per hour on 1 foot of grate.

In the above a principle is delineated, which to my knowledge has been entirely overlooked, and which must be satisfied before we can attain much higher results.

Another glaring defect in all marine boilers, those of the Collins' steamers not excepted, is the want of room necessary for a due mixing of the gases, and a full development of the blaze.

Large quantities of fuel in a narrow and low furnace cannot be consumed without waste. In order to become fully excited and most positive in its action, the blaze of a fire must be at liberty to extend and elongate in the direction of the draught to a distance corresponding to its bulk, and without meeting absorbing obstructions. For illustration I again refer to heating and puddling furnaces. This fact can be readily ascertained in an experimental furnace with adjustable roof. The brightest fire will burn under the highest roof, while the depressing action of a low roof will damp it and reduce the temperature of the furnace.

Economy of space is an important consideration in the planning of a marine boiler, but this may be carried so far as to seriously interfere with the grand object of the boiler. In an efficient boiler, the extension of the furnace should form an empty area, which serves as a receptacle for the caloric stream where the gases become thoroughly mixed and fully ignited before their caloric is expended upon the boiler surface. And for the purpose of allowing ample time to the heat to be absorbed by the tubes, the above space, together with the tube area, should be as large as possible. The arrangement must be so, that the draught between the furnace and the chimney should be very slow, so that all the caloric, or nearly all, may be absorbed before the unconsumed gases are allowed to escape.

The boilers of the *Arctic* have 33 feet of heating surface for 1 foot of grate surface; this allowance is scarcely enough for hard coal—40 to 1 will not prove an excess. But this proportion depends in a great measure upon the velocity of the draught through the area which contains the tube or heating surface. The larger this space, or the longer its extent, the slower the motion of the gases will be, or the more extended their travel, consequently the longer they will remain in contact with the tubes. It is a very general defect in marine boilers that the draught from the furnace to the chimney through the tube area, or through the flues, is nearly uniform, and too rapid. The "hanging-sheets" in the boilers of the Collins' steamers were designed to arrest this rapid flow, but they are not sufficient. The fact is, that the common plan of flue or tube boilers does not admit of a thorough application of the important principle in question, hence the necessity of a radical change.

Other questions of importance have to be considered in the planning of a marine boiler. Strength, facility of construction, and repairs, provisions against unequal contraction and expansion, against incrustation, facility of blowing out, and of cleaning, safety against exposure of heating surface when the ship is rolling or careening; all these are important points, but more or less understood. By the above remarks, I have only attempted to direct attention to such points as are not generally understood, and consequently neglected. In a new plan of boilers which I have invented, all the essential conditions of perfect combustion, radiation, and absorption are fulfilled, and is calculated to produce much higher results than have been obtained heretofore.

In conclusion, I will yet remark, that the subject of *artificial* draught is in a great measure an open question yet. The common fan-blast will answer very well under certain conditions, but in marine boilers, I am satisfied, *exhaustion* by proper mechanical means will work better. The control of large and connected fires can be better maintained by *exhaustion* than by *blast*, and also more economically.

## LOCKING STONES IN FOUNDATIONS OF LIGHT-HOUSES.*

JOHN P. AVERY, *Patentee*, U.S., April 25, 1854.

FIG. 1.

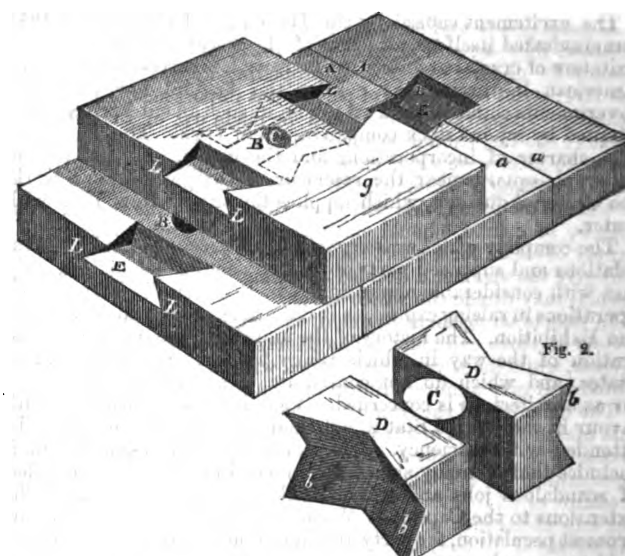


Fig. 2.

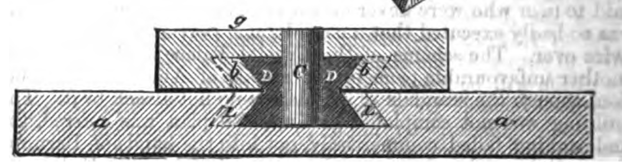

FIG. 3.

FIG. 1 is a perspective view of this system of locking stones, showing one stone placed upon two others, and the whole locked together—the dotted lines showing the form of the dovetails. Fig 2 is a perspective view showing the dovetails or locks, and the manner in which they are forced apart, when it is desired to lock the stones together; and fig. 3 is a vertical section showing three stones locked together—two below and one above. The same letters refer to like parts.

*a, a, a*, represent the bottom stones of a foundation, for instance, in which dovetail slots E, E, E, of a suitable depth are cut, or half that of the dovetails; the said slots being open on the sides which are placed opposite each other, and made wider at their bottom than at their top, thereby forming an inclined projecting lip L, under which the flanges *b, b*, of the dovetails D, D, fit snugly when the key G, is driven between the dovetails. In figs. 1 and 3 a stone *g*, is represented placed on top of the foundation stones *a, a*, and the whole secured together; this stone has a slot E, similar to those in A, A, cut in its bottom surface, and of the same depth as half the height of the dovetails. Thus it will be seen that when these stones are put together, the dovetails will hold equally on each as they fit the same depth in one as in the other. After these dovetails have been placed in the bottom slots, the top stone is placed over them and caused to fit in its slot E. After this is done, the key *c*, or its equivalent, which passes through the hole B, in the top stone, is driven between them, and they are forced apart, which causes their flanges to fit snugly and securely under the inclined projecting lip L, L. By this arrangement of the double-wedge flanged dovetails, constructed as described, and uniting the two adjoining stones in the lower course with the stone which breaks joint with them in the upper course, the stones in the two courses are neatly and expeditiously fitted together, the specified flange-form of the dovetails, when the key is driven home, serving most effectually to draw the stones in the two courses together, face to face, thus making tight the horizonal joint between the courses, and simultaneously making tight the vertical or end joint, as specified, so that the two courses are made expeditiously to become one solid mass, as it were, the flanged dovetails acting as clamps to keep the two courses together.

## REVIEWS.

*New York Crystal Palace: Illustrated Description of the Building.* By GEORGE CARSTENSEN and CHARLES GILDEMEISTER, Architects. New York: Riker, Thorne, and Co. 1854.

The excitement caused by the Hyde-park Exhibition of 1851 communicated itself to all parts of the world, and among other imitators of crystal architecture, more or less successful, were our American brethren. As neither the Federal nor the State governments could be induced to join in such an enterprise, it was adopted by a joint stock company in New York. The State gave it a charter of incorporation, and the city gave it an area in Reservoir-square, near the reservoir of that well-known work, the Croton Aqueduct, which supplies the city of New York with water.

The company which was organised, on account of the political relations and supposed party objects of some of its founders, early met with considerable opposition, which materially cramped its operations in raising capital, as it did afterwards in the conduct of the Exhibition. The history of the undertaking is a curious illustration of the way in which affairs are managed in the United States, and which do not contribute to satisfactory results, so far as architecture is concerned. Vast designs readily meet with favour in the United States, but their execution is not sure to be attended with efficiency. The history of railways, although it includes that of many successful undertakings, yet includes that of scandalous jobs and virtual robberies. The building of the extensions to the Capitol at Washington was attended with the grossest peculation, for party and individual purposes; wages were paid to men who were never on the spot, and even what was done was so badly executed that a considerable portion had to be done twice over. The scheme of the Crystal Palace at New York is another unfavourable page in the annals of American construction, though the scandals of peculation do not attach to it. The building was not completed in time, the plan was marred, the undertaking failed commercially, got into the hands of Barnum, the notorious showman, and is at length sold up. It did not, however, want for the encouragement and support of those in authority. The President opened it in state, though he and his suite got a ducking for their pains, and the English government sent one of the most pretentious missions which has yet reached the shores of the Atlantic. Many of the local and colonial authorities gave their countenance, and the contributions were of a remarkable character. Upon these, reports have been drawn up by the English commissioners, and which have been duly published. In fact, all that the co-operation of Prince Albert could do for the Exhibition was done, with the view of inducing the public on both sides of the water to look upon him as the originator of these exhibitions, and a patron of the useful arts.

The design for the New York Palace was obtained from Messrs. Carstensen and Gildemeister, foreigners, and a great part of the staff engaged in the construction were foreigners. Although the design of the two architects was adopted, and they superintended with a large foreign staff under them, the chief control was in what was called the building department, under Mr. C. E. Detmold, a Hamburgher, but several of whose assistants were native citizens. The surveyors were of foreign origin. The result of the independent organisation, and of the undertaking being intrusted to foreigners, was that, as usual among Germans, they quarrelled among themselves, and Messrs. Carstensen and Gildemeister, the authors of the chronicle of the Palace, lay the blame on Herr Detmold, while Herr Detmold and his party charge it upon the architects, and the committee lay it upon both. It is clear enough, from what we have in the book, that the constructing department and the engineering department did not agree, and there was no want of occasions on which they could express their dissatisfaction with each other. As to the amount of personal blame to be apportioned to either party, we do not think it worth while to consider; the fault lay in the original vice of the organisation, under which such dissension and disagreement was almost inevitable, as few men could have worked harmoniously together under such circumstances, particularly Germans. And further, the committee had not matured their scheme in the first instance. They had not measured their resources; and they went on, from hand to mouth—Yankee fashion—cutting, scheming, and contriving, what is called going-a-head, but really going through a variety of shifts; under which all unity of design, all grandeur of design, all completeness of effect, were sure to be marred, as they have been. The architects endeavoured, in the first instance, to provide sufficient space and a complete design, but the committee directed them to cut down the estimates; while again, at a future period, they were told to provide space, which they could only do by resorting to a make-shift. Then the contracts were let after the same fashion; and as the price of iron rose in the meanwhile, the contractors declined to complete their contracts, and the work was protracted from want of materials. The history of these difficulties and squabbles is a long one; and from all we have heard, the architects have only given us their side, and it is only of interest as showing how these things are managed elsewhere, and that we have little chance of improvement by taking a leaf out of the transatlantic book. In railway making we have learned something, and we are about to apply it usefully in India, for it is an advantage to begin on a small scale, and work on as the traffic increases; but this very system becomes an evil when, as we have said, a great and uniform design is in contemplation.

Messrs. Carstensen and Gildemeister have settled as architects in New York. They furnished the design chiefly with the purpose of showing their abilities and obtaining distinction; they worked for costs out of pocket, receiving not more than eight thousand dollars; and they have published this book partly to explain their work, and partly to vindicate their reputation. The technical part of the book will be read with attention, for the design is meritorious, and the authors bestowed great care in the completion of the works. It contains, likewise, all the plates of details which are necessary for its illustration. It is another of those works which are most creditable to the United States. The work will receive the notice of our professional men for the further reason that the building was executed at a moderate cost under considerable difficulties.

With regard to the origin of the work, the authors give the following account:—

"A charter having been granted by the Legislature of New York, incorporating an Association for the Exhibition of the Industry of all Nations, a committee having been organised, and a lease of Reservoir-square at a nominal rent having been procured from the city government, it was announced that the furnishing of a design for the contemplated building was open to competition. The circumstance of our becoming competitors was purely accidental. We did not know of the lists being open until about three weeks before the final arrangement, when, at the suggestion of our friends, we undertook the task of furnishing the design worthy of the occasion. Previous to the acceptance of our plan by the Board of Directors, the latter entertained exceedingly restricted ideas regarding the limits of the future enterprise. The company was limited in its means; both at home and abroad a feeling of distrust was manifested towards what was considered to be a private speculation rather than a national undertaking, and European states were cautious in giving any promises of co-operation. The committee, therefore, thought it advisable to restrict their expenditure for the edifice to the sum of 175,000 dollars, and to content themselves with a one story building, which should embrace as much as possible of the ground allotted to them on Reservoir-square. If the reader refers to our correspondence with the Board on this subject it will be seen that we foresaw and stated the necessity of providing more space than that originally contemplated. As illustration of the correctness of our views may be found in the fact that although the building designed by us contained (in the shape of galleries) 62,000 square feet more than they imagined would be required, it was found necessary to erect an extra building, in order to contain a machine-arcade and picture gallery, at the sacrifice of much important time; at the risk of serious injury to the symmetry of the principal edifice. In the accompanying illustrations which we furnish of various modifications of our original design made to suit the need of the company, it will be observed that we at first proposed a basement story, which, if carried out, would have given an additional surface of 150,000 square feet, for about the same sum as was afterwards expended on the erection of the somewhat unsightly machine arcade. The prudence of the Board of Directors went even so far in point of economy as to suggest the abolition of galleries altogether. Independently of the artistic incompleteness which would have pervaded an entirely naked shed, such as the Palace would have become had this suggestion been adopted, those who visited the Exhibition after its opening, and observed the crowded effect of many of its departments, will at once perceive how very inadequate the building would have been to meet its practical purpose without those galleries. Had our original plan been adopted in its totality, some serious defects that now exist would have been entirely avoided. The presence of a basement story would have elevated the building about six feet, thus decreasing the unfavourable effect which the heavy masonry of the Reservoir now now produces upon it. But so depressed was the feeling of some members of the Executive, that it was at two different periods suggested to have, instead of a lofty and aerial dome which should give dignity and elegance to the whole structure, an open court in the centre, roofed in with canvas. Even the unprofessional reader can easily realise the effect of so flat and ungainly an edifice, when so closely contrasted with the huge proportions of the Reservoir.

Our plan having met with the approbation of the Board of Directors, and these alterations having been carried out which the smallness of capital of the company rendered unavoidable, our contract was signed on the 26th August, 1852, after which the mechanical departments were called into action. The contracts for the masonry were given out on the 4th of September, and on the 25th of the same month the iron work was contracted for. It was stipulated that the foundation should be ready, and the first necessary castings delivered on the 21st of October. A pattern shop was established in this city, under the superintendence of Messrs. C. J. Shepard and John Purvis, and the contracts for iron were distributed amongst various manufacturers, some in New York City and State; others in New Jersey, Pennsylvania, Delaware, and Connecticut. This distribution of the iron contracts, owing to the failure in making arrangements for the whole supply from any one or two houses in the city, was the occasion afterwards of much inconvenience and disappointment, as will be shown in the course of our statement."

The writers again refer to the pattern shop. They say:

"With regard to those duties which were strictly ours, we do not hesitate to assert that they were punctually performed. If anybody has a right to complain it is ourselves, who on almost every occasion experienced considerable difficulties in getting our designs practically carried out with quickness.

Immediately after the idea of the Crystal Palace was matured, a pattern shop was established expressly for making the necessary patterns for the iron castings to be used in the building. This establishment was abundantly provided with mechanics, and it became of course a matter of economical necessity to keep them continually supplied with designs from which to construct their patterns for the cast-iron work. In obedience to this necessity we furnished these drawings so rapidly that numbers of them remained undisposed of for some weeks and months, either because the workmen were over supplied, or from some defect in the system on which the establishment was conducted. The effect of this arrangement was, however, soon seriously felt. The undivided attention which was given to the cast-iron work interfered so much with the progress of the wrought-iron work, that it was almost entirely laid aside, and although constituting a very essential part of the building, such as the dome, the trusses supporting the same, the roofs, galleries, staircases, &c., it was almost entirely neglected at a period when it should have commanded the principal attention of the superintending engineer.

One of the chief causes of the delays so frequently complained of was the dilatoriness with which the iron materials for the building were delivered. Shortly after the contracts were made the prices of iron were increased, and the contractors appeared unwilling to purchase and deliver at a higher rate than they themselves were to receive according to the terms of their contract. Not having been entrusted by the Board of Directors with the contracting department, we took no part in the giving out of contracts, and had no power to enforce their fulfilment. By the short-coming of contractors and failure of the Executive to hold them to their obligations, we were reduced to the most lamentable expedients to get materials together; we had to search from store to store for angle iron, making what use we best could of such pieces as we were able to procure in this desultory manner, completely reversing the usual order of such matters, and constructing our building with reference to the materials, instead of getting those which would suit our construction. As a signal and eloquent instance of the want of system which pervaded the entire working corps, we may state that the castings for the second story of the building were delivered on the ground a considerable time before those required for the first story were even ready."

The result of all these shortcomings is, that the building has been left in a most incomplete state. The leakage of the roof is one defect, and the condition of the paneling is another:

"Shortly after the palace became roofed, the leakage which occurred was a matter of serious inconvenience and annoyance. If the reader will refer to that part of our technical description which regards the gutters and louvres, he will find that we furnished designs and made suggestions for those parts of the building, which, had they been adopted, would undoubtedly have precluded such a result as leakage. Another plan for gutters, was however, put into execution, suggested by other parties. The end obtained by this alteration from the original plan did not prove to be quite so satisfactory as the directors had anticipated.

In regard to the awnings placed over the louvres to prevent the leakage through them, we object to them for the following reasons;—1. That they spoil the appearance of the building, and prevent proper ventilation. 2. That they have cost too much in time and expense. 3. That they did not fulfil their purpose, which was proved by the first heavy shower. Besides, we feel convinced that after becoming decayed, they will be torn into shreds, and thus injure the appearance of the building.

Most of the outside panels are made of sheet instead of cast-iron, for which latter material we had furnished the necessary drawings, and several patterns as well as castings had been executed accordingly; but as they were considered too heavy and expensive by the superintending engineer, we consented to the substitution with the express understanding that the ornamental mouldings should be affixed to them, which has not been done, giving those panels over the different roofs, and below the cornice of the dome, a rather plain, and, in some instances, a deformed appearance."

Upon the interesting subject of the decoration of the interior, the same want of co-operation was manifested; and the architects have strong ground for complaint that their original design was abandoned, and that they were not consulted on the plan adopted. On this head they strengthen themselves by an appeal to the views of Mr. W. J. Hayter Lewis, the architect of the Panopticon, as expressed by him before the Royal Institute of British Architects. Messrs. Carstensen and Gildemeister observe—

"We cannot omit here to remark that the unsightly appearance of the stoves, with their pipes carried through the whole height of the building, which are employed by the Executive for heating the same, would have been avoided if necessary provisions according to our suggestions had been made in proper time. Nor have we had any part whatever in the distribution of space, or in the decorations of the different departments with their contents. We have only directed the exhibition of Thorwaldsen's statues of *Our Saviour and the Twelve Apostles*, with the baptismal font, which was one of the few departments entirely completed at the opening of the exhibition.

For the decoration of the dome we had devised two designs, besides the one described in the letter in the Appendix. The first was for the ground, a rich blue with gilt or silver stars in relief. The second was as follows:—From the apex of the dome a cluster of silver rays were to radiate down to about a third of its depth, giving the effect of light bursting in through an aperture above. The remaining two-thirds of the dome were to have been coloured in alternate subdued red and white stripes, over which a network was stretched, giving the effect of a huge American ensign having been cast over the dome, and supported in its place by the ribs and the network which would seem to bulge and droop beneath the superincumbent weight. Without wishing to insist upon the superiority of either of these designs over the one adopted, and executed by Mr. Monte Lilla, under the superintendence of Mr. Greenough, we cannot refrain from adverting to the defects of the latter, where the apex or receding point of the dome was painted yellow, which is the most advancing colour in the spectrum, and the base or nearest point a light blue, which is the colour always used to bestow the effect of a receding object. The consequence was that the dome lost a third of its apparent size by this distribution of colours. The yellow brings the top nearer to the spectators, while the blue gives to the base the effect of distance, and the vault which should have looked light, aerial, and expansive, has now been flattened down. We at one time understood that a gentleman from England, Mr. Mould, a pupil of Mr. Owen Jones, offered some meritorious designs for the decoration of the building, which were not accepted. We had not the pleasure to see these designs until seven months after the Crystal Palace was opened, but we think that in a matter so important as the decoration of a building which we designed, it was the duty of the Executive to permit us to have a voice in the affair; a just courtesy which was never granted. On the whole we trust that the reader, after a perusal of this statement, and the accompanying correspondence, will see that whatever mistakes may have occured during the erection, and in the completion of the Crystal Palace, they are not attributable to us."

The details of their design for the decoration are given in an address to the Board:

"Outside the building a lively olive bronze colour, for panels, columns, arches, girders, cornices, towers, &c. The projecting parts of the mouldings to be kept with a lighter shade, and on some of the receding parts; with a darker shade of the same standard colour.

The heads and brackets on the window arches, ornaments over cornice, tower railings, &c., to be gilt; or painted with a colour substituted for gilding.

The window-frames and bars to be painted with a very dark green bronze colour, so as to relieve the shade of the glass. A specimen of this mode of decoration has been executed under our direction, on a section towards the north-west part of the building.

The roof of the lean-tos, aisles, nave, and dome, to be painted with copper-green, or lead colour. The projecting ribs of the dome to be gilt, or receive a colour capable of being substituted for gilding.

All the louvres with a warm straw colour. The outside railings with a greenish bronze colour. Lamp posts and lamps relieved with slight gilding, or a substitute for the same.

Inside of the building.—Columns, girders, arches, &c., with a warm yellow colour, relieved with stripes of a rich deep blue, and red and white. Base pieces, capitals, brackets, mouldings, and other ornaments painted with positive colours, and gilding according to principles existing for moresque decorations. The construction of the roofs, as standards, braces, rafters, purlins, ribs, tie-rods, trusses, &c., with a deep orange colour, relieved, when necessary, with a deep red colour. The ceiling of the lean-tos, aisles, nave, and dome to be painted with white, red, and blue colours, on canvas, forming panels between the intersections of the said purlins, rafters, &c. This part of the decoration should be kept very lively and airy, principally on the dome, as the lightness of the construction will not suffer any heavy looking covering. The borders of those panels should not be too broad, or too complicated in their designs, as the first will not look well, and the last will occupy too long a time in executing; a tasteful and noble simplicity should be the general characteristic of the decoration. For this reason, we should object to the under part of the gallery floors being varnished, as they will appear entirely too heavy and dark, in the immediate vicinity of the lively colours of the girders, and lean-to ceilings—a white colour with a slight tint of either blue or pink, with deep blue or red stripes on the chamfering of beams, &c., would produce, according to our ideas, a much more harmonising and finished effect. The railings of galleries, stairs, &c., to be painted white and varnished; the standards, eagles, and rosettes to be relieved by gilding. Also, for a part of this inside decoration a specimen has been executed, under our direction, in a part of the north-west lean-to. In conclusion, we beg leave to add, that the above mentioned style of decoration is kept in accordance with the tinted designs of the outside and inside perspective views of the building, which we had the honour to present to the Board, when we submitted our plan in competition with others; the only modification made being the bronze colour for the outside, which we found the necessity of, in perceiving the dark green shade thrown by the glass on the whole building, and which materially deteriorates its general effect."

The objections to M. Monte Lilla's treatment of the dome, we believe to be well founded; but the adoption of bronze colour for external details is open to controversy, for a correspondent of the *Athenæum*—probably one of the Great Exhibition officials—in speaking of the Bavarian Crystal Palace, just opened at Munich, says the bronze on the exterior is a complete failure, inasmuch as it deadens it, and materially diminishes the otherwise light effect of glass and iron. It is to be observed, however, that the New York architects advocate a light bronze colour,—what they call a lively olive bronze; but it is questionable whether this would not be too decided, though in that building less glass has been used. It is strange that a sculptor—Mr. Greenough—was the chief director of the colouring.

The general description of the building at New York is as follows:—

"The materials used in the construction are mainly iron and glass,—wood only being employed in the floors, doors, and sashes. The central part is surmounted by the dome 71 feet from the floor to the spring of the arch, which rests on 24 columns, 16 of which form two concentric regular octagons, the one inscribed within, the other circumscribed outside a circle of 100 diameter; the distance of the columns in the latter, 41 ft. 5 in., thus determines the width of four naves, radiating from the centre, and carried up to a height of 67 feet from the ground floor to the ridge of the roof. On each side of the naves the aisles extend to the same length, each 54 feet from the first floor to the highest point of the ceiling. The naves with the aisles form in this manner a Greek cross, over the centre of which the dome rises, and the spaces in the exterior angles of the cross are fitted up with triangular lean-tos, one story 24 feet high, giving to the ground plan on the first floor the form of a nearly regular octagon, at each angle of which an octagonal tower of 8 feet diameter rises to a height of 71 feet.

The whole space thus inclosed, with the exception of the central part under the dome, and the 4 naves, is divided, by columns 27 feet apart from their centres, into square and triangular compartments or bays. On three sides of the building project entrance halls corresponding in width with the naves, and 27 feet deep, with offices attached to each side, 27 feet wide by 18 feet deep, and are subdivided into two stories, the upper ones being accessible from the platform of the adjoining staircases in the main building. The fourth side, situated towards the Croton Reservoir, is left without an entrance.

The second story extends over the aisles, and over two bays of each nave, thus forming an uninterrupted gallery of 54 feet width around the whole building, and accessible from all parts of the structure by 12 large staircases, 4 of which are placed under the dome, and 8 at the ends of the aisles near the entrance halls; 8 winding stairs in the towers facilitate the communication between both stories for the officers of the association.

Three large balconies over the entrance halls and offices are approached from the galleries. The building presents three pricipal fronts to the three streets which inclose it, the architecture of which is sufficiently shown in the accompanying plates.

After the original plan had been adopted, and the structure commenced, it was found necessary to furnish additional space, for which purpose the machine arcade was attached to the eastern side of the building. The space between the latter and the Croton Reservoir was thereby nearly filled up, a narrow passage of 5 feet width only being left according to the requisition of the Croton department. The length of this arcade is 451 ft. 5 in., its greatest width 75 feet, and that of the two story building 21 feet; the first story is partly of the same height as in the main building, the lower parts or sheds are from 13 ft. 4 in. to 16 ft. 4 in. high, and the second story which connects with the galleries of the main building, and forms a picture gallery, with a skylight extending almost its entire length, is 18 ft. 9 in. high without the skylight, which rises 5 ft. 6 in. higher."

With regard to the wrought-iron girders, it is observed:

"Some of these girders, after being put into their places, showed some defects in their lower flange and the diagonals, after the floors were tested with a weight of 85 lb. to the square foot. In consequence of this, tie-rods extending from the top of the second story columns were employed to relieve the standards nearest to the columns, which produce a very bad effect to the eye, although the same security might have been attained by ordinary inverted trusses under the floor, such as were placed according to our advice under four of these girders by Mr. Kroehl, the assistant engineer."

The raising of the dome was thus accomplished:

"The lantern was completed on the ground, and raised between two poles, about 10 feet higher than the required height of the dome. Four derricks were then placed on the bed-plate of the dome, by which the ribs, brought to the spot, on account of their length, in three different pieces each, were, after having been riveted together on the ground, hoisted to their places, bolted and keyed to the bed-plate, and bolted to their shoes in the upper ring, supporting the lantern. When this was done, and the braces adjusted, the lantern was disconnected from the poles, which were then removed. The contractors for raising the building deserve great credit for their skill in raising the dome, which was accomplished in four and a half working days; much is also due to the contractors for the ironwork, the assistant engineer superintending the whole construction and erection of it, and last but not least, to the efficient body of mechanics who, in sunshine and storm, applied themselves steadily to their labours."

Although the details of the Hyde Park Palace were closely studied, and full advantage was taken of the experience and the labours of Messrs. Fox and Henderson, as is duly acknowledged, the New York architects introduced many modifications. One was as to the arrangements for sweeping:

"All the floors are calculated to be laid with tongued and grooved boards, and to receive a number of small moveable reservoirs, or caissons, 2 or 3 feet in diameter, covered by cast-iron perforated rosettes, to answer the purposes of cleanliness. In the London Crystal Palace, the planks of the floors were laid half an inch apart, with a view to a more ready mode of cleaning the place by sweeping the dust, &c., between the boards. Very serious inconveniences arose from this method of laying the floors, among which, the almost certain loss of any small article or trinket that was dropped, was not the least. The proposed system of introducing a number of moveable receptacles of the dust, is calculated to obviate the inconveniences experienced in London, whilst it will retain all the advantages of speedy and thorough sweeping."

Upon the use of glass for the roof, the following observations were made, which are applicable to such structures in climates warmer than ours:

"The different roofs are intended to be covered with lead and tin. The character of a 'Crystal Palace' will be amply preserved by the free use of glass on all sides of the octagon, cross, and dome; but it is believed that a glass-roof, like that used in London, would be pernicious to the interior of the building, as the brightness of our sky would be much too glaring for endurance, if received through the medium which was so appropriate in England. Moreover, a glass-roof would be found the source of serious annoyances, chiefly in winter time for instance, in case of heavy snow."

Some amusing correspondence will be found in the Appendix, on the mode of paying the architects' remuneration,—Brother Jonathan having still a very strong objection to pay hard cash, or even paper, when anything can be done in the way of swapping, so that the poor architects had to take great part of their small remuneration in shares.

---

*Electro-Magnetic Telegraph, with an Historical Account of its Rise, Progress, and Present Condition, &c.* By LAURENCE TURNBULL, M.D. Philadelphia. 1853.

[SECOND NOTICE.]

Before resuming our historical notice of the various steps by which the art of electro-magnetic telegraphing attained its present perfection, we will notice the interesting experiments conducted by Mr. A. Bain, in which the earth was made the source of permanent voltaic electricity.

In 1841, it was found, during some experiments with an electro-magnetic sounding-apparatus, that in consequence of the imperfect insulation of the conducting-wire from the water, the attractive power of the magnet continued, notwithstanding that the circuit was broken. This phenomenon was further investigated at the Polytechnic Institution with great lengths of wire, when the same results were obtained, which afterwards induced Mr. Bain to conclude that a permanent battery might be made by burying in moist earth or water a surface of positive metal and one of negative metal, and establishing a metallic connection between the two by means of a wire. This proposition was accordingly acted upon in Hyde-park, where a copper and a zinc plate were deposited in the earth, and connected by a wire suspended on the railing. On placing a galvanometer to the wire, an electric current was perceived, with which an electrotype process was conducted, and several successful electro-magnetic experiments performed. Mr. Bain patented the application of this mode of producing electric currents to his printing telegraph in 1841; but as this natural battery requires for long distance a great increase in the number of plates, and is capable of producing only very feeble currents, it has been abandoned as a generative source of electricity.

In the year 1840, Mr. W. Sturgeon published in the 'Annals of Electricity,' descriptions of his ingenious and simple systems of indicating telegraphic messages, in which numerals or a combination of numerals are made to represent certain preconcerted signals. In one system the apparatus consists of six soft iron bars, bent into the form of horse-shoe magnets, and covered with copper wire in the usual way. Immediately above each magnet is suspended a lever, having at its short end a cross-piece or keeper, which, when the magnet is excited, is attracted towards the magnet, and raises the long arm of the lever, to the end of which is affixed a circular piece of card bearing a numeral, which becomes apparent to the observer through a circular opening in the dial-plate of the apparatus. These six magnets and levers are so arranged that their respective numbered cards shall appear through openings ranging in a horizontal line in the face or dial-plate, so that the numerals may appear in proper consecutive order. The transmitting instrument consisted of an arrangement of keys, numbered in a corresponding manner to the receiving-magnets, the depression of any or all of which consequently indicated the like numerals at the opposite station. In a modification of his telegraph, Sturgeon employed magnetic needles in place of the levers and magnets. These needles were arranged in a row, and when deflected by the electric current they pointed to a series of numerals marked on the dial-plate, or they might be made to point to letters alphabetically arranged in three horizontal rows. It does not appear that Sturgeon's instruments, although simple and capable of being rapidly worked, have been practically employed.

In 1846, a printing telegraph was tried on the Paris and Rouen line, the invention of Dr. Dujardin, of Lille, which consisted of a transmitting and a receiving instrument, actuated by magneto-electric agency. The receiving instrument was composed of a permanent magnet, each of the two poles of which were enclosed by a coil of wire in connection with one another. Opposite to the two poles was supported a revolving armature, capable of being moved by driving and multiplying wheels, one-sixteenth part of a revolution of the driving-wheel causing the armature to make a quarter-revolution, when a current of electricity was generated and transmitted to the receiving instrument, and returned by the earth. The recording apparatus consisted of a hollow drum of metal, to which a slow rotary motion was imparted by a crank actuated by clockwork; and at the same time the drum received a lateral motion from a screw turned on its axle, in a manner similar to that of Mr. Bain. On this drum was stretched the paper to be acted upon. An electro-magnet was fixed under the drum, which was in connection with the generating magnet at the transmitting-station. In front of this electro-magnet was a pen, consisting of a bent silver wire, dipping in a trough of ink, and soldered to a piece of iron wire, mounted and balanced on a pivot, from which depended a piece of watch-spring, having at its lower end a permanent magnet, which hung immediately in front of the poles of the electro-magnet beneath the drum. On the transmission of a current of electricity, the electro-magnet became magnetised, and in consequence of its north and south poles being opposite to the north and south poles of the permanent magnet attached to the pen, the latter was strongly repelled, which caused the pen to rise from the trough of ink, and to mark the paper surrounding the drum. With Dujardin's telegraph about ninety words were printed per minute, at a distance of 400 miles from the transmitting instrument.

We next come to the printing telegraph of Mr. R. E. House, which is worked in the United States to a considerable extent. Mr. House was occupied six years in developing his invention, which was patented in America in 1848, to date from April 1846, the interim between these dates being occupied by the Examiners in considering whether House's system clashed with that of Morse. The chief apparatus connected with this telegraph consists of the printing machine, a compound axial magnet, the motive power and the letter wheel by which the messages can be read in case of failure of the printing machine. At every station a composing and a printing instrument are required, which last is distinct from the circuit, whilst the former is included in it. The composing instrument consists of an insulated iron frame placed immediately below a set of keys, marked with the letters of the alphabet, a dot and dash. Within this frame is a revolving-shaft, inclosed the greater portion of its length within an iron cylinder, the shaft being made to revolve by a band and pulley. The cylinder is detached from the shaft, but made to revolve with it by a brass flange fastened to the revolving-shaft, and acting against the inner surface of the circuit-wheel. This friction contrivance admits of the revolution of the shaft, whilst the movement of the cylinder can be arrested. The circuit wheel or break is fixed at one end of the cylinder, and is divided into twenty-eight equal spaces, each alternate space being cut away, thus leaving fourteen teeth and fourteen spaces. The revolving-shaft and cylinder form part of the electric circuit, one point of connection being where the shaft rests on the frame, the other through a spring, which presses on the circumference of the circuit-wheel; so that as this wheel, the shaft, and the cylinder revolve, the current is alternately closed and broken. The depression of any one of the keys above the iron frame causes the cylinder to stop, by the key coming in contact with one of a corresponding series of stops, arranged around the cylinder, which has the effect of keeping the circuit either broken or closed, according as either a tooth or a space of the circuit-wheel may happen to be presented to the spring. From one to twenty-eight openings and closings of the circuit take place between the depression of the two different keys or the re-depression of the same one. The rapid electrical pulsations thus produced are transmitted by the circuit of conductors to the magnet and printing machine at another station through a conducting-wire. The helix of the magnet is an intensity coil contained within a steel cylinder, having its axis vertical. Within the helix are arranged six or eight soft iron tubes, soldered to the interior of a short brass tube. A brass rod is suspended from an elastic wire or spring above the magnet, and passes down within the soft iron tubes. Upon this rod is strung six or eight small iron tubes with bell-like flanges. On the transmission of an electric current through the helix, the tubes within the brass tube and those attached to the rod become magnetic; and such is the arrangement of their polarities, that they act by attraction and repulsion, overcome the elasticity of the spring, and bring the moveable magnets down to the fixed ones, which breaks the current, when again the spring separates them. Above these magnets is a valve, having on its outer circumference several grooves, which open into an air-chamber in which a piston moves; the action of the magnets already described allows the air alternately to pass through the grooves to the back and front of the piston within the air-chamber, thus imparting a reciprocating movement to a lever of an escapement connected with the piston. The pallets of this escapement act on the teeth of an escapement-wheel of the printing machine, and cause it to revolve to the extent to which the circuit-wheel of the composing machine has been made to move. A steel type-wheel, marked with the alphabet, a dot and dash, is fixed above and revolves on the same shaft as the escapement-wheel. A mechanical contrivance causes the paper to be presented to the type-wheel, which is inked by a band passing between it and a second toothed wheel. When the type-wheel stops a detent arm revolves, carrying with it an eccentric, which, by means of a connecting-rod, draws the toothed wheel having the paper and colouring-band before it against the type, and an impression is made on the paper. A letter is printed if the circuit remains closed or broken longer than one-tenth of a second; three hundred letters, in the form of Roman capitals, can be printed in one minute. The operator, in transmitting a communication, sets the machine in motion, which gives a signal to the receiving-station, and then, with the message before him, commences to play like a pianist on his key-board, touching in rapid succession those keys marked with the consecutive letters of the information to be transmitted. The receiver at the opposite station having set his machine in motion, sets his type at the dash, sends back a signal that he is ready, and the communication is proceeded with. He can leave his machine, as it will print in his absence; and when the message is completed, he tears off the strip of paper on which it is printed, and forwards it to its destination. As Dr. Turnbull says, "the function of the electric current in this machine, together with the compressed air, is to preserve equal time in the printing and composing machines, that the letters in one may correspond with the other. The electrical pulsations determine the number of spaces or letters which the type-wheel is permitted to advance; they must be at least twenty-five per second to prevent the printing machine from acting. The intervals of time the electric currents are allowed to flow unbroken are equal, and the number of magnetic pulsations necessary to indicate a different succession of letters are exceedingly unequal; from A to B will require one-twenty-eighth of a revolution of the type-wheel and one magnetic pulsation; from A to A will require one entire revolution of the type-wheel and twenty-eight magnetic pulsations." The first line on which this instrument was employed was completed in March 1849, from Philadelphia to New York, since which period it has, we believe, come into almost universal operation in the United States.

From 1847 to the present time the number of improvements in and modifications of existing forms of electro-magnetic telegraphs has been very great, many of them exhibiting much ingenuity and skill, although it is not necessary to describe them to complete our history of the science.

A novel though imperfect method of recording telegraphic despatches, patented in America by C. F. Johnson in 1848, consisted in forming signs by the dropping of balls upon an endless belt moving with a uniform velocity, which imparted impressions upon moving paper.

L. G. Curtis, in 1849, proposed an indicating telegraph, consisting of a disc or dial-plate, marked with numerals or letters, and made to revolve to the desired extent by the alternate breaking and closing of the electric current.

Some of the most important recent improvements in electro-magnetic apparatus are those of Messrs. Henley and Foster, which consist in—first, an arrangement by which a visible index hand is directly acted upon by a single magnet, suspended within the sphere of influence of an electro or other magnet, having each of its extremities converted into two or more poles; secondly, the keeping of the magnetic pointer in one position for any length of time, or imparting to it any number of distinct deflections by means of the induced current, and as rapidly bringing it to its stationary position by the residual magnetism or the reversed inductive current, thus rendering the movements of the needle more rapid and distinct than heretofore; thirdly, an arrangement whereby two distinct currents of equal intensity may be derived from the same magnet, and single or double currents may be sent through any number of instruments at different stations; fourthly, an improved apportionment of the signs or symbols, whereby the number of movements requisite for their production is considerably reduced; fifthly, a current reverser of peculiar construction, which dispenses with the use of magneto apparatuses for deriving currents of electricity, substituting in lieu thereof voltaic batteries, such reverser completing the circuit twice during its motion. This patent, which was obtained in 1849, also included a new compound for covering conducting-wires, and a method of regulating timekeepers from one primary or standard clock, which need not be alluded to here.

Henley's telegraph was experimented with by the French government on the line of railway from Paris to Valenciennes, a distance of 180 miles. The wires were connected so as to treble the length of wire, making 540 miles to and from Paris and back; the magnetic messages being communicated through the first wire, back by the second, through the third, and back again by the earth. In this experiment no batteries were employed, the apparatus being worked first with full power and afterwards with one-twentieth of the power, when the signals were made with remarkable rapidity and distinctness, although the ordinary telegraph of the line, with battery power, was not able to produce the slightest effect.

In 1850, W. S. Thomas proposed the making of signals by the agency of heat, generated or controlled by a current of electricity passed along wires, the signals being flashes of light emitted by points or conductors, marks being produced upon paper by the heated point.

In the same year, J. L. Pulvermacher, of Vienna, patented a method of varying the intensity of the electric current, either by increasing or diminishing the number of elements employed, or by interposing more or less powerful resistance to the current; also the substitution of a letter-cylinder for the letter-wheel ordinarily employed. The application of a double escapement, each capable of assuming four directions, and each producing effects different from those of the others, together with other modifications in the detail of electro-magnetic apparatus.

Ernst W. Siemens effected some important improvements in the construction of magnets, and the methods for obtaining motion for telegraphic purposes by means of one or two electro-magnets revolving on their axes within fixed coils; and also by employing metallic spiral coils or bands, traversed by electric currents, and attracting or repelling each other; or again, by the proximity of such spirals to permanent magnets, which at the same time serve to produce electric currents by induction for working telegraphic apparatus. He further proposed the combination of elecric printing instruments in the same circuit with indicating apparatus, when the magnets, which work the step-by-step motion of either or both instruments break and restore the circuit by the oscillation of the armatures or magnets themselves, together with other valuable suggestions relating to telegraphic mechanism. Siemen's telegraph was submitted to the Academy of Science, Paris, who reported it to possess "incontestable superiority over all other like apparatus," and to surpass in speed all other alphabetic telegraphs.

In June 1850, G. H. Horn proposed an electric telegraph, similar in principle to that of W. S. Thomas, in which the igniting effect of electricity was made, through the medium of a fine platinum point, to burn a hole or holes in a moving fillet of paper. The instrument consisted chiefly in clockwork and spool, required for giving the proper movement to the paper. This register required a quantity current to effect the ignition of the point, and therefore a receiving instrument and local battery were necessary to the efficient working of the receiving apparatus.

Batchelder and Farmer also proposed a similar pyrographic telegraph register, employing a spirit-lamp to heat the marking wire, and recording the signal upon various kinds of paper, such as pink tissue made from linen stock, in the form of a fillet or a large sheet, the slightest contact of the heated wire with which was sufficient to produce a straw-coloured mark.

In the same year was patented, by Thomas Allan, of Edinburgh, an arrangement by which the letters, words, and sentences composing messages were divided into sections or divisions, so that they might be signalled, by means of their number and position, in any given section, thus materially decreasing the labour and expense of telegraphic conveyance. Also, a combination of magnets, arranged in pairs, of convenient shape for permitting the ends or poles of electro-magnets to be introduced between them, thus producing a large accumulation of magnetic power within a small compass. These improvements seem likely to lead to great simplification and economy in working existing needle telegraphs.

We have now traced the progress of the science of electric telegraphing from the earliest discoveries of Œrsted, and the experiments of Winckler, Lemonnier, and others, down to the present systems of Wheatstone, Morse, Henry, Brett, and many others, whose ingenious instruments, actuated by the dynamic force of the electro-magnet, transmit and record, at almost fabulous distances, the various languages of civilised nations. It has not been our province to pronounce as to whom the merit of originating the idea of rendering the electric fluid subservient to the purposes of man, belongs; nor even to decide between the rival claims of Morse, Wheatstone, House, or Davis, to be considered the first to record or print messages by electro-magnetic agency; or those of Brett, Bakewell, or Baggs, as regards the employment of the electric current to decompose or form new chemical combinations. These we have left an open question, and have merely detailed, with the assistance of Dr. Turnbull, the gradual development of this extraordinary science. At the same time, we must observe, that our limited space has prevented us from doing justice or even alluding to the improvements of many who have done much to promote electro-magnetic telegraphing.

It now remains to be shown to what extent these numerous systems have been practically adopted, both in the New and Old

Worlds, commencing with America, which, from the vastness of its territories and the remarkable cheapness with which telegraphs are constructed in that country, possesses the greatest number of miles of telegraph. The moderation of the charges made for the transmission of messages in America has also imparted a stimulus to their extension and general employment, which is wanting in this country, on account of our exorbitant tariff of charges. The bold spirit of enterprise which characterises our transatlantic brethren as much in scientific as in commercial matters, has caused the telegraphic wire to link the remotest verge of civilisation on the western frontier, beyond the Rocky mountains, with the north-eastern extremity of the United States; and the time is not far distant when the Mississippi will be connected with San Francisco, a distance in one unbroken line of 2400 miles. The route selected by the committee for this line, according to the survey of Capt. W. W. Chapman, will commence at the City of Natchez, in the State of Mississippi, pass through a well-settled portion of northern Texas to the town of El Paso, on the Rio Grande, thence to the junction of the Gila and Colorado rivers, crossing at the head of the Gulf of California to San Diego on the Pacific, thence along the coast to Monterey and San Francisco. By this route, the whole line will be south of latitude 33°, and consequently be almost entirely free from the great difficulties to be encountered, owing to the snow and ice on the northern route by the way of the south pass, crossing the Sierra Nevada mountains in latitude 39°. This Pacific Telegraph Company is now fully organised, with Mr. H. O'Reilly, the projector of the scheme, as president, and Mr. T. P. Shaffner as secretary, with a capital of 5,000,000 dollars.

Many of the existing telegraph lines in America are of a length which, from the limited extent of our island, are unknown in this country; as, for instance, the two southern lines, one from Cleveland to New Orleans by Cincinnati, 1200 miles long, the other from Washington to New Orleans, by Fredricksburg, Charlestown, Savannah, and Mobile, which is 1700 miles in length; this line has been extended west to Independence, Missouri. The entire length of telegraphic line from New York to New Orleans, *vià* Charlestown, is 1966 miles, which distance is not worked in one continuous circuit, nor can it be so, on account of the imperfections of known means of insulation. Direct communication can only be effected by the employment of an instrument termed a connector, first invented and applied by E. Cornell, of New York, in the year 1846. The effect of this instrument is to cause one of the circuits into which the line is divided to work the next, and so on through the entire series of short circuits. This instrument has also been used on the New York and Erie, Erie and Michagan, New York to Milwaukie, and New Orleans lines, with perfect success. The total number of miles of telegraph wires in the United States amounted, up to the returns of last year, to 24,375 miles, of which 19,963 miles are worked with Morse instruments; 2400 miles with those of House; and 2012 miles with Bain's apparatus.

After America, England possesses the greatest length of telegraph lines, which are estimated by Dr. Turnbull at 2225 miles, but as this number represents the length of railway lines, and not the total length of telegraph wire, as in the case of the American lines, where Dr. Turnbull (whether for the sake of more favourable contrast of those of his own country with the English, or whether such calculation happens to be the one usually adopted in America, is of little consequence) has multiplied the miles of country over which the telegraph extends by the number of wires employed in working them. But when such course of proceeding is applied to the telegraphic lines of England, the necessary length of wire amounts to 9939 miles, which, considering the relative proportions of the two countries, would doubtless strike the balance rather in our favour than otherwise.

Since 1850, when the estimate above given was made, the electric telegraph has made considerable progress, but to what extent no returns have been given. The instruments usually employed are those of Cooke and Wheatstone, Jacob Brett, and Brett and Little. Bain's electro-chemical telegraph is worked from London to Manchester, and from thence to Liverpool, and also from Edinburgh to Glasgow.

In Prussia, the electric telegraph is worked in a very simple and economical manner, the wires being generally buried, and made to follow in the track of railways; but one wire is employed, and the instruments by which the signals are transmitted and recorded are those of Siemens and Halske, Kramer and Morse, together with Daniell's battery. The total length of wires radiating from Berlin is estimated at 1493 miles.

The Austrian telegraphs extend over a length of 1063 miles principally employing the apparatus of Morse, modified by Robinson; of Bain, modified by Ekling; and those of Storer and Stoehrise.

Owing chiefly to the government surveillance over the telegraphs in France, and the high tariff charged, France is considerably behind most European nations in telegraphic enterprise. The latest returns give no more than 750 miles of electric accommodation, on which the instruments of Brequet and Foy are generally employed, together with those of Wheatstone, Dujardin, and Gardiner. Brett's apparatus is used on the line connecting England and France between Dover and Calais, and Bain's chemical telegraph has been lately introduced.

Saxony and Bavaria have government lines, which connect with the Prussian and Austrian lines, and establish a communication with Berlin, Dresden, Munich, and Vienna. In Saxony, the telegraph wires extend over 265 miles, and in Bavaria over about 455 miles, and are principally worked by Stoehriss's needle instrument and his bell apparatus. The Tuscan lines of wire amount to about 363 miles in length, the telegraphic apparatus being furnished by Brequet and Pierucci.

In Holland, Italy, and Spain, the railroads are generally provided with telegraphs, which, with those of Prussia, Austria, France, Russia, and other countries, are being rapidly brought into connection with each other, and are gradually converging towards our own island, with which, before long, they will be in direct communication.

In the East Indies, a line of telegraph has been constructed between Calcutta and Kedgeree, a distance of seventy-two miles. On this line thick rods are employed in place of wires, which are laid part of the way underground, the remainder being supported upon bamboo poles. No insulating apparatus is used, as the thickness of the conducting materials insures the passage of the electric current, and at the same time prevents danger of breakage by wild beasts, or the swarms of kites and crows that perch upon it in the swamps. A proposition to connect all important places in the British possession is now being rapidly put into execution, and will require about 8800 miles of telegraph wire.

When we reflect that the above and numerous other electric lines have been constructed within the last eight or ten years, and that at the present moment telegraphic projects are afloat, and many of them in construction, in which far greater distances are embraced, and more gigantic difficulties are encountered, than in any telegraph lines already accomplished, we may safely look forward to the not distant period when the whole globe will be covered with a network of electric cords, annihilating space, and linking in a bond of intelligence the most remote nations.

Appended to the work of Dr. Turnbull are chapters on electric insulation and wire protectors from lightning; accompanied by several important telegraph decisions of American courts respecting the claims of Morse and Bain; the Electric Telegraph Company *v.* Brett and Little; and Morse and Vail *v.* F. O. Smith.

In these days of more practical acquaintance with the phenomena and laws of electrical science, we may reasonably expect greater results from such knowledge and, though it would scarcely appear possible, still more perfect electro-magnetic instruments; or probably, the new system termed magneto-electricity, in which the inverse or secondary current induced by magnetic action is made use of, may become more practically developed. These considerations induce us to hope that similar works to that of Dr. Turnbull may appear from time to time, recording the progress of this most serviceable and interesting science.

## STATE AND CONDITION OF THE BRIDGES OVER THE THAMES.

REPORT *of the Select Committee of the House of Commons appointed to inquire into the State and Condition of the Bridges over the Thames, in the Metropolis; to report whether they are adequate to the present vastly increasing traffic; whether it be desirable to construct one or more Bridges over the River; and, if so, at what point or points.*

YOUR committee have examined witnesses with a view to discharging the duty entrusted to them, and have, in the first place, directed their attention to the state and condition of the several metropolitan bridges. With respect to these, they have to report that, with two exceptions, namely, Blackfriars and Westminster, the whole of the metropolitan bridges are, in a satisfactory and durable condition. Southwark, Waterloo, and Vauxhall Bridges, and Charing-cross Foot Bridge are toll-bridges in the hands of private companies. As to Blackfriars Bridge, the evidence brought before your committee leaves no doubt as to its being in an unsatisfactory state; and the Court of Common Council has approved of a proposal for removing the present structure, and replacing it by a new bridge. Your committee do not consider it within their province to report on the condition of Westminster Bridge, as a contract for pulling it down and rebuilding it has actually been entered into.

With regard to the adequacy of the present bridges in the metropolis to accommodate the existing traffic, your committee have examined numerous witnesses, whose opinion they consider valuable as connected with the bridges; and they report that the present accommodation is insufficient; that there is every probability of this deficiency being still further felt, and that it is necessary to adopt measures to mitigate the evil. To meet this end, several schemes have been submitted to your committee: 1st. It is proposed to open free of toll those bridges which are at present private property. 2nd. To increase the width, and consequently the convenience of some of the existing bridges. 3rd. To enlarge and improve the approaches to them. 4th. To make the Thames Tunnel available for traffic. 5th. To construct a tubular iron superway, so as to connect the most important points in the metropolis; and, lastly, to build additional bridges.

After a careful consideration of the evidence which has been brought before them, your committee consider that the expediency of removing the present tolls, on the different bridges between Staines and London Bridge, is established. They find that, by the present system, the traffic is diverted from the direct route; and, in consequence, the open thoroughfares are choked, and rendered at times almost impassable, by the collection of merchandise and passenger traffic, which would disperse and spread itself if there were more channels of escape provided. This inconvenience is especially felt at London Bridge, where not only delay, but even danger is incurred by the concentration of traffic on one spot, owing not only to the ordinary London traffic, but to the additional traffic produced by the neighbouring railway termini. Similar inconvenience is felt at Westminster; and your committee are of opinion, that in both instances it would be materially diminished if the intermediate toll bridges were thrown open to the public. The evidence with respect to the bridges from Vauxhall to Staines establishes the fact that, by the present tolls, not only is the public inconvenienced, local trade impeded, and the accommodation diminished, but that the burden of the tax falls most heavily on those who are least able to bear it.

Your committee are of opinion that, although it may become necessary, owing to the ever-increasing traffic of the metropolis, to build additional bridges, it will be better, in the first instance, to ascertain the effect of throwing the present toll bridges open to the public, provided they can be obtained on reasonable terms.

Upon the question as to whether additional bridges are required, your committee have examined Mr. Brennoch, Mr. Tite, Mr. Page, Mr. M'Lean, and other competent witnesses. These witnesses agree in the necessity for providing further means of communication across the river.

The sites proposed by them are—

1st. Tower Hill, below London Bridge.
2nd. St. Paul's.
3rd. Charing Cross.
4th. Horseferry Road.

Without entering into the comparative merits of these several propositions, your committee are of opinion, that the bridges opposite Charing Cross and St. Paul's will become speedily necessary, especially should the negociation with the proprietors of the toll-paying bridges prove abortive.

With regard to the best mode of providing for the purchase, and the future maintenance, and increase of the bridge accommodation, your committee are decidedly of opinion that a rate to be levied over the whole district to be benefited by the proposed alterations is at once the most just and the most simple plan to be adopted.

## SEPULCHRAL MONUMENTS OF THE CEMETERY OF BONN.

Many of the sepulchres of the famous Rhine University possess not only a historical, but also an artificial importance. Here the very praiseworthy custom of placing faithful counterparts on the graves of the good and illustrious has been much resorted to, as, for the acute observer, the physiognomy of man is perhaps his best biography. The busts of Niebuhr and his spouse placed on his mausoleum are exceedingly well executed; the monument being erected by King Frederic William IV. to his former tutor and teacher. Although the memorial tablet of A. W. Schlegel is much more simple, the bronze bust is one of great resemblance, exhibiting a noble cut of head, with a brow furrowed by many a deep thought. A head of equal importance is that of M. de Rehfues, late Curator of the University; the fine lineaments of which bespeak the spirited author and statesman. Attached to a lateral wall is a monument of the Swedish regicide, Lilienhorn, who concluded in Bonn a life of deep suffering. Equally melancholy stands a high cross of granite amongst weeping willows—the gloomy memorial of a youth of eighteen, distinguished by stately form, poetry, and love; it is that of the suicide, Karl von Hohenhausen, one of a family of poets. More cheerful, because of eternal renown, is the mortuary hillock which conceals the ashes of Melchior Boisserée, the elder of a pair of great men. His fine dwelling, replete with master-paintings of every school, belongs new to the surviving brother, Sulpiz Boisserée, but being of a more eccentric character, he does not receive those numerous foreign guests who formerly thronged around these works of genius. Melchior Boisserée reposes now, after much labour and renown in other lands, on the paternal Rhine, while the Dome-work in the "Holy Cologne" progresses—an eternal memorial of the sure success of any sincere and well-grounded endeavour.

## THE RESTORATION OF THE SOUTH GABLE OF THE CATHEDRAL OF VIENNA.

The Cathedral of St. Stephen, at Vienna, forms, with those of Cologne, Strasburg, and Freiburg, a complex of the finest examples of Pointed architecture. It was as early as 1144, that Henry II. of Babenberg (called Jasomirgott, Duke of Austria) erected, on the ruins of an old chapel, a building which, by succeeding additions and enlargements, grew up to the present huge structure. According to some lately-discovered documents, it was Octavius Falkner, a master mason of Cracow, who built this primeval church, of which, however, nothing but the main walls of the great nave and the west front with the giant's door remain. The whole of the lower part of the western façade betrays the exclusively Romanic style, while the pyramids of the two exterior steeples exhibit already traces of the style of the Pointed architecture. Duke Albert II. first commenced to enlarge the Cathedral. The west side was considerably raised, and it was only under his successors that it was planned according to its present form. In 1359, the foundations of the lofty steeples were laid, which great work was effected by a comparatively humble individual, Master Wezla, of Klosterneuburg. He placed the new steeples above the projections of the nave, as the principal front, which had to remain intact, had already two similar structures. The numerous statues and ornaments which were placed in the interior and exterior of the vast building, were made by U. Helbling, H. Kumph, and C. Horn. The main steeple was not completed until 1433, so that its construction occupied a period of seventy-four years. Here, it seems, the vigour of the middle ages had been expended, as the second steeple was never completed, and only somewhat built over and covered with a copper roofing in 1579. The whole length of the completed steeple is 435 ft. 6 in.; the whole length of the Cathedral 342 feet; the width of the middle nave between the pillars (of 8 feet thickness), is 33½ feet; that of the lateral nave, 28 feet; the height of the middle vaults, 86 feet.

As the completed steeple lays on the southern façade, it is this which presents the finest view of the building, and the richness of ornament is most apparent, the which had just taken hold of Gothic architecture when St. Stephen's, of Vienna, was built. Very richly ornamented are the flying buttresses with the double windows between them; arched vaults, with all the finery of mediæval art, extend before the doors; and the steeple, reaching far into the skies, presents numberless finials, like stone carving. It is to be regretted, that of the four steep gables, which project over the height of the walls, only that on the west side was completed—probably by Puchsbaum, in 1430. This has a perforated pediment, which, beginning above a straight gallery, presents below three collateral gables, above which rises the chief gable, surmounted by a crown. The three other gables have only the appearance of simple walls, and contrast very much with that so highly ornamented. The municipality of Vienna proposes, therefore, to restore or rather rebuild these three gables, which would fully complete the ensemble of this fine old Cathedral. The estimates of each of the gables have been laid down at 18,000 florins.

## CHAMPION'S TAPERING DOUBLE LEVER BRIDGE.*

The accompanying engraving is a perspective view of an improvement in bridges, by Samuel and Thomas Champion, of Washington, U.S.

This bridge is a tapering double lever, skeletonised and balanced upon a pier, reaching, in moderate spans from the pier to either shore, and may be swung round as a draw, opening the whole stream by rollers underneath on the top of the pier.

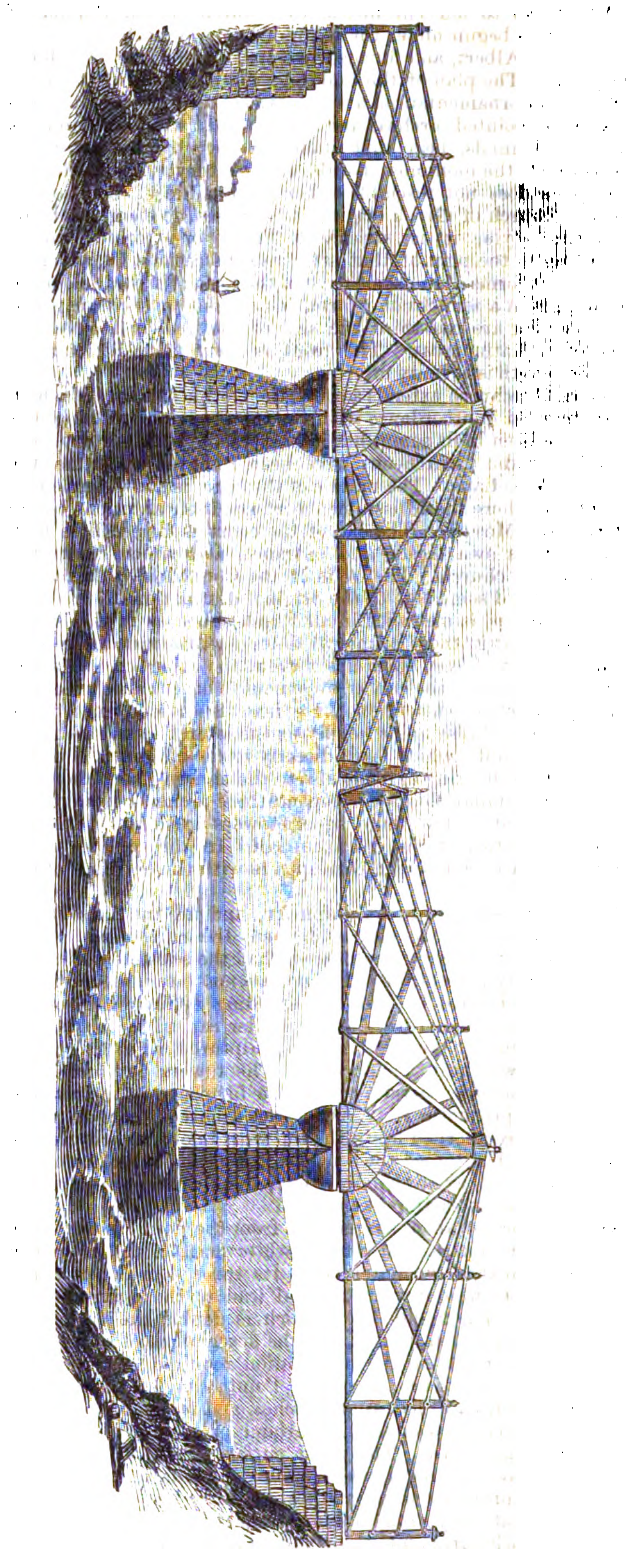
In wide streams, where several spans are required, each section of the length of the bridge will reach from each pier to midway between the piers. Where no draw is required each section may continue in one unbroken connection from the centre of the pier to the foot of the side piers each way beyond. By this plan of bridge, the principal weight and crushing force is thrown to the under side of the bridge, the lighter being above the heavier, giving an opportunity for cross and other bracings, where they are most required.

The commencement of this bridge is in a hub on the pier, in which are recesses for the reception of a series of upward diverging, tapering wrought-iron tubes, radiating like the rays of the half-risen sun, for the purpose of throwing all compression to the foot of the centre column, as all suspension is centered upon the cap on the top of the centre or vertical column, over which, in recesses at the proper angles, all the suspenders pass, and from which they diverge downwards, as the tubes do upwards, each in straight lines—nothing curvilinear in the compression or suspension. These being equal to each other, the expansion is equal; what one gives upward the other does downward, so that the whole remains comparatively stationary.

At proper intervals, throughout the length of the bridge, clamp posts are attached reaching from the upper terminus of the tubes to the lower termini of the suspenders, embracing each tube and suspender as they pass the posts, clamping by bolts through said posts, all tubes, suspenders, and posts, and holding all in a state of rigidity and tension, which is regulated by gib-and-key connections in the suspenders.

By this system, in which the principles of the lever are analysed, and skeletonised—as by placing the crush resistants on the under side, and the stretch or tension resistants on the upper side, with the correct principle of taper properly maintained and proportioned, any desired length and strength of span may be obtained, there being (as the inventors conceive), no limit in the principle, except in cost and expediency, it being cheaper to erect additional piers, where it is practicable to do so, than to increase the size of all parts from the centre between the piers, to the piers at their greatly increased distance apart. It will be perceived that this bridge is never loaded in the centre with burdensome weight, however lengthy the span may be, but remains at rest and equipoise when no train is passing over it. Iron bridges, which are as heavy in the middle as at the piers, are always loaded, and sometimes very heavily, too, by their own weight alone, and are often breaking down, and would do so in a few years if no weight were placed upon them.

Believing this principle to be true and demonstrable, as capable of indefinite extension—that any desired length of span may be obtained for the support of any desired weight, the Messrs. Champion present the same to the consideration and criticism of a discerning and impartial public. They also call particular attention to the capacity of the tapering suspenders for great length of span, far beyond the one size wire suspension, to say nothing of the advantages of the straight suspenders in their permanency and rigidity over the oscillating inverted curve suspender. In this bridge the permanent and suspension meet, and the anchoring is part of the bridge; the shore end (when not intended for a balance swinging draw) is considerably longer from the pier to the abutment than to the centre between the



piers beyond, forming by such additional length, an anchor and counterbalance to the weight of a train between the piers beyond: thereby placing everything in sight above the danger of rust below.

* From the 'Scientific American.'

## THE CATHEDRAL OF NIKOSIA, IN THE ISLAND OF CYPRUS.

By A Recent Traveller in the East.*

According to old chronicles, the church of Sta. Sophia, of Nikosia, was begun under the reign of Henry I. of Lusignan, by Archbishop Albert, and finished in 1228, under Henry II., King of Cyprus. The plan of the building, the ensemble of its architecture, and ornamentation, are in perfect keeping with its style of slender pointed arches; and the portal, windows, and its foliage and finials, bear that stamp of stern symmetry which appertains to the monuments of the 13th century. The Cathedral of Cyprus does not resemble either the Basilica of Constantine nor any church of Greek origin; it possesses no element of the Byzantine style; it is strictly a Frank or Gothic church. According to the plan of that style and the century in which it was built, it forms a handsome nave in the form of a parallelogram, which ends in a semicircular form, and obtains by the transversal naves, which are one-third the size of the principal nave, the form of a Latin cross. The front is forty mètres broad, its exterior length is seventy mètres.

Before the church extends a court, the Gothic entrance of which is ornamented in accordance with that of the main building, but must have been built somewhat later than the 13th century, and several heraldic escutcheons have been removed by either the Turks or Venetians. The middle of the court is now occupied by a fountain, where the Mussulmen perform their ablutions before entering the Mosque. The end of the court is formed by a hall, possessing its own façade and entrance, and which fronts the portal of the church. The Acts of the Council of Nikosia will probably afford some clue to the original destination of this hall, which, however, is met with in all Frank churches of the island. It may be, that in those primæval times it was destined to receive the penitents and keep them apart from the other congregation. Still, the absence of such an arrangement in other churches of the same epoch claims attention. Its floor is divided into three compartments of dissimilar height, as the lateral parts rise above that of the middle, which leads directly to the church. This distinction of the flooring extends also to the church itself, and with the three dissimilar floors correspond three arches, whose pillars are also separate. Two large, square towers are at the north and south extremities of the entrance hall. In the middle of the latter opens a portal, which corresponds with the entrance of the church.

The façade is one of great simplicity, and all the lines of the towers and base are so clearly defined, the rich foliage which adorns them so sharply sculptured, that the scantiness of ornament is hardly perceptible. The portals and lateral doors of the entrance are formed by columns standing behind each other, which are surmounted by a very slender capital, which is only just broad enough to receive the sculptured roses and fern-leaves with which it is adorned. The towers have at their angles little square turrets, which are furnished in their whole length by a prismatic rib. Above the archivolt runs a gable, whose sides are adorned up to the top with knobs, which present a fine relief. The top of the southern tower and the point of the middle gable, &c., exist no more; that part of the building having been ruined by an earthquake in 1491.

At a distance of about six mètres from the portal is the inner façade of the church, entirely of white marble, and of richer ornamentation than the outer one. Its three doors open opposite to those of the outer portal, and lead to the main and the lateral naves. The middle door, which is double the size of the others, has been much injured, but the description of one of the lateral doors supplies all the information required. The upper arcades of the doors are all of the Pointed style; the middle, however, is vaulted in flat, round arches, and in one of the upper apertures a square is visible. A garland of roses in alto-relievo surrounds this square. The inner surface of the vaults represents some leaves of trefoil, which seem to have formed a canopy, under which probably some statues of saints were once placed. Above this first story rests the tympanum and the archivolt. The archivolt, which surmounts the whole, is divided into four circles. Each of these secondary archivolts reposes on a broad leaf, which much resembles a species of arum, a plant to be met with in Cyprus. The inner portion of the arcades is ornamented with garlands in basso-relievo. But the architectural works of the 13th century were of a stern character, and did not permit of that fanciful variation which led in subsequent centuries to a confusion of taste and the rules of art. There, yet, everything seems to have been deeply calculated, everything had its well-ordained plan, and the aspect of those structures was most cheerful and pleasing, notwithstanding the sternness of character which pervaded them.

* From the 'Allgemeine Bauzeitung.'

In its ensemble the Cathedral of Sta. Sophia of Nikosia forms a long nave, whose parts are thus arranged. The entrance hall, has on its anterior end a square, and on its posterior part a round tower; and the central portion, which is divided by the height of the walls of the middle naves into two stories. The apsis, which has buttresses like the nave, is pierced by long windows. Over the lateral naves runs a terrace of 10 feet breadth all around the church; further above, a second platform reaches over the whole middle nave, and concludes the whole structure.

The round tower is furnished with a winding staircase throughout its height, and has five stories, which are marked outward by thick mouldings. It formed part of the old building, but then it reached only to the height of the square towers and the terrace. On the top of the round tower, the Turks have raised two minarets of forty to fifty mètres in height, which overtop all others, and command a vast view of the whole place.

The transverse naves end at this inferior angle in a hexagonal tower, and on their upper corner in a square one, which is less ornamented than that of the portal. The hexagonal tower contains also a winding staircase, and is surmounted by a lantern, at the base of which begins one of those graduated buttresses, which ascend to the upper platform. The middle of the lateral naves was formerly occupied by a large rose window, of which merely the circumference is discernible, as the church has since become a mosque, and the Turks have built it up by masonry work. The choir towards the east forms a semicircle, the ends of which rest on two thick semicircular buttresses. Between these two semicircles, the apsis is supported by six other buttresses, which are divided by mouldings.

The interior of the Cathedral of Nikosia affords less interest than the exterior. It is divided into three naves by two rows of cylindrical columns, the main nave in the middle being nearly twenty mètres broad; the lateral naves ten mètres broad, surround the choir. The number of columns is sixteen; twelve of stone, opposite to the buttresses and the lateral naves, and four of granite around the choir. In the naves there is no trace of wood-carving, neither is there in the altar, pulpit, baptistery, &c. Under the mats and carpets — with which the Turks have covered the whole area—parts of the old stone floor, with numerous French inscriptions and sepulchral tablets are yet to be seen.

The granite columns around the choir have cylindrical capitals. Large leaves, resembling the ancient lotus, expand into scrolls, out of which ivy and vine are projecting. Their ornamentation reminds us of the Corinthian order, as also in the whole combination a tendency towards the antique is unmistakeable. The capitals of the other columns approach the Tuscan and Doric orders. Thus, Sta. Sophia exhibits a strong admixture of classic style, while our capitals of the buildings of the 13th century have already considerably abandoned that character.

Around the central nave runs a small terrace at the height of the columns, which, from distance to distance, is interrupted by staircases. While in most other churches of that date the façade is ornamented by a great rose window, the whole front of the central nave of Sta. Sophia is composed of one large window, which is divided into three compartments, extending from the vault to the top of the door. Six painted windows, covered by an archivolt, occupy the lower story.

Such are the main features of the Cathedral of Cyprus. But if we wish to have an idea how it appeared under the Lusignan Kings, or even under the sway of the Venetian Republic, we must abstract the wooden hoardings and walled-up windows of the Turks, and replace them by stained glass windows. It cannot be supposed, that at an epoch when this brilliant kind of ornamentation pervaded all great works of church architecture, the Cathedral of this kingdom should have been without it; and there are remnants of green and blue glass to be found in the large windows of the second story. The columns of the Cathedral are painted with a white oil-colour up to their capitals, which are relieved by the application of green, yellow, and blue. It is, however, evident that this paint has been either put on recently, or at least renewed; but whether under their present covering another coat of paint exists, could not be ascertained.

## LIGHTNING CONDUCTORS FOR SHIPS.*

By R. B. Forbes.

I have long considered a good lightning conductor for ships a great desideratum, and have employed a good deal of my spare time and money in endeavouring to introduce into our navy, and into our mercantile marine, the conductor of Sir William Snow Harris, which, in the British navy, in the Honourable East India Company's service, and in some of the other navies of Europe, has been adopted; every ship in the British navy has Harris's conductor, and not a pound sterling nor a single life has been lost by lightning since it has been fully adopted. This is a fact which speaks to the humane as well as to that no smaller class who look solely to their own interest.

The Harris conductor has not been used in our navy principally because "there is no appreciation in the navy department for the purchase of a patent right," and it has not been introduced into our mercantile marine because it is too costly.

With a view of bringing into use the same principles at a smaller cost, I turned my attention to a modification of Harris's conductor, and have obtained a patent for it. It consists simply in leaving the masts at or near to the eyes of the lower rigging, and coming down by one of the shrouds on each side, by a system of tubes and sockets in connection with a conductor fixed to the side of the ship. By this process the interior of the ship is avoided, and a simple yet fixed conductor is applied by which the electric fluid is carried off; a ship can be fitted as well afloat as on the stocks, and as well loaded as when empty, and the moderate cost brings it within the range of the *general ideas* of shipowners.

The usual chain or link conductor used in the navy, and in some merchant ships, is good *as far as it goes*, but being very liable to derangement, by reason of the strains and jerks to which it is subject, it is not generally adopted, and does not meet the requirements of a permanent conductor. A copper wire of $\frac{1}{16}$-inch in diameter, is good as far as it goes too, and the same may be said of a wire no larger than a piece of twine, or not larger than sewing silk. A small wire will carry off a small discharge of electricity harmlessly to the mast and ship, but it will fuse in the operation, leaving the mast unprotected. Now, it is desirable to have a conductor permanently fixed to, and incorporated with, the masts and hull of a ship, so that a heavy discharge will be as easily carried off as a small one by a small wire. The conductor which I have patented will do this if it has sufficient surface, and is thoroughly fitted.

I am now only waiting until I can make suitable arrangements with some well-known concern engaged in the manufacture of copper, for the purpose of supplying ships with fixed and reliable conductors, which, if generally adopted, will save many lives and much property.

The underwriters of New York have agreed to make a return of two per cent. of the premium on all ships furnished with suitable lightning conductors; they show a regard for the cause of humanity and for their own interests by making this return; and it is to be hoped that all underwriters will follow this good example. Not that it is the duty of underwriters to encourage these means more than shipowners, but the concession will have the effect to wake up the owners of ships to a sense of their duty in this respect.

* From the 'Scientific American.'

## NOTES OF THE MONTH.

*The General Board of Health.*—Mr. Tom Taylor, barrister-at-law, has been appointed Secretary to the Board, with a salary of 1000*l.* per annum; and Mr. J. F. Campbell, barrister-at-law, Assistant-Secretary, at 600*l.*; Mr. H. Austin, C.E., Consulting Engineer, at 1000*l.*; Mr. Ranger, C.E., Superintending Inspector, at 800*l.* Mr. Rammell and Mr. R. Rawlinson, late Superintending Inspectors, were offered appointments; and have declined. There are to be two Superintending Inspectors. One appointment remains to be made.

*District Surveyor to Parish of Hammersmith.*—Mr. Robert Garland, of Thames Chambers, Adelphi, has been elected by the Magistrates of the County of Middlesex to this office, rendered vacant by the death of his late partner, Mr. James Charles Christopher.

*The Ordnance Survey, Ireland.*—Colonel Hall, R.E., the head of the Ordnance Survey, has been succeeded by Major James at Southampton. Colonel Tucker, late commanding in Dublin, having retired, Captain Leach, now stationed in the Belfast, succeeds him. Captain Barlow, from Enniskillen, succeeds Captain Leach in Belfast. Lieutenant Parsons, from Glasgow, succeeds Captain Barlow at Enniskillen. Captain Leach is now accordingly the senior officer of the Ordnance Survey, Ireland.

*Merthyr Local Board of Health.*—Mr. Henry has been elected Surveyor to the Board, and is to have a salary of 250*l.* a year. There were thirty-two applicants.

*Rio de Janeiro.*—Mr. W. G. Ginty, formerly the Engineer and Manager of the Hydro-Carbon Gas Company, in Manchester, has since his arrival in Rio de Janeiro (to which city he went as Engineer to the Rio de Janeiro Gas Company), received two other appointments. The first is that of Engineer to the New City Canal, and the other that of Engineer to the Praia Grande Gas Company.

*Quicklime in Scotland.*—A large mountain, Zore-More, near Applecross, on the west coast, on being accidentally excavated, presented a substratum of pure quicklime, within five feet of the surface; and by a further excavation, it was ascertained that the whole mountain, except an average surface of 20 feet, consists of lime fit for building and agricultural purposes. On the summit volcanic remains have been found.

*A Willow Dock.*—Such a dock is now being built at La Crosse, Michigan. It is constructed entirely of willow twigs, about 12 feet long, bound in bundles one foot thick, which are so ingeniously arranged and woven together that it is impossible for sand to work out or the water to work in. Each bundle contains about 100 small trees, and it will take 50,000 of these bundles to complete the work. It is said that the willows will sprout and grow, rooting firmly together, thereby forming a living superstructure which will last for ages without the least tendency to decay. Docks like these occur very frequently on the banks of the Rhine in Germany.

*Labourers' Cottages.*—The Bath and West of England Agricultural Society has awarded the premium for the best plans and specifications of labourers' cottages to Mr. Leversedge, of Taunton.

*The Electric Gas.*—The works at Paris are progressing most favourably under the personal inspection of Mr. Shepard, and in a short time this valuable invention will be fairly tested on a large scale at the Hotel des Invalides. The fittings-up are said to be on a most extensive and magnificent scale. Its recommendation for cheapness has been proved at the Napoleon Docks, the works being carried on night and day, and the cost being under one halfpenny per man.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated May* 10.

1046. J. Shepherd, Manchester—Improvements in compound steam-engines

*Dated May* 22.

1133. B. W. Fase, Charles-street, Soho-square—Improved construction of brooch for fastening dresses

*Dated May* 26.

1177. J. Lord, Farnworth, Lancaster—Improvements in the manufacture of articles of ladies' under clothing

*Dated May* 29.

1189. W. Northern, Vauxhall-walk, Lambeth—Improvements in the manufacture of mangers and troughs for stables

*Dated May* 30.

1193. R. Tomlinson, Sale, Chester—Application of a new material or fabric to the manufacture of plasters for medical or surgical purposes

*Dated June* 3.

1235. J. Renton, Bond-street, Vauxhall, and H. Attwood, Holland-street, Blackfriars—Improvement in the manufacture of starch, applicable in part to the solidifying of colours and other substances held in solution or suspension

*Dated June* 5.

1250. L. Brockelbank, Willesden—Improvements in manufacturing lubricating matters

*Dated June* 10.

1281. J. Braithwaite, Gower-street—Improved method of roofing or covering buildings, reservoirs, and other spaces requiring roofs or coverings

*Dated June* 19.

1328. T. M. Fell, King William-street, and W. Cooke, Curzon-street, Hanover-square Improvements in bottles and bottle-stoppers, and in stopping and applying the same

*Dated June* 21.

1358. H. Dembinski, Rue Joubert, Paris—Improvements in heating apparatus

*Dated June* 30.

1438. J. M'Gaffin, Liverpool—Improvements in the manufacture of iron casks and cisterns

*Dated July 1.*

1443. T. R. Harding, Leeds—Improvements in the manufacture of the pins of hackles, combs, and cylinders, used in hackling, combing, and preparing wool, flax, and other fibrous substances, and in the mode of applying them to manufacturing purposes

*Dated July 5.*

1478. J. Venables and A. Mann, Burslem, Stafford—Printing self and other colours in bas-relief or raised work on china, earthenware, glass, parian, stoneware, bricks, blocks, tiles, quarries, hardware, japan, and papier-mache ware

*Dated July 6.*

1479. S. Harvard and J. Womersley, Stoke Holy Cross, Norfolk—Heating crushed seed for making cake, for drying seeds, corn, and other grain, and for feeding mill-stones or other grinding apparatus

1481. J. Arrowsmith, Bilston, Stafford—New or improved method of consuming or suppressing smoke and obtaining motive power therefrom

1483. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in apparatus for breaking in horses. (A communication)

1487. J. H. Johnson, Lincoln's-inn-fields—Improvements in machinery or apparatus for effecting agricultural operations; parts of the said improvements being applicable for the obtainment of motive power for general purposes. (A communication)

1489. J. E. M'Connell, Wolverton, Bucks—Improvements in wheels, axle-boxes, and breaks for railway-carriages

1491. W. Pole, Storey's-gate, Westminster—Improvements in the construction of railways

*Dated July 7.*

1493. W. Lacey, Lozell's-lane, Aston-juxta-Birmingham—New or improved method of making copper rollers, cylinders, and tubes

1494. A. Morison, Inchmichael, Perth—Improved mode of protecting or preserving agricultural and horticultural produce from disease or blight

1495. G. Beard and W. Beard, Cannon-street—Improved needle-depositor

1496. J. Ross, Keighley, York—Improvements in making compounds of chocolate, cocoa, and other ingredients for breakfast, and occasional beverages

1497. A. V. Newton, Chancery-lane—Improved construction of pump for raising and forcing fluids. (A communication)

1498. J. L. Norton, Holland-street, Blackfriars—Improvements in turnstile counting apparatus

1499. J. Ellisdon, Liverpool—Improvements applicable to reading, lounging, and other chairs

1500. H. R. Cottam, Argyle square, King's-cross—Improvements in horse-mangers

*Dated July 8.*

1501. T. Waller, Ratcliff—Improvements in the construction of stoves and other fireplaces

1502. W. Robinson and R. Crighton Manchester—Improvements in machinery or apparatus for rolling metal into suitable shapes or forms

1503. L. Tindall, Scarborough—Improvements in bruising or reducing grain and other substances

1505. Hon. J. Sinclair (commonly called Lord Berriedale), Hill-street—Improvements in the manufacture of paper, and in the production of textile materials

1506. F. L. Bauwens, Pimlico—Improvements in the manufacture of soap

1507. T. S. Whitworth, Salford, Lancaster—Improvements in machinery or apparatus for cutting or shaping wood; parts of which are particularly applicable in the construction of spinning machinery

1508. E. Lord, Todmorden, York—Improvements in machinery for cleaning and carding cotton and other fibrous materials

*Dated July 10.*

1509. D. Beck, Carlton House, Southampton—Improvements in brewing and distilling

1510. S. M. Saxby, South Lambeth—Improvement or improvements in making fast and letting go the cords of window-blinds; which said improvement or improvements may also be applied to the fastening and letting go of ropes, cords, lines, wires, and chains for various other purposes

1511. I. Swindells, Manchester—Improvements in the treatment of wood and vegetable matters for the production of vegetable fibre

1512. G. A. Biddell, Ipswich—Improvements in machines for cutting vegetable and other substances

*Dated July 11.*

1514. E. Wolverson, Aston-juxta-Birmingham—New or improved lock

1516. M. Walker, Horsham, Sussex—Improved construction of cooking-stove

1517. T. R. Harding, Leeds—Improved mode of doffing fibrous materials from hackle cylinders, and gill or porcupine or preparing rollers

1518. C. F. Moore, Portswood-park, Southampton—Improvements in the construction and use of an apparatus, closet or receptacle, to be used instead of a watercloset or other necessary, and which may be either fixed or portable

1519. V. G. A. Cuvier, Seloncourt, France—Improved apparatus, having for its object the combustion of fuel and the utilisation of the gaseous products for heating and other useful metallurgic purposes

*Dated July 12.*

1521. W. Houghton and R. Hoyle, Lancaster—Improvements in machinery for spinning and doubling cotton and other fibrous substances

1522. F. A. Gatty, Accrington, Lancaster—Improvement in the manufacture of printed receipt stamps

1523. M. Townsend, Leicester—Improvements in the manufacture of knitted fabrics

1524. O. Maggs, Bourton, Dorset—Improvements in thrashing-machines

1525. L. Cooke, Sowerby-bridge, York—Improvements in machinery or apparatus for preparing cotton, wool, or other fibrous substances to be spun

1526. J. Knowelden, Church-road, Battersea—Improvements in steam-boiler and other furnaces

1527. T. E. Moore, St. Marylebone—Improvements in apparatus to be used for extinguishing fires

1528. R. Armstrong, Hall-street, City-road, and J. B. Dew, Pentonville—Improved apparatus for consuming smoke

1529. A. J. Loiseau, Paris—Improvements in manufacturing fringes and other plaited fabrics

1530. J. T. Marshall, New York—Improvements in reefing, and furling the sails of ships or other vessels

1532. J. Robertson, Kentish-town—Improvements in the consumption or prevention of smoke

1533. C. D. Gardissal, Boulevard St. Martin, Paris—Stamp-safe

1534. A. E. L. Bellford, Castle-street, Holborn—Improvements in preserving animal substances. (A communication)

*Dated July 13.*

1535. W. Flitcroft, Bolton, Lancaster, and T. Evans, Manchester—Improvements in printing and finishing floor-cloths, or any other fabrics or materials printed in oil colours. (A communication)

1536. A. J. Lane, Surbiton, Surrey—Improvements in breech-loading fire-arms

1537. T. B. Foulkes, Chester—Improvements in the manufacture of self-adjusting gloves

1538. J. Greenwood, Irwell Springs, near Bacup, and R. Smith, Bacup, Lancaster—Improvements in sizeing, stiffening, and finishing textile materials or fabrics

1539. L. Lawson, Paris—Improvements in printing

1540. E. Travis, Oldham, Lancaster—Improvements in machinery or apparatus for indicating and registering the height of water, and also the pressure of steam in steam-boilers or generators

1541. J. Hackett, Derby—New method of fastening the ends of india-rubber elastic cord, and india-rubber elastic web

1542. R. Bodmer, Thavies-inn, Holborn—Application of glass, crystal, or other vitreous material, or of earthenware (ceramique) to certain parts of machinery. (A communication)

1543. J. B. Chauvet, jun., Aix, Provence—New system of anchor

*Dated July 14.*

1545. A. S. Stocker, Poultry—Improvements in axles

1546. W. Bishop, Boston, Lincolnshire—Improvements in machinery or apparatus for ticketing or labelling spools, parcels of the same, or other similar parcels

1547. C. Sewell, Lougton-lodge, Longton-grove, Sydenham—Improvement in spring-hinges for doors and gates

1548. M. Wiburg, Myddleton-square—Improvements in the construction, setting-up, and distribution of types for printing

1549. J. McGaffin, Liverpool—Improvements in the mode of corrugating angular iron

1550. J. McGaffin, Liverpool—Improvements in the construction of iron bridges

1551. J. Derham, Bradford, York—Improved machinery for combing wool and other fibrous substances

1552. A. P. Price, Margate—Improvements in the distillation of wood and of other vegetable substances

1553. J. B. Dechanet and A. D. Sisco, Paris—Improvements in the construction of railway carriages

*Dated July 15.*

1554. E. H. Briadley, Longton, Stafford—Improvements in printing or ornamenting china, earthenware, and glass

1555. J. Taylor, Burnley, Lancaster—Improved clothes-peg. (A communication)

1556. R. Waller, Manchester—Improvements in the manufacture of letters and figures, and of ornamental signboards and other tablets, and in affixing letters, figures, or ornaments to glass

1557. F. V. Guyard, Gravelines, France—Improvements in the electro-telegraphic communications for preventing mischances during the passage of trains on railways

1558. T. Wright, George-yard, Lombard-street—Improvements in the permanent way of railways

1559. J. Ashworth, Turton, Lancaster—Improvements in apparatus to be employed in the construction of the permanent way of railways

1560. T. Summerfield, Birmingham—Manufacture of chromatic glass and glass-faced bricks, which said bricks are applicable to face-work or fronts of buildings, basements, pilasters, stringcourses, door and window heads, modillions, cornices in part or whole, or other purposes where a superior finish and durability are required; a part of which is also applicable to bricks made wholly of clay

1561. W. Hunt, Tipton, Stafford—Improvements in utilising certain compounds produced in the process of galvanising iron, and in the application of the same and similar compounds to certain useful purposes

1562. G. W. Kelsey, Hope Farm, near Folkstone, Kent—Improvements in air-engines

1563. M. F. Wagstaffe, Walcot-place, Lambeth, and J. W. Perkins, Poplar-terrace, Poplar—Improvements in obtaining metals from ores and oxides

1564. J. Spires, Cleveland-street, Fitzroy-square—Improvements applicable to boots and shoes

*Dated July 17.*

1565. J. B. Denton, London—Improved hoes and spuds

1566. T. M. Woodyatt, Kinver Mills, Stafford—Improvement or improvements in consuming or suppressing the smoke of steam-engine boiler and other furnaces

1567. G. North, Lewisham-road, Kent—Improved apparatus to be attached to garments for protecting watches, purses, and other articles from being stolen from the person

1568. W. Warcup, Lyndhurst-villa, Coronation-road, Bristol—Improvements in the construction of springs for carriages and similar purposes

1569. J. Lockhart, Paisley, Renfrew—Improvements in the manufacture of bobbins

1570. J. Fowler, jun., Temple-gate, Bristol—Improvements in draining ploughs

1571. J. Livesey, New Lenton, Nottingham—Improvements in lace machinery, and in fabrics manufactured by such machinery

*Dated July 18.*

1572. J. Barlow, Accrington, Lancaster—Improvements in the mode or method of extracting gluten from wheat or flour, and preparing the residuum for sizeing purposes

1573. H. Hitchins, King William-street, and W. Batley, Dean-street—Combinations of materials suitable for mouldings and medallions, and to be employed as a substitute for wood, gutta-percha, and other like materials

1574. M. C. Hill, Dublin—Improvement in bonnets and in bonnet-frames

1576. R. Hornsby, Grantham, Lincoln—Improvement in the straw-shaking apparatus of thrashing-machines

1577. A. E. L. Bellford, Castle-street, Holborn—New kind of piston. (A communication)

1578. G. Twigg and A. L. Sylvester, Birmingham—Improvements in apparatus or machinery for stamping or pressing metals

1579. P. Cato, Liverpool—Improved trough or manger for holding the provender of horses, cattle, and other animals

1580. W. B. Johnson, Manchester—Improvements in steam-engines

1581. A. Dalgety, Florence-road, Deptford—Improvements in the reduction of friction

1582. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in zincography. (A communication)

1583. S. Mitchell, Dewsbury, York—Improvements in the manufacture of cards for carding wool, cotton, silk, and other fibrous materials

*Dated July 19.*

1584. J. C. Brown, Cheltenham—Improvements in the manufacture of camp-bedsteads

1585. J. Whiteley, J. Slater, and W. H. Crossley, Halifax, York—Improvements in machinery or apparatus for preparing and spinning wool and other fibrous substances

1586. J. Longley, Hunslet-road, Leeds—Machine for turning and finishing tubs, pails, casks, and other wooden vessels of an elliptic, oval, or other eccentric form

1587. W. Ball, Rothwell Kettering, Northampton—Improvements in drills

1588. M. Mitchell, Stoke Newington—Improvement in furnaces having for object the consumption of smoke

1589. F. H. Wenham, Effra-vale, Lodge-bridge, Brixton—Improvements in steam-engines

*Dated July 20.*

1590. J. Sudbury, Halsted, Essex, and S. Wright, Clare, Sussex—Improvements in taps and valves, and in the method of working them for the purpose of regulating the passage of fluids

1591. R. Roberts, Manchester—Improvements in machinery for preparing to be spun cotton and other fibres

1592. J. B. Gillet, Adge (Herault), France—Improvements in capstans, winches, and windlasses

1593. G. Jackson, Manchester—Improvements in the construction of tents

1594. J. Barnes, Church, Lancaster—Improvements in furnaces or fireplaces

1595. F. Whitehead and W. Whitehead, Crayford, Kent—Improvements in safety-lamps

1596. J. Hackett, Derby—Covering india-rubber thread, whether vulcanised or otherwise, with sewing-silk, and with other articles
1597. W. Palliser, Comragh, Waterford—Improvements in projectiles for fire-arms and ordnance generally

*Dated July 21.*

1598. T. Chambers, jun., Colkirk, Norfolk—Improvements in machinery for distributing manure
1600. T. Delabarre and L. Bonnet, Grenelle, Paris—Preservation of meat in its natural state, and without being cooked
1601. A. B. J. Jean and A. A. Hugues, Paris—Improvements in reducing the friction of axles, bearings, or other rotatory rubbing surfaces in machinery
1602. A. V. Newton, Chancery-lane—Improved construction of metallic spring. (A communication)
1603. J. T. Moss, Arundel-street, Strand—Improvements applicable to apparatus for roasting meat and other edible substances
1604. J. Knight, Birmingham, and J. Stubbs, Oldbury, Worcester—Improvement or improvements in the manufacture of bricks, tiles, pipes, and such other articles as are or may be made of clay; which improvement or improvements may also be applied to the manufacture of artificial fuel, and to other mixing and tempering processes
1605. I. Alexandre and A. Sommerville, Birmingham—Improvement or improvements in boots and shoes, and in socks or inner soles for boots and shoes
1609. J. Sedgwick, Lewisham, Kent—Improvements in shipbuilding
1610. M. A. Stevens, West Derby-street, Liverpool—Improvements in bonnets
1611. C. Harratt, Royal Exchange-buildings—Improvements in fastenings for shipbuilding
1612. H. Francis, Strand—Improvement in feeding fuel on to the fire-bars of boiler and other furnaces

*Dated July 22.*

1613. J. Lamb, Newcastle-under-Lyne, Stafford—Improvements in or applicable to machines for making paper. (A communication)
1614. T. Firth, Huddersfield, and J. Wilson, Mirfield, West Riding—Improvements in finishing woollen, worsted, silk, and other woven fabrics, and in the apparatus employed therein
1615. J. H. Young, College-street, Camden-town—Improvements in gathering grain and other crops, and securing the same
1616. W. S. Losh, Wreay Syke, near Carlisle—Improvements in bleaching
1617. J. Bainbridge, Ely-place, Holborn—Improvements in fire-grates, stoves, furnaces, and other similar contrivances
1618. W. Johnson, Lincoln's-inn-fields—Improvements in the treatment, cleansing, and dyeing of fibrous and textile materials. (A communication)
1619. J. Dilks, Parliament-street, Nottingham—Application of printed or painted linen, cotton, or other textile fabric, either plain or ornamental, for binding more effectually than heretofore packets or parcels of lace, hosiery, or other articles

*Dated July 24.*

1620. R. F. Hutchins, Whitechapel-road—Constructing the cylinders or engines worked by steam, air, or other fluid body, in a circular form or plan, by which means more power is obtained from a given quantity of the said fluid body in cases where a circular motion is required than by any other known form of cylinder
1622. J. H. Johnson, Lincoln's-inn-fields—Improvements in the preparation of silk. (A communication from C. L. A. Williott, St. Quentin, France)
1624. G. F. Wilson and G. Payne, Belmont, Vauxhall—Improvements in distilling fatty and oily matters
1625. A. E. L. Bellford, Castle-street, Holborn—Improvements in kneading-machines. (A communication)
1626. B. Cole, jun., Deardsend, Hertford—Improved agricultural machinery or apparatus for ploughing and grubbing

*Dated July 25.*

1627. F. Preston, Manchester—Improvements in machinery for preparing cotton and other fibrous materials
1629. W. Grundy, Bury, Lancaster—Improvements in the manufacture of drugget. (A communication)
1630. E. Hallum, Steckport—Improvements in machines for preparing, spinning, and doubling cotton and other fibrous substances
1632. P. Spence, Pendleton, Lancaster—Improvements in obtaining sulphur from iron pyrites and other substances containing sulphur, and in apparatus for effecting the same
1633. T. Bell and H. Scholefield, South Shields—Improvements in the manufacture of borax
1634. W. S. Garland and J. Glasson, Stafford—Means of consuming smoke in furnaces
1635. J. C. Hurd, Medway, Worcester, U. S.—Improved machine and process for picking, burring, and cleaning cotton, wool, and for tearing up and reducing old fabrics to be re-spun
1636. J. McGaffin, Liverpool—Improvements in constructing and applying heads to metal casks and vessels

*Dated July 26.*

1637. J. Lamacraft, Westbourne-grove—Improvements in envelopes or means for securing letters, notes, and similar documents
1638. J. A. Cutting, Boston, U. S.—Improved process of taking photographic pictures upon glass, and also of beautifying and preserving the same
1639. W. Church and S. A. Goddard, Birmingham—Improvement or improvements in ordnance
1640. A. Oppenheimer, Manchester—Improvements in the manufacture of mohair velvet or mohair plush, and worsted velvet or worsted plush
1641. J. C. Purnelle, Tachbrook-street, Pimlico—Improvements in obtaining and applying motive power
1642. A. E. L. Bellford, Castle-street, Holborn—Improved mill for grinding paint and other moist substances. (A communication from C. W. Brown, Boston, U. S.)
1643. L. C. Koeffler, Rochdale, Lancaster—Improvements in finishing or polishing yarns or threads
1644. E. A. Pontifex, Shoe-lane, and C. Glassford, Ashburnham-grove, Greenwich—Improvements in obtaining soft lead from hard lead, for the separation of the impurities in hard lead, and for the separtion of antimony from these impurities
1645. T. Huckvale, Choice-hill, near Chipping Norton—Improvements in machinery for gathering crops
1646. P. A. Godefroy, King's Mead Cottages, Islington—Improvements in purifying coal, naphtha, and turpentine
1650. A. E. L. Bellford, Castle-street, Holborn—Improvements in soldering metals. (A communication)

*Dated July 27.*

1651. G. Mumby, Hunter-street, Brunswick-square—Improvements in bearings, and in the prevention of friction
1652. R. C. Burleigh, Northumberland-street, Charing-cross—Improvements in guns, and in the shot or other projectiles fired therefrom
1654. F. D. Molvé and P. Martin, Paris—Improvements in heating water for feeding boilers of locomotives and marine steam-engines
1655. S. Varley, Stamford, Lincoln—Improvements in the construction of reaping machinery
1656. W. Shorrocks, Farnworth, Lancaster—Improvements in presser-flyers for preparing cotton and other fibrous substances for spinning
1657. S. Frankham, Greenland-place, Judd-street—Improvement in the construction of furnaces
1658. B. H. Jenks, Bridesburg, U. S.—Improving the art of weaving, being an improvement in looms for weaving fancy fabrics
1659. H. Wickens, Tokenhouse-yard—Improvements in the means of giving signals on railways, and for other purposes
1660. N. Miller and R. Graham, Guide-bridge, Lancaster—Improvements in the construction of certain parts of the permanent way of railways, commonly called crossings
1661. A. Law, Glasgow—Improvements in cranes, or lifting and lowering apparatus

*Dated July 28.*

1662. G. L. Scott and S. Bennett, Manchester—Improvements in springs for pressing together rollers for mangling and other purposes
1663. A. Guild, Salford, and J. Pendlebury, jun., Manchester—Improvements in apparatus for scouring or bleaching
1665. R. Johnson, Manchester—Improvements in coating and insulating wire
1666. F. Morton, Liverpool—Improvements applicable to girders or rafters to be used in the construction of roofs, bridges, buildings, and other erections
1667. A. H. Petit, Paris—Improved mode of joining pipes
1668. S. Clift, Manchester—Improvements in making paper, pasteboard, and papier-mache
1669. J. Gilbertson, Hertford, Herts—Improvement in supplying air in furnaces

*Dated July 29.*

1670. R. J. Keen, Liverpool—Improvements in the mariner's compass
1672. E. Burke, Upper Thames-street, and A. S. Stocker, Poultry—Improvements in the manufacture of metallic tubes and such like articles
1674. W. H. Smith, Bloomsbury—Improvements in the permanent way of railways
1675. G. E. B. Collasson—Improvements in the means of arresting or checking the progress of trains on railways. (A communication)
1676. J. Y. Bourland, Manchester—Improvements in machinery for preparing and spinning fibrous materials
1677. J Fawcett, Gateshead, Durham—Apparatus for regulating and economising the consumption of gas generally, but more particularly when employed for the purposes of illumination
1678. G. H. Ingall, Warnford-court, Throgmorton-street—Improvements in elastic bands for holding books and papers
1681. H. Walduck, Warwick-court, Gray's-inn—Improvements in propelling vessels
1682. G. Thatcher, Welton Midsomer Norton, Somerset—Improvements in the manufacture of woven fabrics, yarns, cordage, ropes, paper, and pasteboard, by the application of a material not hitherto used for such purposes

*Dated July 31.*

1684. H. Adams, Leonidas-terrace, Deptford—Revolving ventilator
1685. H. Green, Liverpool—Improved apparatus applicable to the hanging of doors, gates, and windows, and for closing or holding open the same when required
1686. J. Green and W. Jackson, Leeds—Improvements in mortising-machines
1688. T. R. Bridson, Bolton-le-Moors—Improvements in preparing cotton for manufacturing purposes

*Dated August 1.*

1689. E. Gillman, Twickenham—Improvements in the manufacture of papier-mache and other similar articles from certain vegetable substances
1690. J. F. Bouneau, Paris—Improvements in propelling ships
1691. T. Evans, jun. Belmont-terrace, Lewisham—Improvements in the rigging of ships and all other vessels using or carrying sails, whether propelled by steam or otherwise, or on whatsoever sea, river, or other water navigated
1692. C. R. Read, Moorgate-street—Improvements in slide-valves of steam-engines. (A communication)
1693. J. M'Gaffin, Liverpool—An improvement in the manufacture of sheet-metal pipes
1694. W. E. Newton, Chancery-lane—Improvements in the construction of repeating fire-arms. (A communication)
1695. R. A. Brooman, Fleet-street—Improvements in machinery for dressing flax, hemp, and other like fibrous substances. (A communication)
1696. T. E. Merritt, Maidstone—Improvements in apparatus for taking photographic pictures in the open air
1697. J. S. Holland, Woolwich—Improvements in locks

*Dated August 2.*

1698. J. Griffiths, Wickham market, Suffolk—A new or improved lever bit for horses
1699. S. Lees, Salford—Improvements in machinery or apparatus to used in purifying gas for illumination
1700. G. H. Palmer, Adelaide-road, Hampstead—Improvements in guns, gun carriage, and appurtenances, and in the manipulation or working of guns
1701. C. Chevron, Paris—Improvements in looms for weaving
1702. J. Brown, Stockport—Improvement in the method of consuming smoke
1703. P. G. de Seresina, Bedford-row—Improvements in treating flax and hemp

*Dated August 3.*

1705. W. Rye and W. Crowther, Oldham—Improvements in steam-engines
1707. W. Gossage, Widnes, Lancaster—Improvements in the manufacture of certain kinds of soap and other detergent compounds

*Dated August 4.*

1709. L. P. Miles, Ravensbourne-park, Lewisham—Improvements in the construction of locks.
1711. S. L. Taylor, Cottonend. Bedford—Improvements in constructing and arranging the beaters and dressing machinery of thrashing machines
1713. A. Kortright, James-street, Adelphi—Improvements in marine and surveying compasses

*Dated August 5.*

1715. A. Boissonneau, Paris—Improvements in artificial eyes.
1717. C. F. Stansbury, Cornhill—Improvements in locomotive and steam boiler furnaces. (A communication from J. Amory and W. Parrott, Boston, U.S.)
1719. C. F. Stansbury, Cornhill—Improved air-tight vessels. (A communication from R. Arthur, Washington, U.S.)
1721. J. Gathercole, Eltham, Kent—Improvements in bordering, or producing devices upon the edges of envelopes, letter paper, or other articles of stationery

## PATENTS APPLIED FOR WITH COMPLETE SPECIFICATION.

1606. N. Callan, Maynooth College, Kildare—A means by which iron of every kind may be protected against the action of the weather and of various corroding substances, so that iron thus protected will anwer for roofing, for cisterns, baths, gutters, window frames, telegraphic wires, for marine and various other purposes; and by which brass and copper may be similarly protected—July 21
1607. A. E. L. Bellford, Castle-street, Holborn—Improvements in breech-loading fire-arms.—July 21
1653. W. B. Caulfield, Cole Harbour, Blackwall—The manufacture of brushes to be used in cleaning the small tubes of steam-boilers, and for other purposes.—July 27
1671. P. G. Harris, Buckingham-street, Adelphi—Improvements in locomotive engines. (A communication.)—July 29
1673. E. Burke, Upper Thames-street—Improvements in instruments for withdrawing corks and in uncorking bottles.—July 29
1756. T. Lawrence, Birmingham—Improvements in the manufacture of bayonet blades, and in machinery or apparatus to be employed for that purpose—Aug. 11.

ASHPITEL & WHICHCORD, Architects.

## KIDDERMINSTER BATHS AND WASH-HOUSES.

*(With an Engraving, Plate XXXIII.)*

The borough of Kidderminster contains a population of something under 20,000 souls, and the town council have adopted the Act for the Establishment of Public Baths and Wash-houses; and, after due consideration, have resolved to erect the building represented in our engraving, under the charge of Messrs. Ashpitel and Whichcord, as architects.

We have much pleasure in directing public attention to this building, inasmuch as, while providing the requisite accommodation for a town of moderate size, it is not so large and costly as to induce any fear of it being a burden upon the ratepayers. The unwieldy dimensions, and consequent cost entailed upon many towns, has been the means of paralysing the more general adoption of these valuable institutions; and we have not failed from the first to impress upon our readers the advisability of confining cost within moderate compass.

The Kidderminster plan entirely coincides with this view, and, as will be seen in our illustration, the elevation is neat and modest; but the material is good and substantial, the walls being red brick, and the dressings of the stone of the county, while the brackets and ornamental portion of the cornice are of terra-cotta.

The interior arrangements are, generally speaking, similar to the baths and wash-houses already erected by these architects. As usual, the centre is the pay-office, dividing the entrance for one sex from that of the other. There is one large swimming-bath, 38 feet by 30 feet, and twelve men's ordinary size baths, divided into two classes; also shower-baths and a vapour-bath. The ladies' department is entirely distinct, and consists of a waiting-room, two bath-rooms, and a plunge-bath. The wash-house is also distinct, and has a separate entrance. This part of the establishment is on a small scale. The detail of the arrangements comprise all those improved matters which experience has suggested. The baths are of porcelain (glazed), and the divisions of the baths of slab-slate; in short, all those little minutiæ have been strictly attended to which ensure purity and cleanliness for the bathers, rapidity and economy in the working of the machinery, and a careful attention to make every gallon of water and every ton of coals do their duty.

The building is one story in height, and is, of course, lighted and ventilated from the roof, which is partly of glass. The centre building over the office and waiting-rooms is an exception, being carried up so that the first-floor is the residence of the superintending officer.

The cost of this building, with all its fittings and machinery, will not exceed 2500*l.*

From the best data furnished in reference to the working of these institutions, we may fairly presume that not only will such an establishment be self-supporting, but, if worked with care and judgment, prove to be remunerative. In towns of similar size to Kidderminster, it is found the weekly number of bathers is 1100 in summer, and 450 in the winter months. This is a low average, and would give 775 bathers a week throughout the year. The scale of charges varies from 6*d.* first-class to 2*d.* for a second-class warm bath. Taking the average at 4*d.*, gives a return of 12*l.* 18*s.* 4*d.*, which, with the small amount from the wash-house, would raise the average weekly returns to 14*l.* The expenses would be as follows:—

| | Per annum. £ s. d. | Per week. £ s. d. |
|---|---|---|
| Wages of staff: | | |
| Superintendant and matron, being also money takers — House, &c. | 80 0 0 | |
| Stoker, mechanic | 65 0 0 | |
| Boy to assist | 19 10 0 | |
| First male attendant | 41 12 0 | |
| First female attendant | 39 0 0 | |
| Total wages | 245 2 0 | 4 10 0 |
| Coals, 200 tons | 80 0 0 | |
| Gas | 25 0 0 | |
| Washing towels | 13 12 6 | |
| Printing and stationary | 15 0 0 | |
| Mops, brushes, and brooms | 15 0 0 | |
| Taxes and sundries | 50 0 0 | |
| | 198 12 6 | 3 16 0 |
| Total cost per week | | £8 6 0 |

Which, being deducted from the returns, would give an excess of receipts over expenditure of 5*l.* weekly, or something like 10 per cent. We have much pleasure in being able to offer the above calculations, as they are the result of existing facts.

No one now doubts the value of these salutary institutions; and the only reason we can conceive why they have not become more general, is the fear of rates and consequent opposition of ratepayers. But experience has now proved, that where due economy is used in the first erection; where the machinery and fittings are durable and of the most appropriate kind, and, consequently, the most economical; where the buildings are so contrived that the least amount of attendants' labour is required; and where careful attention has been given to those parts of the establishment implying the daily consumption of coal and water, so as to ensure the best machinery for the economical use of both,—when these matters are attended to, and done well, then there is no doubt of entire success.

## THE HOUSES OF PARLIAMENT.

*Tenth Report of the Commissioners on the Fine Arts, to the Queen.*

The series of eight Fresco-paintings in the Upper Waiting Hall is now completed. In first proposing that the apartment should be decorated with paintings executed in that method, we observed, viz., in our report of the 7th of August 1845, that we were "desirous to afford opportunities for the further practice of Fresco-painting, and for the cultivation of the style of design which is fitted for it, * * * provided the architectural arrangements and the light should, on the completion of the apartment, be found to be adapted for the purpose." The room was ultimately found to be but scantily lighted, but we conceived that, as the paintings would admit of being closely inspected, that objection was in itself less important; while, on the other hand, it might not be without its use experimentally, by suggesting a treatment adapted to such a condition.

We have now to add that, apart from the important objects, more or less attained in the designs referred to, of appropriate conception and expression in reference to the subjects, these experimental works will be of use in showing what are the external qualities generally essential in Fresco-painting, and especially so under given local circumstances. It will be for artists to consider, in witnessing the effect of these works, to what extent the great requisite of distinctness, as resulting, in its perfection, from intelligible forms, perspicuous arrangement, and the judicious distribution of light and dark masses, has or has not been kept in view, subject to the local conditions of light, the size of the apartment, and the dimensions of the paintings; and subject to the general technical conditions of Fresco-painting, —a method requiring, from its comparatively limited resources, an especial attention to simplicity and significance in representation.

In the House of Lords, eleven of the eighteen metal statues of Barons and Prelates are now placed in the niches intended to receive them. The seven remaining statues are the only works, coming under our superintendence, now to be completed for this chamber.*

In St. Stephen's Hall, without as yet contemplating the execution of the Frescoes intended for that locality, we propose that the series of twelve marble statues of eminent statesmen named in our fourth report, bearing date the 25th of April 1845, should be gradually completed. Accordingly, in addition to the three already executed and placed in the Hall, we have given commissions to five artists to execute each a statue of one of such personages.

With regard to the Prince's Chamber, which we propose to decorate with statues, bas-reliefs, and other works, as detailed in our seventh report, dated the 13th July 1847, we have commissioned John Gibson, R.A., to execute a statue of your Majesty, with figures of Justice and Clemency, and with bas-reliefs on the pedestal, to be placed in the recess on the north side of the apartment. We have also employed Mr. William Theed to prepare a series of bas-reliefs, to be subsequently cast in metal, for the panels on the walls.

Of the Frescoes intended for your Majesty's Robing Room, undertaken by William Dyce, R.A., and illustrative of the

* See Journal, *ante* p. 85, for an "Account of the Amount of all Commissions for Works of Art to various Artists for the Decoration of the New Palace of Westminster, from its commencement to the present time."

Legend of King Arthur, as proposed in our seventh report, four have been completed. As it appears that the artist will now be enabled to devote his whole time to these works, they will, it is hoped, in future proceed more rapidly. With respect to the four paintings referred to, we consider them altogether satisfactory, whether regarded in their general treatment, or as examples of the method of Fresco-painting.

We have commissioned John Rogers Herbert, R.A., to prepare a series of designs for Frescoes to be executed in the Peer's Robing Room, according to a scheme also indicated in our seventh report. The room itself is not yet built, and it is therefore expected that the artist's designs will be completed by the time the walls are in a fit state to receive Frescoes.

We have also given our attention to the decoration of the principal corridors connecting the Central Hall with the two Houses of Parliament. We have accordingly commissioned Edward Matthew Ward, A.R.A., to undertake the Commons' Corridor, and Charles West Cope, R.A., to undertake the Peers' Corridor. The subjects intended for these localities are enumerated in our seventh report, in which it is also proposed that the pictures should be painted in oil.

We further propose to commission Daniel Maclise, R.A., to paint in fresco, in the Painted Chamber or Conference Hall, the subject of the marriage of Strongbow and Eva, the subject being one of the series selected by us for that apartment. The design for the Fresco so proposed to be executed will be adapted, according to the requirements of Fresco, from an oil picture of the same subject executed by the artist on his own account, and which he has treated with great ability.

In our last report, dated the 11th of March 1850, we stated that the Lords Commissioners of your Majesty's Treasury had consented to propose to Parliament an annual expenditure amounting to four thousand pounds to defray the cost of the various works recommended by us. Since that period we have, with the sanction of their lordships, continued to submit to Parliament an annual estimate accordingly. The limitation of the expenditure as stated may however be regarded as a cause of delay in the prosecution of some of the works.

---

Lord Palmerston has notified that her Majesty approves of the Report, and has directed the Lords Commissioners of the Treasury to submit to Parliament estimates in conformity with the recommendations contained therein.

## ON THE EMPLOYMENT OF A SOLUTION OF STARCH IN FRESCO PAINTING.

By W. Dyce, R.A.

TO SIR C. L. EASTLAKE, P.R.A., SECRETARY FINE ARTS COMMISSION.

In some observations on fresco addressed by me to the Commissioners on the Fine Arts in 1846, and printed by them in their Seventh Report, I had occasion to refer to the difficulties experienced by fresco painters in the use of ultramarine and some other pigments; and I suggested that if a solution of starch or of the caseous element of milk were mixed with the colours, their adherence to the intonaco might probably be reckoned upon with certainty. This was a mere suggestion based on the known fact that both these substances form, with quicklime, a compound which, when it is dry, is insoluble in water.

Since that time, however, I have had ample opportunity of submitting one of the suggested expedients to the test of experiment, and the result has been so satisfactory that I think it desirable to put the commissioners in possession of the fact, to be recorded for the benefit of future painters in fresco.

If either of the suggested expedients was likely to answer, it seemed to me that the use of starch would present fewest difficulties of manipulation; I accordingly tried it first, and with so successful a result that I have thought it useless to attempt the employment of *caseine*; but I may mention that since my suggestion respecting it was made, a Scottish gentlemen has discovered and obtained a patent for a process of calico printing by means of a vehicle prepared from caseine and quicklime, which probably might be employed in fresco painting for the purposes which I have attained by the use of a solution of starch. This vehicle is prepared by dissolving caseine in the liquid ammonia of commerce, and adding to the solution a certain proportion of quicklime, the mixture then being diluted with water to any required consistency; and the inventor of the process (who entered into communication with me partly in consequence of the suggestions I had made in the paper referred to) thinks if his vehicle were employed in fresco-painting and mixed with all the colours, it would not be necessary to prepare the intonaco day by day, and, provided some expedient were adopted to keep it in a damp state, that even large pictures might be executed without, or at most with very few, joinings in the plaster.

This, however, I have not tried; partly from want of time, but chiefly because the more simple vehicle of a weak solution of starch, if it would not answer the same purpose, at least accomplishes the more limited object I had in view so perfectly, as to leave little to desire.

The use of ultramarine in a nearly pure state, hitherto the *crux* of fresco painters, presents, when the pigment is combined with a weak solution of starch, no difficulty whatever. It may be applied with tolerable certainty of effect even when the intonaco has become, as it does at the end of a day, hard and partially crystallised at the surface.

These conditions, however, must be attended to. In the first place the solution must be so weak that when cold it shall scarcely assume the form of a jelly.

Secondly, it must be used on the day on which it is prepared. On the second day it undergoes some change (I do not know what), which has the effect of causing the colours mixed with it to dry in streaks or blotches. If the same tint, therefore, has to be used on consecutive days, it must be prepared before hand with water, and the vehicle added only to so much of the pigment as may be required for the day's work.

Thirdly, the effect of the vehicle in fixing the colours cannot be depended upon with certainty unless the pigments contain a small portion of lime. This may seem to be an obstacle to the employment of colours in a perfectly pure state, but in practice this is of little consequence: in the first place because such a pigment as ultramarine (with which I am chiefly now concerned) can scarcely, except in minor details, be used with good effect in a pure state; and secondly, because the quantity of lime sufficient to insure the combination on which the action of the vehicle depends, is so small as hardly to affect the purity of the tint to any appreciable extent; and besides, the trifling loss of depth occasioned by the admixture of white may be easily corrected by the addition of black, which, though it imparts a certain greyness to the tint when it is wet, does not affect its blueness when the plaster is dry.

In preparing a tint of ultramarine in which the pigment is to be used in as pure a state as may be, I first make up the required tint with the least possible quantity of water; it is then diluted with the solution of starch to the proper consistency, and a small portion of lime added to it. The addition of the lime has the immediate effect of curdling or imperfectly solidifying the mixture. To remove this it must be triturated in a mortar, worked with the palette-knife on a slab, or, which generally is sufficient, stirred for some time with a stiff brush until the consistency of cream is attained. If the proper degree of fluidity should not be restored, a little water may be added.

It is, of course, desirable that the adherence of pigments with which starch has been mixed should in all cases depend on the chemical combination of the starch and lime; but it is certain that to a limited extent the glutinous quality of starch is sufficient of itself to secure the adherence of the colour under circumstances in which little or no chemical action can take place. As for instance, at the end of a day when the intonaco has become quite hard on the surface, I have found small touches and washes of pure colour (such as ultramarine or the transparent oxide of chromium unmixed with white) to adhere perfectly if applied with the solution of starch, which if applied with the water only would have dried on the surface of the intonaco in the form of powder.

On the durability of the process it is premature to express any opinion, as my experience only extends over three or four years; but as yet I am unable to trace in those portions of the frescoes in the Queen's Robing-room painted by means of it, the least symptom of that whitened, bleached, and inharmonious look which makes its appearance in blues, painted in the old way, almost before the paint has become dry.*

*The Oaks, Norwood, November* 21, 1853. W. Dyce.

* Accompanying the above paper in the Commissioners' Report is another, bearing upon the same subject, "On Silica, and some of its Applications to the Arts," by Rev. J. Barlow, M.A. This paper will be found at p. 382 of our present Number.

## OPENING OF ST. GEORGE'S-HALL, LIVERPOOL.*

This majestic structure, which may fearlessly challenge comparison with the old glory of the classic temples of Greece or Rome, was inaugurated on the 18th ult. with a ceremony befitting the interest of the occasion. While we regret the absence of royalty, as unfortunate in its immediate effects on the proceedings, we congratulate the town on the fact that the great hall has in itself elements which will make its inauguration more memorable than if it relied only on the more transient advantages of her Majesty's presence. To the young architect, Mr. Elmes, whose delicate constitution broke down under the gigantic undertaking to which he had given birth; to Mr. Cockerell, his adviser and friend, who has since that event directed and superintended the construction of the building, preparing designs when they were required, and perfecting in some instances the crude plans of Mr. Elmes; and to the St. George's-hall committee, with Mr. J. B. Lloyd as the most zealous and untiring member of it, the inhabitants of Liverpool are indebted for the erection and construction of this magnificent edifice, which, in the face of difficulties that would have been insurmountable by men of ordinary capacity, has been erected and well-nigh finished in the unexampled short space of fourteen years. There is, we believe, no other instance on record in which a building of such magnificent proportions, of such external boldness of execution, and internal elaborate profusion of ornament, has progressed with so much rapidity. It is, however, greatly to be regretted, that Mr. Elmes did not live to witness this triumph of his genius. One great mistake, in particular, would have been avoided. He would never have permitted the erection of an organ at the end of the large hall, blocking up the entrance to the Nisi Prius court, and thus deplorably interfering with the grandeur of the effect which would have been produced by the whole length of the building being open to the glance. The mistake, however, has now been made, and there seems to be little chance of rectifying it.

Another inconvenience which would have been prevented, had it pleased Providence to spare the life of Mr. Elmes, is the claim by another artist to the design of St. George's-hall. During Mr. Elmes' practice in London, he tenanted chambers with Mr. Bardwell, of Queen-street, Westminster, who, for the last four or years, has persisted in alleging that Mr. Elmes stole from him the entire design, with the exception of the present roof, which he substituted for a dome. This assertion has been renewed by Mr. Bardwell within the last few days, in a letter to Mr. Joseph Boult, in which he states that, before St. George's-hall was contemplated, he sent in designs for the Fitzwilliam Museum, at Cambridge; that the committee of taste having called in Mr. Cockerell, that gentlemen gave the preference to a design by Mr. Basevi; that this design was, therefore, accepted, and that Mr. Bardwell's was sent home; that Mr. Elmes saw and admired it; and that, in point of fact, he copied it, with the exception of the dome, which he replaced by the present roof. It will be remembered that Mr. Bardwell sent his model to the Great Exhibition of 1851, and affixed to it these words:—"Parent of St. George's-hall, Liverpool;" and it is said that Mr. Earle wrote for an explanation; that he got it, but never made it public; and that, in consequence, Mr. Bardwell has appealed at this telling time to the architects of Liverpool.

We are informed that Mr. Boult, one of the secretaries of the Liverpool Architectural Society, knowing that Mr. Rawlinson, the civil engineer, enjoyed Mr. Elmes' intimacy, sent him a copy of Mr. Bardwell's letter, and that Mr. Rawlinson in reply expressed his conviction that Mr. Bardwell's claim was not well founded, and that he did not believe he was entitled to the honour he coveted. The correspondence is in the hands of Mr. Boult, and will no doubt form the subject of some discussion, either before the Architectural Society or in the public prints. It has been suggested, we believe, that Mr. Bardwell should bring his model to Liverpool, and exhibit it at a meeting of the Architectural Society. Our own impression, backed by that of professional gentlemen of experience, is, that there may be some similarity between the designs, but that it is entirely accidental. The matter is certainly deserving of the closest inquiry, an inquiry, however, in which some attention should be made to the lamented fact, that the accused is not here to defend himself. It is somewhat strange that Mr. Bardwell permitted his injuries, for injuries he had if his statement be true, to lie dormant until after Mr. Elmes' death.

As a mass of building, St. George's-hall is, perhaps, the finest specimen of architecture produced in modern times. It is constructed by a legitimate application of the principles of the Corinthian order, having a fine dipteral or double portico of eight columns in front and four within, at the south end; a grand colonnade on the east side, which is pseudo-dipteral or with the depth of two columniations, but with only one rank of columns; and a circular portico of eight columns at the north end. These last are attached to piers; and the west front, or back, as some persons might call it, is columnar in character; these columns, like the semi-columns or antæ on the opposite side, being square. The whole building is a parallelogram more than 300 feet long, with lateral projections on each side of the central portion, which is occupied by what is strictly to be called St. George's-hall, while the north and south ends comprise respectively the civil and crown courts. But before we take our readers inside we must dwell a little on the exterior. The portico at the south end rises from a platform or base of sixteen steps, which have been doubled in depth, by reduction in number to one-half at the corners, to give a massive appearance, more in accordance with the great size of the columns, than the more convenient steps for ascent in the centre and at the sides. The pediment is filled with an elaborate composition of figures intended to represent Great Britain or Britannia, attended by Liverpool and the River Mersey, receiving the tribute of the world, through the intervention of Commerce, Science, and Art. This *groupe* was designed by Mr. Cockerell.

Unfortunately, Mr. Elmes did not leave detailed drawings, and it is difficult to understand, amongst other things, how he would have proposed to get over the inequalities of the site, being on the slope of a hill. For instance, the steps of the south portico terminate on a terrace, at a considerable height above the street; and a temporary, for we hope it is only a temporary means of access, has been provided by two obscure flights of narrow steps, cut to the right and left, out of the substance of the terrace or lower platform, the entrance to which is closed by elaborate bronzed iron railing and gateway, with two polished red granite gateposts of very peculiar shape. The east colonnade, or portico, is raised by nine or ten steps above the lower platform, which is again raised by a similar number of steps above the base-court. This platform, or terrace, extends round the south-end and the east side of the central portion of the building, and Mr. Cockerell has placed two pedestals on each side of the south portico, on a line with the columns of the east side, "to complete the geometrical form of the building," and he has surrounded the south end by a commonplace balustrade, of the shape almost universally adopted. One of the angles of this terrace is formed by a massive red granite pedestal, but unpolished, and on which the architect has suggested a piece of sculpture may be placed. The east side of the north and south portions of the building is formed by square columns, closed about one-third of their height up by a panelled wall, affording spaces for statues on the top between the columns; and square blocks on the face to be carved into artistic decoration. The depth of the portico on this side has been partly obtained by recessing it into the body of the edifice. There are three doorways in it, corresponding with three entrances into the great hall, and communicating by means of the corridor, which extends nearly the whole length of the building, to the Courts of Law. There is no pediment to this portico, which would, perhaps, be more strictly termed a colonnade, but it is only surmounted by the architrave and entablature which extend round the structure. Above this main mass there rises a small attic story, and within that again another larger attic story, if we can be justified in calling both these portions by that name.

The exterior, taken as a whole, is Grecian Anglicised—that is, the Grecian type is to some extent adapted to the exigencies of this climate, and the requirements of the present age. In the eastern and southern fronts the treatment is more severely classical than in the northern and western; windows are almost entirely excluded, the rooms on that side (chiefly used as ante-rooms) being lighted from above; the only exceptions are two four-light windows in the east portico, but these are so treated that they entirely harmonise with the prevailing sentiment. We are aware that the isolated antis, or square columns, are exceptional with rigid classicalists, but their use in this instance seems justified by their position in the line of a wall, and by the contrast they present to the fluted circular columns of the porticoes.

* A description, with engravings of the St. George's Hall, will be found in the Journal for 1843, Vol. VI. p. 330. The descriptive particulars in our present Number we have abridged from the 'Liverpool Albion,' and the 'Liverpool Mercury.'

In the other parts windows are freely introduced wherever they are requisite; so that there is an agreeable variety in the composition of the whole, no two views of the building being similar. Mr. Huggins has made some excellent remarks upon the increased effect that this edifice will gain by the liberal introduction of sculpture: his suggestions will be found at the end of the present paper.

If we turn to precedent, we find that the Greeks represented their Public Games and Incidents combined with manners and customs which were familiar to the whole people; the myths of all their deities were "familiar as household words," and required no handbooks for their explanation. With us they are *caviare* to to the multitude: it is the scholar only by whom they are really appreciated. Is, then, the pleasure of many to bend to a few? And is the revival of the arts to be still further delayed by continually disgusting the public at large with unpolite reminders of their want of classical cultivation? There is some hope that other tastes will in time prevail, and that when the plaster casts in the north vestibule have fulfilled their temporary purpose, they will be supplied by bassi relievi, in which English people generally can feel interested, and comprehend without the aid of an interpreter. Mr. Cockerell's taste is so scholarly and classical that he is apt to overlook the distance that separates him from the general public, and, perhaps, rather to contemn the feeling that would cater to their unclassical culture. But he does his own ability great injustice when he so restricts the circle of his admirers, and also deprives many of that refined enjoyment he is so well qualified to give. It is not likely that commercial men will feel complimented by the frequent introduction of Mercury and his emblems, when they learn that he was the patron of thieves as well as of merchants, which seems to imply that one sort of men is just as good as another. The lictor's rod, when shorn of its authoritative axe, seems likely to remind the profane vulgar of a chimney-sweeper's machine, and to excite amusement rather than respect. And even cultivated Englishmen, unless ultra-scholars, may rebel against the monogram "S.P.Q.L.," inasmuch as they may think modern Liverpool, though not an empire city, is in many respects superior to ancient Rome; and that, as the British empire lives in active energy, she should impress her distinctive character on the monuments she bequeaths to history.

### *Description of the Interior.*

On entering the building through the principal entrance in the east portico, and turning to the right along the eastern corridor, the three rooms on the right hand are for witnesses, and adjoining them on the north is a retiring room for the jury; then the vestibule of the north entrance, in which is a descent of several steps, giving access from three doors on the level of the street, on the right and left of which are cloak-rooms, under the floor of the upper vestibule. This vestibule is in the shape or plan called horse-shoe; that is, it consists of a large semicircle with the addition of a small parallelogram, the semicircle being outwards; round the interior of the semicircle is a gallery on the level of the upper floor of the vestibule, the rest of the area being occupied by the steps and "crush-room." The vestibule is finished in an extremely simple manner, the order introduced is Doric, freely treated, the wall spaces between the pilasters decorated with casts of bassi-relievi after the Elgin marbles. From this vestibule are two staircases giving access to the small concert-room, which is small in comparison with the great hall, but is calculated to accommodate an audience of 1200 or 1500 persons. This room is over the vestibule and of the same shape, the orchestra being placed on the straight side. The room is to be fitted up with seats on the floor and in boxes, but is unfinished.

Returning to the principal floor, and entering the western corridor, the first room on the right hand, after leaving the north vestibule, is the under-sheriff's room, then the prothonotary's office, a retiring-room for solicitors, a room for the clerks of barristers and solicitors, a retiring-room for the jury, the court of the vice-chancellor of the Duchy of Lancaster, 29 ft. 6 in. by 23 ft., with a retiring-room; a robing-room for barristers; the library, 41 ft. by 23 ft., a second robing-room for barristers; the sheriff's court, 29 ft. 6 in. by 23 ft., with retiring-room; a retiring-room for the jury, the crown-office, office for the clerks of the crown and peace—a room for arbitrations bringing us to the south-west angle of the building. Then proceeding through a handsome staircase, we enter the south vestibule, having access through one large door into the south portico. Passing through the vestibule we enter another staircase, in which is the muniment-room, entered through a retiring-room; and again entering the eastern corridor, we find three witness-rooms, corresponding with those at the north end of the same corridor. The centre of the building is occupied by the great hall, with the civil court to the north, and the crown court to the south, each court being provided with the usual retiring-room for the presiding judge. The courts and hall are of course entered from the corridors, as also the judges' retiring-rooms. If now we return to the staircase in the south-east corner, and ascend to the upper floor, we find the retiring-room for the grand jury at the top of the stairs, and the grand jury-room over the south vestibule. Passing through this room we come to the staircase in the south-west angle, out of which is a waiting-room for witnesses in attendance upon the grand jury, and then, proceeding along the western corridor, we have on the left hand a store-room, the high-sheriff's room, committee-room, or room for arbitrations, the office for the clerk of prosecutions at sessions; and at the north end of this corridor four retiring-rooms in connection with the smaller concert-room, the centre portion of this corridor forming the western gallery of the hall. In the basement on the west side of the building, beginning at the south end, are two rooms for gaolers, and four rooms for the housekeeper. Then the culinary department, including butler's pantry, larder, wine cellar, and extensive accommodation for cooking, furnished with two large hoists to raise the dinner to the western corridor for conveyance into the hall. At the north end of the basement are six rooms for the keeper of the court. Near each end of the basement is a hydrant immediately connected with the main from the reservoir.

In the sub-basement are thirteen cells for prisoners awaiting trial, one of which is appropriated to the gas-meter of the great hall; a kitchen for the turnkeys, lumber-rooms, and cellars for fuel, &c. Without the building, at this level, is a carriage porch, with gates at each end. During the assizes the prisoners for trial are brought in the van each morning from Kirkdale, and entering this porch at the south end, the gates are secured before the door of the van is unbarred. The prisoners are then disposed in their several cells, which are fitted up with every requisite, including a bell to which a signal-plate is attached. Should a prisoner require attention, he pulls his bell, and the signal-plate flies out from the wall, and enables the attendant to see at once in which cell he is required. In connection with the dock, in the court, is a staircase communicating with the basement of the building, by which the prisoners are led in as their cases are called on; and in order to prevent loss of time by having to fetch each prisoner from his cell, as required, there is a waiting-room attached to these stairs, where those immediately in succession to the one in court are kept in readiness.

The whole of the basement and sub-basement to the east of the western corridor, with the exception of stairs to the docks and the waiting-rooms for prisoners, is appropriated to Dr. Reid, whose ventilating and warming apparatus, with furnaces and steam-engine, occupy a great part of the basement, where there is also another steam-engine to blow the organ.

### *The Hall.*

Returning to the east entrance, it is to be regretted that this, the principal approach to the interior of an edifice of such importance, should be so meagre internally. The utter absence of any vestibule forms a marked contrast with the two secondary entrances at the north and south ends, which, especially the former, are as spacious and imposing internally, as the sudden admission into the east corridor from the central entrance is the reverse. Such an arrangement necessarily impresses the observer that the ground is too confined in depth for the edifice which is placed upon it; and he cannot but regret that the area in front was not a little more contracted, as the abstraction of the space requisite for a handsome vestibule would scarcely be observable in so large a piece of ground, besides that additional comfort would have been given by the vestibule to the hall. From the central portico admission is gained by three doors into the corridor, and thence by three other doors *vis-a-vis* into the hall, which is entered upon a platform, surrounding the interior of the magnificent apartment, at a level of 18 inches above its true floor. This difference of level appears to be made for the purposes of ventilation, as the riser of the platform is formed of cast-iron diagonal tracery. The length of the hall is 169 feet, from north to south, including the recesses at each end, the width 74 feet, exclusive of the galleries, which are constructed over the east and west corridors, and 13 feet in depth, making the total width at this level 100 feet. On each side of the hall are six columns of polished porphyry from Peterhead, dividing the length into five compartments; from the entablature on these columns springs the vaulted ceiling, which is in one span, from column to column, across the hall. The galleries are divided into *quasi* boxes by massive piers built behind each column to form the abutment of the vault, which is constructed of hollow bricks, at the suggestion of Mr. Rawlinson, C.E., of London. The great vault is intersected on each side by lateral arches, springing from pillar to pillar across the front of the galleries, giving more loftiness to the design,, and concentrating the thrust of the arch upon the columns and their massive abutments. Both the main vault and lateral arches are semicircles in section.

The arched ceiling, 84 feet above the ground, is formed of plaster upon the brick vaulting. Above the crown of the lateral arches the ceiling of the main vault is divided into three great divisions in the circumference of the arch, and into five great divisions in its length; thus forming fifteen primary compartments in the whole ceiling. Each of these is again subdivided according to a general design, which consists of a small square panel, containing a golden star in each angle of the primary divisions. Between these four small panels are oblong ornamented panels. The upper horizontal panel is filled with mouldings intersecting diagonally; the ground of the lozenge so formed is the brick vault, the perforations of the hollow bricks relieving the heaviness of the flat surface. The lower horizontal panel contains mermaids carrying lyres or blowing conch shells, on either side of a mask or the head of a trident. The two vertical panels contain the caduceus or a lictor's rod, both terminated in enriched finials. The centre of each primary compartment is filled with a coat of arms or the device of St. George and the Dragon: in the central compartment are the royal arms, flanked east and west by the arms of the county of Lancaster; north and south of the royal arms are the county arms, flanked by the arms of the borough of Liverpool; and north and south of the county arms are the borough arms, flanked by St. George and Dragon. The mouldings of the panels are enriched in various ways, chiefly with the guilloche and egg-and-dart. The effect of the ceiling above the crown of the lateral arches is extremely pleasing, that effect being greatly augmented by the judicious yet sparing introduction of colour (light cobalt blue) as the ground of the panel, and gilding and colouring in the arms and devices.

At the intersections of the lateral arches are the prows of vessels, on the antique model, from which are suspended the gas pendants for lighting the hall; and the spandrels of these arches are filled with allegorical female figures of colossal size, said to represent the Virtues. Below these is the entablature of the polished porphyry columns, the caps of which are of plaster; painted in imitation of the porphyry; the curvilinear frieze of the entablature is also painted porphyry, which seems rather erroneous, since it subjects the painter to an unequal competition with nature, or throws suspicion upon the genuineness of the natural production. The columns stand upon a dado of red and blue granite, all polished, and continued round the hall, the combination of colours very agreeable. In the wall at the back of the boxes, on the west side, are large windows, rising nearly to the entablature; above the entablature the semicircular space included within the arch is divided into compartments, containing in the centre arch the arms of Liverpool, modelled in plaster; in the arch north and south of this is the device of St. George and the Dragon; and north and south of these the county arms, and under each coat of arms or device is the monogram "S.P.Q.L." ["Senatus Populus Que Liverpooliensis"] in a wreath of oak leaves. The arched recesses on the east side are similar except that there are no windows, the plaster on the wall being divided into horizontal rustications.

Between the piers built behind the columns is a balustrade in front of the gallery, which is constructed of square dies of green marble, with moulded balusters of alabaster, or Derbyshire spar, and a hand-rail of black marble. Below this balustrade the wall space is occupied, in three compartments on each side, by handsome brass doors of elaborate design, with a niche on either side of each. On the south of the central west door is Noble's fine statue of Sir Robert Peel. The figure is erect in the attitude of speech, dressed in the well-known frock coat, relieved by the drapery of a cloak. In the other two compartments, on each side, the wall space is divided into three niches, one square and two semicircular; the backs of the square niches are formed of green marble. In the southern square niche on the west side is Gibson's statue of George Stephenson, who is represented sitting, and the likeness is more correct than in Baily's statue at Euston-square. These statues show how much such accessories will add to the splendour and interest of the hall.

Every available spot within the hall has been painted or filled with coloured material. Much remains yet to be done, and it will be difficult to form an opinion of the general effect until it is more nearly completed, and the scaffolding and other working appliances removed. The width of the hall is about 75 feet. The five windows on the west side are 18 feet high, and 8 feet 6 inches in width, and there are two semicircular windows at the ends, 33 by 17 feet. It is contemplated to fill these with stained glass, and designs were sent in by various parties. The first prize was awarded to Mr. Miller, of London; and the second to Messrs. Pilkington, of St. Helens. The latter gentlemen applied to Mr. Frank Howard for designs, and he proposed to fill one semicircle with an illustration of the Law, and the other with an illustration of the Arts; the window facing the central entrance with a St. George and the Dragon, occupying the whole space; Commerce and Industry in the side windows; and in the intermediate windows an ornamental design, admitting medallions of Mr. Elmes, the architect, Roscoe, Canning, Huskisson, and other distinguished men connected with the town. What will be done is not yet determined; but temporary glazing of sufficiently hideous character has been adopted.

At each end of the hall is a semicircular-headed recess, square on plan, and the width of the great vault: that at the south is finished with columns of porphyry, similar to those which carry the lateral arches, and a screen of smaller columns of grey granite, and handsome brass tracery, similar to the doors; this screen divides the hall from the crown court. The recess at the north end was to have been finished in the same way, but as no place had been provided for the organ, it is here erected, and the two porphyry colums have been removed to the exterior of the building, and are erected opposite the railway station—their alleged purpose being to carry lamps.

### *The Floor.*

The floor is composed of encaustic tiles, manufactured by Messrs. Minton, Hollins, and Co., of Stoke-upon-Trent, and is the largest pavement of the kind in existence. The design is very elaborate, but has been very successfully carried out, although it presented great difficulties of a technical character. It is difficult to give a correct idea of the design by a comparison with any other, ancient or modern; and although there are many fine examples of tile paving in the churches and palaces on the continent, and in some of our own cathedrals and conventual churches, yet they cannot be quoted for the purpose of conveying a true idea of the pavement in St. George's Hall, whether as regards its great size, the arrangement of the design, or, especially, as regards its colouring.

The antique practice of tile making, as appears from the existing remains of ancient works, confined the manufacturer to the use of few colours or tints. The method commonly used seems to have been this:—A piece of well-tempered clay having been prepared of a proper size (usually about 6 inches square, and 1 inch in thickness), a die, having some ornament in relievo, was pressed upon it; the indented pattern thus produced was then filled in with clay of some other colour, generally white; the tile was then covered with a metallic glaze, which imparted to the ground (usually red) a deeper and richer colour, and gave the white ornament a yellowish hue. These tiles were often arranged in sets of 4, 16, or more, and were intersected with bands of plain tiles, of a self-colour, such as black, red, and white, and frequently displayed great geometrical skill and beauty of effect. Good examples may be seen in the churches of St. Denis and St. Omer, in France, and specimens from the abbeys of Juvaulx, Westminster, and other buildings in England. The modern process of encaustic tile making, as adopted by Messrs. Minton, Hollins, and Co., enables them to produce not only a far greater variety and brilliancy of colour in the general effect of a pavement, but admits of several colours being placed upon a single tile, thus producing the soft effect of fine mosaic work, in a much more durable and less expensive material.

The extreme length of the floor is 140 feet, the breadth 72 feet, containing upwards of 30,000 tiles. The general form of the design may be described as consisting of three large circles, the largest being in the centre, and two smaller ones, one on either side of the great circle, towards the end of the hall.

These two smaller circles are each surrounded by four still smaller, the form being then terminated at each end by a semicircle, of a radius equal to that of the great circle in the middle of the design.

In the centre of the pavement are introduced the royal arms, in proper colours, on a deep blue ground, 5 feet in diameter, surrounded by a wreath of laurel, and mounted on a star of 16 points, the spaces between the points being filled up with rich ornament and the caduceus of Mercury, thus forming an elaborate centre piece, of 15 feet diameter. This is enclosed by a narrow border of stone, and then follow rich bands of classical ornament, and a frieze of "life-bearing ornament," composed of tritons, sea-nymphs, dolphins, genii, tridents, and other attributes of Neptune, displaying great merit in design and successful execution. This is again bordered by richly ornamented bands to the outside of the great circle, making a diameter of about 42 feet.

In the centre of the two smaller circles are the arms of the corporation of Liverpool, also in proper colours on a blue ground, 3 feet in diameter, and surrounded in like manner to the great central compartment by consecutive rings and bands of ornament.

In the other small circles are introduced the Star of St. George, the Rose, Thistle, and Shamrock, with suitable borders which intersect at the junction of the circles with each other, after the manner of the Roman guilloche, or chain ornament, thus bringing the whole together into one grand form.

The semicircles at the ends are treated in the same style of ornamentation as the great central circle, and are incorporated, by the interlacing bands, with the central forms of the design.

The rest of the floor is filled in with a rich diaper work, divided into panels of various sizes by diagonal bands of plain chocolate-coloured tiles, having an ornamented tile at each intersection. In each of the largest of these divisions are placed alternately the Rose, Thistle, and Shamrock. The floor to the extent of about seven feet from the walls is raised about 18 inches from the central part, forming a sort of platform or pathway all round the hall. This is also laid with tiles of a similar character to the other parts of the pavement; and opposite each of the side doors is a circular compartment of rich colour, having in the centre a dolphin in proper colours on a deep blue ground, with wave-scroll ornament, &c. The spaces between them are filled with diaper work, with appropriate borders. The space immediately under the organ gallery is laid with a beautiful panel of about 20 feet diameter, having in the centre the crest of H.R.H. the Prince of Wales, within a laurel wreath, and surrounded by bands of richly decorated tiles.

In the border which surrounds the diaper work on the platform, and opposite each of the polished granite columns, are inserted inscriptions and mottos in Latin and English, relative to those virtues, sciences, and arts typified by the figures in the spandrels of the arches above—the lateral arches of the hall. At each end of the hall, also, inscriptions are introduced. Those near the organ relate to music; and those at the oposite end, leading to the entrance to the court, are relative to justice and government.

On entering the hall by the south entrance, and descending the steps, we read on the right hand—

"A king shall rule in righteousness, and princes shall rule in judgment."

And

"Libertatis honos et sceptra jura decori."

Proceeding onwards, opposite the figure of Prudence, we read—

"Nullum numen abest si sit Prudentia."
"I, Wisdom, dwell with Prudence."

Next opposite the figure of Fortitude is placed—

"Tu ne cedi malis sed contra audentior ito."
"In the Lord I have righteousness and strength."

Then underneath the figure of Science we have—

"Felix qui potuit rerum cognoscere causas."
"The fear of the Lord is the beginning of knowledge."

Next comes Art, beneath which is inscribed—

"Ars operum inventrix naturæ que æmula prolis"
"He hath given me skill that he might be honoured."

Then Justice, opposite which we have—

"Discit justitiam moniti et non temere divos."
"By me kings reign and princes decree justice."

Next Temperance, when we have—

"Ne quid nimis."

And we are admonished to—

"Add to knowledge temperance."

Then proceeding round towards the organ gallery we read—

"Praise Him with stringed instruments and organs."

And

"Fortia facta monet curarum et dulci levamen."

The mottos on the other side of the hall being the same, but in reversed order, according to the figures above them; and at each corner of the floor appears the motto of the corporation—

"Deus nobis hæc otia fecit."

It is said that the cost of the floor is 2000*l.*, but the precise amount is uncertain. It is, however, asserted on good authority that the sum, whatever it is, is considerably below the cost to the manufacturers, and that this is mainly attributable to the liberality of Mr. Minton, who, in a worthy spirit, on undertaking the work, determined to spare no amount of labour and expense to render the pavement as perfect as possible, and in every respect worthy of the noble hall of which it forms an important decoration.

### *The Brass Doors.*

At the three entrances on the east and west sides of the hall are six pairs of massive brass doors and frames of very elaborate design. They are fixed to marble jambs, and have a rich and imposing effect. Each pair of doors, including the frames, measures 12 ft. 8 in. high by 6 ft. 4 in. wide. The frames are very bold, of a receding outline, with a rich leafage moulding, which terminates against the marble jambs; in the hollow or recess of the frames is a large egg-and-dart ovolo, running all round. The doors are hung to the frames with strong gun-metal hinges with steel centres; they are 2½ inches thick, but not of solid brass; they have a hollow core with a covering of sheet brass of a thickness of 8 lb. to the superficial foot. The core is composed of 1½-inch square metal, put together in a form to prevent racking; each door has a circular panel in the centre brought out by an enriched bead and other mouldings, with a receding disc, having a head of Mercury in the centre. The foliated panels are of very rich design, and appear to run through the disc, starting at the base with two dolphins, the tails entwined, supporting a trident which runs up the whole length of the panel, with foliated scrolls intersecting it throughout, and in which is a small band with the monogram "S.P.Q.L." The doors are panelled with enriched mouldings on one side, and studded with rosettes on the other or outside; also panelled with a plain bold moulding to receive plate glass. One valve of the door is fastened by a rack bolt shooting top and bottom, the other by a two-bolt lock.

Over each door is a square light, constructed in the same manner as the doors, but the foliage is different. In the centre is the liver, the crest of the town of Liverpool, running round which is a bold wreath of oak leaves, and from the wreaths on each side springs a bold scroll, terminated with the honeysuckle. Each pair of doors, including the frame, weighs 43 cwt.

The screen at the south end of the hall, and dividing it from the crown court, is of similar design and construction. It is 21 feet long and 12 feet high, and weighs 74 cwt. This screen has one pair of folding and two single doors, on the same principle as those at the sides of the hall.

The total cost of these doors is about 6000*l.* They were made by Mr. Potter, of South Moulton-street, London, from the design and under the superintendence of Mr. Cockerell.

There is a smaller screen in brass to be fixed under the organ gallery, 10 feet wide and 8 feet high, in four compartments of the same construction.

At the south entrance of the building will be a large and massive pair of bronze doors, 21 feet high and 11 feet wide: they are of rich design, and weigh about 7 tons. Each leaf weighs in itself about 2½ tons, and works very freely; but as the labour of opening and shutting these doors frequently would be very great, there will be a wicket in one of them.

These are the largest metal doors in England.

### *The Gas Pendants.*

These splendid decorations are in brass and bronze, and each weighs about a ton. Yet, massive as they are, they look light, graceful, and elegant—a result due to the felicity of the design, the harmony of the parts, and the delicacy of the work. They are Grecian in design; not purely so, but the spirit and feeling of the Greek forms have been preserved with no little tact and skill. Each pendant is about 17 feet in height, suspended by a cable-formed rod, with elegant bosses at intervals, 20 feet in length, so that the entire work is 37 feet high, with a diameter at the widest part of 8 or 9 feet. From a small canopy descend two rows of cables, wrought in brass. The outer row upholds a large corona, and the upper row a smaller corona beneath, from which again depends an elegantly shaped basket, terminating at the bottom in a richly decorated pendant, and knob, or globe. On the upper rim of the canopy is placed alternately a five-pointed star and the liver. Each point of the star emits a brilliant jet of gas. Beneath the birds and stars is a border formed of the acanthus placed alternately with rams' heads; and beneath these runs a border of the echinus. To the inner portion of the latter are attached the chains which support the rings or coronæ below. The larger corona, fixed in the middle of the pendant, is decorated by the prows of ancient galleys, each armed with a projecting spike issuing from a boar's mouth, and alternately with boldly carved masks, the execution of which is very good. Above each prow rises a large star, five-pointed like those on the canopy, and also emitting a jet of flame from each point. On the lower and smaller corona the liver re-appears, and the masks and stars are again introduced. The basket (the sides of which are perforated with the Greek anthemion) recedes in graceful lines, till at the lowest part it narrows into a stem clasped by acanthus leaves, below which are a series of tasteful mouldings, ending in the final globe. There are ten pendants, and each bears 140 lights. The design is at once appropriate and novel. It does not, as is too often the case, block out all beyond; but, on the contrary, will serve to heighten the effect of the architectural ornamentation with which it will be placed in juxtaposition, inasmuch as, from its peculiar character, every detail may be seen through the interstices of the pendant. The delicately pale bronze and the rich gilding which alternate have a very fine effect. The rapidity of the production of these pendants is very remarkable; three months have not elapsed since the order for these, and a multitude of smaller chandeliers, brackets, &c., was given. The workmanship of the pendants is admirably finished, and reflects great credit upon the manufacturers, Messrs. Messenger and Son, of Birmingham. The illuminating effect is very brilliant; the great height at which the lights are fixed protecting the audience from all offensive glare, and securing that agreeably soft light which is so admired.

### *The Organ.*

It was the intention of Mr. Elmes to produce a vista from court to court through the hall, the entire length of the three apartments being nearly 300 feet. It is much to be regretted that the important provision in a music hall, of the organ and orchestra, was overlooked, as, placed as they now are, they have necessarily an intrusive appearance, and seriously interfere with the effect of the hall and with the available space.

This gigantic instrument is the joint production of Dr. S. S. Wesley and Mr. H. Willis. The case has been constructed from the designs of Mr. Cockerell. Its entire cost will probably be between 8000*l*. and 9000*l*. The choir and solo organ is not yet completed; but it is expected that the whole instrument will be perfectly finished in six weeks or two months. In consequence of the delay in the progress of the building, and the difficulty of getting all the works completed by this period, the voicing of the instrument has been done under very great disadvantages.

The instrument consists of four rows of keys, from G to A, *i. e.*, GG to A in altissimo, 63 notes; and two octaves and half of pedals, from C to F, *i. e.*, CCC to F, 30 notes. There are 108 stops, and 8000 pipes, varying in length from 32 feet to ⅜-inch, ten octaves apart.

The bellows of this great instrument are worked by two steam-engines, which furnish an aggregate power of ten horses, and were constructed by Messrs. Fawcett and Preston. The largest pipe has an area equal to 2 ft. 8 in. by 2 ft. 5 in., whilst the smallest is less than ⅛-inch in diameter. The notes are ten octaves apart.

The grand source of the wind is from two immense bellows, each having three feeders, placed in the vaults below the hall. These are blown by a steam-engine, consisting of a pair of oscillating cylinders. There are, besides, twelve other bellows, or reservoirs, each giving its own appropriate pressure of air to those stops or pipes which it supplies.

The pneumatic lever is applied to each of the manuals distinctly, and also distinctly or separately to the manual couplers. To the pedal organ there is a double set of pneumatic levers; but the most elaborate use of this power is found in its application to the combination of stops. Here we have it exhibited in a compound form to each organ individually, and to the whole collectively, where, by one operation, the player is enabled to produce a combination of stops upon the entire instrument at once. This movement appears in a series of six handsome gilt knobs, placed immediately under each set of manuals, at about two keys' distance from each other, occupying a central position, and always within reach of one or other of the performer's thumbs. The pneumatic lever is also applied to the opening and shutting of the swell louvres and some other important purposes. The very extensive use Mr. Willis has made of this extraordinary power seems to have rendered any deviation from the ordinary valves, in immediate connection with the pipes, unnecessary, excepting in the pedal organ, where the large pipes have a very peculiar valve for their supply, which is quiet, sound, and free from the resistance resulting from the compressed air.

### *Crown Court.*

To the south of the great hall is the crown court, which is rectangular on plan, 50 feet by 47 feet, with a recess or niche, with semicircular head, of 32 ft. 6 in. by 6 feet, in which the bench sits. The general arrangement of this court resembles the hall, inasmuch as there is one main vault, supported by three lateral arches, which spring from four columns of polished porphyry. Between the cap of the columns and the spring of the arch an entablature is interposed, which is returned on the sides of each column, and is supported at the wall end by pilasters, also of polished porphyry. The ceiling is panelled. The light is admitted through the centre of the principal vault by curvilinear windows, the glazing of which is only temporary. The ceiling is painted stone colour, with the mouldings relieved in white, and has a very agreeable effect. The fittings are of oak, and the walls to a considerable height are painted in imitation of oak-beaded match boarding. The court is divided from the hall by the columns and screen before described.

### *Nisi Prius Court.*

At the north end of the hall is the civil court, which is also rectangular, 50 feet by 46 ft. 6 in., with a niche for the bench 32 ft. 6 in. by 5 ft. 6 in. The arrangement of this court is different from the other, and it appears to be somewhat larger, though actually of rather smaller dimensions. The basilica type is adhered to, but the lateral columns of polished porphyry are nearer to the walls, and the entablature is continuous in the length of the court, there being no lateral arches. From the cornice rises the vault over the centre of the court, which is semicircular in section, with the upper segment of the semicircle retrenched; on the chord-line are flat windows for the admission of light, the glazing of which is also temporary. The ceiling of the side compartment, or aisles between the columns and the walls, is flat, but coffered. The niche for the bench resembles that in the crown court in being square on plan and finished with a semi-arch; but the columns, in both of grey granite, are differently disposed. These fittings are likewise of oak, but the ceiling and walls are not yet painted.

---

The day which witnessed the close of the musical entertainments was distinguished by the opening of the campaign of science under the auspices of the British Association, who do Liverpool the honour of holding their twenty-fourth annual meeting there. This naturally carries us back in imagination to about the same time in the year 1837, when this learned body there held one of their important and eventful meetings, and at which Dr. Lardner read his memorable and ill-fated paper on steam navigation. On that occasion the Earl of Burleigh occupied the chair.

---

Sir—The just celebrity of St. George's Hall, as an intellectual application of Greek architecture to a modern purpose, and, in most respects, one of the noblest buildings in the empire, must invest with more than ordinary interest for the people of Liverpool the masonic and other mechanical operations now going on around it. All will be anxious that the accessories and finishings of the exterior be in every respect worthy of, and suitable to, the main structure, between which and its external appendages a perfect harmony should reign; a harmony arising out of unity of conception, congruity and relation of the parts, each (whether architectural or sculptural) rendered completely subservient and *actively* beneficial to the effect of the principal subject, namely, the building.

To any one, however, acquainted with the commonest principles of art, the operations alluded to must, for a considerable time past, have worn a very suspicious aspect, and must have at length furnished ground for something more than fear that the resulting forms will not only fail in embellishing the building but be seriously detrimental to its character and beauty.

For what else, in the first place, can be said of the granite columns just raised in Lime-street? What purpose but that of destroying all unity can be answered by vertical objects so placed that, from every good point of view, they must cut up the principal façade into two or three sections? Had the building been a Gothic one, with pinnacled buttresses and a predominance of perpendicular lines, the case would have been different; but the characteristic charm of St. George's Hall is the binding up of its varied parts—its open courts and solid walls—into one harmonious mass, by the all-embracing and all-uniting horizontal lines, —and this is seriously affected, if not utterly destroyed, by these interfering and intersecting objects. What may be the actual intention of these columns it is unnecessary to inquire, for no form or finish they can now assume can either give them a right meaning and justification, or render them innoxious.

But this is not all. Than the edifice in question there is perhaps no building, except the Greek temple itself, that is more dependant on its columns and pilasters for its æsthetic qualities; indeed, the exterior may be said to be made up of columns, and its most striking beauty to consist of the graces of peristylar perspective. For the embellishment of its fore-ground, therefore, no form, used on such a scale, could possibly be worse adapted than the Corinthian column, as in the nature of things, it could not fail to dwarf the corresponding features in the building, and weaken the effect of columnar grandeur throughout.

But besides the form and loftiness of these pillars, their polish and superior richness of material and warmth of colour, must be not a little injurious; for such qualities will inevitably detract from the delicacy and beauty of the façades, and thus impoverish what they were designed to enrich, and diminish results they ought to heighten.

It will perhaps be answered, that erections similarly proportioned in the shape of obelisks were placed in front of Egyptian temples, where, it is allowed, all is harmony and consistency. This is true. But the Egyptian obelisk, though somewhat similar in proportion, was of a very different nature to the Greek column; and so far from dividing or otherwise injuring the mighty mass of the temple propylæum, must, on the contrary, by its slender, needle-like shape, have greatly enhanced the qualities which it (the temple front) was designed and intended to embody.

While the Lime-street columns, by their abacus and capital, declare their fragmentary and imperfect nature in themselves, and bear unmistakeable reference to an horizontal beam or lintel with which they should be weighted, the Egyptian obelisk is a pillar *per se*, based on an entirely different type, and suggesting like a plant, ideas of growth and aspiration. And, as if to make this idea more distinct, and prevent the possibility of its being mistaken for a ceiling or lintel-bearer, its designer pointed the top into a square pyramid. The sight of an Egyptian obelisk or Turkish minaret might make us blush for our monumental columns.

And this is not the only feature of the accessories of St. George's Hall that is injurious in its tendency. The entire surrounding balustrade is an appendage that no architect can look upon without distrust, the balusters being of far too elegant a form—too flowing and sensuous in line, and the whole balustrade too minute and complex in division, for harmony with the lineal severity and simplicity of the edifice, the extreme angularity of which it must render more apparent by its introduction near the eye, and on a level with the basement, where, above all, should be preserved an unbroken massiveness and simplicity.

Would not the expense that is thus worse than thrown away have procured the much-needed embellishments for the building itself? Would it not have crowned the front and principal portico with statues (one over each of the columns), or surmounted the pedestals at the extremities of its summit by figure groups? Whether or not, such embellishments of that portico is requisite, if only to balance the pediment sculpture at the south end, and give it its due decoration as the grand entrance, a distinction to which its superior breadth and columnar dignity, as well as its central position, unmistakeably points.

I hinted above at the impropriety of using the columnar form for any purpose but that of supporting an entablature. I did so under the impression that it is not too late to fear a Liverpool reproduction of the Trajan pillar, that conjunction of architecture and sculpture by which common-sense has been so often insulted —an arrangement of art-elements which degrades the columns to the rank of its own pedestal, and wherein, the principle of subordination being lost sight of, it can serve no other purpose than that of eclipsing the statue by its richness of capital, if it does not, by its aerial position, throw it out of sight altogether. Let us trust, however, that in this, as well as in some other particulars, we shall not see repeated in our St. George's-place the absurdities of Trafalgar-square.

In penning these remarks I have but slight hope of their effecting in any degree the remedy of the complained-of evils; and my apology for this intrusion on your space must chiefly be the fact that the credit of the architectural profession demands that some such protest be recorded.

SAMUEL HUGGINS.

*Liverpool, August* 21, 1854.

---

SIR—At the conclusion of my former letter on this subject I suggested the embellishment, by statues, of the great central portico as a means of producing a right balance and consistency in the building, but did not urge, or with sufficient emphasis urge, its abstract claim as a condition of completeness. To do this I must again trespass briefly on your space.

The species of embellishment in question, the grandest conceivable one of architecture, would, I unhesitatingly maintain, have been due to the building, though not a particle of sculpture had been inserted in the south pediment. It is an addition imperatively demanded by its rank and style, lacking which the whole must fail of its legitimate and rightful effect, and fall short in general power over the mind of far inferior edifices, wherein the conception has been fully developed by phonetic sculpture; for the absence of which no array of elegant balustrade, or elaborate pallisading, or granite lamp-posts, will atone. Statues over the broad colonnade of the central portico, disposed as should be found best, and varied and relieved by groups at the extremities, while they would find an excellent background in the astylar wall of the receding crown of the building or attic, which would receive much-needed relief from them in return, would give life and soul to the centre, and through it to the entire body of the structure. For such embellishment would not be merely the addition of beautiful accessories, but, when treated in the true spirit of the architecture out of which it should appear to have grown as a thing of like essence, and each figure seem the genius of the architectural mass beneath it, it would be a transfusion of life and beauty through the whole, awaking it, as it were, to a new existence, and raising it to a higher and purer region of art.

It was for such adornment and vivification of architecture that statuary and figure sculpture had birth in ancient art. In Greece, whence the elemental origin of St. George's Hall, as well as in mediæval Europe, architecture and sculpture grew up together, and like body and spirit, could not, without death to the former, be separated; and in Egypt sculpture seems to have had no separate existence. It was exclusively the handmaid of temple and palace architecture, *i. e.*, of high architecture, in which, in all great periods of art, want of figure sculpture has been looked upon as want of full being or entity.

I am not of the opinion recently expressed by a popular writer on the subject, that sculpture is the entire essence of architecture. The latter I hold to be a great art in the possession of proportion and form, and I believe that a fabric of exquisite beauty might be produced without any contribution from the high class of sculpture in question. But in great monumental works of the rank claimed for St. George's Hall, a certain amount of statuary and other sculpture is an essential element, without which it cannot have full existence, but must remain so far immature and undeveloped.

Architectural skill has been directed to the bringing of the surrounding neighbourhood into keeping with so noble a centre, and giving the latter, by the erection of other handsome buildings in its vicinity, a few congenial and worthy associates. This is a very laudable and well-conceived object, and the plan laid down for it reflects credit on the young architect of "the proposed St. George's-place." But the "improvement" for which I contend has a prior and loftier claim, for there must be more propriety in first, by suitable sculptural adornment, hiding the nakedness of the building itself, and giving it the full garment of its beauty.

Nor need the expense of all this be any bar to its accomplishment. For the cost of architectural figures is, or may be rendered, very slight in comparison with that of independent attitudenising statues, by the broad and simple mode of treatment and absence of finish which the spirit of the architecture and their distance from the eye would dictate; and the aid of the eminent professional sculptor would only be necessary in the preparation of minature clay models, from which all the grandeur of form and greatness of style that could be put into them, all the qualities appreciable at the height from which they would be seen, could be translated by superior stone or marble masons into the solid material.

I need not enlarge upon the humanising and elevating influence upon the general mind that such a work is calculated to exert when thus complete, rejoicing in the potency of symmetrical grace and the beauty resulting from the full union of architecture and sculpture. Let the latter be rightly conceived and treated,—let it be employed to embody, not Greek or Roman legends, as it has too often been, but ideas and images drawn from our own history and poetry, and with which the English and Christian mind has sympathy, and the whole would stand forth in its architectural chasteness and artistic significance, a power for good, for discipline and refinement of humanity which few now dream of, but which it is the mission of art to accomplish, and failing which, it is but a costly and culpable luxury.

The subject out of which this has arisen I brought a fortnight ago before the public with extreme reluctance, and not till the common sense of the people, as well as the art of the architect, was insulted by forms which, should they remain, will remain as laughing stocks, and to which a couple of decapitated statues, or the two detached legs of a colossus, reared on the same spot, would scarcely be a parallel in absurdity.

SAMUEL HUGGINS.

*Liverpool, Sept.* 1, 1854.

## THE COMBUSTION OF COAL AND THE STRUCTURE OF FURNACES.*

THEORY and practice are commonly far apart, and various branches of science are seldom successfully applied by the same individual. The theory of combustion has been studied by some very eminent philosophers, and is laid down in every text-book, and yet it certainly enters but very little into the minds of those who fashion furnaces for consuming fuel, or of those who have the feeding of them. Mr. Charles Wye Williams, whose former labours were reviewed fourteen years ago in this *Journal*, claims the merit of having first made the theory harmonise with the practice, or in the words of Sir Robert Kane, has been "the first to place this subject in its important and just aspect." Beyond this Mr. Williams claims little, though he has certainly been among the most zealous advocates of improvement; and this is shown even to the present time by the issue of an improved edition of his book, or rather of a new book. Although the author of some important inventions, Mr. Williams is at present a disinterested advocate, as his patent of 1839 has expired. He has the enthusiasm of an author and an inventor, which is stronger in its influence than pecuniary interest; and he has, besides, the prestige of his high character and great success in the undertaking which he has conducted.

It was as one of the managers of the great company for Irish steam navigation, that Mr. Williams was led to consider the operation of the marine engine, and he has caused many important experiments to be performed, besides publishing the results of his own observations. It was as early as 1823, that Mr. Williams first gave his attention to the subject. Marine engines have naturally engaged him to a greater extent, but he has applied the same principles to the land engine and the locomotive. Taking up peculiar and practical points, of importance to the engineer, we think it desirable that Mr. Williams's views should come under consideration on the fitting occasion of their promulgation in a more comprehensive form.

The work as now arranged resolves itself chiefly under two parts—first, as to the theory, and second, as to the practice; and under each the various divisions are systematically considered in separate chapters, with appropriate illustrations. In a subject so comprehensive, and which is to a great extent controversial, it is difficult to go over the whole ground taken up by the author, and we must, therefore, limit ourselves to a more general notice of his opinions, and to a particular portion of the work.

James Watt, whose attainments in science were as extensive as the range of his inventive genius, did not allow the subject of combustion to escape him, and indeed it formed the ground of one of his patents. The state of chemical science was, however, in the last century so little advanced, and particularly with regard to the gaseous elements, that Watt was able to do but little. He recognised the error, rather than the cause or the remedy; nor is this surprising when we remember that he himself was one of the discoverers of the composition of water—a great stage in the progress of chemical science, and priority in which he contested with several brother philosophers. The gases occupied much of his attention, as the establishment at Bristol proves, and though he sought there a special application, it was dependent on the study of their general properties.

Many other practical men have given their attention to the same question, and many are the mechanical improvements which have been suggested and put in operation; but it is nevertheless true that our mechanical engineers have neglected the chemical relations of combustion, although it comes essentially within the domain of chemistry. Mr. Williams, M. Peclet, and others who have made a special study of these phenomena, necessarily claim a greater share of our attention. It is on the conviction of the neglect of practical men, that Mr. Williams begins with the elements, and considers the volumes and weight of the several combinations; and it is necessary to do this, because the ordinary perusal of a chemical work does not make a deep impression, nor convey the exact idea. One chief object is to point out the quantity of atmospheric air requisite for combination with the several gaseous compounds. The combinations of carbon are of the more importance, because the combination called carbonic oxide is one very readily produced, and is very little attended to; whereas it is requisite this oxide should not be produced during combustion, nor any other form but carbonic acid. In discussing these points, Mr. Williams rests on the authority of the most eminent chemists, and the only novelty is the form in which he places them before practical men, but this, in a practical point of view, is a great thing.

While ten cubic feet of air are required to supply two cubic feet of oxygen to effect the combustion of one cubic foot of coal gas, it is an essential consideration that the air should not be vitiated nor deteriorated, and yet under the ordinary arrangements the air requisite for one part of the operation has been already deoxygenated in the previous stage. In this respect Mr. Williams strongly controverts the theories of Mr. Tredgold, and particularly his recommendation to pass the whole supply of atmospheric air through the ashpit. Mr. Williams contends that one portion of air shall be applied to the carbonaceous element in combustion, and another portion to the gaseous products. He is a great advocate for the supply in jets (as instanced in the accompanying engravings), or the Argand principle. Mr. Williams very pithily

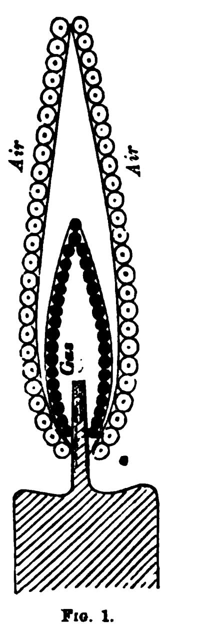

FIG. 1.

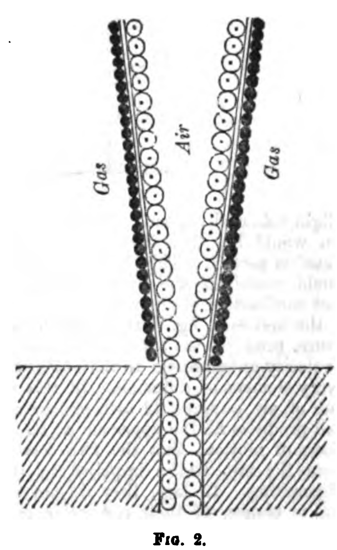

FIG. 2.

observes, that it is too readily taken for granted that if air by any means be introduced into the fuel in the furnace, it will as a

* 'The Combustion of Coal and the Prevention of Smoke chemically and practically considered.' By C. WYE WILLIAMS, Esq., Assoc. Inst. C.E. London: Weale. 1854.

matter of course mix with the gas or other combustible, in a proper manner, and assume the state suitable for combustion, whatever be the nature or state of such fuel; whereas, it may just as well be assumed that bringing together given quantities of nitre, sulphur, and charcoal, in masses, will constitute gunpowder.

"With reference to the *mode* of introducing the air, (says Mr. Williams), it is not a little remarkable (so slow is scientific progress when opposed to established custom) that many, to the present, overlook, or even dispute the difference in effect, when it is introduced through *one*, or *numerous* orifices. In illustration, then, of the effect of introducing the air *in a divided form*, let us take the case of a boiler furnace of modern and approved form, where the air enters by a *single orifice*, and compare it with that shown where it enters through 100 or more orifices.

In the first example (if the body of air be not too great), the effect may be favourable, to some extent, in preventing the generation of dense smoke. Inasmuch, however, as the quantity of air thus introduced, is chemically inadequate to the combustion of the gas, much of the latter must escape *unconsumed*, though not in the form of smoke, but *other force*,—*that other force* is just what is here required. Thus, in the present instance, we must either change the direction of the current of the air, *or give it the right direction from the beginning*.

Now, instead of a single aperture, let the air enter through a hundred or more apertures, as in fig. 4. Here the force and direction of *the current* will be avoided, and the required diffusive action produced on passing the bridge. Instead of the refrigeratory influence of the air, as in the first case, there will be a succession of igniting atoms, or groups, which Sir H. Davy calls, 'explosive mixtures,' each producing combustion with its high temperature. These are distinctly perceptible from the sight holes at H.

The same results will follow, whether the single or numerous orifices are placed at the *door*, or at the *bridge end* of a furnace, as in fig. 5. In this case, the diffusion will be more immediate and effective.

On this point it may be well to notice the oft-repeated fact, that the avoiding dense smoke may be obtained by leaving the fire-door *ajar*. Now, so far from this being a discouragement, or argument against the use of numerous small orifices, it absolutely confirms both the principle and practice; for, if allowing a *given quantity* of air to enter in a thin film at the edge of the door have a good effect, we are thereby encouraged to allow the *entire complement* to enter by other and *more*

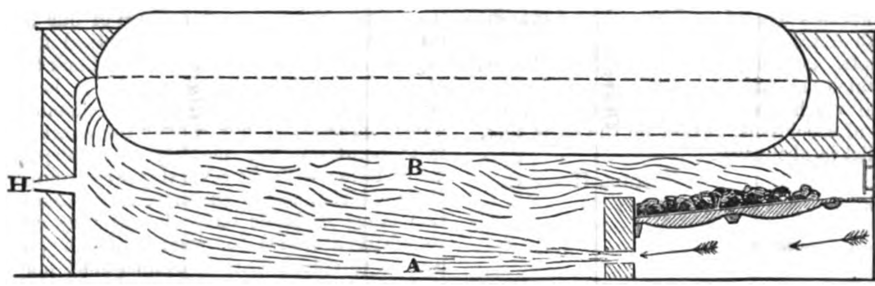

FIG. 3.

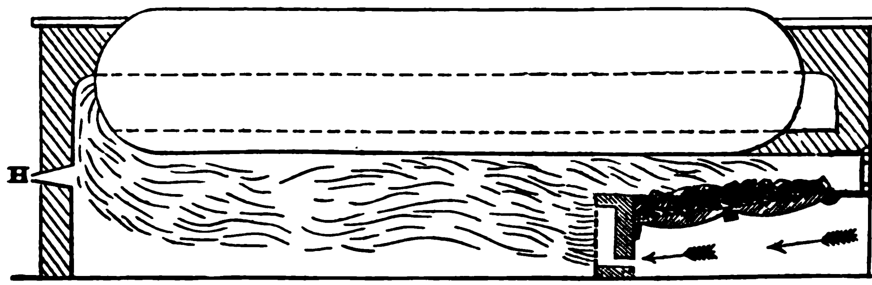

FIG. 4.

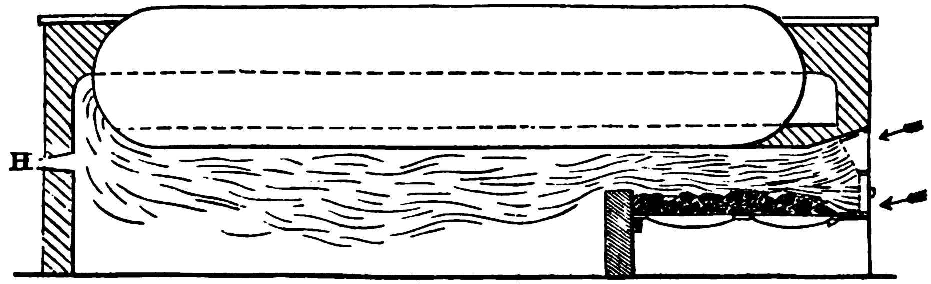

FIG. 5.

as a light coloured vapour. In such case, however, the inference usually drawn would be, that the area of admission was sufficient, and the combustion perfect. This, however, would be erroneous; besides, that it would constitute the mere non-appearance of smoke as the test of perfect combustion of the gas.

In the first case, fig. 3, the body of air, by passing through a single aperture, produces the action of a strong current, and obtains a direction and velocity antagonistic to that *lateral motion* of its particles which is the very element of diffusion. In this case, passing along the flue, the stream of air pursues its own course at the lower level A, while the heated products fill the *upper one* at B. It is here evident, according to the laws of motion, that the two forces, *acting in the same direction*, prevent the two bodies impelled by them (the air and the gas) from amalgamating. In fact, they do not come into contact, except in the strata, or planes, of their respective proximate surfaces. The cooling influence of the air, however, goes on in the flue, and produces a result the reverse of what was then most desired. In this case, the velocity of the current is opposed to the desired diffusion; and as, by the laws of motion, matter cannot change its direction unless by the introduction of *some* *numerous films* or apertures. If, indeed, allowing the door to be *ajar*, with an opening of one inch, were sufficient for the admission of *the entire volume* required, nothing further will be desired. The moment, however, the aperture is enlarged by opening the door wider, to allow that required volume to enter, the injurious and cooling influences of the body and current of air become self-evident, and the result confirmed by the reduced temperature in the flue, as indicated by the pyrometer.

Of the advantageous effect produced by *mechanical agency*, in promoting immediate diffusion between the air and the gas, the following experiments are quite conclusive.

Let figures 6, 7, and 8, represent each a tin apparatus with its glass chimney, similar to the ordinary Argand burner,—the gas is admitted the same way in all three—the difference to be noted is, *in the manner in which the air is admitted*. In all these cases, the quantity of both gas and air was the same.

In fig. 6, no air is admitted from below; and the gas, consequently, does not meet with any until it reaches the top of the glass, where it is ignited, producing a dark smoky flame.

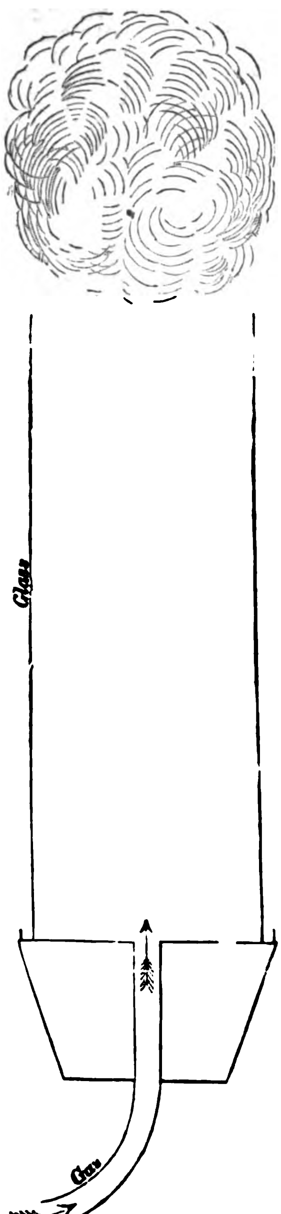

Fig. 6.

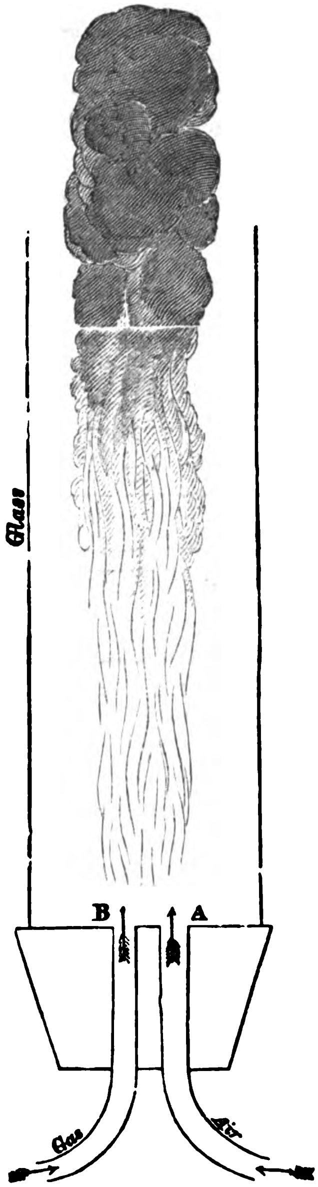

Fig. 7.

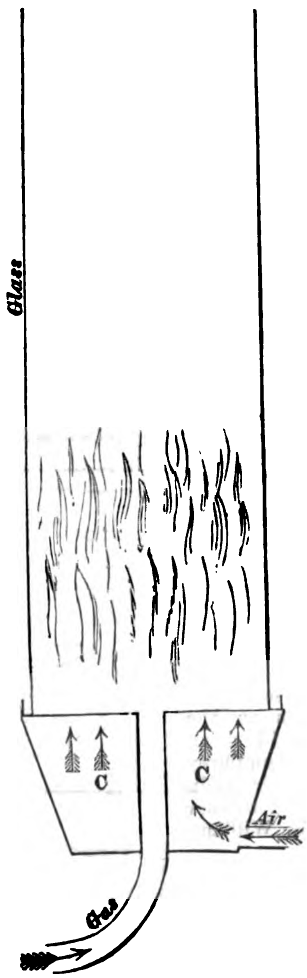

Fig. 8.

In fig. 7, air is admitted from below, and rises through the orifice at A, concurrently with the gas at the orifice B. On being ignited, one long flame is produced, of a dark colour, and ending in a smoky top.

In fig. 8, the air is introduced from below, and into the chamber C, C, from which it issues through a perforated plate, like the rose of a watering pot; thus producing immediate mixture with the gas. On being ignited, a short, clear, and brilliant flame was produced, as in the ordinary Argand gas burner.

The *heating powers* of the flames were then tested, by placing a vessel of cold water over each. When over fig. 7, it required 14 minutes to raise the water to 200°, whereas, over fig. 8, it reached 200° in 9 minutes.

Now, the difference of effect produced in those three experiments corresponds with what takes place in furnaces and their flues, when the air is excluded, and when it is admitted through a single or through numerous orifices.

Of the importance of *mechanical agency*, in promoting the rapid diffusion or mixture of the air and the gas, the modes adopted on the continent for rendering the coke gas, or *carbonic oxide*, available, are conclusive and instructive.

M. Peclet has given ample details of the mode of effecting the combustion of this gas (the existence of which has, for a long time, been practically ignored in this country), in the manufacture of iron, and even in the puddling furnaces, where the most intense heat is required.

M. Peclet states that the process at Treveray, in France, (see figs. 9 and 10) is preferable to that adopted in Germany, and for the following reasons, which are quite to the point of our present inquiry.

First, the air and the gas are better incorporated; secondly, the relative quantities of the gas being brought into contact with the air are more easily regulated; thirdly, combustion is effected by the introduction of the smallest excess of air.

In the apparatus, as shown in the section, fig. 10, fifty jets of air issue, each in the centre of fifty jets of the gas (carbonic oxide), led from the cupolas of the melting furnaces. On examination of the process here exhibited, the mixing and combustion, it will be seen, takes place *on the instant*, and before the flame and heat enter the chamber of the furnace at F. By this arrangement, M. Peclet observes, 'that the highest temperature that the arts can require is here obtained.' It is strange that the practical and commercial value of this gas, which is so wastefully expended at our manufactories, at the summit of the cupolas, but so well understood, and economised in France and Germany, is only just now being recognised in this country."

Another experiment on the operation of the jet principle is illustrated in the following extract:—

"The main object being the introducing the air in a divided state to the gaseous atmosphere of the furnace chamber, the following experiment was made:—The centre bar of a boiler, 4 feet long was taken out, and over the vacant space an iron plate was introduced, bent in the form as shown in fig. 11.

Here, the upper portion of the bent plate, projecting 3 inches above the fuel, was punched with five rows of half-inch holes, through which the air issued in fifty-six streams. Adequate mixture was thus instantly obtained, as in the Argand gas burner; the appearance as viewed through the sight-holes at the end of the boilers, being even brilliant, and as if *streams of flame* instead of *streams of air*, had issued from the numerous orifices. It is needless to add, that nowhere could a cooling effect be produced, notwithstanding the great volume of air so introduced.

This led to the enlarging the door-end of the furnaces sufficiently to admit the required number of apertures and full supply of air; an arrangement which has been for years in successful operation, both in marine and land boilers.

In practice, the great difficulty lay in adapting the plan to marine boilers, the doorways of which are made so contracted, as to render it impossible to introduce the required number of half-inch orifices, as hereafter will be shown."

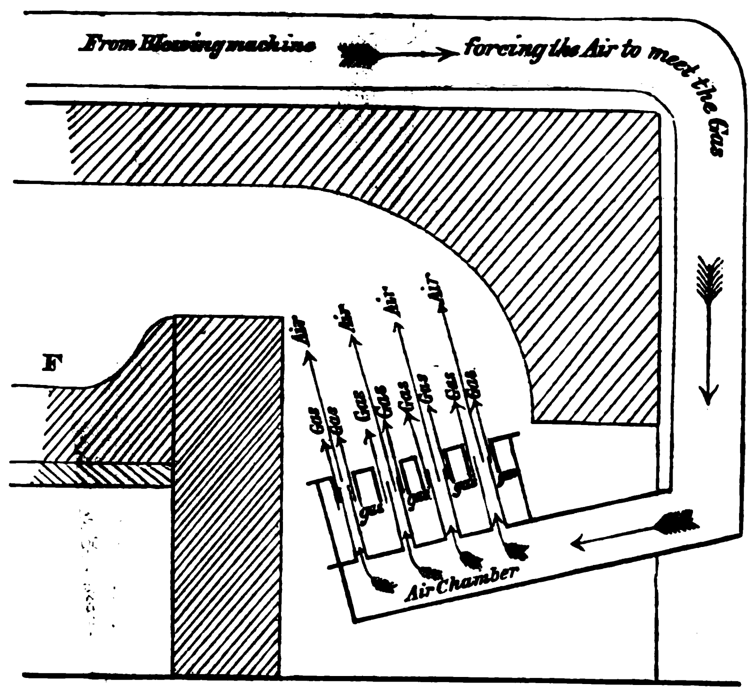

Fig. 9.

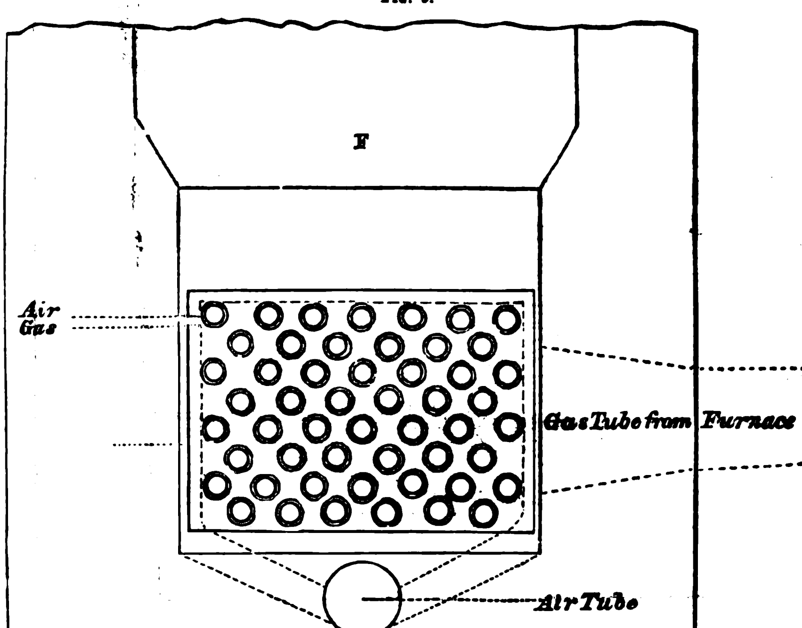

Fig. 10.

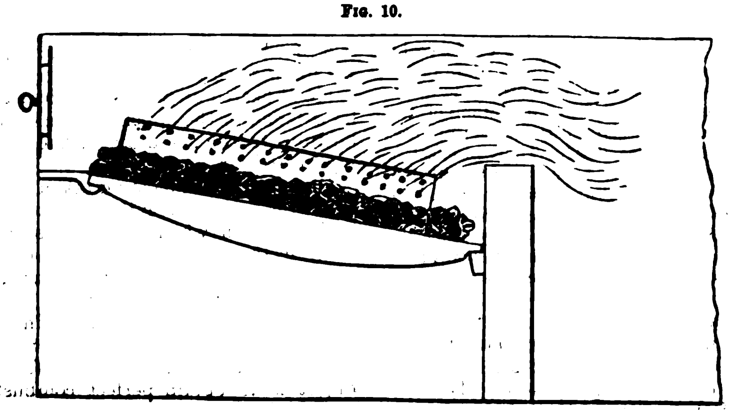

Fig. 11.

In the course of some investigations on the principles laid down by Sir Humphrey Davy, and their application to the tubular boiler, Mr. Williams observes:—

"On examination of what passes in furnaces *using coal*, we see the direct connection between its effect, and what Sir H. Davy so clearly points out as the means of *extinguishing the flame*. On looking into a *flue boiler* from the back end, a body of flame will be seen flashing along from the bridge, and if air be properly introduced, extending a distance of 20 to 30 feet. This is the appearance which has to be sustained *until the process of combustion be completed*, if we would have the full measure of heat developed.

On the other hand, looking into a *tubular* boiler, across the smoke-box, the light of the flame may be seen through the tubes; but on entering their orifices, or at a short distance within them, it will appear to be suddenly cut short and extinguished and converted into smoke, as shown in fig. 12.

The distance, then, to which flame will penetrate tubes, *before being extinguished*, will depend on the rapidity of the current, — the size of the orifices, — and the quantity and character of the gaseous products, *entering in company and contact with it*. These products are, from

Coke . { Carbonic Acid and Nitrogen.
Gas ... { Carbonic Acid, Nitrogen, and Steam.

Here we have the very incombustible gases referred to by Sir H. Davy, —not even in small, but in very large quantities, —forced into the most intimate possible mixture with the flame. The result necessarily must be, the reduction of its temperature, and consequent extinguishment.

Impressed with the importance of the connection between temperature and ignition, Sir H. Davy dwells on the fact, and repeats, that 'flame, whether produced from the combustion of *large or small quantities* of explosive mixture (gas and air), may always be extinguished or destroyed by *cooling agencies*; and *in proportion to the heat required to carry on combustion, so it is the more easily destroyed*.'"

Mr. Williams does not apply these remarks to those locomotive boilers where coke alone is used. He particularly discriminates between the various constructions of engine, and the various kinds of fuel employed. He says:—

"In speaking of the evils of the tubular system, these remarks have no reference to its application in locomotive boilers, where *coke alone* is used, and for this self-evident reason, that no hydrogen-carbon gas or fuliginous flame has there to be encountered. In the tubes of the locomotive there is, in fact, no chemical or practical reason why the heat may not be abstracted from the products with the greatest rapidity.

With reference to the size and sectional area of the tubes, we even deceive ourselves as to what that area practically is. When, for instance, it is intended to give an area of 2 or 3 inches, it will not be sufficient merely to provide tubes of 2 or 3

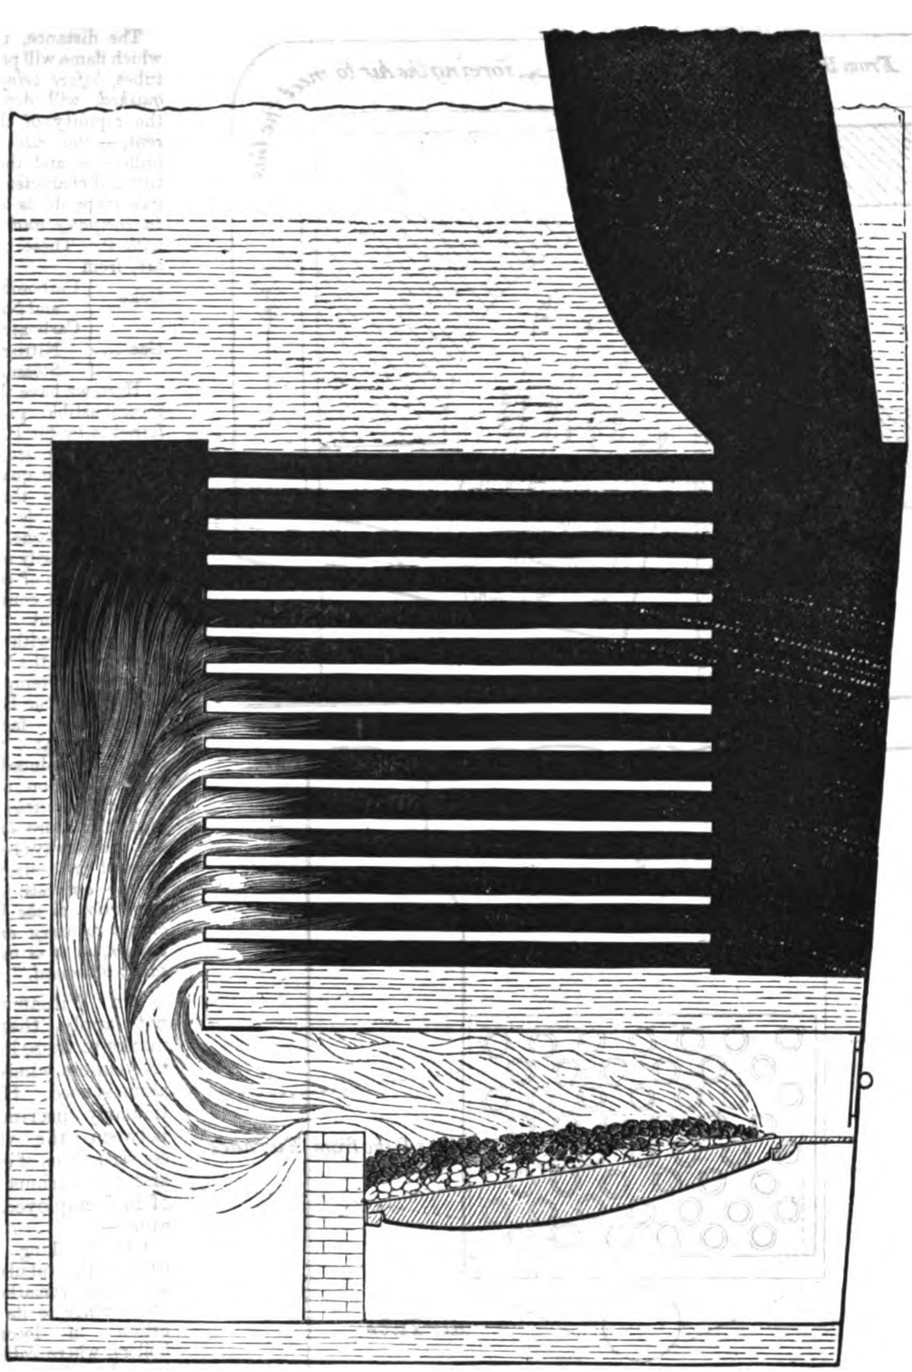

Fig. 12.

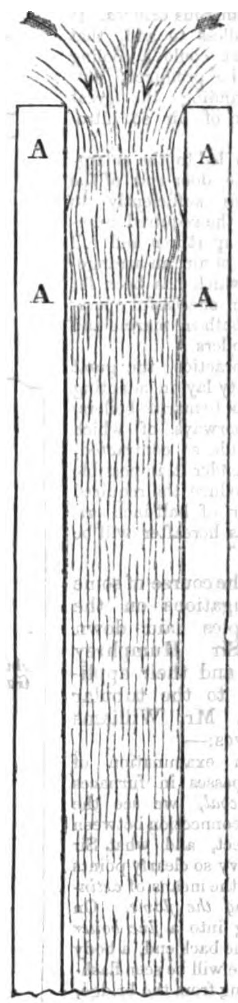

Fig. 13.

inches diameter. Allowance must be made for the effect produced by the rapidity or *pressure* of the body (whether it be flame, gas, air, or water), forcing an entrance into a restricted orifice. The true and available area, that which directly influences the mixing operation of the several bodies simultaneously forcing themselves through the orifices, will then be, not as at A, in fig. 13, but as at A′. Thus, in effect, a tube of 3 inches of internal area will practically have one of but 2¼ or 2 inches, and so in proportion to the size of the tube, and the amount of pressure exercised by the current. So little, however, has this been considered, that not unfrequently the ferrule, or iron ring by which the tubes are fastened to the face-plate, is inconsiderately placed *within their orifices*; thus still more seriously contracting the working area."

A very important subject and one almost distinct, is that referring to the circulation of water in the boiler, and which as it is treated by Mr. Williams at length, cannot fairly be comprised in the brief space we could now give to it. There is likewise a copious discussion of the merits of the tubular system, and Mr. Williams objects to its application for marine purposes He likewise enters on an investigation of the doctrines as to the value of heated air for feeding furnaces of boilers, and here again he is found in the opponent ranks, and is consequently in direct hostility to the patentees of the numerous inventions for applying heated air.

One ground of objection taken by Mr. Williams to the tubular system is grounded on the generation of a large quantity of water in furnaces in which coal gas is produced and consumed, which being in the form of steam becomes the largest product of that combustion. This results from bituminous coal containing from 5 to 6 per cent. of hydrogen.

The smoke question is only incidentally and collaterally discussed, because Mr. Williams considers that instead of attention being directed to contrivances for consuming smoke, the chief object is to obtain perfect combustion, when no smoke will be produced.

There is scarcely a portion of a subject so important and so difficult, and we may add so perplexing, to the practical man, that Mr. Williams has not elaborately and carefully treated. That of DRAUGHT is one essential to the well-working of the steam engine, of whatever class, and we are tempted to lay before our readers the views of Mr. Williams. This we shall do at some length, though were it not for the well-known zeal and liberality of Mr. Williams on a favourite subject, we should feel some delicacy in extracting so copiously from a work on which much labour has been bestowed, and the circulation of which at any rate interests the reputation of the author, even where it is not one of profit. We must, however, trust to his motives and our own to obtain his excuse.

In treating this branch of the discussion, Mr. Williams has frequently availed himself of the labours of M. Peclet, an authority to whom we have had many occasions to refer in the pages of this *Journal*. Mr. Williams observes:—

"The draught, or current of air passing through a furnace, is occasioned by the difference in weight between the column of air within the chimney, and that of an external column of the same proportions,—the 'ascent of the internal heated air,' as Dr. Ure observes, 'depending on the diminution of its specific gravity,—the amount of unbalanced weight being the effective cause of the draught.' Since, then, this levity of the inside air is the result of increased temperature, the question here for consideration is, how that temperature may be obtained with the least expenditure of fuel.

In marine boilers numerous cases of deficiency of draught will be found to arise from an injudicious arrangement of the flues, and the conflicting currents of the heated products within them.

Notwithstanding the importance of the subject, still but little attention has been given to the causes of these currents and deficient draught. M. Peclet having examined the subject with great care and practical research, his details are so copious, and his remarks so much to the point, that it will be well to give them due attention, and the more so as the subject has not hitherto been examined by any writer in England.

Among the inconveniences experienced, a prominent one may here be mentioned, as being of frequent occurrence, namely, a deficient draught in the side or *wing furnaces* of boilers.

M. Peclet observes, 'Where several tubes or flues open into one common flue, the currents are continued beyond their orifices, and by their mutual action, affect or modify their respective forces. If, for example, two flues A and B (see fig. 14) enter the common flue C, by orifices *opposite each other*, the influence of their currents on each other will be *nil*, *if they have equal rapidity*; because the whole will pass as if they had struck against a plane fixed between them. If, however, the currents be unequal, *that which has the greatest rapidity will reduce the speed of the other*, and more or less have the effect of closing the orifice through which the latter flowed.'

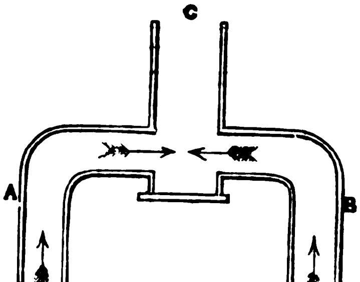

FIG. 14.

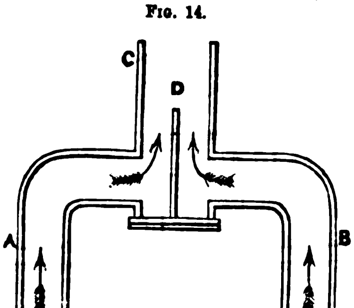

FIG. 15.

'So many proofs of this,' he adds, 'may be adduced, as to put the fact beyond doubt.' 'These streams of air,' he continues 'in this respect, act on each other as streams of water. It is already known by the experiments of Savart, that where two streams of water of the same sectional area, act in opposite directions, and that one of them has even but little more speed than the other, the latter is pushed back, and the influence felt up to its source. The result of this collision in the flue may be avoided by the diaphragm D (fig. 15).' Such conflicting currents may be found in almost all marine boilers, yet pass unnoticed, even where the draught is manifestly deficient in consequence.

Again, 'phenomena of the same kind will be produced where the courses of two flues are at *right angles to each other*, as in fig. 16. These effects may also be avoided by the diaphragm D (fig. 17).' This also is of frequent occurrence, and seriously affects the general draught, as will hereafter be shown.

Again, 'Where the chimney or flue is common to several furnaces, the arrangement should be such that the streams, or currents of heated gas, should not interfere with each other. Fig. 18 represents the arrangement that should be adopted in such cases.' It is needless to observe how frequent this state of things occurs, and how little attention is given to it.

FIG. 16.

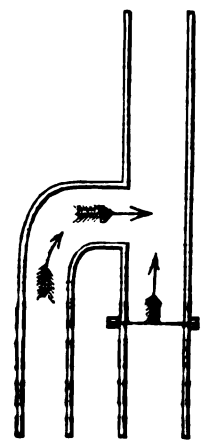

FIG. 17.

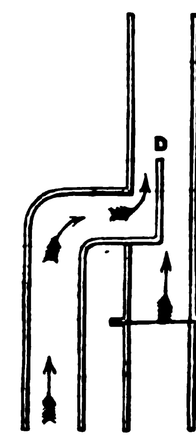

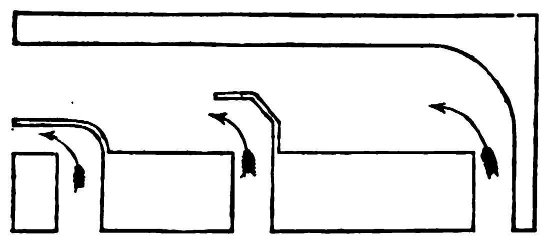

FIG. 18.

'So, where a current of hot products issues horizontally into a chimney, it may happen that its draught would be *entirely destroyed*, if the rapidity of such current was considerable, as it would then have the effect of shutting the chimney like a damper.' He then describes what occurred at a soda manufactory, with a chimney for general draught, which he had to construct, and which was also connected with a flue from another apparatus, as shown in fig. 19. In this case, 'the current from the one flue completely neutralised that of the other.' This he remedied by the partition P.

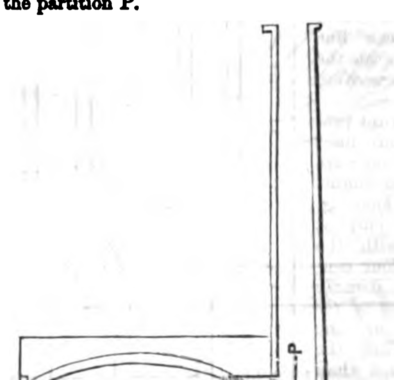

FIG. 19.

Again, where three flues enter a funnel from *three different points*, it is evident, he observes, that 'the diaphragms should be so placed as to leave each current an adequate section of the chimney,' as in fig. 20. The circumstance here referred to may be found to exist in almost all marine boilers. Rarely, however, is the interposition of these diaphragms thought of, yet numerous instances of the derangement of the draught, particularly of the wing boilers, must be within the knowledge of all engineers.

Let us now apply these judicious practical observations. The first boilers of the *Great Britain*, screw steamer, are in point. The arrangements of these boilers have already been noticed with reference to their impeding the due circulation of the water. We have now to consider them in respect to their influence on *the draught.*

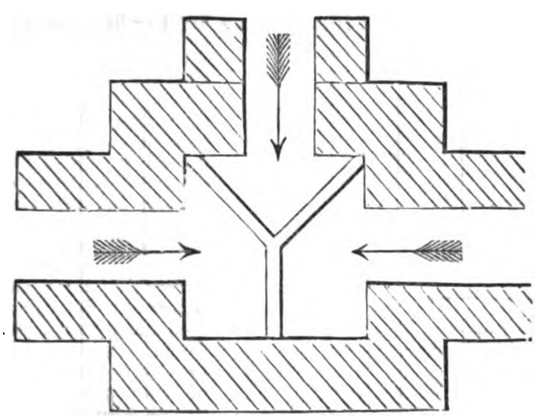

FIG. 20.

In these boilers, attention was given, almost exclusively, to two objects:—providing the largest possible amount of *fire grate areas,* and the largest aggregate of internal *heating surface.* As to the former, almost the entire area of these large boilers may be compared to an aggregate of furnaces. Nevertheless, there was no command of steam, and the engineer stated, that the wing boilers were unequal in draught to the centre ones. The deficiency of draught in the furnaces of the side boilers will easily be accounted for on examining the plan of the upper tier of flues, and the numerous collisions where the heated products from twenty-four large furnaces entered the funnels, as shown in fig. 21.

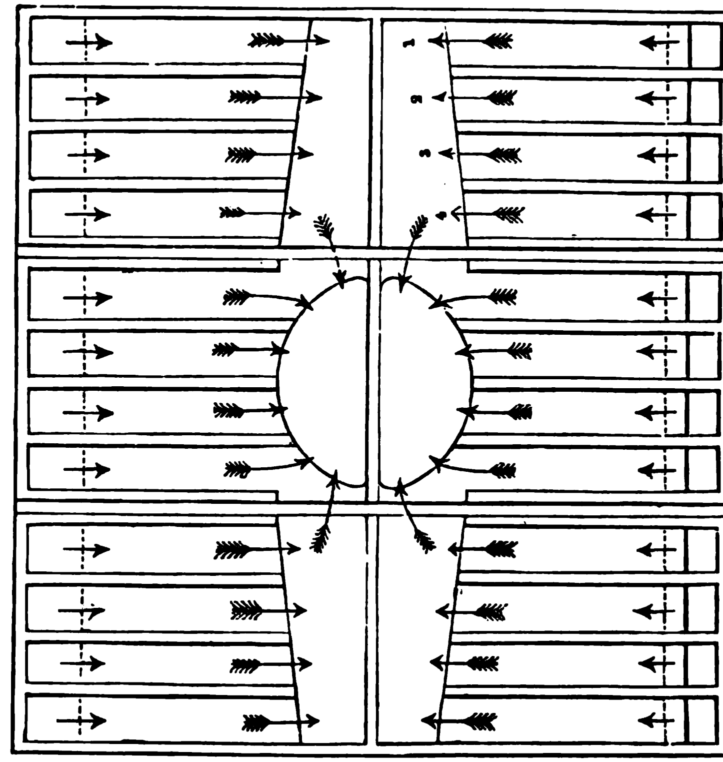

FIG. 21.

The flues from the four furnaces of each wing boiler, are here made to enter one common cross flue—each thwarting the current of the preceding one. No. 1 being checked by No. 2—which crosses it at right angles—which, in its turn, was checked by No. 3, and so on—the same mal-arrangement taking place in each of the sixteen flues of the four wing boilers. These, it will be seen, are the direct cases adduced by M. Peclet, where the products and current from one flue act as a damper on the *draught of its preceding one.*

Again, the joint products of the four flues of each wing boiler are made to enter the funnel by a single opening, which is not only at *right angles* with the flues from the four centre boilers, but *directly opposite to those of the wing boilers* on the other side. Thus the flues of no less than eight furnaces, all entering by a single opening are brought into direct collision with those of the other four, and in the most certain way to affect the draught of all. Here we have a combination of the evils referred to by M. Peclet.

The case of the boilers of the *Great Liverpool,* is a still greater violation of the rules which should regulate the draught. Here, there being but a single tier of flues, the required

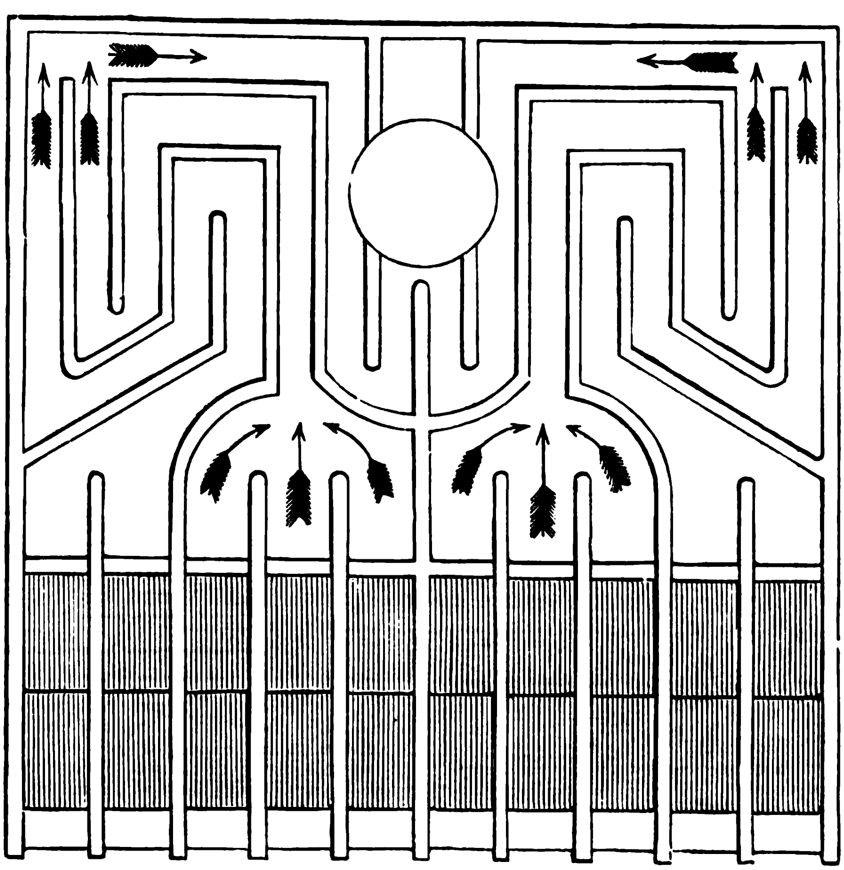

FIG. 22.

aggregate of *heating internal surface* was obtained by the labyrinth of windings shown in fig. 22.

In the first place, the flames from the three centre furnaces of each half of the boiler are forced into a single flue of but 13¾ inches wide, as shown by the arrows. Again, the gaseous products of each set of three centre furnaces, and which are necessarily the more powerful, are made to enter the single back flue at *right angles,* and across the current of products from the two wing furnaces, as shown by the enlarged view in fig. 23. It is scarcely possible to conceive a more direct case of collision, or a more effectual damper by the hotter and larger current from three furnaces, on the smaller current from the two wing furnaces. In these boilers, it is manifest that nine-tenths of the steam was produced by the plates in connection with *the furnaces alone,* and by a system of continued forcing; the long run of flues being filled with dense black smoke.

A considerable improvement was affected by constructing furnaces *in pairs,* as in fig. 24. This had the important advantage of rendering any interference with the supply of air unnecessary, by giving uniformity to the quantity of gas passing from the bridge to the flue; since, by firing the two furnaces *alternately*, the supply of gas is equalised on entering the flue from the bridges.

This plan, it will be seen, had the disadvantage of the *split flue* at the back end, where, as M. Peclet observes, *the hotter or stronger current will always neutralise the other.* In practice, a strong or hot current of gaseous products will not, voluntarily, divide itself, to meet the arrangements of the flues: the whole, or nearly so, will pass either to one or the other, in proportion to the temperature then in the flue, or to the length of the course each has to run to the funnel.

The plan shown at fig. 25 exhibited a great improvement in the former, and has for many years been found the most efficient in practice.

The plan as in fig. 26, was adopted with a view of dividing the gaseous products, and thus spreading the heat along a double surface. This, however, was quite defective, in as much as a gaseous stream cannot be induced to divide itself contrary to the laws governing the currents of fluids; the hottest and shortest course being always taken by the gaseous products.

The plan of a land boiler, as in fig. 27, is that of a still more objectionable effort to divide the current into two smaller flues, with the view of increasing the internal surface. Here, the flues, after passing under the cylindrical boiler, and returning through a central flue, is expected to divide itself into two streams, one to pass on each side of the boiler, on their way to the chimney. This is the case referred to by M. Peclet. A commission he observes, from the *Société Industrielle* of the Grand Duchy of Hesse, made a series of experiments to determine the influence of the circulation of the

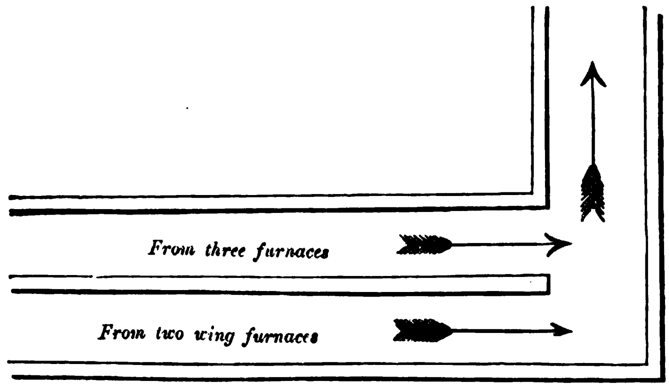

FIG. 23.

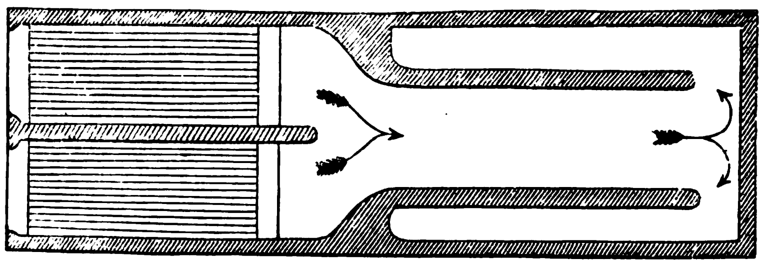

FIG. 24.

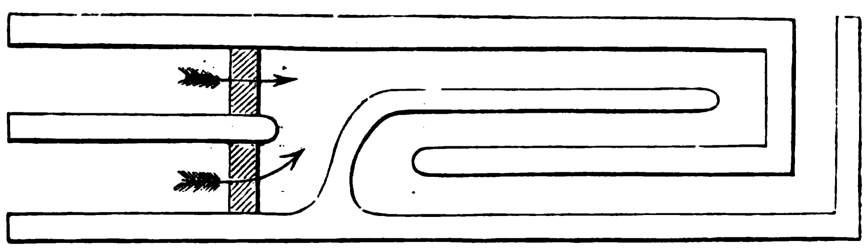

FIG. 25.

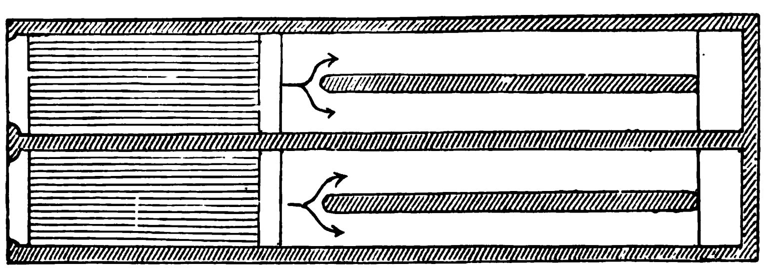

FIG. 26.

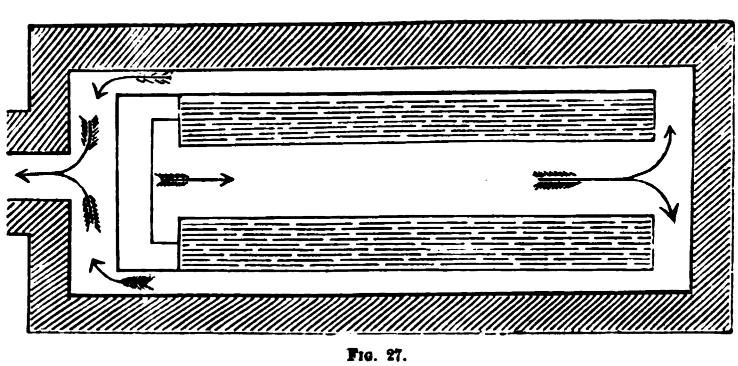

FIG. 27.

products of combustion round boilers. By these it was proved, that the flue passing round the boiler had a considerable effect on the amount of evaporation. It was also established, that if the products pass simultaneously by the two side flues, *they will not distribute themselves equally, and will only pass by that which presents the least resistance.**

On the *external* circumstances that influence the draught, M. Peclet adduces many proofs of the importance of avoiding any interference with the introduction of the air, by reason of the *direction of the wind outside the building.* This is a circumstance which has excited no attention from our engineers. In marine boilers, placed low down in the vessel, the direction of the wind with reference to that of the current entering the furnace, has often a considerable effect on the efficiency of the combustion. So, if the wind is opposed to the motion of the vessel or the reverse. The importance of this consideration is exemplified where the vessel contains two boilers, having their furnaces facing different ways. In such case, according to the direction of the wind, or the motion of the vessel, one boiler will have a better draught that the other.

That the relative direction of the wind, and the vessel, exercises a considerable influence, is proved by the fact, that the furnaces in some vessels will have a sufficient draught, and generate a sufficiency of steam, when going *head to wind*, but be deficient in draught when going *before the wind.* These circumstances merit more attention than is given to them."

* "The hot air, after passing through the lower part of the boiler, returns to the front by a centre flue, passing to the chimney simultaneously by two side flues. By this arrangement, the heating surfaces are more available, but it is difficult to divide equally the hot air into the two side flues. Almost always the current is greater in one than in the other, and the hot air will pass *but through one of them.* In that case it will be necessary to have registers at the end of each."

The views of Mr. Williams are strongly and heartily expressed, and many will differ from him, and the more particularly as he has discussed the opinions of every author on combustion, and the plans of every inventor; sometimes appealing to a corroborative proof, but often assailing the main or peculiar principle or distinction. Thus the voices and pens of many will be against him, and controversy will direct attention to the book; but it has merits which will secure for it at all times the weight of authority and the interest of practical and inquiring men. It is one of the most important contributions which has been made to this subject, because it comes from an able and independent man.

## PILE-DRIVING MACHINERY.

JOHN BOWER, *Patentee*, February 3, 1853.

(*With an Engraving, Plate* XXXIV.)

THE invention consists in the adaptation and application to engines for driving piles of a suitable tackle with stops, to be worked continuously by the barrel or capstan, such tackle being mounted in such a manner at the upper and lower part of the framework as to preserve the required degree of uniformity in the tension of the same during its working. The ram also is so formed, and has fixed to it a pair of spring jaws likewise so formed, that the tackle or endless rope or chain may pass through, but that the stops on the tackle may catch on a portion of the said jaws, and carry the ram upwards, until it is brought into contact with a wedge-formed trigger fixed in the framework; which trigger, in passing into a cavity in the ram, passes also between the arms of the jaws on the opposite side of their centre of motion from that at which they hold the said stops, and thereby opens the jaws and disengages the ram. Immediately on the disengagement of the ram, the spring or springs again close the jaws, so that they may be in the position to be caught by the next stop or projection on the tackle. The distance at which the stops are to be placed apart depends on the height of fall required for ram.

They should be equidistant, and always exceed the length of fall in a degree proportioned to the relative velocities of the tackle in rising and the ram in its descent as a falling body, so as to prevent the shock that would be occasioned by a stop coming in contact with the falling ram. The intervals or distances between the stops are so arranged as to bring a stop under the ram immediately after it has given the stroke or blow to the pile, which stop, by the motion of the barrel or capstan, carries the ram upwards until it is disengaged; and this operation is continued without interruption, the rotary motion in one direction of the working barrel or capstan being undisturbed throughout. In order, however, that the invention may be fully understood, we proceed to describe the accompanying Plate, which contains several figures, representing the different parts of an engine for driving piles, constructed according to the invention.

Fig. 1 is a front elevation of the engine; fig. 2 is a side elevation; fig. 3 is a back elevation of the same; fig. 4 is a horizontal section (on an enlarged scale) in the dotted line of fig. 2. A, A, are standards or guides for the ram in its ascents and descents; B, B, are stints, stays, and ladder; C, is a capstan, through which motion is communicated to the machine; D, is the ram, being formed with arms or projections *d, d* (which passes between the standards or guides A, A, the front part of the ram extending a short distance over the front of the guides); these arms or projections have holes in them through which wedges E, E, are passed behind the standards or guides A, A, and in this manner the ram is kept within the guides. These parts are shown in the detached fig. 4, also enlarged. F, F, in the same figure represent a pair of spring shears fixed to the head of the ram D, by a screw-bolt, washer and nut, or otherwise, so as to form a centre of motion for the shears, which are crossed at the centre, and extend in the form of arms F and *g*, confined towards the end by a spring or springs G, by which means the jaws *g, g*, and *ff*, are kept close until their arms *a, a*, are forced apart. The spring G, may consist of a band of vulcanised india-rubber, or a metal spring or springs of spiral or other forms, and may be variously applied to the arms F, for the purpose of closing the jaws. These arms F, lie over a recess or cavity Z, in the head of the ram, by passing into which between the arms F, the wedge-formed trigger (see figs. 1 and 2) forces the arms apart, and opens the jaws at the time required. V, is the tackle, with stops W, placed at suitable intervals thereon, as above described. This tackle may consist of a hempen rope with metal cones for stops, or a wire rope with like stops, as at fig. 6; or it may consist of a metal chain with stops, as fig. 7; or a chain of the form represented at fig. 8, with stops to catch on a bar in the jaws. I, is a pulley in the upper part of the standards A, A, over which the tackle V, passes. This pulley is mounted on a carriage H, which is capable of being adjusted to its required position by means of the capstan-nut L. M, is a pulley at the lower part of the standards A, A, under which the tackle V, passes. This pulley is mounted in a carriage M, which is susceptible of a slight degree of vertical movement, being connected to the lower end of a spiral spring P, or india-rubber band, now attached below (to the bar O, fixed in standards A, A); an additional use of these two pulleys I and N, is to regulate the tension of the tackle, and to obviate the necessity for shifting the engine as the work proceeds.

By means of the pulley I, mounted as described, the tackle is tightened or slackened, in order to secure the power of lift, and it may also be removed by the same means; but there is likewise a further use of the said pulley. In driving piles along the straight side of a cofferdam, and using the endless rope or chain above referred to, it would be found that the same length of tackle would not suit for driving more than one or two piles in the same row until the engine was shifted.

By means of the sliding-carriage H, however, the same tackle may be worked without alteration at variable distances within the range of the screw J. Thus, to increase the working distance, the carriage H, with its pulley must be lowered by the screw, and the engine moved forward; and to decrease the same, the carriage with its pulley must be raised by the same means, and the engine moved back. By means of the pulley N, mounted as described, the inconvenience of the slackening of the tackle consequent on the lifting of the weight, and of the shifting of the same in "singing," may be obviated. The tackle having been tightened by means of the screw attached to the pulley I, the carriage M, of pulley N, is drawn upwards so as to compress the spring P, tightly. Motion having commenced on the barrel on the first slackening of the tackle (from either lifting or singing) the spring P, exerts its force and produces the tightness required for effectual working.

Immediately afterwards the motion of the capstan tightens the tackle, and the spring P, yielding to the pressure upon it occasioned thereby, the carriage M, is drawn up to its first position, and thus the required tension is maintained throughout.

These pulleys I and N, may also be mounted in fixed bearings in the standards A, A, without the adjusting-screw J, and spiral spring P, but the arrangement above described is preferred. Q, is the trigger carriage or frame; R, is the trigger, which is fixed at its required altitude by the screw U, and passes through the plate T (see fig. 5), which is thereby secured at any required height at the back of the standards or guides A, A; the screw is turned by means of the vice-handle S. The length of the fall of the ram is regulated by the position in which the trigger is fixed in the standards.

The operation of the engine is as follows. The ram D, being in its place between the standards or guides A, A, and the tackle arranged as described, the latter is adjusted to a proper degree of tension by means of a screw J, belonging to the pulley I. On power being applied, and the capstan C, turned, the tackle V, moves freely upwards between the jaws *g*, until one of the stops or projections W, arrives under the said jaws, when the thicker part of the cone catches against the same, and being upon the under surface of the jaws, carries the ram.

This motion of the ram is continued until it arrives at the under part of the trigger R, which passes into the recess Z, in the ram, and its arms being wedge-formed, force apart the arms F, F, on the opposite side of the centre of motion of the jaws *g, g*, and cause the jaws to open suddenly, by which the stop at once loses its hold on the jaws, and passes through them, the ram thus disengaged falling freely on to the pile-head. As soon as the ram falls from the trigger, the pressure of the wedge-formed arms of the same against the arms F, F, of the jaws ceases, and the spring or springs G, again close the jaws *g, g*, in readiness to receive the next stop or projection W, on the tackle G.

The inventor does not mean or intend to confine himself to the precise forms and arrangement of the parts shown and described. The improvements may be applied with advantage to some pile-driving engines in ordinary use.

*Claims.*—1. The adaptation and application to engines for driving piles of an endless tackle with stops and suitable pulleys, together with a form and construction of ram capable of being raised to its required height, and allowed to fall at regular intervals, without interrupting the uniform course of the working barrel or capstan, as described; 2. The arrangement of upper and lower pulleys mounted in carriages, capable of adjustment by means of a screw and spiral spring, for the purpose of regulating the tension of the tackle and obviating the necessity for moving the engine so frequently during the course of the work, as described.

## SEWERAGE AND WATER SUPPLY OF KELSO.

*Report of* James Brunlees, C.E., Manchester.

In compliance with a resolution passed by the chief magistrates and commissioners of police, of the "Burgh" of Kelso, Mr. Brunlees has prepared "plans, sections, estimates, and a report for the sewerage of the town." We subjoin an epitome of the report, with brief necessary explanations, touching the locality. The desiderata contemplated in the report are—

I. An efficient system of sewerage effectual for the under drainage of the lowest buildings in the town, and embracing its entire extent; including, also, the drainage of suburban meadows, the present condition of which induces prejudicial atmospheric influences; and

II. A constant and copious supply of wholesome water, ample in quantity for public and domestic purposes, and available for use at the top of the highest buildings in the town. The governing considerations, in relation to the materials, dimensions, and character generally, of the works recommended in the report, have been economy, efficiency, permanent self-action, and durability.

Kelso is situated on the banks of the River Tweed, about 22 miles above Berwick, and nearly opposite the confluence of the rivers Tweed and Teviot. The water-course is from 400 to 500 feet wide, and contains a large body of water, passing at a moderately rapid rate. The population of the town is about 5000. Kelso presents a picturesque appearance, but is a very irregularly built town, and extends over considerably greater space in certain directions than the population might seem to indicate. The greater part of the town is built upon low-lying "Inch," with a gentle slope from the north bank of the river; a ridge of considerable elevation (the chalkheugh) running in a transverse direction from the Tweed, and abutting on its banks, divides about a fifth of the town, on the up-stream side, from the major portion.

The district is pleasant and salubrious; but the important sanitary advantages, which the site of Kelso places within reach, have not hitherto been realised, and the consequences of this neglect may be traced in the virulence of the attacks which have been sustained, by cholera and other pestilential scourges. The drainage of the town is extremely defective; it may be said, indeed, with perfect truth, that there is a total absence of anything deserving the name of a *system* of drainage, and the authorities have for a considerable time been fully alive to the vital importance of providing a remedy for this great defect. The sewage, and animal and vegetable refuse matter, which should be carried off by underground watertight channels, has been allowed for the most part to flow or stagnate on the surface, or has been collected in heaps, pits, or cesspools. The principal sewer, which runs alongside a number of houses, and which is very limited in extent, is a drain of 2 feet square, built of rough stones with open joints, and covered with flags which form the footpath.

The worn and imperfect joints of this drain afford a passage for constant streams of miasmata, which pollute the atmosphere; and the rude masonry of its sides and bottom permits the sewage to percolate, and actually ooze out in the houses in its neighbourhood. A considerable portion of the streets are nearly level, and many of them, from the absence of means of absorption for surface water, are submerged and impassable for a considerable time after a heavy rainfall.

The natural peculiarities of the site of the town suggests three divisions of sewerage—

(1.) The first division embraces the principal streets, and most compactly built part of the town, and about three-fifths of its extent. The aim has been to throw as much of the sewage as the levels permitted, into this division. The discharge for this main portion will be at the Bullet Loan, a point on the down-stream side of the town sufficiently remote to prevent the possibility of offence to the inhabitants by any exhalations from it. This division includes a main sewer from the Bullet Loan to the Coldstream-road, thence to the Coal-market, up the Wood-market, and through the south and west sides of the market place to near the Flesh-market in Roxburgh-street. Also another main sewer from the Coal-market to the top of the Horse-market, terminating on the east side of the market-place. This main and branches embrace about 1205 yards. It is proposed to construct them egg-shaped—the main 3 ft. 9 in. by 2 ft. 6 in.; the branches 3 ft. 4 in. by 2 ft. 3 in. The inverts to be of radiated brickwork set in cement, the sides and top arch to be of rubble. This form is preferred to secure an equable and rapid flow, and the combination of material is recommended for economy, bricks being expensive in that locality. The inclination of these mains is very favourable, being 1 in 250 throughout. The mains being placed sufficiently deep to drain the lowest buildings in the town, necessitates their being at a considerable depth from the surface (from 8 to 12 feet); but the uniform and rapid flow which will be secured, will effectually prevent silting or any deposit of material in the sewers, and this important advantage is an ample equivalent for the extra expense incurred from this circumstance. The subordinate sewers in this division aggregate about 2715 yards, and are to be of earthenware half-socketed pipes, varying from 9 to 15 inches diameter, as the areas to be drained and other circumstances suggest.

(2.) The second division embraces the upper part of the town, which is divided from the principal division by the intercepting ridge already referred to. The heavy expense which would be incurred in tunnelling this ridge, has prevented Mr. Brunlees from throwing the sewage of this into the principal division, which he would otherwise have done, discharging the whole by one outlet. The main sewer in this division will be a 21-inch barrel culvert of brickwork, about 46 yards long, with a discharge into the river at the bottom of Dispensary-lane.

To render the discharge inoffensive, the culvert will be supplemented by iron piping, secured by masonry, carried well out into the river for the immediate and complete dispersion of the sewage. The subordinate sewers in this division embrace about 1434 yards of earthenware pipes, from 9 to 15 inches diameter.

(3.) The third, or mill divison, is of an exceptional character, and the area drained by it is very small. It lies between the river and the lines of the first division, and consists of a few short and unimportant streets close to the Tweed, and having a direct fall into the stream. The levels necessitate the summary drainage of this small portion into the river at once, and this may be done without incurring the possibility of annoyance from the result. This division aggregates about 300 yards, and will be of 12 and 15 inch earthenware pipes.

The main and tributary sewers are laid in straight lines, as far as possible, with connecting curves of as wide radii as the situations permit.

The sewers throughout are calculated to carry off a rainfall of one inch per hour in addition to house drainage, so that submerged streets may no longer be feared.

The gradients of the pipe-drains are all remarkably favourable, varying from 1 in 250, to 1 in 10, the average being about 1 in 100.

The town is long and narrow, and most of the cross streets are short, and this circumstance has happily facilitated the endeavour to obtain throughout the most rapid inclinations possible.

Mr. Brunlees discusses in his report the value of sewage for agricultural purposes, its chemical elements, deodorisation, the best mode of treating it, &c., and recommends the construction of two covered tanks at the outlet of the principal division, each tank to be capable of containing a week's sewage. He fortifies this recommendation by quotations from the most distinguished chemical authorities, by statements of important illustrative facts, and by an estimate of the pecuniary result. Taking the value of the refuse from each inhabitant on this division, at the low figure of 2*s*. 6*d*. per annum, he estimates the net profit at nearly 300*l*. per annum, and this is exclusive of the liquid sewage. He proposes to construct these tanks on such a level as will give the greatest facility for loading from them, and for running off the liquid sewage. In relation to saving the sewage, but primarily and urgently on sanitary grounds, he recommends the substitution of waterclosets and soil-pans for privies and cesspools; and urges, that until the one kind of convenience is employed to the supercession of the other, the advantages of ample water supply, and an efficient system of sewerage, can only be very partially realised.

The suburban "meadows" Mr. Brunlees proposes to drain in the usual manner, cutting off the water-shed from the northward by a deep intercepting drain on the upper side of the meadows. By this means he believes that the producing cause of fogs will be removed, that the humidity of the locality will be materially diminished, and the temperature improved.

Water may be supplied to the town by three methods:—1st, by pumping from the Tweed; 2nd, by pumping the water that may be collected in the "meadows," afforded by the water-shed from the West Broomlands plantation, and the high grounds to the northwards; and 3rd, by gravitation from the River Eden at the top of Stitchell Linn. The last plan is recommended for adoption, on a full consideration of the efficient action of the works, the quantity and quality of the supply, the annual cost of maintenance, and ultimate economy.

Stitchell Linn is about 94 feet above the market-place. It is proposed to convey the water by pipes, in the ordinary way, to a service reservoir at the "Shoulder of Mutton Plantation," at a level of about 60 feet above the market-place. The supply would thus be constant, and at high pressure. The estimated supply is at the rate of 20 gallons per day per head for 6000 inhabitants, which leaves ample margin for flushing the sewers and other public purposes, as well as for increase of the population. The estimated cost of the sewerage, draining, and manure-tanks, is 3764*l*., and of the waterworks is 3473*l*.

The plans and estimates, &c., are based upon a minute and complete survey of the "Burgh," made for the express purpose.

## THE REPORT ON RAILWAYS FOR 1853.

By Captain Galton, R.E.

The length of new lines of railway sanctioned by the legislature in the United Kingdom during the year 1853, was 940 miles, which amount is very considerably greater than that sanctioned during any year since 1847. Of this amount, 589 miles were in England, 80 miles in Scotland, and 271 miles in Ireland.

Among the most important of the new lines in England appear to be the following, viz.:—A line from Strood to Canterbury, by which the communication by railway along the South bank of the Thames will be rendered continuous as far as the North Foreland. The Portsmouth Railway, by which a direct communication will be afforded between Portsmouth and the metropolis. An extension of the Midland Railway from Leicester to Hitchin on the Great Northern Railway, by which a second line of communication will be afforded from the Midland districts to the metropolis, and the Worcester and Hereford Railway, by which a more direct road will be opened between the Midland Counties and South Wales.

In Ireland the most important line would appear to be the Londonderry and Coleraine Railway, by which a direct route will be afforded between Belfast and Londonderry; and the Londonderry, Coleraine, and Sligo Railway, which will afford a direct railway communication from Sligo to Londonderry and to Dublin.

The total length of railway which has been authorised by Parliament to the end of 1853 is 12,688 miles. Of this number of miles 7686 have been opened for traffic, leaving 5002 miles to be completed; but the compulsory powers of 2838 miles have expired without being exercised, or the railways being opened to the end of 1853. The length of railways for the construction of which Parliamentary powers exist is 2164 miles. The length of railway opened previously to December 1843, was 2036 miles. The length opened in the year 1844 was 204 miles; in 1845, 296 miles; in 1846, 606 miles; in 1847, 803 miles; in 1848, 1182 miles; in 1849, 869 miles; in 1850, 625 miles; in 1851, 269 miles; in 1852, 446 miles; in 1853, 350 miles; making the total length then opened 7686 miles; of which 5848 miles are in England, 995 in Scotland, and 843 miles in Ireland. The length of narrow gauge railway, including the Irish gauge of 5¼ feet, is 6965 miles, of the broad gauge 626 miles, and of the mixed gauge 95 miles. The number of railway companies having single lines of railway at the end of 1853 was 97, the length of single narrow gauge lines, including the Irish gauge, 1543 miles, of broad gauge 112 miles, and of mixed gauge 53 miles—total, 1708 miles; of which 1135 miles of single line are in England, 132 miles in Scotland, and 441 miles in Ireland.

Of the single line opened at the end of the year 1852, 32 miles 46 chains in England, and 41 miles 76 chains in Ireland, have been made double during the year 1853.

The total length of new line which was opened during the year 1853 amounted to 350 miles.

Of the lines opened in England, the principal ones are—the Oxford, Worcester, and Wolverhampton Railway from Wolvercot to Evesham, by which the manufacturing districts near Birmingham, the town of Worcester, and the important agricultural districts between Worcester and Oxford are accommodated with a direct route to London; the Newport, Abergavenny, and Hereford Railway, by which a direct route is afforded from Birkenhead to South Wales; and the Thirsk and Malton, and Malton and Driffield Railways, by which railway communication is afforded to an important district in Yorkshire.

In Scotland the only line of importance opened for traffic was the Deeside Railway. In Ireland, the most important lines are the Waterford and Kilkenny, and Waterford and Limerick Railways, by which Waterford has been connected with the Irish railway system; and the railway from Killarney to the Great Southern and Western Railway.

All these lines of railway were inspected, previous to being opened for traffic, by officers of the Railway Department of the Board of Trade, who required the opening to be postponed in twenty-eight instances. The total number of inspections which were required to be performed by the officers amounted to fifty-eight.

Of the railways opened during 1853, twenty-five portions of railway, representing a total length of 298 miles, consisted of single line open at the end of 1853, viz., 1708 miles, was between one-fourth and one-fifth of the whole amount of railway open. It is to be observed that the length of single line open at the end of 1852 was 1485 miles, and at the end of 1851, 1307 miles. A single line of railway cannot be worked with safety except under special regulations, so framed as to prevent the possibility of engines or trains moving in opposite directions, from meeting on the single line; such regulations are, however, inconsistent with a large amount of traffic. In all cases of single lines opened during 1853, the regulations required generally either that the trains should be worked by means of one engine moving backwards and forwards over the line, or over particular portions of it; or that some particular man should be appointed to accompany the trains moving over the portions of single line. And in cases where the electric telegraph is in use, the regulations required were, that the persons employed to start trains should be distinctly responsible for ascertaining, before starting the trains, that the line is clear so far as the next station.

The amount of capital invested in railways at the end of 1852 was 264,165,680*l*., of which 161,400,256*l*. consisted of ordinary capital, 38,700,755*l*. of preference capital, and 64,064,668*l*. of loans. The amount of capital raised for railway purposes, in 1849, was 29,574,720*l*.; in 1850, 10,522,967*l*.; in 1851, 7,970,151*l*.; and in 1852, 16,398,993*l*.; thus increasing the amount invested in railways at the end of 1849 from 229,747,778*l*. to 264,165,680*l*. at the end of 1852. The amount of money which was raised by railway companies during 1853 has not yet been returned to Parliament; but it may be assumed not to have been less than that raised during 1852, and it is therefore probable that the whole sum raised by railway companies to the end of 1853 is not less than 281,000,000*l*., of which about 42,000,000*l*. may be assumed to have been preferential capital, and nearly 70,000,000*l*. would appear to have been borrowed on the security of the undertakings.

The number of miles of railway in course of construction on the 30th of June, 1853, was 682 miles, and the number of men employed on them was 37,764. The number of miles open for traffic at that date was 6512, and the number of men employed 80,409. The number of men employed on railways open for traffic was 9·5 per mile in 1852, and 10·7 per mile in 1853.

The total number of passengers conveyed on railways in the United Kingdom in the year 1853 amounted to 102,286,660; the number in 1852 had been 89,135,729. The total receipts from all sources of traffic amounted in 1853 to 18,035,879*l*., and in 1852 to 15,710,554*l*.

The receipts from goods have increased from 4,750,504*l*. in 1849, to 8,112,477*l*. in 1853, being an increase of from 1090*l*. per mile in 1849 to 1415*l*. per mile in 1853; and whilst the receipts from passengers in 1849 were larger than the receipts from goods in the proportion of 53·42 to 46·48, in 1853 the contrary was the case, viz., the percentage of the passenger traffic was 47·45, and of the goods traffic 52·55.

In Scotland the progress of traffic on railways has been similar.

The mean length of railway open during the year has increased from 795·5 miles open in 1849 to 987 miles open in 1853. The number of passengers conveyed in 1849 amounted to 7,902,228, and in 1853 to 10,999,224, which represents 9993 per mile in 1849, against 11,246 per mile in 1853. The relative number of passengers of each class conveyed would appear to have slightly varied, the number of first and third-class passengers having increased, and the number of second-class passengers having diminished, the number in 1849 being 720 first-class passengers per mile, 2035 second-class passengers per mile, and 6997 third-class passengers per mile, against 1107 first-class, 1971 second-class, 8165 third-class passengers per mile in 1853. The receipts from passengers having increased from 540,778*l.* to 697,712; or from 680*l.* per mile in 1849 to 713*l.* per mile in 1853; and the proportion of receipts from each class conveyed having been, in 1849, 149*l.* per mile for first-class, 196*l.* per mile for second-class, and 331*l.* per mile from third-class passengers, against 181*l.* per mile from first-class, 179*l.* per mile from second-class, and 345*l.* per mile from third-class passengers in 1853.

It would, therefore, appear that in Scotland the third-class traffic preponderates considerably both as regards numbers and receipts. There is also in the Scotch lines a preponderance in the receipts from goods traffic over the receipts from passenger traffic.

The amount received from goods in 1849 was 650,640*l.*, and in 1853 it was 1,068,016*l.*, representing 818*l.* per mile in 1849, against 1075*l.* per mile in 1853. The relative proportions of the two descriptions of traffic were, in 1849, passenger traffic 45·38, and goods traffic 54·62; and in 1853 the receipts from goods traffic amounted to 60·48 per cent. of the whole traffic.

The mean length of railway opened in Ireland in the year 1849 was 428 miles, and in the year 1853 it was 771 miles.

The total number of passengers conveyed in 1849 amounted to 6,059,947, or 14,142 per mile; and in 1853 it amounted to 7,074,475, or 9175 per mile.

The receipts from goods are also largely increasing, and they bear every year an increasing proportion to passenger traffic.

With respect to accidents, it appears that in 1852, 217 persons were killed, and 486 injured on the railways in the United Kingdom out of a gross total of 89,135,729 passengers; of these persons 181 were killed and 413 were injured in England; 24 were killed and 71 injured in Scotland; and 11 were killed and 2 injured in Ireland. In the year 1853, out of a gross total of 102,286,660 passengers conveyed by the railways of the United Kingdom, 305 were killed and 449 injured; of these, 243 were killed and 369 injured in England; 37 were killed and 68 injured in Scotland; and 25 were killed and 12 injured in Ireland.

## CONDITION OF THE THAMES MARSHES.

*Analysis of the Evidence given before the Select Committee appointed by the House of Commons to inquire into the Sanitary and Agricultural State of the Marshes on the Sides of the Thames, the Means for their Improvement, the existing Legal Powers for the Purpose, and the Necessity for further Legislation thereon.*

Peter Bossey, Fellow of the College of Surgeons, a Medical Practitioner residing at Woolwich, and in practice there for 30 years.—The town of Woolwich is situated on the south side of the Thames, on a little projecting spur from Shooter's-hill, and is bordered on either side by marshes; on the west side by a small amount of marsh, the Charlton marshes, between Woolwich and Greenwich; on the east side by a larger tract, and on the opposite side of the river by the Essex marshes. The town is divided into the eastern district and the western district; it is so divided by the registrar. The eastern district is exposed to the malaria of the marshes, the western district is nearly exempt from it. The marshes on the east form a considerable tract bordering the river; the general impression is that they are about four miles in length between Woolwich and Erith, and varying in breadth from three-quarters of a mile to a mile and a-half between the hills and the river. They are occasionally flooded, which is generally followed by malaria when the water has evaporated, and especially in the autumn and winter of the year. In the spring and summer the evaporation goes on. But there are several sources of this wet condition. The first is the leakage or infiltration from the river itself; the marshes are below the level of the river in that district; consequently there is a leakage through or under the banks. This is evident by what is observed in superficial wells, which are sunk in the marshes for some distance inland; the water in some of these wells will rise and fall according to the ebb and flow of the tide. The amount of this rise and fall in a well recently sunk in the Royal Arsenal, at 250 yards from the river, has been determined by Mr. Senday, the clerk of the works, to be 2 ft. 2 in. every tide, and 2 inches more during the spring tides. Another source of the moisture of the marshes is the land springs, which are particularly abundant. The drainage of these marshes is defective; has seen lately an accumulation of rank and decaying vegetation being cleansed from the ditches. There is unquestionably a greater amount of fever and ague in Woolwich and its neighbourhood than in Chatham. It is difficult to acquire a knowledge of the exact degree of their prevalence beyond one's own observation, but is confident that in Woolwich and its neighbourhood, owing to the wetness of the marshes and their deficient drainage, by the accumulation of rank and decaying vegetation, there is a malaria produced, and there is an excess of moisture which is also detrimental to health. The population of Woolwich, according to the census of 1851, was 32,069. Attributes the large amount of sickness at Woolwich to the malaria which arises from the marshes above East Woolwich. There is no question that this might be prevented by a more efficient system of drainage. Illness increases in the spring when the malaria arises from the water going off and the land drying. Any scheme which would drain the marshes quicker would shorten the period when the malaria is increasing, and prevent the deposit of decaying vegetation. Is confident effective drainage would lessen the amount of disease. Remembered seeing last winter the marshes opposite the Thames under water for a very considerable tract; the marshes on the south side were in places covered. The south or Kent side is not generally flooded, for the reason that it is a sandy loam; the marshes consist of loam on the surface, then there is sand overlying the chalk. The Woolwich marshes are flooded by the upland water coming down. The leakage through or beneath the banks offers an impediment to the running away of the water which comes down from above; it keeps the land in a wet condition, and so obliges the water to flow over the surface or into the ditches. Has heard that formerly the water of the Thames occasionally flowed over the sea-wall and through the banks. The storm waters are dammed back by the embankment. Believes that there is but one sluice so low in the marsh wall that the water can run away at any other time than at low tide; they are only partially flooded on the Woolwich side; if they are not covered, probably the ditches are full, and the land is wet. On the other side has seen it flooded, but it is not the ordinary condition of the marshes. The malaria exercises an influence over a very large extent; has seen ague and remittent fever in the hills as well as in the valleys as far as Woolwich-common and Shooter's-hill; knows that it prevails even beyond those places; the registrar's return shows that it influences London. Malaria varies in intensity; it is, perhaps, most intense in the morning and in the summer season, after there has been a great evaporation going on under a hot sun. In the early mornings, at 3 or 4 o'clock, a little fog arises upon the marsh, perhaps not above 3 ft. high, which is exceedingly offensive upon going into it; has taken a very severe remittent fever and ague from passing through that fog; persons who are out early in the morning in the marshes, before the fog is dissipated, suffer very much from ague, whilst others who live upon the hill and are above the fog, suffer considerably less. Fog does not occur when there is a large quantity of water upon the land, but generally in the summer, when there is least. The peculiarity in the marsh, which had given rise or added a good deal to the epidemics of 1845-6-7, was this: the owners of the marshes, or the persons who used them, had dammed up many of the ditches, so that they were for a long time in a very unclean state; this was followed by a very great extension of ague and intermittent fever. Some horses had been affected with the staggers, and it was supposed to have been produced by their drinking salt water; some of the sluices in the marsh banks are so high that they only admit the water at half-tide, consequently it comes in in a very brackish state. The graziers, to avoid this, increased the number of pens in the marshes, and kept the upland water, so that the cattle could drink nothing but fresh water. Does not know if this damming up exists now. The sanitary condition of Woolwich of late years has rather degenerated. There has been an increase of fever, and also an increase of ague.

James Stewart.—Resides on Woolwich-common; was, until lately, Inspector-General of the Ordnance Medical Department, and has had many years' experience as to the sanitary condition of Woolwich. The night-guard at the Arsenal is especially unhealthy, in consequence of the malaria from the marshes; the malaria is clearly the cause of the fever and ague so locally prevalent; the higher parts of the town are not so unhealthy as the lower parts; there is greater prevalence of ague when the wind is from the north or north-east, that is, when blowing from the marshes; and also when the weather is very hot. Considerable improvement may be anticipated in the health of Woolwich by an effective drainage of the marshes. There is now more arable land than formerly, and consequently more drainage. It is supposed that malarious air is very dense; there is no test for malaria, either mechanical or chemical. Generally a fog is perceived lying over malarious land; there is a kind of haze that falls over the land, and when the sun touches it it rises; that is from the effects of the sun. Thinks it can be proved almost, from what is known of certain localities, that malaria will be carried up the slope of a hill by a light wind; it is never known to descend again from the crest of the hill. Accounts in this way for the agues which happen on Sandy-hill and Plumstead-common. If you take a certain height the land is entirely exempt; still the malaria will travel up a slope. The increase of buildings on the low and unhealthy ground near Plumstead tends to increase the mortality in East Woolwich. There is greater prevalence of ague when a hot summer follows a wet winter. There is liability to remittent fever even if the marshes were very dry.

George Farr, Surgeon in the Ordnance Medical Department at Woolwich.—Has been abroad till lately since 1846; previously passed ten years at Woolwich. Amongst the artillerymen admitted into the hospital at Woolwich, there is a great deal of intermittent fever, and some remittent fever, the former in the spring of the year and the latter towards autumn; the predisposing cause, no doubt, is the malaria of the neighbourhood; diarrhœa arises from the same cause; rheumatism and tic doloreux are also common. The place he conceives to have the greatest proportion of attacks of diseases incident to malaria, next to Woolwich, is about the lakes of Canada. There it was more violent, a more swiftly progressing disease, a remittent fever very frequently terminating fatally in twenty hours. A great many men died of ague during the construction of the Rideau canal.

Rev. William Acworth, Vicar of Plumstead.—The poor children do not attend school in consequence of the prevalence of ague among themselves and their parents, and the expenses consequent thereon. Was compelled to remove from the Vicarage, which was in the marshes, to higher ground, which is perfectly healthy.

William Dickson, Farmer and Land Agent at East Wyckham, near Welling, Kent.—Holds sixty-two acres of marsh land, part under the plough, part under grass. The water is penned up too high sometimes; even now the water is going back in the furrows on the meadow land. There is no drainage upon his land, because there is no outfall. The damage to a crop of wheat per acre, taking it at the lowest, is a quarter of wheat per acre per annum. Calculates the loss with respect to the quantity of hay is upon the average from one-half to three-quarters of a load per acre; a load contains 18 cwt. There is a deterioration of 1*l.* and even 2*l.* a load. Grows upon the upland a-quarter to the acre more wheat on the average than on the marsh land; is satisfied that he could get five quarters to the acre upon the marsh land if it were laid dry. The staple of the marsh lands is not all the same; the land of the lower level next to Erith is of a thinner nature. There was not so much deposit left by the river, because it lies near to the tidal stream, which when receding carried with it the deposit. The marshes do not want lime as a manure; there is lime in the river, from washing the chalk cliffs about Gravesend, which is carried up by the tide, and mixed with the London manure that flows down, and is deposited upon the mud, from whence it finds its way to the marshes. It is a deposit of carbonate of lime, which is next to lime. Has no doubt, speaking as a practical agriculturist, that his marsh land would pay for draining; the obstacles to its being drained are, a great many persons occupying marsh land are graziers, and they like to see plenty of water, as the cowkeepers say the cows will not give milk without they have plenty of water to drink, therefore they pen it to make a head; their land would be the better for drainage, but they are prejudiced. The obstacles, in point of fact, to the drainage of this land, which would be a benefit, not only in an agricultural point of view, but as regards health, are the prejudices of a number of people, who take a mistaken view of the results of draining. With reference to the application of lime, it is well known that it is of no use to apply lime to wet land; but supposing the land were well drained, the farmers would apply lime to it, and therefore increase the value of the land for growing purposes. Suffered last year in making hay, from the water coming back upon the meadow land. His workmen live in the uplands; they will not stop all night in the marshes. Does not keep sheep upon the marshes; is afraid of the rot; they are usually sent in the spring and summer and latter end of the year; they feed there as long as the ground is dry, and when the wet comes on they are removed. It would be possible to provide a supply of fresh water for the stock and cattle in the marshes if they were properly drained; before the South-Eastern Railway carried their conduits under the railway, the managing man of the commissioners did not look sufficiently to one of the conduits under the railway, where the main sewer is, and the banks of that sewer have been made for several years, by the accumulation of the drift from the uplands caused by the fresh water coming in; they have allowed that increase to sink down into solid ground, and now the water rides level with the top of his ground, and the banks being of a sandy and porous nature the water gets into his fields. The cattle could get plenty of fresh water to drink even if the marshes were made thoroughly dry, because the conduits to the river have only to be enlarged, and the mains deepened, to fill the ditches with water, and then deepen the approaches to the drinking places. It is only required to deepen the ponds, and a supply of fresh water can be had; the water should be lowered down so that a drain 3½ feet deep could be made. There is not any force in the objection which is made by the owners of the milch cows, that they will not get plenty of water; they will get plenty of water, only they want it dammed up to the top that it may make a fence. The lowering the water in the marshes by a drain 3½ feet deep would cause an increase in the temperature of the ground; better crops could be had, and water always had by having deeper ditches or larger approaches to that water. On his land there is 6 feet of what is called marsh deposits from the river, upon a bed of peat; chalk is below the peat, it crops out in the uplands. Does not think peat water so good as fresh water. If the ditches were deepened, that would be sufficient. The mud covers the peat; the water does not get to the peat; it forms a nasty drain over it, which is very prejudicial in the spring and autumn. The average rent of land in the marshes is 30*s.* to 40*s.* and 50*s.* an acre; generally there is more given for grass than for arable land; in some places, where it is accommodation land, 60*s.* has been given by butchers. Supposing 30*s.* an acre was now paid for cultivated land, the increased rent, if the land were laid thoroughly dry, would be 5*s.* to 10*s.* an acre. In his opinion there is no want of outfall and no physical difficulty in the way of draining the marshes; plenty of outfall could be got if the sluices were only increased in size and the mains deepened; it does not require any large engineering work. He would rather give 50*s* for an acre well drained than 2*l.* for the undrained. Does not conceive that it would be possible, under present arrangements, to obtain the consent of the necessary number to drain the marshes; it would require an act of parliament. The cost of cultivation on the drained is much the same as on the undrained, except that you pay a little more and have a better crop. The great object of the persons who hold this land in not wishing to have it drained, is to have the ditches as a fence. If those ditches were made deep, they would serve as fences just as they do now; it wants the water to be lower in the ditches, and then you can deepen the drains; the ditches would be just as effectual for fences after they were drained as before; the ponds and approaches must be made deeper where the cattle drink.

William Stockley, Senior Veterinary Surgeon of the Ordnance.—Has been sixty years in the service. When young horses are exposed to marshy, wet situations, there is a peculiar disease generated which arises from the damp and from the impurity of the low marsh lands, which is a disease of the chest and produces water; it is a disease of the pleura; instead of its going on to inflammation it goes on to produce water in the chest. We remove them generally in time, but we never return those who are affected by the marshes. They recover upon the high ground where the Infirmary is situated, and become strong again if they are detected in time. There is precisely the same effect produced in all situations of that kind. No doubt the malaria is debilitating to their constitution; it runs on from inflammation, which is produced by damp, to debility and water; there is nothing peculiar in these marshes to any others which he has seen. When the land has become dry and the air is light, there is no disease among the horses; we keep them in sheds during the winter, and when they are turned out the weather has become warm.

J. Flint South, Surgeon at St. Thomas's Hospital.—Resides at Blackheath-park. His knowledge of the marshes originated in having been appointed last year a member of the sanitary committee of Charlton, and the Walscot district of that parish having been assigned to him, with some others, to overlook. He then made a report to the sanitary Board, of which the following is the substance:—The Charlton marshes are very much lower than the river, from which they are protected by an artificial bank about 10 or 12 feet high. One or two large spring ditches run through them, carrying off the spring water, and also the drainage, from the private ditches; but for the most part the private ditches are very imperfectly looked after. In the river bank are one or two sluices in connection with the spring ditches, which are opened at very irregular times, as may suit the occupiers of the land in their immediate neighbourhood; and consequently, during the greater part of the year, the ditches are in a very filthy, nasty state, very offensive, and full of decayed vegetable matter and mud. The drainage generally is extremely imperfect. Between a private road which separates Charlton parish from Greenwich parish, one part, the eastward side being in Charlton, in the occupation of Mr. Roberts, and the westward side being Mr. Angerstein's property—between that road and Woolwich parish, which is separated from Charlton by a road called the Manor-way, almost the whole of the land is swampy. Even at a very short distance from the surface, if a trench only 12 or 18 inches is dug, it soon fills, and the drainage does not run away. A vast number of houses have been built, and are still building, particularly towards the east end of the marsh, which is in a very swampy, unhealthy condition; many of the tenants state that they cannot keep their ground floors dry, and not even the hearthstones, in some instances. The only drainage from those houses, at the time when he visited them last autumn with other members of the sanitary committee, were some small drains about 18 inches wide, and about as many deep, into which the drainage from the cesspools and from the houses ran; part got away as it could, by soaking into the ground and by evaporation. Where it could not get away quite so quickly, it spread over a large space, and formed very stinking, standing pools of water. Running into these a great number of 6-inch drain pipes are also laid. He went over the district that morning, on purpose to see if any alteration had been made. Is informed, that under the direction of the surveyor of Roupell's estate, to which the greater part of this property belongs, large 12-inch pipes are now being put down, and run into the spring ditches belonging to the Commissioners (although without the right, he believes, to do so), in place of the narrow gutters which were mentioned above as being so offensive; and communicating with them are small pipe-drains for the house sewage, and each two houses having one small pipe drain. It will make the ditches sewers. Thinks the sluice by Charlton pier is regularly opened, but believes the sluice which is by Mr. Angerstein's property, just to the westward of Charlton parish, is raised or put down as it may suit the purpose of the farmers occupying the land.

Sir Culling Eardley, Bart.—Resides at Belvidere, close to the Erith marshes. The neighbourhood of the marshes is in a continual state of ague, which deters persons from settling in the vicinity. It is impossible for the district commissioners of sewers to move in the matter, as it is necessary, but impracticable, to obtain the consent of three-fourths of the proprietors or occupiers in order to carry out a system of drainage. Has been for a good many years a commissioner of the North Level of the Bedford Level, and there is a very striking contrast between the thorough drainage of that district, a long way from the metropolis, and the very defective drainage of our district, which is close upon the metropolis. It has been stated that London stands upon about 20,000 acres of land. Upon the north-east there abuts the Thames marsh district of 32,000 acres of undrained land; this is equivalent to a person living in a house of 20 feet frontage, with a marsh of 32 feet abutting upon it. In the North Level the drainage has been thoroughly effected, by means of applications which might be very easily adopted in this district. The Bedford Level is drained by natural outfall; but the great means which has rendered that district well drained is, that a certain number of persons were chosen by the proprietors who possess their confidence; they have no difficulty in taxing the country, they have very large powers of taxation. Both steam and windmills are entirely superseded. The river Nene has been deepened down to the sea, and by that means a completely natural system of drainage has been obtained. In the Nene the waters flow off only at low water; there are sluices which open at high and shut at low water; but engineers report that the Thames marshes might be drained in the same manner.

Charles John Pinchin, Surgeon in practice at Gravesend.—Bears testimony to the prevalence of ague and severe marsh fevers in and around Gravesend.

James Russell, Farmer.—Had a large farm in the parish of Plumstead; at his own expense under-drained about 200 acres, and found a considerable benefit by it. Thinks all the land in the parish requires under-draining in the marshes. Finds his crops very much improved since he under-drained the land. Has no doubt all the land in the marshes is equal to his, and that they would benefit equally if they were under-drained. The average expense of draining the 200 acres was about 5*l.* or 5*l.* 10*s.* an acre.

David Corbet, M.D., residing at Orsett, in Essex.—The whole type of disease which prevails in his district indicates a malarious and badly-drained country. The influence of the malaria extends a considerable distance; has known it extend as high as Laindon Hills, the name of a parish standing off the marshes and very high.

Richard Heath, Surgeon, Grays.—Fevers and agues are the prevailing diseases in his district; in drained marshes cases of ague are rarely heard of. Questions if any system of drainage would remove the fogs, because fogs occur where there are no marsh lands.

John Manley, M.D., Barking.—The health of Barking has improved considerably within the last fifteen or eighteen years; accounts for this change by the great improvement which has taken place in the drainage of the Barking marshes. It has been brought about by having additional sluices put down, by which means the water is carried off; the ditches are not full, and the ground itself is better drained; it is not swampy.

John Haywood, Clerk to the Commissioners of Sewers for the limits extending from Lombard's-wall to Gravesend-bridge.—The date of the commission is June 30th 1853, being a renewal of commissions which have existed 200 or 300 years; the first was established under 23 Henry VIII. It issues from Chancery, and is directed to persons named by the lord chancellor and chief justice; there are ninety-five commissioners at present; it is an unpaid commission. The tax for drainage works is levied on the occupier, who may or may not claim it from the proprietor. The Commissioners are obliged to charge to each year the expenditure which may take place. The consent of three-fourths of the owners and occupiers is necessary, in order to raise money to be distributed over a period of fourteen years. The tax is always raised by scot, payable in the year. It is highly expedient, for the sake of justice to all parties, and for the improvement of the land, that there should be power to undertake the necessary drainage works, to raise a large sum at once, and to extend its payment by the occupiers, &c. over a period of years. No new works of any kind can be undertaken without consent. The power of occupiers to dam up the water in the private ditches, and the inability of the commissioners to interfere, is productive of very injurious effects. It would be expedient to grant similar powers to the Sewers Commissioners, as were given to the Inclosure Commissioners; if the commissioners were empowered to do new works, unless three-fourths or any stated number objected after notice which might be prescribed, that would probably very materially do away with the difficulties. Upon the survey each year, the commissioners are attended by their surveyor (who is a paid, permanent officer), by the clerk, and by the expenditor; they then inspect the work which has been done during the previous year, and the expenditor produces to them, as they go along, an estimate of the work required for the forthcoming year; the material outlay is for the repair of the Thames embankment. Every year after the survey is made, the commissioners hold an annual meeting, at which they pass the previous year's accounts of the whole of the levels, and any one may attend if he thinks proper. They then make an estimate of the cost for the forthcoming year, and direct the warrants for the levying of scots to be prepared; and then, at a subsequent meeting, the warrants are issued. The books are open for the inspection of any landowner or occupier. The commissioners can levy what amount they please when the works are consented to. The great number of occupiers is the main difficulty to the consents being obtained.

Entirely concurs with the views of Mr. Easton, as given in his report. There is no private act with reference to these marshes; the commissioners work entirely under the public act commonly termed "Hodges' Act." One of the points of this act was to give the commissioners additional powers, with the consent of three-fourths of the owners and occupiers. Before that time the commissioners could do no new works whatever. Then came "Hodges' Act, which said, "You shall have power to do new works, but we will give a controlling power to the owners and occupiers to the extent of three-fourths of the value." Every sluice has a flap to it, which is a self-acting flap, and the outlet is cleansed and discharged by itself, upon the subsidence of every tide; no salt water, throughout the whole of the levels, is admitted. The surveyor is the man to whom, in the first instance, these flaps are entrusted, and then he has under him two or three other persons whose duty it is to see daily to the sluices. The surveyor is paid a stated salary of 100*l.* a-year; it occupies the whole of his time. There is not any power in the commissioners when they see the private ditches in a dangerous state, to compel the owners to repair them; such a provision would be advantageous. In one of the levels, the Stone Great Level, which is a small level, the commissioners having the consent of three-fourths of the owners and occupiers, put down a new sluice at a lower level, and the benefit throughout the whole of that level since has been found very great. Objects to the commissioners being elected by the owners and occupiers.

Robert Westley Hall Dare, a Landed Proprietor in the parishes of Rainham and Wennington, also a Commissioner of Sewers for the district.—His experience of the agricultural state of the marshes is, that drainage is exceedingly wanting; not only these marshes, but the lands both east and west, as far as Barking and as far as Grays. A great portion of the lands between Rainham and Barking are under arable cultivation. Has often known a crop of potatoes to be twice planted and twice flooded in a year. Within the last three years has also known the same accident to happen to crops of wheat; yet, in spite of that, the produce of everything that has not perished by the water is of the most magnificent description; it is land which is capable of growing wheat and potatoes (if the disease does not take them) alternately, without intermission and without manure, for any number of years. Has observed that there are a great many old intersecting walls and high places which have been formed at different levels by the deposit of the river. In all cases in which the level is higher, the grass is finer and of a more fattening quality; in many cases those high places are as much as eight feet above the level of the water. He feels justified, therefore, in concluding that if the waters were reduced over the whole levels to a proportionate depth below the general surface, the quality of all the grass would come to the same pitch as it now is upon those isolated spots.

Samuel Westwood, Occupier of Land at Laindon-Hill.—Is a commissioner of sewers on the level beginning at West Thurrock, just below Purfleet, and from thence down to Fobbing. In the level of Fobbing about one-fifth is in arable culture, the remainder in grass; on the level of Mucking to Tilbury, about a-fourth is arable; and in another level, Chadwell to Grays, a-fourth. They are very indifferently drained. A marsh bailiff is appointed to inspect the works, at a salary of 150*l.* a-year. Suggests the appointment of a paid commissioner in each district. Thinks a Board in London would not do at all; in cases of breach, where there is a great extent of water pressing upon heavy walling, it requires somebody upon the spot.

John Ayrton Paris, M.D., President of the College of Physicians.—Bears testimony to the existence of ague in the Eastern part of London as attributable to the influence of the Thames marshes.

W. W. Gull, M.D.—From Woolwich along the line of the Thames, even up beyond Westminster, we are frequently receiving cases of distinct ague and other direct effects of miasm at Guy's Hospital, both into the house and as out patients; about half come from Woolwich and Erith, and the other cases we get from the Isle of Dogs, Greenwich, Deptford, Rotherhithe, Wapping, Shadwell, Bethnal-green, and Whitechapel; we get them along the Thames from Bermondsey and Lambeth, and even from the place upon which these Houses are standing; from Westminster we have marked cases of miasmatic influence. The marsh is one of the most fruitful sources of miasm; has no doubt that London, on the banks of the Thames, is miasmatic. There is no doubt, taking the whole of the population of London, that the draining has had very much to do with lessening the miasmatic condition of London of late years. We however, even now see miasm not only producing ague, but having a distinct influence upon other diseases. The common fever of London in certain seasons assumes, to use our language, quite a miasmatic type. We find persons suffering under typhus and typhoid fevers suddenly losing the characteristics of the fever, and assuming quite an aguish character; cannot say that it has increased of late; it is uncertain in its appearance; we have it in some seasons, and we lose it in others. An effectual drainage of the marshes would remove a fertile source of malaria. The large amount of mud on the banks of the Thames has an injurious effect upon health; for a large portion of the twenty-four hours it is left exposed to the air, when it must be evaporating noxious gases. Marsh miasms are conveyed, no doubt, a considerable distance; sufficiently authentic cases are recorded to show that the influence of marsh miasm extends several miles. Dr. John Macculloch, who wrote a very careful work upon the subject of miasm, gives several instances of its conveyance to that distance; but as the metropolis itself is miasmatic, it would be difficult to separate the effects of the two sources of influence. During this week I find in one of the journals a paper stating that many cases of ague have during this spring been admitted into St. George's Hospital, which the writer supposes may have come from Brompton or Chelsea.

Thomas Webster Rammell, C.E.—Has been directed by the Board of Health to examine the marshes. Has examined the marsh lands generally on both sides of the river. The gross extent of marsh land between London and Sheerness, on the north side, is about 22,000 acres; and on the south side rather more than 16,000 acres; being a total of nearly 39,000 acres. The marshes are divided into separate areas by the high lands which come down to the river Commencing on the north side, the first area of marsh land is the Isle of Dogs, which contains about 400 acres. There is then a very extensive area extending from Blackwall down to Purfleet, where the high land touches the river: that I have calculated in three separate areas, of 2900 acres, 2400, and 2000; making altogether about 7000 acres in that level. There is then on the north side, an area between Purfleet and Grays containing nearly 1000 acres. Then there is, between Grays and Tilbury, an area of about 3000 acres. These areas have been roughly measured from the Ordnance map. Under the Metropolitan Commission are the Isle of Dogs and part of Greenwich marsh, making together about 580 acres. There is then a commission extending over Dagenham, on the north side of the river; that appears to extend from Blackwall down to Rainham, and contains about 5500 acres. Then there is a commission with about 6500 acres, on the north side, between Rainham and a point beyond East Tilbury, just opposite Hope Point. There is then a portion on the north side, near Fobbing, containing about 3300 acres, and which is under a separate commission. Then there is Canvey Island, which appears to be under a separate commission; it contains about 4000 acres. Then there seem to be about 3000 acres of land out of commission on the north side. On the south side, from the Isle of Grain up to Gravesend, there are about 11,000 acres in commission. The extent of marsh land below Gravesend, down to Sheerness, is about 11,000 acres. —The witness was requested by the chairman to state particularly, with regard to the Erith and Plumstead levels, what works are required to carry out a more efficient system of drainage. He said, that area he would take to be 3000 acres of land, about half of which is under arable cultivation, the other half being meadow and pasture. This level is under a commission, extending from Lombard's-wall to Northfleet; the whole of that area is below the high-water level of neap tides; Lombard's-wall is the boundary between the district of the Metropolitan Sewers Commission and the commission alluded to. The lowest parts of that area are about 7 ft. 6 in. above the low water of neap tides; some parts of that level rise as much as 10 feet above the low water of neap tides. A neap tide on the 4th July last rose 14 feet. An ordinary spring tide will rise 18 ft. 6 in. The Plumstead and Erith level is subdivided into fields by ditches, which serve the double purpose of fences and of reservoirs for supplying water to the cattle. The total length of ditch upon the area is about 84½ miles, which, at an average width of 6 feet for each ditch, will give about 60 acres of land. Found the level of the water in the ditches to be generally such as not to admit of subsoil drainage; should take 3 ft. 6 in. to 4 feet as the depth of subsoil drainage. The area is at present drained by five sluices, which are at levels respectively of 3 ft. 6 in., 3 feet, 3 ft. 6 in., and 2 feet above the level of neap tides. The best mode of improving this district would be to get rid, as far as possible, of the stagnant water in the ditches. The five sluices close by ordinary wooden flaps at the rising of the tide; one is of cast-iron; they are self-acting. Proposes to subdivide the land, so as to prevent the stock from the grass land getting into the arable land, by using the ditch partly as a fence, and planting quick on one side, with a line of posts and rails to protect it. The abolition of the ditches involves the question of water supply to the cattle, as well as of fencing. Twenty miles of the ditches might be abolished; the remaining 64½ miles might be laid dry, and a hedge fence added to them. Would partially fill up the abolished ditches, sloping the ground on either side; there would be a clear gain in the value of the land obtained, after the works are completed. Witness then described the works he proposed for the drainage of the marshes. He divided them, first, into main works of drainage; secondly, into works of water supply for the cattle; thirdly, into works of fencing; and fourthly, works of subsoil drainage. The main works which he proposed would cost about 8000*l.*; they would consist of a main cut through the centre of the level, with other cuts leading to five outfall sluices, those sluices being placed at a level of 2 feet above low water of neap tides. The works would be laid out in give-and-take lines; in some cases there might be a positive interchange of land; it would be necessary to have some power of changing. Would make the cuts five yards wide; and then, for ensuring a change of water in the main cut in dry weather, proposes to fix three inlet sluices, the cost being included in the estimate of 8000*l.* The water supply for the cattle would be best obtained by storage reservoirs at the foot of the high lands adjoining the marshes, and conveyed to the separate fields in iron pipes; the cost of these works he estimates at 3900*l.* The cost of the fencing he puts down at 8400*l.*; proposes to have quick planted on one side of the ditch, protected for the time by a three-railed post and rail fence; has estimated that at the rate at which fences on the side of railways have been done. The subsoil draining of 3000 acres is taken at 16,500*l.* or 5*l.* 10*s.* an acre; proposes to do it from 3 ft. 6 in. to 4 feet deep. Considers that a two-inch pipe would be sufficient; would lay the lines about eight yards apart. Has taken 1*d.* a yard for the laying, and 1*d.* a yard for the pipe; the whole of the works described would involve a total outlay of 36,800*l.* on those 3000 acres of land; or 12*l.* 4*s.* 10*d.* per acre. The outlay per acre on the main works will be 2*l.* 13*s.* 2*d.*; on those for the supply of water, 1*l.* 5*s.* 8*d.*; the fences will cost 2*l.* 16*s.*, and subsoil drainage 5*l.* 10*s.* Supposing the money to be borrowed at 4 per cent., and to be paid off by equal annual instalments of principal and interest in thirty years, it would require 3*s.* 1*d.* per acre per annum for the main works; for the water supply 1*s.* 7*d.*; for the fences 3*s.* 4*d.*, for the subsoil drainage 6*s.* 5*d.*; making a total of 14*s.* 5*d.* per acre per annum. Imagines that the annual expense of keeping up this fencing, clearing the quick, and so on, would not exceed the present annual expenses of keeping up the fences properly, as the one would balance the other; did not receive the instructions to inquire into this matter more than ten days ago; is not prepared to give evidence on minor points. Does not calculate in the 3*s.* 4*d.* the annual expense of keeping up the fences; the 3*s.* 4*d.* represents the annual instalment per acre for that item, spread over thirty years. Supposes the posts and rails would last about ten years, and by that time the quick will be sufficiently strong to serve as a fence. Proposes emptying the ditches of water. Has thought of the plan of deepening those ditches, and retaining them as fences; but no material improvement in the health of the district would take place unless the water be got rid of; the mere lowering of the ditches would not improve the health of the district. Does not know how a circulation of water is to be got through the ditches; and unless there is a change of water, does not see how there is to be an improvement. Thinks the diseases which are incident to low situations are not affected by the mud which is on the outside of the wall; the malaria is chiefly due to the stagnant water in the marshes; either water held up in the soil itself, or contained in the ditches. The outlet sluices will be of cast-iron, the drain pipes of earthenware. Has made no calculation on the subject of the improved value of the land after these works are completed; it is rather an agricultural question than an engineering one. It would not be necessary if these ditches were deepened to any extent to have them walled up with stone; the deepening would not be more than nine inches or a foot; most of them are now some 4 or 5 feet deep. Thinks no material improvement would take place unless the present stagnant water be removed; conceives the works he proposes are not larger than would be necessary for that purpose. The opening of the private ditches would not keep the water flowing; by so doing the level of the stagnant water is simply lowered, not removed; for many months of the year there is no water going down those ditches. Perhaps the subsoil drainage might not be considered a necessary work, but with that exception considers the works are necessary works; the subsoil drainage is very nearly half the amount. The value of this marsh land is about 60*l.* an acre; these works would cost a fifth part of their value. With regard to the subdivision of these fields, his idea would be to throw them all together, and have the power for an exchange of land of the different owners. The proposed division, taking into account the abolished ditches, would lay the land into about 20-acre fields over the whole area. Proposes five main sluices, and to fix those at a level of about two feet; practically it will be a perfect level across the marshes; it would contain about one foot of water at the lowest; it will be water which might be changed with the inlet sluices; it will be water admitted from the river. In dry seasons should take in water; but in the winter should not want it, because there would be sufficient hill water coming down; his object would be to prevent the water becoming stagnant. The only improvement of which the district is susceptible is getting rid of the stagnant water; he means the stagnant water partly in the soil itself (which could be got rid of by subsoil drainage), but that chiefly in the ditches. Without subsoil drainage, does not consider that the mere fact of getting rid of the stagnant water in the ditches would thoroughly drain the land; it would not have any practical effect upon the stagnant water in the land. The necessary consequence of draining the ditches would be, that there would be no water for the stock; the reservoirs proposed for supplying the stock can be filled by a system of ponds throughout the level; would get the water for the ponds from the subsoil drains. Should propose to construct these reservoirs and make them each capable of holding 500,000 gallons; would lay a system of pipes from the reservoirs, and the whole of these works of water supply would cost about 4000*l.*; The actual cost of supplying water would be nothing; the tanks would be supplied by self-acting ball-cocks. Assumes that the expense of management would not be greater than it now is over the level; it might be slightly increased. Without subsoil drainage the main works might improve the sanitary condition of the district; omitting the subsoil draining would reduce the estimate by 5*l.* 10*s.* an acre. The land would derive a benefit from subsoil drainage to a greater extent than the amount of outlay; assumes that the subsoil drainage would pay for itself.

JAMES EASTON, Civil Engineer.—His attention has been called to the state of the Plumstead and Erith marshes for the last ten or twelve years. The marshes have been greatly improved since 1847, when we lowered some of the ditches and regulated the water supply; but the commissioners had not power to carry out all that he then suggested. His report of 1847 was not only with reference to draining, but as to the repairs of the walls, and putting them into a proper state. The steamboats going up and down the river have so much washed away the underside of the banks, that the stone paving for protecting the banks is washed down more than it used to be. His investigation was with a view of seeing what it would cost to put the walls into a permanent state of repair, and for that purpose the report of 1847 was made. The report of 1853 was more with regard to the draining. After the works that he suggested in 1847 were carried out, in going over the marshes again in 1853, he found that ague had been very much less, from lowering the ditches and not having so much water in them. The ditches were lowered as far as the commissioners had power at that time, and since then the health of the neighbourhood has been very much improved. Has given the commissioners a plan for draining these marshes thoroughly. It is by lowering the present sluices to within a short distance of low-water mark. For instance, the Green Level Sluice could be lowered 3 feet (the bottom of the sluice is 4 feet above low water); the Great Breach Sluice, 6 ft. 2 in.; and the Abbey Level Sluice, 3 ft. 18 in. The Old Corn Marsh was 6 ft. 6 in. and the Crab Tree was 5 ft. 6 in. In arranging this drainage has cut the drains as near as possible to suit the different occupiers and owners, so as not to subdivide the land belonging to any individual. In the intermediate fields the report suggested the filling up of as many ditches as could be. A very considerable quantity could be filled up by enlarging the fields belonging to the same owner, by the

throwing two or more fields into one, and not interfere either with the drinking places for the cattle or the subsoil draining Lowering the water in the ditches would enable the parties to thorough drain. There would be outfall sufficient. Improvement has already resulted from subsoil draining; Mr. Russell has subsoiled many of his fields with very good effect. If the ditches were lowered throughout the whole level, the same improvement would follow; believes the farmers would do it themselves within a few years; but they have not the means, because some of the ditches will not admit of it; but by lowering them altogether it could be accomplished without interfering with the drinking places for the cattle. The difficulty is, a portion of the ditches are not under the command of the commissioners; conceives that to carry out any perfect system of drainage, it would be necessary that the whole of the ditches, those which are called sluices and those which are called cuts, should be under one management. The amount of his estimate of the expense was an outlay of about 30*s*. an acre; that would not include the whole system of thorough drainage, but thinks it would make a complete system of general drainage of the marshes, and would allow of the other being done; the drainage would be effected to such an extent, that the land would be put in such a condition that every farmer could subsoil for himself. The difficulty of draining these lands is the defective nature of the outfalls from the fields into the various ditches; his scheme would remedy that evil. The main outfalls run into the river, and by lowering those an outfall in the other drains is gained. Does not know that there has been any alteration in the bed of the river of late years, so as to account for the fact that the sluices have been made too high; at the time these sluices were put in, thorough draining was not thought of, particularly in that sort of land. The only inconvenience from the sluices being very low is in case of repairs being necessary; there are sluices upon some of the lower levels very nearly level with low-water mark. He would lay the sluices as nearly level as possible, to get a greater fall. The effect of a fall in that distance would not be great, it being only about 100 feet long, although 100 feet is considered a long sluice. The ordinary breadth of the sea-wall at the base where the sluice goes through, varies from 60 to 100 feet; some may be 50 feet. Does not know whether Mr. Rammell has discovered that in the whole of the marshes on the Kentish side there are springs of water issuing from the chalk; and there is an immense quantity in that level, quite enough to spread all over the ditches if it is managed properly; they are main springs out of the chalk; they occur in all the lower levels; they run out in the ditches, and they rise in the ditches, as though they were ordained to feed the cattle. There are not springs always rising in marshes. In the marshes under this commission, there are five or six beautiful springs flowing up. From the want of greater power in the commissioners we have had some difficulty in arranging the water all over the level, for the cattle. The evil arises from the want of a uniform system of drainage throughout the level. If the commissioners had proper powers to carry out a system of drainage, has no doubt it would be done; does not see any engineering difficulties. Thinks the drainage of the marshes would pay commercially; it would pay at his estimate. It would not pay at an estimate of 14*s*. 5*d*. an acre additional rent per annum, without thorough draining; the mere lowering of the sluices would not increase it so much as that, but it would give to the farmers the means of thorough draining. The 14*s*. 5*d*. of which the last witness spoke as the annual expense per acre included thorough drainage. The rental of the land in the marshes varies; including the wall scot, it is about 50*s*.; the wall scot is from 7*s*. to 8*s*.; it is worth about two guineas an acre; the wall scot is deducted. The owners and occupiers are not favourable to a large outlay. In sinking the main ditches below what they are at present, has not made any calculation as to the necessity of making them much broader than they are at the top. The deepening would not be much, except in a few places; where the principal deepening takes place the land is low, and is near the river; there are two or three places in the marsh where the land surface is very near the water surface, and the ditches could be sunk enough to drain the land without inconvenience as to width. There would not be any necessity for walling to keep up the banks, or any additional cost to the proprietors of the lands in maintaining those ditches perfectly clear and in order; has had experience of that from the works which were executed in 1847. In lowering these ditches the subsoil into which we get is clay; there is no wash at all. The total estimate for the works which the commissioners propose to carry out for the portion in the commissioners' hands was about 1670*l*., including the sluices; then, for sinking the private ditches and preparing drinking places for the cattle, he estimated the expense at 1721*l*. Does not think it would do to choose the commissioners generally from the farmers; in most districts you find but few farmers who would be intelligent enough for it; generally speaking, thinks they are jealous of each other, and are afraid of one having more done than another. Should say that a better commission would be chosen from the gentlemen in the neighbourhood, with probably a few of the most intelligent of the farmers.

## REVIEWS.

*Details of Gothic Architecture, Measured and Drawn from Existing Examples.* By JAMES K. COLLING, Architect. London: Bogue. No. 33.

(*With an Engraving, Plate* XXXV.)

During the progress of this work, through the kindness of the proprietors, we have heretofore been enabled to give in our pages several specimen plates, to which we now add another, devoted to a Doorway in Bocking Church, Essex, which may be considered a fine sample of existing ancient scroll iron-work. Besides this, there are five other plates in the number before us, of Early English work, embracing chaste and well-proportioned doorways from Barkby Church, Leicestershire; examples of piers, capitals, and bases, with ornaments from the springing of arches and vaulting shafts from the Churches of Boxgrove and Broadwater, Sussex. The whole of the subjects in this number are well chosen, for reference, as to simplicity of design, and suitableness for adaptation.

As this work is now very rapidly advancing to its completion, it may not be amiss to inform our architectural friends, to whom it may yet be unknown, that it will contain when complete nearly two hundred plates, showing an almost encyclopædic mass of well-selected detail, which must prove of the greatest value in assisting the profession engaged in rearing Gothic structures throughout the country, whether they wish to consult it for exterior or interior construction. By the plates being clearly drawn to a large scale, one great evil has been obviated which attended most of our architectural works; and, we may add, that we believe the entire series of illustrations have been first published in the pages of our author.

*Picturesque Atlas of the Railway over the Sœmmering, Austria.* By CARL GENGA. Vienna: Gerold and Son. 1854.

This truly splendid work is the production of the director of the above-named railway, Carl Genga, knight, who, in 1842, was dispatched to the United States for the purpose of studying the construction of the railways of that country, and who, after his return, projected the plan of the one under notice. This volume contains a number of statistical data on Austrian railways in general, and the Sœmmering line especially, with a series of beautiful drawings of that gigantic and surprising undertaking—placing before the profession and the public the result of each grand and praiseworthy exertion.

*Suggestions for Improvements in the Sewerage of Cities and Towns.* By CHARLES F. MOORE, M.D. Dublin: Hodges and Smith. 1854. pp. 12.

The author of this pamphlet, a member of the medical profession for eighteen years, does not think it advisable to interfere with the long-tried and useful egg-shaped sewers, but suggests that, the present water-closet system in the houses of the upper and middle classes should be retained. Every five, ten, or more houses of such classes to be provided with a filtering and deodorising cistern, divided into compartments furnished with a self-regulating apparatus which would cause a discharge of disinfecting powder, as dry peat powder, powdered gypsum, peat charcoal, coal ashes, lime, or other deodorising solid or fluid, proportioned to the ingress of house sewage,—the latter to be conveyed from each house by earthen pipes properly set in a bed of masonry, or small brick sewers, or other suitable means, and at such an inclination as to insure proper discharge; also each deodorising cistern to be provided with a suitable exit channel for filtered and deodorised fluid to convey the same into main-street sewers. Every such cistern to be placed in a convenient position in a back street, lane, open space, or yard, that it may be daily emptied of all its solid or semi-solid contents, and that it shall be so constructed that its compartments shall permit of this being done without inconvenience or interruption to the house sewage, and so as to permit the removal of its contents by suitable trap-doors or sluices; the whole to be made of flags or strong slate, or other suitable material,—due attention to be paid to position of said cistern as to fall, &c. And it is suggested that persons in the immediate vicinity of such cisterns should have a portion of proceeds of sale of contents under some circumstances. District overseers to keep constant supervision over the state of such cisterns.

In all lodging-houses, hospitals, barracks, poor-houses, and houses of the lower classes, the author would have closets of simple construction, yet such as would insure immediate deodorisation, applicable to both solid and fluid sewage, or either as the case might determine, and either in connection with the general sewage or not (although he would prefer separation of solid and fluid matters for many reasons); the process of deodorisation to be effected by drawing a simple valve or other contrivance whereby a quantity of powdered gypsum, dry powder of peat, peat charcoal, coal ashes, lime, or other deodorising substance, should be discharged upon the matters in such closet. Each closet to be cleaned out thoroughly at least once a day in winter, and twice daily in summer, and contents to be removed in covered wagons or barges, or by railway, and at once sent to the country as manure. As no water should be used in these closets, the bulk of matters to be removed would be very small; and as the closet-pans would be made portable, no difficulty would be experienced in emptying them into wagons.

## ON SILICA AND SOME OF ITS APPLICATIONS TO THE ARTS.[1]

By Rev. J. Barlow, M.A., F.R.S., V.P.R.I.

Silica is one of the most abundant substances known. Quartz, common sand, &c., flint, chalcedony, opal, &c., and a variety of sand described by Mr. J. T. Way,[2] may respectively be taken as examples of crystallised and uncrystallised silica. Under all these forms silica is capable of combining with bases as an acid. Heat is however essentially necessary to effect this combination, a combination of which all the well-known silicates, whether natural, as feldspar, mica, clay, &c., or artificial, as glass, &c., are the results. The common forms of insoluble glass are produced by the union of silica with more than one base. But, when combined with an alkaline base only, silica forms a soluble glass, the degree of solubility of which depends on the proportion which the siliceous acid bears to this alkaline base. This soluble silicated alkali (or water-glass) may be prepared by various processes. If sand be used, 15 parts of fine sand, thoroughly incorporated with 8 parts of carbonate of soda, or with 10 of carbonate of potass and 1 of charcoal fused in a furnace, will produce a silicated alkali which is soluble in boiling water. Messrs. Ransomes obtain this silicated alkali by dissolving broken flints in a solution of caustic alkali at a temperature of 300° Fah.[3] And, more recently, Mr. Way has observed that the sand which he has described will combine with caustic alkali at boiling heat, also producing a water-glass.

This water-glass has been applied to several important purposes, three of which were specially noticed.

I. *To protect building-stones from decay.* The stone surfaces of buildings, by being exposed to the action of the atmosphere, become liable to disintegration from various causes. Moisture is absorbed into their pores. The tendency of their particles to separate, in consequence of expansion and contraction, produced by alternation of temperature, is thus increased. Sulphurous acid is always present in the atmosphere of smoke-burning cities, and cannot but corrode the calcareous and magnesian ingredients of oolites and dolomites. It is true that good stone resists these sources of injury for an indefinite time, but such a material is rarely obtained. As a preventive of destruction, whether arising from physical or chemical causes, it has been proposed to saturate the surfaces of the stones with a solution of the water-glass.

It is well known that the affinity of silica for alkali is so feeble that it may be separated from this base by the weakest acids, even by carbonic acid. According to the expectation of those who recommend the silication of stone, the carbonic acid of the atmosphere will set the silica free from the water-glass, and the silica, thus separated, will be deposited within the pores and around the particles of the stone. The points of contact of these particles will thus be enlarged, and a sort of glazing of insoluble silica will be formed sufficient to protect the stone against the effects of moisture, &c. This cause of protection applies chiefly to sandstones. But wherever carbonate of lime or carbonate of magnesia enters notably into the composition of the building-stone, then an additional chemical action, also protective of the stone, is expected to take place between these carbonates and the water-glass. Kuhlmann[4] remarks "Toutes les fois que l'on met en contact un sel insoluble avec la dissolution d'un sel dont l'acide peut former avec la base du sel insoluble un sel plus insoluble encore, il y a échange; mais le plus souvent cet échange n'est que partiel." In consequence of this "partial exchange" an insoluble salt of lime may be looked for whenever a solution of water-glass is made to act on the carbonate of lime or carbonate of magnesia existing in oolitic or dolomitic building-stones.

This expectation, however, has not been alogether sanctioned by experiment. A gentlemen, eminently conversant with building materials,[5] immersed a piece of Caen stone in a solution of silicate of potass in the month of January 1849. This fragment, together with a portion of the block from which it had been separated, was placed on the roof of a building in order that it might be fully exposed to the action of atmosphere and climate. After four years the silicated and the unsilicated specimens were found to be both in the same condition, both to be equally corroded. These specimens were exhibited in the theatre of the Institution. But whatever ultimate results may ensue from this process, the immediate effects on the stone are remarkable. Two portions of Caen stone were exhibited, one of which had been soaked in a solution of water-glass two months before. The surface of the unsilicated specimen was soft, readily abraded when brushed with water, and its calcareous ingredients dissolved in a weak solution of sulphurous acid. The silicated surface, on the other hand, was perceptibly hard, and resisted the action of water and of dilute acid when similarly applied.[6]

II. Another proposed use of the water-glass is that of *hardening cements, mortars,* &c., so as to render them impermeable by water.

Fourteen years since, Anthon[7] of Prague proposed several applications of the water-glass. Among others he suggested the rendering mortars waterproof. He also suggests that this substance might be beneficially employed as a substitute for size in whitewashing and staining walls. It was demonstrated by several experiments that carbonate of lime mixed up with a weak solution of water-glass and applied as a whitewash to surfaces, was not washed off by sponging with water, and that common whitewash laid on in the usual manner with size, was rendered equally adhesive when washed over with water-glass.

III. *The Stereochrome of Fuchs.*

The formation of an insoluble cement by means of the water-glass, whenever the carbonic acid of the atmosphere acts on this substance, or whenever it is brought in contact with a lime-salt, has been applied by Fuchs to a most important purpose. The stereochrome is essentially the process of fresco secco[8] invested with the capability of receiving and perpetuating works of the highest artistic character, and which may be executed on a vast scale. Fuch's method is as follows[9]:—

"Clean and washed quartz-sand is mixed with the smallest quantity of lime which will enable the plasterer to place it on the wall. The surface is then taken off with an iron scraper in order

[8] Vide Eastlake's Materials for a History of Oil Painting, p. 142.

[9] These particulars were obtained by Dr. Hofmann from Mr. Echter. A stereochromic picture by Echter, and a sample of the water-glass as prepared by Fuchs, were also exhibited by Dr. Hofmann.

to remove the layer formed in contact with the atmosphere, the wall being still moist during this operation. The wall is then allowed to dry; after drying it is just in the state in which it could be rubbed off by the finger. The wall has now to be fixed, *i. e.*, moistened with water-glass.[10] (An important point is not to use too much water-glass in moistening the wall.) This operation is usually performed with a brush. The wall must be left in such a condition as to be capable of receiving colours when afterwards painted on. If, as frequently happens, the wall has been too strongly fixed, the surface has to be removed with pumice and to be fixed again. Being fixed in this manner, the wall is suffered to dry. Before the painter begins he moistens the part on which he purposes to work with distilled water, squirted on by a syringe. He then paints: if he wishes to repaint any part he moistens again. As soon as the picture is finished, it is syringed over with water-glass. After the wall is dry, the syringing is continued as long as a wet sponge can remove any of the colour. An efflorescence of carbonate of soda sometimes appears on the picture soon after its completion. This may be removed, either by syringing with water, or may be left to the action of the atmosphere." Not to dwell on the obvious advantages possessed by the stereochrome over the real fresco, (such as its admitting of being retouched and its dispensing with joinings), it appears that damp and atmospheric influences, notoriously destructive of real fresco, do not injure pictures executed by this process.

[11] The following crucial experiment was made on one of these pictures. It was suspended for twelve months in the open air, under the principal chimney of the New Museum at Berlin; "during that time it was exposed to sunshine," "mist, snow, and rain," and nevertheless "retained its full brilliancy of colour."

The stereochrome has been adopted on a grand scale by Kaulbach, in decorating the interior of the great national edifice at Berlin already alluded to. These decorations are now in progress, and will consist of historical pictures[12] (the dimensions of which are 21 feet in height and 24½ feet in width), single colossal figures, friezes, arabesques, chiaroscuro subjects, &c. On the effect of the three finished pictures, it has been remarked by one whose opinion is entitled to respect, that they have all the brilliancy and vigour of oil paintings, while there is the absence of that dazzling confusion which new oil paintings are apt to present, unless they are viewed in one direction, which the spectator has to seek for.

Mr. A. Church has suggested that if the surface of oolitic stones (such as Caen stone) is found to be protected by the process already described, it might be used, as a natural intonaco, to receive coloured designs, &c., for exterior decorations; the painting would then be cemented to the stone by the action of the water-glass.

Mr. Church has also executed designs of leaves on a sort of terra-cotta, prepared from a variety of Way's silica rock, consisting of 75 parts clay and 25 of soluble silica. This surface, after being hardened by heat, is very well adapted for receiving colours in the first instance, and for retaining them after silication.

## NEW NATIONAL GALLERY.

Sir—I see, with great regret, that it is stated in your publication that the Chancellor of the Exchequer is not pledged to throw the designs for the New National Gallery open to public competition. I am sorry for this, for, whatever the evils of the system as a grievance upon the architects, competitions are productive of public good. Such a work as a New National Gallery would be a stimulus to architectural exertion, and a means, by the exhibition of the drawings, of creating a public interest for architecture. I hope, therefore, we shall have a competition. At all events, I hope the selected plans may be exhibited, and not smuggled as those of the British Museum were attempted to be.

*Gower-street, Sept.* 20, 1854. ARCHITECTUS.

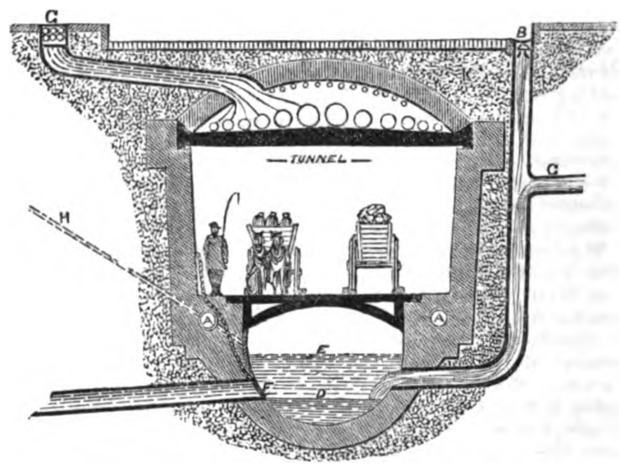
[10] The composition of the specimen produced was—Silica, 23·21 per cent.; Soda, 8·90 per cent.; Potass, 2·52 per cent.; and the specific gravity of the solution was 3·81.

[11] Communication from Mr. George Bunsen.

[12] Three of these pictures are finished, viz. 1. The Fall of Babel; 2. Die Blüthe Griechenlands ('the golden age of Grecian art and poetry'); 3. The Fall of Jerusalem (an engraving of this picture was exhibited by Mr. Ackerman).—Two other compositions are drawn, viz. 4. The Battle of the Huns; 5. The Crusaders' arrival before Jerusalem.—6. This subject not yet decided on.

## AUSTIN'S SUB-WAY.

It is here proposed to provide for all the desiderata required in our main London streets—for drainage, waterage, gasage, electro-wirage, railage, or any other "age" connected therewith. The engraving speaks for itself. A large sewer occupies the lower part, from which overflow pipes run into the river, at intervals, to take off quickly the storm or continued rain water. Mr. William Austin (of Mr. Peto's establishment), the inventor, or projector, proposes to run his large drains from streets, into sewers constructed at a considerable depth on each side of the river (beneath the shores), between high and low water mark; to convey the soil to the extreme parts of London, to be pumped up into reservoirs, for purposes of manure, or discharged into the river below the influence of the tide, beyond Barking Creek. Over the sewer of streets, is a strong, continued stage of iron and wood, upon which runs the railway and tramway, with a footway on each side. Over these are strong iron girders to carry the main pipes for gas, water, &c.; these girders are placed at sufficient distances apart to suit the lengths of the pipes. A strong brick arch spans the whole; the spandrils and crown of arch, filled in with concrete, receives the paving. An "eye" and horizontal shaft is formed through arch to footways, fronting each house, for the service pipes (at regulated distances) to pass on to the supply pipes, laid in an opening trunk running lengthways and level with paths. The electric wires are suspended to the soffit of the arch. The sewer and tunnel is proposed to be ventilated by coke fires and shafts, and iron man-hole traps will be placed at intervals in crown of arch. No effluvia can ascend from the house drains to the streets through gully-holes, as all would be effectually water-trapped.



A, A. Horizontal Flues for collecting foul gases from Sewer.
B. Patent Water-Trap over Gully-hole.
C. House Sewage Pipe.
D. Low Level of Sewage waters.
E. Flood Level of Storm waters.
F. Outflow to River.
G. Supply Pipes.
H. Pipe to Fires for Consuming Foul Gases from Sewers.

This scheme may appear too great for unpractical men, but we see no immediate reason why it cannot be practically carried out, with a saving in the long run; for the constant wear of the pipes underground, and consequent leakage, besides the expensive nuisance of taking up the paving on every occasion of repair, would be avoided, and would soon repay the extra cost. An opportunity now occurs when the experiment might be tried with advantage, if it be true that the new Victoria-street sewer—that "sink-hole of expense"—is to be rebuilt; a sub-way might be formed under Victoria-street, which would be a grand experiment, and could be done there with less annoyance or cost than in any other street in London, and might be given as an example to the authorities in large towns, who are only now beginning to think of draining them. But why suggest so feasible a scheme, when millions are being spent abroad in war, with a right good will, and simple thousands, or even hundreds, begrudged for the benefit of the health and comfort of the people at home?

## STOPPAGE OF CANALS.

The new water-weed, about which a good deal has been said lately, and which has proved so serious an evil wherever it has shown itself, is not the only difficulty that has recently attended the working of canals in this country, a still more alarming hindrance to their traffic being the short supply of the element employed for its conveyance. The Huddersfield Canal, extending from Huddersfield to Ashton-under-Lyne (about twenty miles), where it communicates with the Ashton and Oldham Canals to Manchester, was closed on the 6th inst., in consequence of the supply of water not being sufficient to keep it open for traffic. The Macclesfield Canal, which leaves the Trent and Mersey Canal near the Harecastle tunnel, on the North Staffordshire Railway at the northern end of the Potteries, and extends to Marple, near Stockport, where it joins the Peak Forest Canal, was closed last Thursday from the same cause, and we understand that the Caldon branch of the Trent and Mersey Canal, near Leek, in Staffordshire, has also been closed. The managers of the Rochdale Canal have given notice that vessels navigating that canal are not to draw more than 3 ft. 8 in. of water, and, unless there is a considerable fall of rain, not only this canal, but also the Ashton and Oldham and Peak Forest Canals, leased by the Manchester, Sheffield, and Lincolnshire Railway Company, and the Trent and Mersey Canal, will have to be entirely closed very shortly. The Ashton and Oldham and Peak Forest Canals must have been closed on Monday but for the rain, which has fallen since Saturday night, and the "favourable" weather which prevails in that district gives some hope that an entire stoppage may be averted; but a very considerable additional supply will be required to allow of more than a continually interrupted navigation for some weeks to come. In the district traversed by these canals there was no supply worth mentioning, available for canal purposes, from the time of the melting of the snow in January, till July, when there would have been a suspension of working but for the fall of rain which took place between the 9th and 19th of that month. The Bridgewater Canal, between Manchester and Runcorn, is fortunately situated, for all the canals we have mentioned "lock down" into it and supply it with water, and consequently it may be expected to keep open longest; but the water—always scarce at this season of the year—is now very much reduced, and, as the sewerage of the filthy river Medlock in Manchester drains into it, the absence of any large supply of purer water has caused a most offensive and unhealthy stench to arise from this canal, which is perceptible at a considerable distance from the banks. Unless some effectual steps are taken to remedy this, it will prove very injurious to the district between Manchester and Altrincham, in which, during the last few years, the facilities of railway communication have induced a great influx of out-of-town residents, whose business lies within the city, but who will of course be desirous to escape the dangerous proximity of such a nuisance. This threatened suspension of upwards of 200 miles of canal communication must be a very serious interruption to the traffic of the district which it traverses. On the Ashton and Oldham, Peak Forest, and Macclesfield Canals, 86 miles in all, the average amount conveyed is 25,000 tons per week; upwards of 4000 tons being carried by the Macclesfield Canal, which has been already shut. Some of these canals, although they have been in existence more than half-a-century, have never been known to stop, and certainly none of them have been reduced to that extremity during the last forty years. On the contrary, previously to the opening of the immense reservoirs at Woodhead, the corporation of Manchester were supplied with 200,000,000 gallons, or 2000*l.* to 3000*l.* worth yearly, from the surplus waters of the three canals last-named, which during this year would have had none to spare if it had been required. By these three canals, also, about 2000 tons of lime per week are conveyed from the mountainous districts of Derbyshire to Manchester and the neighbourhood, and also a large quantity of coals. In fact, the bulk of the manufacturers of Manchester have relied upon the canals for their supply of both coals and water, and, in the absence of stores of their own, they will be put to great inconvenience by the threatened drying up of their resources. Since the above was written we are informed that the Macclesfield Canal has been reopened, but at present there is only water sufficient for three or four days' working.—*Times*, Sept. 21.

## THE PHILADELPHIA GASWORKS.

John C. Cresson, *Engineer.*

(*With an Engraving, Plate* XXXVI.)

The consumption of coals in the United States for gas purposes is largely on the increase. On the seaboard a large proportion is obtained either direct from Great Britain or from the bituminous coal deposits in the British North American colonies. In the Atlantic States, south of New York, the oolite coal field of Virginia furnishes a portion of the necessary supplies, the remainder being generally obtained from this country. In the States west of the Alleghanies the entire supply is obtained from the nearest coal field. Owing to the expenses attending the transport of the raw materials, and the difficulty in disposing of the secondary products, the prices charged for the gas are in general very much higher than in England. In all cases, however, it has been found that a reduction in the selling price has been immediately followed by an increased consumption. The common ⌂ shaped iron retort is in general use. In one or two establishments clay retorts had been tried, but have not worked so well as the others. The following is a summary of details of manufacture in the establishment at Philadelphia

These works are in the hands of the Municipal Corporation; capital invested 1,400,000 dols., originally commenced and carried on as private undertaking, and subsequently purchased by the city; its direction and general government being vested in a board of trustees, by whom it has been carried on since that period. Mr. Cresson is the engineer, under whose management the works have reached their present state of prosperity and efficiency, and under whose superintendence the new works have been erected. These are remarkable, not more on account of their magnitude than on account of the combination of engineering skill with ornamental finish, which Mr. Cresson has displayed in their arrangement. As a gasholder of this magnitude in England is rare, and as some novelties in construction have been introduced with perfect success into this one, we give engravings of the gasholder, with descriptive working details.

*Description of Gasholder at the Philadelphia Gasworks*—The following are the dimensions and working details of the great telescope gasholder at these works. It is 160 feet in diameter, and 90 feet high, with 12 guide towers built of cast-iron and stone, in an ornamental form The *inner or upper section* is 158 ft. 6 in. diameter and 45 feet deep (20 rows of sheets, 16 rows of No. 12, 2 rows of No. 11, and 2 rows of No. 10.

Bottom angle iron, 3" × 3" × ½ } Cup, No. 10 sheets and butts, 20 inches
Outer angle iron, 3" × 3" × ½ } deep and 6½ wide in the clear.

24 legs of cast-iron, each in five lengths.

Top curb (angle iron), 4" × 4" × ½; 3 rings of angle iron at equal distances, 2½" × 2½" × ½.

48 guide-plates, riveted to the legs with hot rivets 4" × ¾.

Crown, straight rise of 4 feet to centre.

Crown-plate, 4 feet diameter by ½-inch thick; 16 rows of sheets; crown-rows Nos. 8 and 10; rest No. 12, except the outer which is No. 11.

King-post, No. 3, boiler iron 25 feet long and 30 inches diameter; top ring, 4" × 4" × ½; bottom ring, 4" × 4" × ½.

Two rings for nut at end of bolt, 4" × 1"; bottom plate ⅜-inch thick.

All bolts and nuts for crown end of bars, 1¼".

Crown to be on 7 rings of plate and angle iron.

No. 1 plate, 3" × ⅜. No. 2 angle, 3" × 3" × ⅜. No. 3 plate, 3" × ½. No. 4 double angle T 3" × 3 × ⅜, so arranged as to break joint. No. 5 plate, 4" × ½. No. 6 angle, 3" × 3" × ⅜. No. 7 plate, 4" × ⅜.

All plate-rings secured at the joints with butt plates.

24 trusses of round and square bar iron, each truss having 7 struts. On 1st and 2nd ring, 1¼ inch square; on 3rd ring, 1 inch square; on 4th (main strut), bars of 3" × ⅜", riveted at distances of 1 foot, and blocked apart with ⅜" washers; on 5th and 7th, double struts of 1 inch square bars; on 6th double struts of plate; each leg two bars of 2" × ½", similarly secured with No. 4 (see drawing) round iron tension rods of sizes marked in drawing.

The crown to be enclosed in a wrought railing 16 inches high; 2 rails of 1 inch round iron, and secured to the outer angle iron by 48 staunchеons braced with 48 ½-inch round rods.

*Lower Section.*—160 feet diameter, and 45 feet deep; sides, 20 rows of sheets (17 rows of No. 14; 1 row of No. 11; top row No. 10; bottom row No. 12).

Cup, same as upper section; bottom angle iron 3" × 3" × ½".

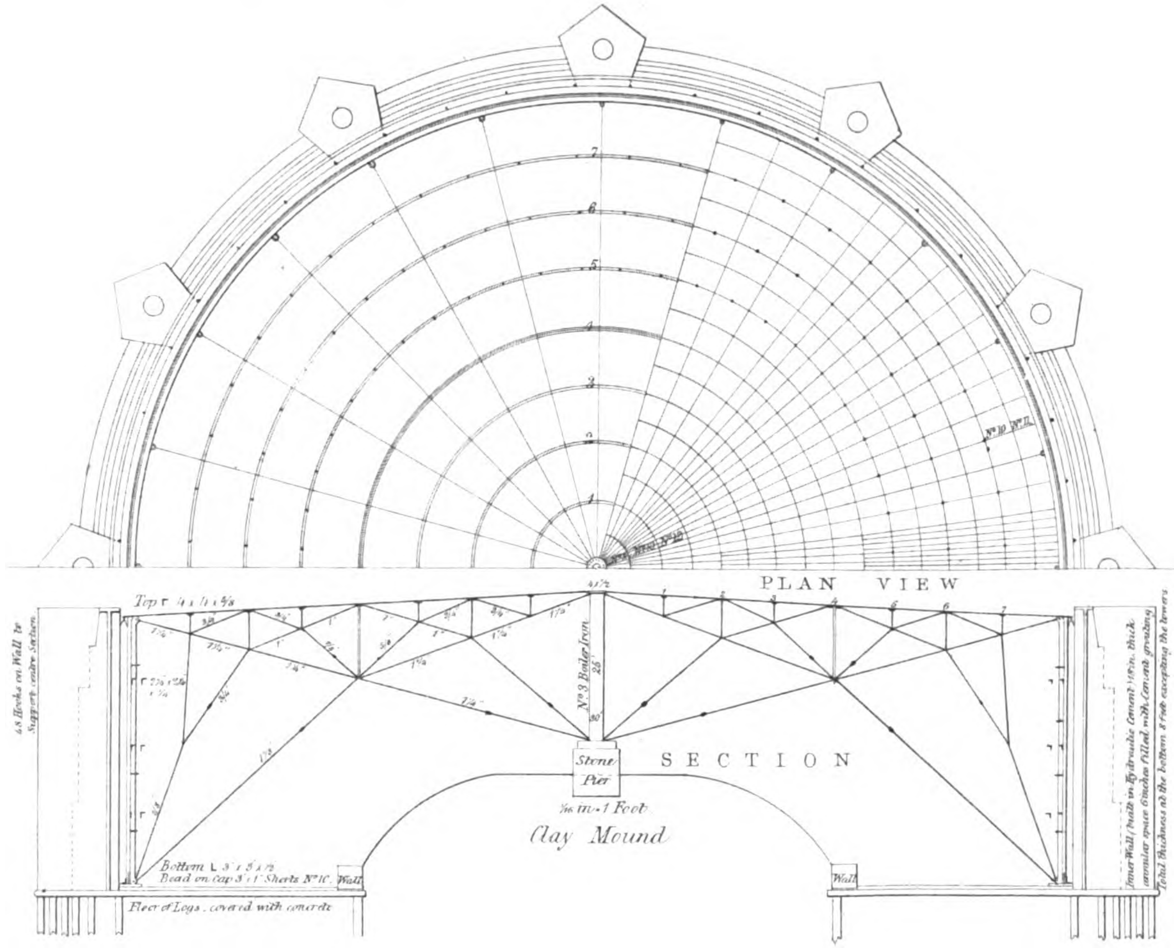
24 rollers and carriages on the cup between the sections.

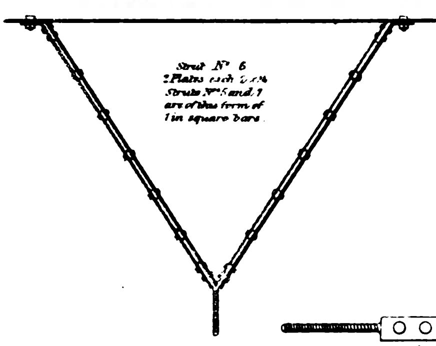
24 rollers and carriages on the cup on guides.

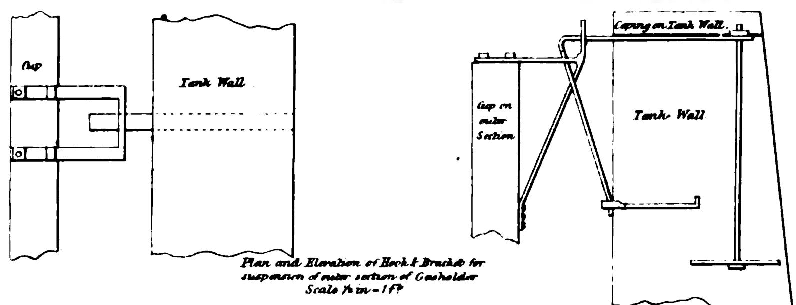
36 hooks for suspension from the tanks.

Aggregate make (1852), 232,000,000 feet; present price $2 per 1000 feet.

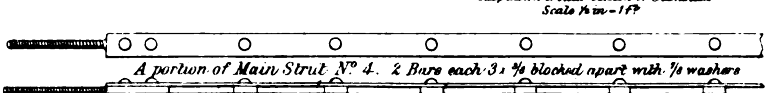
# TELESCOPE GASHOLDER AT THE PHILADELPHIA GAS WORKS



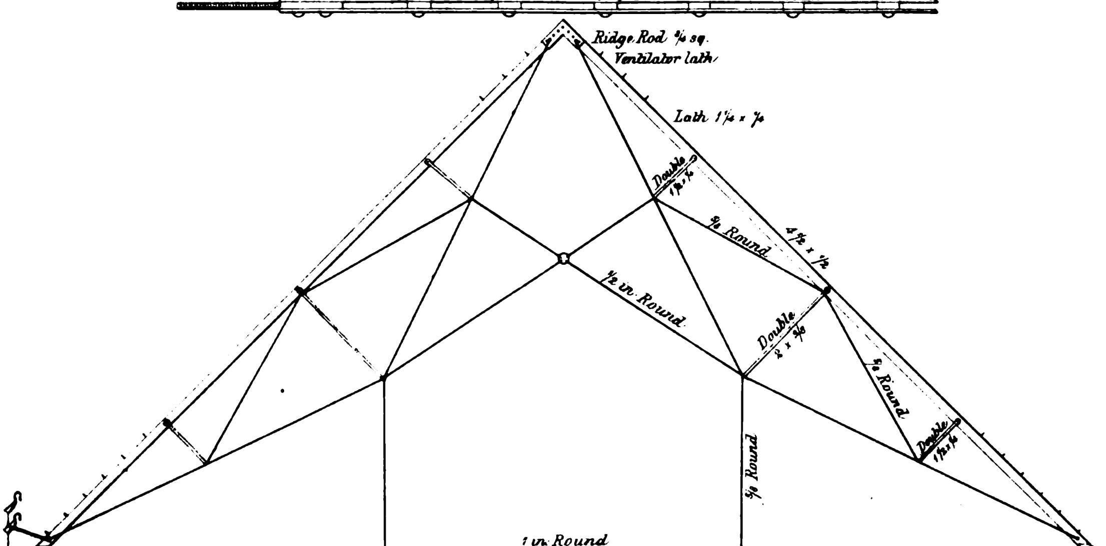




Plan and Elevation of Hook & Brackets for suspension of outer section of Gasholder Scale ½ in = 1 ft



A portion of Main Strut No 4. 2 Bars each 3 x ⅜ blocked apart with ⅞ washers



ONE HALF OF SKELETON ROOF OF RETORT HOUSE.

Street-lamps charged $20 per annum; average consumption of each, 28,000 feet; the city lighting, &c.

The coals used are the oolite from Richmond, Virginia; the West Pennsylvania coals from Pittsburg; the Pictou; and English, from Newcastle and Wigan, in various proportions, giving an average produce of 4 cubic feet per lb. of coal. The Richmond coal yields from 3·92 to 4·5 feet per lb.

The secondary products are not very remunerative; gas tar is readily saleable at 50 cents per barrel of 30 gallons; the coke meets with a heavy sale at 5 cents per bushel; the lime costs 3 cents per bushel, and sells readily to the farmer at the same price; the ammonia liquor is given or thrown away.

Labourers, chiefly Irish and German; wages average about—firemen, $9¼ = 2*l.* 0*s.* 8*d.* per week; labourers, $1 12c. = 4*s.* 8*d.*; and mechanics, $2 per day.

## FIRE-EXTINGUISHING WORKS IN DOCKYARDS.

TO BERNAL OSBORNE, ESQ., SECRETARY OF THE ADMIRALTY, ETC.

Sir,—The late conflagration in Chatham Dockyard induces me again to call the attention of the Lords of the Admiralty to the fire-extinguishing works in her Majesty's dockyards, and to the expediency of instituting and of enforcing regulations for their conservancy and frequent use.

I know that in Chatham-yard, fire-extinguishing works were constructed conformably to the late Sir Samuel Bentham's plans, that they were similar to those he devised in the last century, and shortly afterwards introduced in Portsmouth-yard. I know that by means of these works, fire was frequently extinguished on several occasions. I also speak from unquestionable authority when I assert, that one of Sir Samuel's important provisions has fallen into desuetude in that dockyard, namely, the throwing water over a burning mass *directly* from hose screwed upon the fire-cocks, without the intervention of engines worked by men; and it may be observed, that, however well hand-engines are distributed in that yard, and however speedily manned by day, they would be of no avail whatever by night until, to work them, men from without could be roused from sleep and assembled in the yard.

For the extinction of the disastrous fire at Chatham, I understand that hand-engines only were employed, and I have reason to believe that the proper use of Sir Samuel's fire-extinguishing works was altogether unknown. The value of the property consumed I have no means of estimating; still less can I know the depredations that resulted from the admission to the yard of a host of strangers, or the delays to the economical progress of general service resulting from the destruction of so much machinery.

That machinery was not erected till after the abolition of Sir Samuel's office, or surely he would have introduced for its protection the same expedients that he had devised for the wood mills at Portsmouth—namely, on every floor pipes leading from an elevated reservoir, and hose attached to them, so that, on the outbreak of fire, water could instantly be thrown upon it by simply turning a cock.

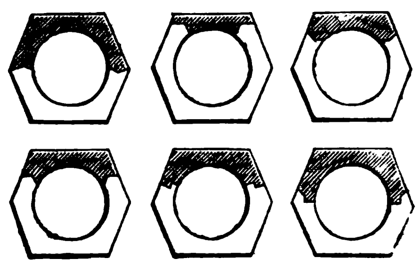
There is reason to believe that the fire-extinguishing works in both Plymouth and Sheerness Dockyards have not been kept in working order; but in Pembroke-yard they appear to be well attended to—and mark the contrast. A fire broke out at Pembroke-yard in the boatswain's cabin about *midnight*, on the 25th January, 1853. This fire was discovered by the police. A sergeant of that force immediately threw a *bucket* of water upon the burning matter, which was quickly succeeded by more water in *buckets*, which sufficed to keep the fire in check until a *hose was screwed on the fire-cock* at a short distance from the spot. The time consumed in bringing that hose to use was no more than about *ten minutes* after the discovery of the fire, thus it appears that the fire was promptly extinguished by the fire-extinguishing works alone.

I would again venture to suggest, that as no persons other than the police are likely to be by night in every part of a dockyard, the police it should be that should be familiarised with the application of the hose, and that, to do so, no means seem so effectual as that of accustoming them to use the fire-extinguishing works for as many purposes as possible; for instance, for watering the yard, for washing store-house windows and the fronts of buildings, &c.

*Hampstead, August 16th*, 1854. M. S. Bentham.

## AUSTIN'S PATENT HEXAGONAL SEPARATING DRAIN-PIPES.

The object of this invention is to afford ready access for clearance from any obstructions, and to prevent the present waste by breakage consequent upon the clearing of socketed pipes. These tubes are also available for casing over telegraphic wires, for service-pipes for gas, water, &c., the latter now rapidly corroding and decaying from contact with damp ground.



In the accompanying sections, the scored or cross-line portions show the separating joints or divisions which resist lateral or side thrust. The tiles or pipes, when packed, form close stowage, saving one-third room over round pipes, and avoiding rolling and breakage.

On this form of construction (honeycomb) Mr. Austin has also patented casks or barrels for dry and wet goods, forming thereby compact stowing on board ship in dock or warehouse.

## REPORT OF THE COMMISSIONERS OF PATENTS.*

In pursuance of several orders of the Commissioners of Patents, the whole business of the Commissioners relating to patents, from the petition for the allowance of provisional protection to the printing, publication, and sale of the specification, is now conducted in one office.

The office of the Commissioners is in Southampton-buildings, Chancery-lane, in a set of chambers lately occupied by the Masters in Chancery, and is open to the public from ten to four o'clock every day.

The number of applications for provisional protection recorded within the fifteen months from the 1st October, 1852, to the 31st December, 1853, was 4256; the number of patents passed thereon, all having become due on the 30th June last, was 3099; and the number of applications lapsed or forfeited, the applicants having neglected to proceed for their patents within the six months of provisional protection, was 1157.

The number of applications recorded within the first three months of the operation of the Act, was 1211.

The number of applications recorded within the year 1853, was 3045.

Though the Act received the royal assent on the 1st July, 1852, yet its operation was deferred to the 1st October following. During the intervening period almost all applications for patents were suspended, and this sufficiently accounts for the large number of applications (1211) recorded within the quarter ending 31st December, 1852, compared with the number (3045) recorded for the whole year 1853.

The number of applications recorded in the first six months of the current year, was 1440, showing a probable decrease of 165 applications upon the year 1854, as compared with the number of the year 1853.

All the specifications filed in the office upon the patents passed under the Act from 1st October, 1852, to the 30th June last, 3099 in number, have been printed and published, together with lithographed outline copies of the drawings accompanying the same; and these are sold to the public, either separately or in the series for the year, at the cost price of the printing and paper. The price of a specification of the average length of letter-press, and drawings, is eight-pence.

There is no arrear in the printing and publication of the specifications filed since the commencement of the Act. Each specification is printed and published within three weeks of its deposit in the office.

Under the 15 and 16 Vict. c. 115 s. 4, a printed copy of the

* Compiled from the Report presented to Parliament, August 7, 1854.

specification, duly certified and sealed in the commissioners' office, may be received in evidence of the original document in any court within the United Kingdom of Great Britain and Ireland and the colonies; the printed copy is certified on payment by the applicant of one shilling for the seal, and the charge of the draughtsman for colouring the prints of drawings is paid by the applicant.

Printed certified copies of all the specifications filed in the office from the 1st October, 1852, to the present time, with coloured printed copies of the drawings, have been sent to the office of the Director of Chancery in Edinburgh, and the enrolment office of the Court of Chancery in Dublin, pursuant to the Act, 1852, and the Act 16 and 17 Vict. c. 115; and such copies are open to the inspection of the public in the respective offices.

Certified copies of all the patents passed since the commencement of the Act, and certified copies of the record books of assignments of patents and licences, with copies of such assignments and licences, have also been sent to the Chancery offices in Edinburgh and Dublin, pursuant to the Act.

The whole series of specifications of patents for reaping machines, and drawings accompanying the same, from the first enrolled, 4th July, 1799, to the present time, have been printed and published, and are sold at the cost price of the printing and paper, either separately or altogether, with an appendix in one volume. The appendix, compiled by Mr. Woodcroft, from a great variety of authorities and works, describes the instruments for reaping grain published and in use, from the earliest period to the present time.

The whole series of specifications of patents for firearms, cannon, shot, shell, cartridges, weapons, accoutrements, and the machinery for their manufacture, and the drawings accompanying the same, from the earliest recorded, 15th May, 1718, to the present time, have been printed and published in like manner. An appendix is in preparation, and will shortly be published.

The Secretary of State for the Home Department has required the publication of all the specifications of patents for the consumption of smoke in furnaces, and for the making of drainage tiles applicable to sewerage; and the Board of Admiralty has required the publication of the specifications of patents for improvements in propelling ships; these three subjects are now in preparation.

Pending the publication of the old specifications, necessarily a work of time, printed certified copies for evidence in courts of justice, for counsel, and for other purposes, of any of the old specifications, may be obtained on application at the Patent Office, the applicant paying the cost of putting the drawings upon the stone and colouring the number of prints he may require, and the Commissioners paying the cost of letter-press and paper, or, in the absence of drawings, the applicant paying the cost of letter-press and paper; by this arrangement, the applicant obtains twelve or fourteen certified printed evidence copies at a low price, and the Commissioners obtain the prints of drawings, or the letter-press and paper for their future publication of the specification, free of cost. 100 old specifications have been printed in this manner within the last few months.

Mr. Woodcroft's chronological and alphabetical indexes of all the specifications of patents enrolled in Chancery, from 1617 to the 1st October, 1852, 14,359 in number, have been published in three imperial octavo volumes, and are sold at 50*s.*, the cost price of printing and paper. Mr. Woodcroft's index, arranging these specifications according to the subject matter, is in the hands of the printer, and will shortly be published.

Indexes in the same chronological, alphabetical, and subject-matter form of all the specifications filed in the office under the new law, will be made in continuation, and published periodically.

The prints of specifications, the indexes, and all other printed papers, will in future be sold in the Patent Office, and not at the Queen's Printers as heretofore. The publications are sold to all persons applying for them at the cost price of each, and no trade discount is allowed. Booksellers and agents, however, charge a commission to the persons for whom they purchase these works.

The Commissioners have established a public library of research within the Patent Office, to consist of the scientific and mechanical works of all nations; convenient rooms are provided for the purpose, and the library will be open to the public within a few weeks.

A journal, entitled *The Commissioners of Patents Journal*, has been published twice a week since the commencement of the present year, and it will be continued. It contains the various notices appearing in the *Gazette* on the subjects of patents, and a variety of other notices and useful information and instruction for the guidance of applicants in proceeding for their patents. It is proposed to publish in the journal the names of patentees, and the titles of patents granted in other countries; also a notification from time to time of the date of the expiration of each patent as it may become void, either by reason of non-payment of the stamp duties of 50*l.* and 100*l.* at the expiration of the third and seventh years respectively, pursuant to the Act, or at the full term of fourteen years; and also from time to time a list of the inventions provisionally protected, lapsed or forfeited by reason of the applicants having neglected to proceed for their patents within the six months of provisional protection. The price of the journal to subscribers, is 30*s.* per annum.

## THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

The twenty-fourth meeting of the British Association commenced at Liverpool on the 20th ult. It had been previously arranged that all the proceedings should take place in St. George's Hall, but this was found to be impossible, in consequence of the musical performances with which the inauguration of the hall was celebrated; and the first general meeting of the members therefore took place in the Philharmonic Hall, which is scarcely less capacious than the more pretensious and more highly-decorated hall in which they were first appointed to assemble. The muster of members seemed small when spread over such an extensive area, but there were about 1200 in the room, the number being nearly double that of the Hull meeting last year. The President for this year (Lord Harrowby) was inducted into the chair by Mr. Hopkins, and then read a paper on the progress of science during the past year, the matter, as he said, having been supplied to him by different gentlemen eminent in their respective branches of study. At the conclusion of the President's address, which was, under such circumstances, less interesting than usual, the thanks of the meeting were proposed by Lord Derby, in a speech that had no pretension to scientific illustration, and in which his lordship said he had been educated in the pre-scientific age. Sir Charles Lyell, in seconding the motion, alluded, rather more pointedly than seemed agreeable, to the former absence of scientific education in the University of Oxford, and expressed a hope, that from the gleams of improvement which were now visible, there would result a system of education better adapted to the present state of knowledge.

On the following morning the different sections assembled, but in consequence of the want of time to make preparations, several of the rooms appropriated for the purpose were unfinished, and at the time fixed for the meeting of the Mechanical Section, carpenters were at work finishing the wooden benches and tables; nor was it till nearly 12 o'clock that the place where the members were to assemble was ready for them. The Physical Section was nearly as unfinished, and over a large portion of the room there was no ceiling. St. George's Hall has, in fact, been opened too soon, and the want of completeness is evident in many parts. The place appointed for the Mechanical Section was an open hall at the north entrance, and the proceedings were continually interrupted by the noises of persons passing through to other sections. The following is a list of the officers appointed for the Mechanical Section:—

*President.*—John Scott Russell, Esq., M.A., F.R.S.

*Vice-Presidents.*—William Fairbairn, Esq., M.A., F.R.S.; Joseph Locke, Esq., M.P.; James Nasmyth, Esq., C.E.; Professor Walker, F.R.S.; Henry Booth, Esq.; John F. Bateman, Esq., F.G.S.

*Secretaries.*—James Oldham, Esq., C.E.; John Grantham, Esq., C.E.; James Thomson, Esq., C.E.

*Committee.*—Dr. Scoresby, F.R.S.; George Lowe, F.R.S; John George Appold, F.R.S.; John S. Enys, F.R.S.; Richard Roberts, C.E.; John Laird, Esq.; John Vernon, Esq.; W. G. Armstrong, C.E.; Walter F. Macgregor, C.E.; C. W. Williams, Esq.; John Hick, C.E.; Joseph Whitworth, Esq.; Alfred King, Esq.; R. B. Grantham, F.G.S.; Andrew Henderson, Esq.

On the meeting of the section on Thursday morning, the President stated, that in consequence of some of the members who had sent in papers not being prepared, and others being absent, the proceedings would be adjourned till the following morning.

The said committee had been enabled, however, to classify the subjects so as to appoint separate days for each. Friday would be appropriated to naval architecture and steam navigation; Saturday to the combustion of fuel and to steam-boiler explosions; Monday to railways and telegraphs; and Tuesday would be appropriated to miscellaneous subjects. On the following morning the President opened the proceedings of the section by a communication

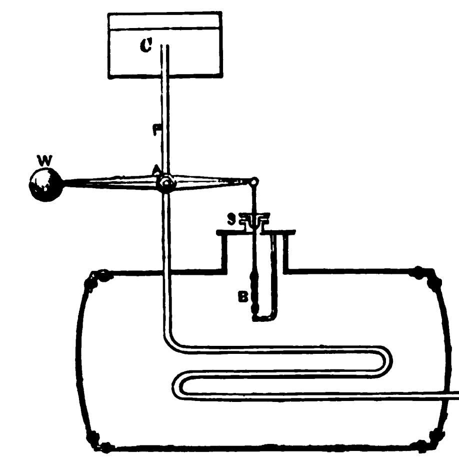
ON NAVAL ARCHITECTURE AND STEAM NAVIGATION.

Mr. Russell commenced by explaining the elementary principles of navigation, and the forms of ships requisite to produce stability, speed, and windwardness. He then entered into the consideration of the wave principle of construction, and stated the important part which the British Association had taken in establishing that principle. He mentioned as a striking instance of the difficulty with which old prejudices are removed, that formerly, on the capture of smuggler vessels, which were built on the plan of having long concave bows and bluff sterns, such a shape being considered exactly contrary to what a ship ought to have, the helm was changed, and the ship was made to sail stern foremost. When shipbuilders came to be more enlightened on the subject, they found that they must have a hollow water-line at the bow. There was in addition to this, another very important principle which had been discovered. That was, the virtue of length. If you wanted the particles of water to go out of the way of the vessel when going very fast, you must allow the particles time to do so. It was found that it was more easy to push a vessel with an elongated body through the water at great speed, than the short vessel which had been in use. This was reduced to a regular principle, the result of which was that it was now certain that 24 feet of length in the entrance lines of a vessel would give eight miles an hour easily; to go at sixteen miles an hour, the entrance lines should be nearly 96 feet; to give twenty-four miles an hour, the entrance should be 216 feet. They could not therefore expect to get twenty-four miles an hour until they had made up their minds to build ships something like 400 feet long. Now, from all the experiments he had made, and had seen made, these facts were undoubted; they would therefore perceive why such a large vessel as the *Himalaya* had such great speed. The *Himalaya* had a length of 350 feet, and had obtained the greatest speed for the smallest power, of any merchant vessel hitherto. If, in a like manner, they looked at the large clipper ships of 2000 and 3000 tons burthen now built, they would find that the principle was taken advantage of, and that their bows were elongated to a great length. The difficulty of building large ships was, however, increased by the want of materials sufficiently large for strength, until the adoption of iron. It had not yet been found practicable to join planks of wood together sufficiently strong to obtain the strength of an uniform plank, and until this was done, they could not safely use timber for building large ships. But by employing iron they would have an equally strong material of any size, the joints being almost stronger than the plates. There was a very distinguished man in that neighbourhood, Mr. Ashton Smith, and a very distinguished shipbuilder, Mr. Laird. Mr. Smith thought nothing of building ships of 120 horse-power and 600 tons burthen, merely to see how they would go, and he had had the idea at exactly the same time that the British Association were carrying on their researches, that the long hollow line was good for something. Mr. Smith endeavoured to try it, and set about inventing such a ship, and he accordingly built one, which was the first ship that went fifteen miles an hour. Mr. Laird very early coincided with Mr. Ashton Smith in his views regarding the hollow line, and very speedily adopted it, and, he believed, had made a great many ships on that principle. Mr. Vernon and Mr. Grantham had built such ships, and Liverpool upon the whole had contributed in a very fair degree towards the introduction of the new principle in shipbuilding, and he hoped that their discussion here would encourage shipbuilders not to be afraid, not to keep it a secret, but to go boldly and openly upon the hollow water line, and the more they did so, the faster they would go. Having alluded to the building of the *Great Western*, and subsequently of the *Great Britain*, and the prophetic doubts expressed at first regarding the fate of each, the President proceeded to describe the great vessel now being built by him on the Thames for the Eastern Steam Navigation Company, to trade with India and Australia. He showed how the difficulty of carrying coals, and having to stop for them and buy them at high rates at St. Vincent, the Cape of Good Hope, and sometimes the Mauritius, created such an expense that no freights could cover; he showed how it became necessary to construct a vessel large enough to carry her own coals all the way. When, therefore, he told them that the vessel being constructed, was expected to make the voyage in thirty days, carrying a freight of 6000 tons, with 500 first-class, 600 second-class, and 1000 third-class passengers—having three tiers of decks, eight feet each in height—that she was 675 feet long, 83 feet beam, 60 feet deep; when he told them that he had just measured St. George's Hall, and found that it would not fairly represent this ship, being 169 feet instead of 675 feet long—that up to the top of the hall it was only 82 feet high, and up to the spring of the arch about the height of the ship—that the breadth of St. George's hall was only 77 feet, being 6 feet narrower than the hold of the ship, it would give them the nearest approximation he could convey to the size of the vessel.

Mr. Fairbairn said he was one of those who had had doubts whether a ship of that size could be built of sufficient strength; but having seen all the plans, he now felt persuaded that it would not be deficient in the requisite strength. It would be constructed on the same principle as the Britannia bridge, and when they saw that structure sustaining itself without bending, though it had no intermediate support, there could be no doubt that that large ship would be able to bear a gale of wind without bending.

PREVENTION OF BOILER EXPLOSIONS.

Mr. H. Dircks read a paper on the Prevention of Boiler Explosions. The plan he proposed is a modification of the fusible plug, by employing a chain that holds a weight, one link of which is made of fusible metal. When the heat of the steam in the boiler is raised above the point at which it is intended the boiler should be worked, the link of the chain gives way, the weight pulls open a stop-cock, and admits a current of cold water through a tube that passes through the boiler, and thus diminishes the heat and reduces the pressure. The accompanying sketch will

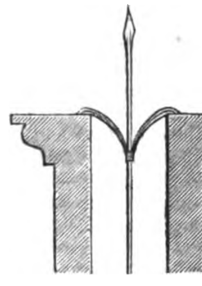


best explain the mode of operation. The pipe P, coming from the cistern C, passes through the boiler; and when the stop-cock A, is opened, a current of cold water is sent through the tube in the boiler. The link B, of the chain is made of fusible metal, and when the heat becomes too great, the metal is melted, and the weight W, opens the stop-cock. A stuffing box S, is introduced, through which the connecting-rod passes.

In the discussion that followed, the invention seemed to be considered of a nature not practically useful, and to participate in the defects of the fusible plugs which have been before tried without advantage.

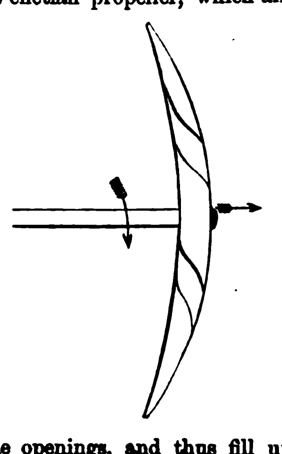
LIGHTNING CONDUCTORS.

Mr. Nasmyth read a paper on Lightning Conductors as applied to tall chimneys, and explained a mode of fixing such conductors for the purpose of securing more perfect insulation. The common plan of fixing a metal rod on the outside by holdfasts into the brickwork has been frequently attended with accidents, the lightning having entered the chimney at the points of attachment, and torn away the bricks so as to do great damage. The plan proposed by Mr. Nasmyth removed this difficulty by suspending the lightning-conductor inside the chimney. The mode of doing this is sketched in the accompanying figure. He said that a tall chimney thus protected had stood uninjured during several severe thunderstorms, whilst chimneys in the neighbourhood protected in the usual manner had been damaged. A short discussion took place on this plan of insulating conductors. Professor Faraday stated that it agreed with his views, which were that lightning-conductors should always be placed inside buildings, and not on the outside. He had been consulted on the question of placing the lightning-conductor on the Duke of York's pillar, and he then recommended that it should be placed inside, but his advice was disregarded. The practical part of the question which more particularly required attention to be directed to it in the Mechanical Section was, to avoid as much as possible the introduction of metal-work detached from the conductor. In the fixing of stones by running lead at the joints, there is considerable danger, unless there be a continuous metallic conductor leading from such metallic fastenings to the earth. The introduction of glass insulators between a lightning-conductor and the wall of a building is an absurdity, as the very short distance from the conductor to the brickwork compared with the distance the lightning passes from the clouds to the earth, is insignificant.



### VENETIAN SCREW PROPELLER.

Mr. GRANTHAM read a paper on Mr. Fisher's Venetian Screw Propeller, so called from the blades of the screw having openings like those of a Venetian blind. Mr. Grantham said, that in the use of the common screw propeller, the action of the blades on the water produces a kind of vacuum at the back, which resists the onward progress of the ship; and it was to avoid this that Mr. Fisher had invented the Venetian propeller, which allowed



the water to pass through the openings, and thus fill up the counteracting draught of water. This propeller had been tried successfully in the Birkenhead docks, and it had also been applied experimentally to her Majesty's yacht the *Fairy*, with promising results. The accompanying woodcuts represent two views of the propeller: one as seen in section, and the other showing the number and directions of the openings in a single blade.

### THE VENTILATION OF EMIGRANT SHIPS.

Mr. JOHN CUNNINGHAM read a paper on the Ventilation of Emigrant Ships, and explained a plan invented by Mr. William Ashley, for giving more perfect ventilation; and for thus avoiding the injurious effects now frequently produced by the over-crowding of such ships. The supply of air to the cabins is effected by two fans worked by a three horse-power engine, so as to produce 450 revolutions per minute. The air is forced down a main air-shaft to side trunk-flues, which extend along each side of the vessel. Small branch flues to the cabins, and other parts of the ship requiring ventilation, are joined into the main trunk-flues. Each is provided with sliding or revolving ventilators to regulate the requisite amount of supply. There is a vessel at the top of the section for disinfecting or for cooling the atmosphere. A tank at the bottom is charged with water containing the disinfecting fluid, and a truncated cone, termed a sprayor, is inverted with the smaller end into the fluid; its upper end spreads out, and is perforated. This vessel rotates rapidly, and the fluid by the centrifugal force is drawn up and thrown out in spray, through which the air must pass into the fanners, thus becoming impregnated in its passage with the disinfecting material, such as the chloride of zinc or of lime. By placing a few bucketfuls of ice per diem in the tank, the water may be cooled, and, consequently, the air reduced in temperature. The cost of providing a steam-engine, boiler, and apparatus complete, including flues, &c., for a ship of 1500 tons burthen, similar to the plans exhibited, is estimated at between 250*l.* and 300*l.* The quantity of fuel required to keep the engine at work night and day for 100 days would be about twenty tons. In addition to the process of ventilation, it is proposed also to adapt the engine to several other purposes, such as the loading and discharging of the vessel, lifting the anchors, pumping the ship, and supplying water to the waterclosets, and for cleaning the decks. Further, it is proposed to apply the waste steam to the purposes of cooking.

## ACTION OF SEA-WATER ON CEMENTS.*

By MM. MALAGUTI and DUROCHER.

FOR several years past the attention of scientific men and of engineers has been occupied with the question of the destructive action exercised by sea-water upon hydraulic mortars. M. Vicat, in seeking to explain this disastrous phenomenon, has shown that the sea-water acts by its tendency to dissolve the lime of the mortars, which is then replaced by magnesia; but hitherto no efficacious means have been pointed out to prevent or neutralise this dissolving influence. We only know, in general, that the strongest hydraulic mortars, the cements or mixtures of lime and puzzolanas, which have set the most rapidly, are those which appear to best resist these causes of decomposition. Nevertheless, even amongst mortars and cements which set with equal rapidity and are of nearly equal strength, it will be found that some possess very different powers of resistance, without its being possible *a priori* to distinguish, either by analysis or a quick trial, those on the stability of which complete confidence may be reposed.

In this state of uncertainty, we thought that, by the study of the cements which resist the decomposing action of sea-water conjointly with analyses of the hydraulic limes and cements incapable of withstanding its action, as well as of the products of the resulting decomposition, it might be possible to throw some light upon this question, whose difficulty is equal to its importance.

The samples, sixteen in number, upon which we experimented were the hydraulic limes of Paviers and Doué, and the mortars made from them, Boulogne, Portland, Pouilly, Vassy, and Parker's cements. We are indebted for them to the kindness of those skilful engineers of the Ponts et Chaussées, MM. Jebuvier, Watier, and Bellanger, to whom we desire to express our thanks.

The mode which we have followed in our researches consisted in examining the modifications which were produced in the proportions of the different elements, in comparing the compositions of the substances plunged in sea-water with that of similar substances which were not immersed. But as we had no samples of mortars of lime and sand which had set under fresh water to compare with those immersed in sea-water, the examination of the latter could only be made by comparing their composition with that of the lime employed in their preparation. In these comparisons we had to deduct the sand, and to reduce the compositions found for the mortar to those which they would have had if no sand had been used. We shall not detail here all the results which the discussion of our analyses revealed to us, and which are recorded in our complete memoir; we shall merely direct attention to the most prominent ones, which prove how complicated these phenomena of decomposition are.

Two cylinders of the hydraulic lime of Paviers were immersed, under similar conditions, in sea-water during eighteen months.

* 'Remarks on the Resistance offered by Hydraulic Limes and Cements to the Destructive Action of Sea-Water.' By MM. MALAGUTI and DUROCHER. (Comptes Rendus de l'Académie des Sciences, 24th July 1854).—From the 'Dublin Monthly Journal of Industrial Progress.'

PERSPECTIVE VIEW OF THE TOWN HALL, BUILDINGS & MARKETS, BRADFORD, WILTS.

One of them lost an enormous quantity of lime and gained little magnesia; but to compensate for this, it fixed a quantity of carbonic acid almost sufficient to saturate the two earthy bases. An appreciable quantity of silicic acid was carried off with a little alumina. It appeared that a hydrated silicate of alumina was separated from the mortar at the same time with the lime, whilst carbonic acid was substituted for the constituents which disappeared. The alteration of the other cylinder was not so considerable; the loss in lime, and the gain in carbonic acid, were not so great; but, on the other hand, the quantity of magnesia substituted for the lime was double, and a little more silicate of alumina was abstracted. The same phenomena were observed with a mortar made with this lime.

Two prisms of this mortar were immersed during eighteen months in sea-water. One of these prisms had no appearance of a well-marked alteration, whilst the second was in a very advanced stage of decomposition. It was found that some lime had, nevertheless, been eliminated, that a considerable proportion of carbonic acid had been fixed, and that the proportions of magnesia, silica, and alumina had not undergone an appreciable change. The prism in which the alteration was considerably advanced had undergone a true transformation in respect to its composition. A considerable quantity of lime was replaced by more than an equivalent quantity of magnesia, and the carbonic acid had not sensibly changed; on the other hand, the silica and alumina had appreciably augmented.

Are we to seek for an explanation of these so different results in the non-homogeneity of the hydraulic lime which had served to make the experiments? We may remark that, in the deposit of Paviers, the different beds of hydraulic limestone have not the same composition. The alteration which the mortar produced from the lime of Doué underwent, consisted in the loss of a considerable quantity of lime, without the substitution of magnesia, and by the fixation of a great quantity of carbonic acid.

With regard to the alteration of cements, that of Boulogne, previously moistened with fresh water, began to crack after an immersion of eight months in sea-water; nevertheless, its chemical composition did not sensibly change. It was quite different with Portland cement, which cracked in every direction under the action of sea-water, fixed as much carbonic acid as it contained in its normal state, and, finally, it had lost a little lime, which was substituted by a very small quantity of magnesia. Lastly, a mortar prepared with one volume of Portland cement, and two volumes of quartzose sand, immersed during a year in sea-water, exhibited no trace of alteration, unless it gained some carbonic acid.

In fine, the facts which we have brought forward, and all those which are detailed in our memoir, prove that the decomposition of limes, cements, and mortars by sea-water, do not constantly take place in the same manner; the substitution of magnesia for lime takes place sometimes, but not always, and as it is accompanied by the addition of carbonic acid, the altered mortar consists of a hydro-silicate of alumina, and of a double carbonate, which tends to approach dolomite in composition. But there are cases where the lime disappears without the introduction of magnesia, and the phenomena appears then to occur as if it had been produced in water free from salt, but charged with carbonic acid. Further, in the alteration effected in mortars moderately hydraulic, there is a division of the constituents of the mortar into two compounds, the one rich in earthy carbonates, the other rich in alumina, coming to the surface and forming a snowy deposit, which the waves remove. This partition is not effected, or at least it only takes place very slowly, in the very hard and rapidly setting cements or mortars. The alteration which is produced in the latter consists in a simple cracking of the mass, and in the disappearance of a small quantity of lime, with or without its being substituted by magnesia, and in both cases there is a tendency to diminish in volume, whence results the cracking of the mass.

It only remains for us to speak of those cements which are considered to best withstand the action of sea-water. Hitherto the cements of Pouilly, Vassy, and Parker have been looked upon as the most stable. A circumstance struck us in the analysis of these three cements: it is, that they are very rich in oxide of iron, and that that of Parker, which is the best resisting, is exactly the richest. We have, in fact, found 7 per cent. of oxide of iron in the cements of Pouilly and Vassy, and nearly 14 per cent. in that of Parker. Hence we have been led to consider whether the presence of oxide of iron does not powerfully contribute to give to those cements the property of resisting the decomposing influence of sea-water. In order to justify this opinion, it became necessary to institute experimental researches, by making ferruginous cements and exposing them to the action of sea-water. But before doing so, we had to ascertain whether oxide of iron contained in cements and mortars did not behave as an inert substance. Thus we had to examine how far this oxide was capable of forming, in the humid way, combinations with lime. With this object in view, we formed directly kinds of puzzolanas. by making mixtures of silica and a little lime with alumina and oxide of iron, and then studied the action of lime-water on these mixtures, previously heated to a dull redness. After immersion for some time, these substances augmented in volume, and possessed the most remarkable characters. Each of them divided itself into two distinct compounds, one of which attached itself to the bottom of the flask, and had gained considerable cohesion and adherence; whilst the other assumed a flocculent aspect; it swelled out more and more, and rose to about 15 or 16 centimetres above the bottom. In analysing these different compounds, we have found that the quantity of lime precipitated is independent of the presence of alumina, whilst it is augmented by the presence of oxide of iron. Further, we have recognised that the flocculent compound was the richest in alumina, and that the concreted deposit was richest in oxide of iron.

These synthetical experiments having apparently demonstrated that oxide of iron is not an inert constituent of hydraulic cements, we believe that we may conclude that the presence of this oxide would contribute to give stability to mortars and cements immersed in sea-water. It remains, in fact, to be ascertained whether cements or artificial hydraulic limes, formed by the addition of lime to ferruginous clays, or mixtures of clay with hydrated peroxide of iron, or even mixtures of clay and substances capable of generating oxide of iron, will not be attacked by sea-water. But these experiments require a considerable time, and in the meantime it may be useful to give publicity to the results which we have obtained, as they may be useful to those engaged in the constructien of hydraulic works, and further, because it is of the greatest importance that they should be verified by experience. Whatever may be the future value which the test of experience may reserve to our inductions, two facts have at all events been well established.

1. Those cements which are reported as the best for resisting the destructive action of sea-water always contain a notable quantity of peroxide of iron.

2. Certain combinations of silica, alumina, and lime, give, under otherwise similar conditions, very different reactions, according as they are deficient in, or contain large quantities of oxide of iron.

## CEMETERY ESTATE.

SIR—As I may be accused of unduly representing the cemetery estate near the City of London and Tower Hamlets Cemetery, at Stratford, I may inform you that in a late visit I found a number of bricks and materials on one of the small plots; but whether to build a brick vault or a cellar I do not know. The cramped size of the plots makes the whole affair, and building societies generally, look ridiculous. VIATOR.

*September* 22, 1854.

## CHRIST-CHURCH, NEWGATE STREET.

It has been pointed out to us that by the removal of the houses in Newgate-street, for the purposes of widening that thoroughfare, the spire and front of Christchurch can now be advantageously seen, as well as the fine mathematical school of the time of Charles II. The latter is a good specimen of brick ornamentations, but looks dull and dingy. It will bear cleaning up. The spire of the church has a good effect, and it will be a great pity if the opportunity is lost of making part of the space available for an approach to the church, and a vista of the spire. The church is a fine one, but is now hidden; whereas, it may be made a great ornament to the street, and to an important line of thoroughfare. The plan of the church is a little askew, but from the construction of the spire, it is not so objectionable to the spectator as it might otherwise be. We hope the inhabitants of Newgate-street will press upon their constituents in the Corporation the necessity of making the improvement at once. St. Bride's was thus brought forward, to the great advantage of Fleet-street,

## PHENOMENA CONNECTED WITH THE MOTION OF LIQUIDS.*

By Professor TYNDALL.

THE lecturer commenced by referring to certain phenomena exhibited by liquids, and at variance with our commonly received notions as to their non-cohesive character. According to Donny, when the air has been, as far as possible, expelled from water by persistent boiling, such water possesses an extraordinary cohesive power, sufficient, indeed, to permit of its being heated at a temperature of 275° Fahr. without boiling. The adhesion of water, thus prepared, to the surface of a glass tube, was shown experimentally; the force being sufficient to sustain a column of water of considerable height. The contractile force of a soap-bubble was referred to, and the lecturer passed on to the exhibition of the phenomena resulting from the shock of two opposing liquid veins. In this case, though the forces are in opposite directions, motion is not annihilated; but the liquid, as first shown by Savart, spreads out so as to form a thin transparent film, the plane of which is at right angles to the direction of the jets. By varying the pressure on one side or the other, or by making the jets of different diameters, the plane film could be converted into a curved one, and sometimes actually caused to close, so as to form a pellucid sack. A vein was caused to fall vertically upon a brass disk upwards of three inches in diameter. The liquid spread laterally on all sides, and formed an umbrella-shaped pellicle of great size and beauty. With a disk of an inch in diameter a pellicle of at least equal magnitude was formed. When a candle was placed underneath the curved sheet of water, a very singular effect was produced. The film above the candle was instantly dissipated, and on moving the candle, its motion was followed by a corresponding change of the aqueous surface. On turning a suitable cock, so as to lessen the pressure, the curvature of the film became increased, until, finally, the molecular action of the water caused it to form a curve returning upon itself, and exhibiting the appearance of a large flask. When the film completely embraced the vertical stem which supported the brass disk, a change in the form of the liquid flask was observed. The latter became elongated, and was sometimes divided into two portions, one of which glided down the vertical stem and was broken at its base. When the jet was projected vertically upwards, large sheets were also obtained. The jet was also suffered to fall into small hollow cones of various apertures, and the shape of the liquid sheet received thereby some beautiful modifications. The enclosed sides of the hollow cone gave the liquid an ascending motion, which, combined with the action of gravity, caused the film to bend, and constitute a work of great beauty.

* Paper read at the Royal Institution.

## NOTES OF THE MONTH.

*Ironmongers' Estate.*—The Worshipful Company of Ironmongers, in consequence of the falling in of many leases in their valuable estate in St. Luke's, are now engaged in extensive building operations. Five houses are to be built in Brick-lane.

*Hackney Union.*—With a view to economy, the Guardians of the Hackney Union are constructing new washhouses and drying rooms.

*Hoxton Schools.*—The large schools for one thousand children, attached to the Wesleyan Chapel in the New North-road, are now in progress.

*New Tilbury.*—Sheet piling is being laid down to form a large embankment behind the railway landing-stage.

*Purfleet.*—A new bridge, road, and other works, are now being carried out on the Ordnance property at Purfleet.

*Cheshunt.*—The site of the new Cemetery has at length been agreed upon, and two chapels, entrance lodge, &c., are to be constructed.

*Newcastle-upon-Tyne.*—The Northumbrians are determined to vie with the Liverpool men. St. George's Hall is just opened, so the capital of the northern counties is to have a new town-hall, music-hall, and public offices.

*Coventry and Warwickshire Freehold Land Society.*—The society have taken active possession of their estate in the parish of St. Michael's, Coventry. Streets are being made, and footpaths paved. The estate is at Red-lane.

*Counties Permanent Building Investment and Land Society.*—The High Park estate, at Smethwick, is being laid out under the direction of Mr. Clark, of Birmingham. A new street is formed upon it, properly sewered.

*Christchurch, N.Z.*—Measures are in progress to build a new Presbyterian church in this settlement. A town-hall is likewise in progress, for which a new site has been chosen.

*Lyttelton, N.Z.*—The Wesleyans have raised subscriptions to build a chapel in this part of the Canterbury settlement. Our readers will remember that the Canterbury settlement was intended to be an exclusive Church of England settlement.

*Barbadoes.*—Bridgetown is affected by the cholera in more ways than one. It seems there are a considerable number of moveable wooden houses within the limits of the city, and the authorities have felt called upon in consequence of the death of the owners by cholera, and the attempt of other parties to move the houses from their present sites, to give notice against all such undue tampering. There is, however, a determination on the part of the authorities to improve the city altogether, for we find that the cholera infected the worst lanes of the city, and the health commissioners are determined to get the place into a more healthy state if they can. By a new ordinance just published, we see that all buildings hereafter to be erected in the city or within three hundred yards of the limits thereof, are to be made of brick or stone, or bricks and stones together, or brick nogging, except balconies and the frames of doors and windows. Barbadoes being liable to earthquakes, light building materials and low houses are nevertheless necessary.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated May* 17.

1097. J. M. Rabier, Paris—Improvements in keels of ships and vessels

*Dated May* 23.

1147. L. E. Dufour, Paris—Improvements in breech-loading fire-arms

*Dated June* 20.

1349. R. Reeves, Bratton Westbury, Wilts—Improvements in drills for drilling liquid manure

*Dated June* 26.

1405. H. Mantegus, Rouen—Improvements in the manufacture of boots, shoes, goloshes, or in shoe-making generally

*Dated July* 5.

1477. T. Grubb, Dublin—Improvements in microscopes

*Dated July* 6.

1485. W. N. Nicholson, Newark—Improvements in hay-making machines, part of which improvements is applicable to carriages generally

1490. N. M. Caralli, Glasgow—Improvements in the manufacture or production of ornamental fabrics

*Dated July* 8.

1504. J. H. Johnson, Lincoln's-inn-fields—Improvements in the manufacture of carbonates of soda. (A communication)

*Dated July* 12.

1531. W. A. Gilbee, South-street, Finsbury—Improvements in the application to weaving of certain textile plants not hitherto employed, either alone or in combination with silk, cotton, and other fibrous substances. (A communication)

*Dated July* 13.

1544. R. J. Maryon, York-road, Lambeth—Improvements in the construction of, and arrangement of, and application of, steam-engines for the better means of transmitting motion, and of applying steam or other motive power

*Dated July* 18.

1575. C. M. Archer, St. James's-gardens, Haverstock-hill—Treating all kinds of paper whereon any printing, engraving, engrossing, letter-writing, or lithographing has been printed or impressed, so that the said printing, engraving, engrossed, letter-writing, or lithographing may be completely removed, discharged, or obliterated from the said paper, and so that the said paper may be readily re-used in sheets or be reconverted and worked up again into its primitive pulp by the ordinary method, and be again manufactured into and be used as paper

*Dated July* 21.

1599. Sir J. S. Lillie, Pall Mall—Improvements in fire arms

1608. R. A. Brooman, Fleet-street—Improvements in treating raw silk fabrics while being dressed and dyed. (A communication from C. Jandin and A. Duval, Lyons, France)

*Dated July* 24.

1621. R. Roberts, Manchester—Improvements in machinery for punching, drilling, and riveting

1623. A. Dastets, Paris—The extraction of a substance for supplying the place of quinine

*Dated July* 25.

1628. H. Chaumont and J. B. Bavelier, Dijon—Improvements in the manner of treating beetroot, and all other sugary and feculent vegetables

1631. A. V. Newton, Chancery-lane—Improvement in the process of converting wood into paper. (A communication)

*Dated July* 26.

1647. W. L. Tizard. Aldgate—Improvements in fermentation and in apparatus employed therein

1648. P. V. Delaye, Paris—Improvements in printing-blocks

1649. C. Luques, Boulevart St. Martin—Improved centrifugal governor

*Dated July* 28.

1664. R. H. Thompson, Old Charlton, Kent—A universal self-acting sawing machine.

*Dated July* 29.

1679. A. E. L. Bellford, Castle-street, Holborn—Improved method of engraving. (A communication)

1680. E. J. J. Dixon, Bangor—Improvements in apparatus for teaching reading and arithmetic

*Dated July* 31.

1683. J. C. D. Demay, Leicester-square—Preventing the accidents on railways with the aid of a right line of iron; and in stopping the trains almost instantaneously. (A communication from A.C. Cardot)

1687. A. V. Newton, Chancery-lane—Improved mode of extracting sulphur from compounds of india-rubber and sulphur. (A communication)

*Dated August* 3.

1704. H. Gerner, Moorgate-street—Improvements in the construction of omnibuses, parts of which are applicable to carriages generally

1706. C. Tetley, Thurlow-villas, Dulwich—Improvements in rotatory engines to be worked by steam or water

*Dated August* 4.

1708. E. Hallen, Cornwall-road, Lambeth—Improvements in chairs, chair-bedsteads, and other seats and bedsteads

1710. M. A. Dayley, London-street, Fitzroy-square—Improvements in furnaces for the purpose of consuming smoke and economising fuel

1712. E. Hamilton, Edinburgh—Improvements in the manufacture or production of beverages or occasional drinks

1714. C. W. Harrison, Richmond—Improvements in obtaining and applying electric currents, and in the treatment of certain products derived in obtaining the same, part or parts of which improvements is or are applicable to the production of motive power

*Dated August* 5.

1716. C. F. Stansbury, of the firm of Nourse and Co., Cornhill—Improvements in machinery for making rope. (A communication from W. Robinson, jun., Warsaw, New York)

1718. C. F. Stansbury, of the firm of Nourse and Co., Cornhill—Improvements in cut nail machines. (A communication from T. H. Barlow, Lexington, Kentucky)

1720. J. Cunningham, Beith, Ayr—Improvements in the preparation or production of printing surfaces

1722. J. H. Johnson, Lincoln's-inn-fields—Improvements in the manufacture of railway and other wheels. (A communication from H. U. Petin and J. M. Gaudet, Rive de Gier, France)

*Dated August* 7.

1723. G. W. Yapp, Cornhill—Improvements in steam boiler and other furnaces

1724. E. Alexandre, Paris—Improvements in concertinas

1725. G. A. Cox, Lochee, Dundee—Improvements in machinery or apparatus for winding yarns or threads

1726. J. B. T. Aubert and F. A. Cossus, Paris—Improvements in obtaining fibre from woollen rags

1727. J. H. B. Thwaites, Bristol—Improvements in apparatus to facilitate the communication by cypher

1728. J. Knight, Stamford—Improvements in engines to be worked by steam, air or other fluids or liquids

1729. E. F. Duquesne, Brussels—Improved mode of manufacturing gas for illumination

1730. S. Lucas, Dronfield Foundry, near Sheffield—Improved mode of manufacturing steel

*Dated August* 8.

1731. H. Dircks, Moorgate-street—Improvements in steam-engine boiler furnaces and other furnaces for the prevention of smoke

1732. T. Waterhouse, Sheffield—Improvements in machinery for cutting files. (A communication)

1733. H. Stoy, St. John's-road, Battersea Rise—Stopping of engines and carriages on railways, and also vehicles of every description on the common roads

1734. J. Hulme, Manchester—Improvements in apparatus for preventing the explosion of steam-boilers, for measuring the pressure of steam and other fluids, and in heating water for the supply of steam-boilers

1735. H. Turner, Leeds—Improvements in preparing hides and in cutting them into straps for driving machinery

1736. H. Moorhouse, Denton—Improvements in certain parts of machinery or apparatus used in preparing cotton, wool, or other fibrous materials to be spun

1737. C. White, Tachbrook-street, Pimlico—Improvements in printing-blocks for printing ornamental or decorative paper

1738. A. Corvi, Paris—Improvements in musical instruments

1739. A. Ogg, Glasgow—A new composition applicable to the cementing of leather.

1740. E. Webb, Worcester—Improved power loom for weaving horse-hair, and other fibrous substances where the weft or shoot is not composed of a continuous thread

1741. W. White, York Villa, Bayswater—Improvement in deodorising the contents of cesspools, privies, and also like matters in other places

*Dated August* 9.

1742. W. C. Pitt, Pimlico—Improvements in the construction of knobs and roses, used with locks, latches, and such like fastenings as are constructed with spindles. (A communication)

1743. T. Kaye, Grange Moor, York—Improvements in the means of reversing the direction of motion of steam-engines

1744. P. Oulton, Dublin—Improvements in obtaining motive power

1745. W. A. Gilbee, South-street—Improvements in hydraulic machines. (A communication)

1746. J. B. A. M. Jobard, Brussels—A new system of pump

1747. J. Lucas, Lincoln—Improved machinery for pulping or reducing vegetable substances

1748. J. Livesey, Nottingham—Improvements in the manufacture of fringes

1749. J. Hackett, Derby—Improvements in the manufacture of garments or of parts of garments, or of appendages or appliances to garments

*Dated August* 10.

1750. W. H. Clabburn, Norwich—Improvements in the manufacture of shawls and scarfs

1751. E. W. Uren, Devon—A new or improved machine and arrangements of machinery for the manufacturing of bricks, pipes, tiles, and artificial stone from clay and other plastic materials

*Dated August* 11.

1752. E. Monson, Birmingham—Improved machinery for manufacturing, cleansing, and polishing daguerreotype plates

1753. S. Bickerton, Oldham—Improved gas-light governor or regulator, which invention is also applicable to regulating the supply of water and other fluids

1754. J. Reimann and F. Sauerman, Prussia—Improvements in fire-arms

1755. P. G. Greville, Lombard-street—Improvements in the manufacture of cards for working wool and cotton. (A communication)

1757. J. Tennant, Shields Monkton, Ayr—Improvements in grubbers for agricultural purposes

1758. W. Blundell, New Broad-street, London—Improved apparatus for treating or preparing any part of the human body requiring to be surgically operated upon, for the purpose of totally or partially benumbing the sense of feeling at the desired part of the human body.

*Dated August* 12.

1759. T. Cox, Southampton-street, Strand—Improvements in stools, cushions, and hassocks

1760. J. Gibson, Paddington—Improvements in the manufacture of railway wheels

1761. T. G. Taylor, King's Arm's-yard—The use of application of the stalk of the hop plant in the manufacture of paper, pasteboard and millboard, cordage, rope, and textile fabrics

1762. W. Woodcock, Earl's-court Brewery, Brompton—Improvement in the combustion of fuel

1763. P. A. Roguier, Paris—A new mode of treating and curing varicose veins of the human body. (A communication)

1764. G. Weston, Sheffield—Improved veneering apparatus

1765. J. B. Daines, Charles-place, De Beauvoir-square—Improved mode of treating surfaces of stone, plaster, and cement, for the preservation of the same from decay

1766. J. Petrie, jun., Rochdale—Improvements in machinery for drying wool

*Dated August* 14.

1767. J. T. Stoneham, Manchester,—Improvements in the mode or method of rendering woven fabrics waterproof, and in the substance or composition used for the purpose

1768. H. L. E. D. Hennebutte, Esquermes les Lille Nord, France—Improvements in the manufacture of varnishes

1769. J. Moore, Manchester, S. Beswick, Failsworth, and B. Wilson, Woodhouses—Improvements in the manufacture of piled goods or fabrics

1770. P. Haworth, Manchester—Improved belt, band, or strap-fastener

1771. W. Todd and J. Todd, Haywood, Lancaster—Improvements in power-looms for weaving

1772. W. Crosland, Hulme, Lancaster—Improvements in machinery or apparatus for governing or regulating the speed of steam-engines, or other motive-power engines

1773. H. Smith, Smethwick—Improvements in the manufacture of wrought-iron wheels

1774. J. Beardmore, jun., Stowage, Deptford—Improvements in supplying air to furnaces

*Dated August* 15.

1775. J. Greaves and C. M. Greaves, Birmingham—Improvement or improvements in the manufacture of certain kinds of spectacle frames

1776. B. O. Stratford, Earl of Aldborough, Wicklow, Ireland—Improvements in projectiles

1777. J. Norton, Cork—Improvements in bolts and projectiles for fire-arms

1778. J. W. Taylor and C. J. Taylor, Nottingham—The employment of adhesive imitation embroidery to lace, muslin, silk, woollen, cotton, or other fabrics, such embroidery being formed of cut, pressed, or stamped patterns of velvet, crape, or other materials

*Dated August* 16.

1779. R. Caunce, Bolton-le-Moors, Lancaster—Improvements in machinery for preparing cotton and other fibrous materials

1780. J. Coupland, Southampton—The preparation and manufacture of a pulp to supersede the use of rags and similar fabrics in the manufacture of paper

1781. T. Atkins, sen., Oxford—Improvements in the mode of preparing land, constructing machinery, and other apparatus for applying and maintaining an under current arterial circulation of fluid manure, gases, vapours, and air to the seeds and roots of plants

1784. F. Higginston, King William-street City—Improvements in the mode of laying, directing, and aiming with ordnance, ship, garrison, and battering guns and field-pieces of every description.

1785. S. Frankham, Greenland-place—Improved means of consuming smoke and economising fuel in furnaces

1786. E. Carr and W. Crosby, Sheffield—Burning or consuming smoke in furnaces and fires for engine-boilers.

1787. W. Konnard, Queen-street, Holborn—Improvements in attaching door or other knobs and handles

1788. E. Manière, J. Baptiste, A. Piette, and J. F. Mermet, all of Bedford-row, Holborn—The conversion of peat into colours

1789. W. Siddons, Birmingham—Improvements in locks for guns and other fire-arms

1790. J. Lamb and T. Lamb, Kidderminster—Improvements in Jacquard machinery, and in the apparatus connected therewith

1791. E. Hamilton, Edinburgh—Improvements in the manufacture or production of beverages or occasional drinks

1792. T. Wallworth, Manchester—Improvements in purifying and treating grain, and in dressing flour, and in machinery for these purposes

1793. W. Johnson, Lincoln's-inn-fields—Improvements in furnaces and in the consumption or prevention of smoke. (A communication from E. Lambert, Troyes, France)

1794. W. Johnson, Lincoln's-inn-fields—Improvements in windlass

*Dated August* 17.

1795. C. Cowper, Southampton-buildings, Chancery-lane—Improvements in the felting of hats, and in machinery for that purpose. (A communication)

1796. J. T. Wright and E. P. Wright, Birmingham—Improvement or improvements in the manufacture of ropes, cords, lines, and twines

1797. J. Hackett, Derby—Manufacture of new and improved fabrics of cotton and of linen, and of cotton and linen combined

1798. C. Blake, St. Leonard's, Sussex—Improvement in or addition to doors, and door and window frames

1799. R. Griffiths, Strand—Improvement in the manufacture of brushes

1800. J. Bernard, Carlton-chambers, Regent-street—Improvements in the manufacture of boots and shoes, or other coverings for the feet

1801. L. C. Koeffler, Rochdale—Improvements in extracting colouring matter, also applicable for extracting size or glue from animal substances

*Dated August* 18.

1802. S. Spaldin, Hull—Improvements in apparatus for preventing loss of life at sea

1803. E. Trenery, Stourbridge, Worcester—A new or improved machine for driving piles

1804. W. Baker, Birmingham—New or improved method of manufacturing the bezils or rings used in glazing the dials of clocks and barometers, and for other like purposes

1805. J. F. Walton, Sarrat-hall, Hertford—Improvements in obtaining impressions from lithographic stones or plates

1806. J. R. Hill, Princes-street, Stamford-street — Improvements in machinery for pulverising metallic ores or other similar hard substances

1807. J. P. Clarke, Leicester—Improvements in the manufacture of reels for reeling of cotton, linen, thread, silk, or other fibrous material

1808. T. W. Rammell, Trafalgar-square—Improvements in stoves and fireplaces

1809. W. E. Newton, Chancery-lane—Improved machinery for cutting files and rasps. (A communication)

1810. A. V. Newton, Chancery-lane—Improvements in direct-acting marine engines. (A communication)

1811. J. Coney, Birmingham—Improved construction of corkscrew

1812. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in preserving corn and other dry seed. (A communication)

1813. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improved composition for fixing lithographs and engravings on canvas after being transposed or reproduced by a printing-press. (A communication)

1814. W. Ker and M. Ker, Tottenham-court-road—Improvement in the frames of expanding-tables

1816. S. Kershaw and J. Taylor, Heywood, Lancaster—Improvements in carding-engnies.

1817. E. Lund, Manchester—Improvements in cocks, valves, water-plugs, and flexible joints
1818. F. Mathieu, Bartlett's-building, Holborn—Improvements in filters
1819. W. Johnson, Lincoln's-inn-fields—Improvements in moulding or shaping articles of vulcanised caoutchouc. (A communication)
1820. W. Johnson, Lincoln's-inn-fields—Improvements in the manufacture of hat-bodies. (A communication)

*Dated August* 19.

1821. W. Fox and W. H. Fox, Compton-street, Middlesex—Improvements in furnaces to facilitate the combustion of smoke
1822. C. O'Neill, Liverpool—Improvements in the mode or method of fitting-up or fixing the berths in emigrant ships or other vessels
1824. J. Barrows, Handsworth, Stafford—A new or improved instrument to be used in cutting loaves of bread and other articles of food
1825. N. Brough, Birmingham—A new or improved dress-fastening
1826. J. Hodgson, Liverpool—Improvements in the construction of iron vessels
1827. J. Allen, and J. Taylor, North-street, Aberdeen—Improvements in the construction of rotatory engines
1828. G. T. Smartt, Doncaster—Economising the use of grease, oil, or other lubricating articles in axle-boxes
1829. G. N. Lamb, St. Helen's, Lancaster—Improvements in the manufacture of Portland cement
1830. W. V. Greenwood and J. Saxby, Brighton—Improvements in signal-lamps
1831. J. Worrall, jun., Salford—Improvements in the method of cutting fustians, cotton velvets, and other piled goods or fabrics

*Dated August* 21.

1833. T. S. Simpson, St. Anne's-place, Limehouse—Improvements in sashes
1834. T. Miller, Fairfield-place, Stepney—Improvements in apparatus for raising coals and other weights from the holds of ships and other places
1835. W. H. Smith, Philadelphia, H. Bessemer, Baxter-house, St. Pancras, and R. Longsdon, Hornsey-lane—Improvements in the manufacture and treatment of slag and vitreous substances, and the combination of other substances therewith
1836. S. T. Jones, Union-court, Old Broad-street—Improvements to reduce and wash minerals to extract metal therefrom, especially gold
1837. J. Grist, Islington—Improvements in machinery for the manufacture of casks, barrels, and other similar articles
1838. R. B. Cooley, High-street, Nottingham—Improvement in gloves

*Dated August* 22.

1840. A. Jacquelain, Paris—Improvements in the manufacture of gas for illumination and heat
1841. W. Johnson, Lincoln's-inn-fields—Improvements in the manufacture of carding apparatus for the preparation of fibrous materials. (A communication)
1842. W. H. Meriwether, Morley's Hotel, Strand—Improvements in the construction of fences and hurdles
1843. R. Benton, Saltley Hall, Birmingham—Improvements in marine and railway telegraphs
1844. J. Buchanan, Leamington Priors—Improvements in marine engines
1845. W. H. Meriwether, Morley's Hotel, Strand—Improvements in producing surfaces for lying, reclining, or sitting upon
1846. J. L. Hancock, Milford Haven—Improved pneumatic safety-inkstand
1847. W. E. Newton, Chancery-lane—Improvements in carding engines. (A communication)
1848. C. Blunt, Sydenham, Kent, and J. J. W. Watson, Wandsworth—Improved description of artificial fuel

*Dated August* 23.

1849. W. S. Smith, Charlotte-street, Fitzroy-square—Improvements in pianofortes
1851. J. Norton, Cork—An igniter or apparatus for igniting explosive and combustible materials
1853. M. Curtis, Manchester, W. H. Rhodes, Gorton, and J. Wain, Greenacres Moor, Oldham—Improvements in certain machines for spinning and doubling cotton and other fibrous substances
1854. A. B. Bérard, Paris—Improvements in the manufacture of gas coke and other products from coal, and in apparatus for that purpose
1855. P. Fairbairn and T. Greenwood, Leeds—Improvements in machinery for preparing to be spun cotton, wool, flax, silk, and other fibrous materials
1856. J. L. P. J. B. H. Bouvet, Paris—Improved suction apparatus for pumping and exhausting purposes

*Dated August* 24.

1857. H. Frost, Sheffield—…ovements in furnaces or fireplaces for steam generators and other purposes
1858. W. Brooke, Martin's-lane, Cannon-street—Consuming smoke, and condensing noxious and other gases and vapours, and converting the products thereof to valuable purposes, which now escape to the injury of animal and vegetable life
1859. J. Horrocks, Pilkington, Lancaster—Improvements in pin cops, or pin-bobbins, or spools for weaving
1860. T. Hayter, the King's Head, Southwark—Improvements in apparatus for holding straps for sharpening razors
1861. H. G. de Châteauneuf, Paris—Improvements in the process and apparatus for washing
1862. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in apparatus for illuminating. (A communication)

*Dated August* 25.

1864. R. B. Froggart, Manchester—Improvements in the mode or method of purifying, clarifying, and reducing the specific gravity of oils or fatty bodies, and also of clarifying fermented liquids with the machinery or apparatus used in the said processes
1865. J. H. Tuck, Pall Mall—Improvements in packing for pistons, piston-rods, valves, and other uses
1866. J. T. Skinner, Georgiana-street, Camden Town—Improved apparatus for rendering the shunts or points of railways self-acting, applicable also to the working of railway signals
1868. H. Bessemer, Baxter-house, Old Saint Pancras-road—Improvements in guns for throwing projectiles for naval and military purposes
1869. W. Woodcock, Earl's-court Brewery, Brompton—Improvement in the construction of furnaces

*Dated August* 26.

1870. G. Wall, Manchester—Improvements in machinery or apparatus for the manufacture of pottery
1871. H. Davey, Kent-street, Southwark—Consuming smoke in furnaces
1872. J. Gedge, Wellington-street South—Improvements in boring instruments, known as augers, bits, or gimlets. (A communication from R. Cook, U. S.)
1873. W. Smith and T. Phillips, Snow-hill, London—A new mode of constructing and connecting pipes or tubes for gas, water, or steam purposes
1874. C. M. P. de Kermoal, Paris—Improved system for preserving and transporting animal and other alimentary substances
1876. H. Francis, Strand—A machine for scutching flax, hemp, and other like fibrous material
1877. P. Fairbairn, Leeds, and R. Dempster, Bessbrook, near Newry, Armagh—Improvements in machinery for carding, drawing, and spinning tow and tow waste

*Dated August* 28.

1878. A. A. Legras, Paris—Improved apparatus for regulating the level or flow of liquids
1879. T. Carr, Liverpool—Improvements in steering apparatus
1880. R. M'Connell, Glasgow—Improvements in shutter for doors and windows
1881. J. Donovan, Church-path, Hackney—Improved mode of constructing steam boiler and other furnaces for the purpose of consuming smoke
1882. J. Kirkham, Tonbridge-place, New-road and T. N. Kirkham, Edith-grove, West Brompton—Improvements in the process of manufacturing and purifying gases for lighting and heating, and in apparatus to be employed therein
1883. G. Burch, Waltham-cross, Cheshunt—Improvements in the manufacture of pulp
1884. J. Gray, Strand-street, Liverpool—Improvements in the mariner's compass

*Dated August* 29.

1885. I. J. Machin, St. Giles-in-the-Fields—Improvements in cutting screws
1886. J. L. Hancock, Milford Haven, Pembroke—Improvements in machinery for draining land
1887. J. Burridge, Great Portland-street—Improvements in apparatus for closing fire-places
1888. J. Gray, Dublin—A self-acting flushing-apparatus, which may be arranged for registering the quantity of water or other liquid flowing through it
1889. T. McNally, William-street, Blackfriars—Improvements applicable to window-sashes or shutters
1890. L. N. Langlois and J. B. Clavières, Paris—A new mode of constructing steam-boilers
1891. J. de Redon, Paris—A new machine for cutting or preparing wood to be used in the manufacture of paper
1892. J. Seithen, Wakefield-street, Brunswick-square—Improvements in the manufacture of cases or envelopes for covering bottles
1893. J. F. Williams, Artillery-place West, Bunhill-row—Improvements in joining cast-iron tubes

*Dated August* 30.

1895. J. Mathieu, Paris—Improvements in pumps. (A communication)
1896. W. Campion, Nottingham—Improvements in the manufacture of warp fabrics
1898. W. Nimmo, Pendleton, Lancaster—Improvements in machinery or apparatus for producing ornamental woven fabrics
1900. J. Seithen, Wakefield-street, Brunswick-square—Improvements in apparatus for cutting squares of cork
1901. W. Symington, King William-street, London—Improvements in apparatus for heating air by means of steam

*Dated August* 31.

1902. M. N. Illakowicz, Maddox-street, London—Improvements in picture frames
1903. R. C. Witty, Torriano-avenue, Camden-road-villas—Improvements in illumination by means of artificial light
1905. J. Bernard, Club-chambers, Regent-street—Improvements in the manufacture of combs
1906. E. König, Rue du Temple, Paris—Improvements in manumotive carriages
1907. W. Campion, Nottingham—Improvements in rotary knitting-machinery
1908. J. M. Dunlop, Manchester—Improvements in machinery or apparatus for preparing, cleaning, and cutting india-rubber and gutta-percha. (Partly a communication)

*Dated September* 1.

1910. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improved soap, to which he gives the name of saponitoline. (A communication)
1911. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in apparatus for retarding and stopping railway carriages. (A communication)
1912. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improved process of manufacturing alcohol from the stem and ear of maize. (A communication)
1913. M. L. Lindheim, Paris—Improvements in the manufacture of bonnets and caps
1914. J. Danks, Birmingham—Improvement or improvements in inkstands, which improvement or improvements may also be applied to the stoppers of bottles, the packing of pistons, and other like purposes

*Dated September* 2.

1915. J. Worthington, Manchester—Improvements in counters or fittings of shops, warehouses, and offices, for arranging, preserving, and exhibiting articles therein
1916. H. Edwards and J. Hodson, Islington—Improvements in the formation of envelopes
1917. G. Lewis, High Cross-street, St. Martin's, Liecester—Improvements in the construction of locks
1918. W. Finley, Aylesford, Kent—Improvements in machinery for manufacturing bricks and tiles
1919. H. B. Barlow, Manchester—Improvements in machinery for cleaning cotton and other fibrous materials. (A communication)
1920. N. Callan, Maynooth-college, Kildare—Improvements in certain galvanic batteries
1921. P. A. Decoster, Paris—Improvements in extracting the saccharine parts of the sugar-reeds, and of other sacchariferous substances

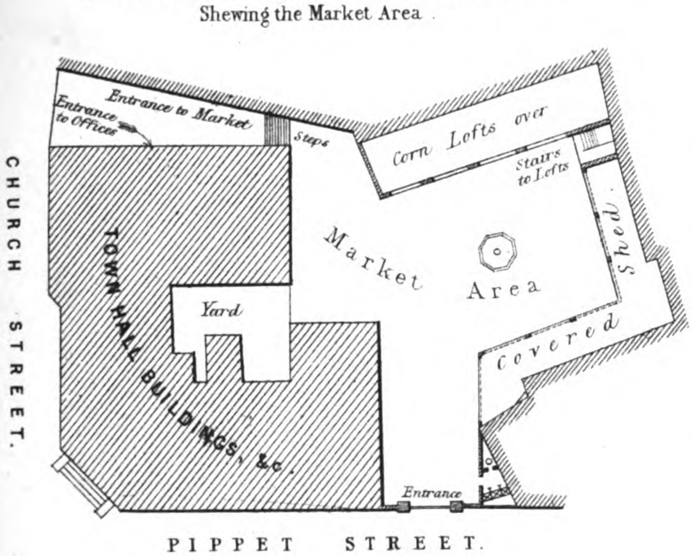
PLAN OF TOWN-HALL-BUILDINGS &c. BRADFORD, WILTS.
Shewing the Market Area.



*Scale 24 feet = 1 Inch.*

J. R. Jobbins

## NEW TOWN HALL AND COVERED MARKET, BRADFORD.

(*With Engravings, Plates* XXXVII. *and* XXXVIII.)

These buildings are exceedingly well situated at the corner of Church and Pippet streets, and have as commanding a frontage as could be desired, and the hill in the rear forms a most picturesque background. The design was chosen in competition; the style, which is Early Elizabethan, being thought more suitable than any other for the town of Bradford. The stone used is the red-bed, from Farleigh Down, for the dressings and ornamental work, and the Bradford freestone for the range work. The buildings are to be covered with stone-tile.

As will be seen by the plans, the buildings comprise four distinct arrangements, having no communication with each other: First, on the ground-floor, entering in Pippet-street, is the county police-station, comprising dwellings for the superintendent and two policemen, with their families, and three separate cells for prisoners, with all requisite yards and conveniences. Secondly, the principal entrance in the tower leads to the large hall, of which particulars are given below. Thirdly, in Church-street, a shop and dwelling-house. Fourthly, a suite of offices, suitable for a solicitor or public officer.

The first-floor is approached by a handsome double staircase lighted by two domes, and comprises the large assembly-hall, 50 feet by 30 feet; committee or ante room, 23 feet by 17 feet; and the three rooms forming the literary and mechanics' institute—viz., reading-room and library, each, 12 ft. 6 in. by 13 ft. 8 in.; the institute-room, 24 feet by 17 feet, with all requisite conveniences, &c.

The assembly-room will be used for the meetings of the magistrates, and for the sittings of the county-court, with the committee-room adjoining. It is lighted by two large oriel windows, and is 20 feet high to the springing of the roof (inside), which is in the form of a semi-ellipse, with moulded ribs, and boarding at the back, stained and varnished. The other rooms on this floor are 14 feet high.

On the second-floor, over the stations, are eight sleeping-apartments for the police, and over the committee-room and in tower the bedrooms to the dwelling-house. The tower is 80 feet high, covered with galvanised iron; it has two rooms in it over the staircase.

There are two entrances to the markets, the principal being in Pippet-street. They consist of an open area with covered sheds all round, and a cheese-room with corn-lofts over; a conduit and fountain is to be placed in the centre of the area.

The contracts were taken at 3000*l.*, by Messrs. Long and Spinder, of Bradford; exclusive of old materials, which were valued at about 300*l.* more, not including, however, grates, chimney-pieces, gas, or any other fittings. It is expected the buildings will be completed in the spring of next year.

## THE BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

***Abstract of Papers read at the Meeting held at Liverpool,* 1854.**

The scientific business of the recent meeting at Liverpool was brought to a close on Wednesday the 27th ult. The papers read in the Mechanical Section were neither so numerous nor so important as those at the meeting last year; nor were the other sections remarkable either for the novelty or interest of the matters brought before them. In point of numbers, however, the attendance at Liverpool doubled that at Hull, and the members of the Association met with a reception more cordial and hospitable than any they have experienced for some years past. Independently of the funds subscribed for the usual expenditure at the soirées, the mayor gave two entertainments—one to the most distinguished members of the Association, and another to all those who were not inhabitants of the town; and a handsome entertainment was also provided by the inhabitants of St. Helen's to about four hundred ladies and gentlemen, who joined the excursion on Thursday to see the principal manufactures of that place. Many of the people of Liverpool threw open their houses to receive the members of the Association during the time of the meeting, and the proceedings passed off with great eclat, to which the magnificent hall in which the meetings were held largely contributed.

The general committee at their last meeting recommended grants of money out of the funds of the Association, to the amount of 751*l.*, of which the sum of 500*l.* was for the Kew Observatory, and 100*l.* for Strickland's ornithological synonyms; but no part of the money was appropriated to investigations connected with mechanical science. Among the applications recommended to be made to the government was one for an early publication of the heights of ground determined by the Trigonometrical Survey; the levels of the sea which are the base of the observations; and the reasons which have guided the selection of the *places* where the sea levels were taken; also for considering the subject of navigation of iron ships; and for rendering the system of letters patent more available to the benefit of inventors.

The meeting of the Association next year will be at Glasgow, early in September, and the Duke of Argyle is appointed President.

### ON THE MEANS OF REALISING THE ADVANTAGES OF THE AIR-ENGINE.

The author, Mr. W. J. Macquorn Rankine, divides this paper into four sections. In the *first*, are explained the two fundamental laws of the mechanical action of heat, and their application to determine the efficiency of theoretically-perfect engines working between given limits of temperature; and it is shown, that as the efficiency increases with the distance between those limits, and as it is easy to employ air with safety at temperatures far exceeding that at which the pressure of steam would cease to be safe and manageable, the maximum theoretical efficiency of air-engines, consistent with safety, is much higher than that of steam-engines. For example, at the temperature of 650° Fahr., at which the air-engine has been successfully worked, the pressure of steam is 2100 lb. on the square inch; while that of air is optional, being regulated by the density at which the air is employed.

In the *second* section, the various causes of waste of heat and power in steam-engines are classified, and the actual efficiency of steam-engines is compared with their maximum theoretical efficiency, and also with the maximum actual efficiency which may reasonably be supposed to be attainable in the steam-engine by means of any probable mechanical improvements.

The following are estimates of the consumption of bituminous coal, of a specified quality, per horse-power per hour:—

1. For a theoretically-perfect engine working between such limits of temperature as are usual in steam-engines ........ ............... 1·86 lb.
2. For a double-acting steam-engine improved to the utmost probable extent .............. 2·50 lb.
3. For a well-constructed, properly-worked, ordinary, double-acting steam-engine, on an average ...................................... 4·00 lb.

In the *third* section, the causes of waste of heat and power in air-engines are classified in a manner analogous to that applied to steam-engines; and the actual efficiencies of those previous air-engines as to which satisfactory experimental data have been obtained—namely, Stirling's engine, and Ericsson's engine of 1852—are compared with the efficiencies of theoretically-perfect engines working between the same limits of temperature; the results being as follows, so far as they relate to the consumption of coal of the specified quality, per horse-power per hour:—

| | Actual Consumption. | Consumption of a theoretically-perfect engine. |
|---|---|---|
| Stirling's engine........... | 2·20 lb. | 0·73 lb. |
| Ericsson's engine of 1852 | 2·80 lb. | 0·82 lb. |

It is thus proved that an air-engine has actually been made to work successfully, and to realise an economy of fuel considerably superior to that of ordinary steam-engines; and, in fact, surpassing the utmost limit to which it is probable that the economy of double-acting steam-engines can ever be brought. Stirling's engine, as finally improved, was compact in its dimensions, easily worked, not liable to get out of order, and consumed less oil and required fewer repairs, than any steam-engine. Still the advantages shown by that engine over steam-engines were not so great as to induce practical men to overcome their natural repugnance to exchange a long-tried method for a new one. Another circumstance caused Stirling's and Ericsson's engines to meet with neglect from scientific men—namely, that both were by some persons represented as instances of *power created out of nothing*—the popular delusion commonly called "the perpetual motion."

It is shown that Stirling's air-engine, as compared with a theoretically-perfect air-engine wasted two-thirds of its fuel, and Ericsson's somewhat more.

Two obvious and powerful causes of that waste of fuel are traced—1, deficiency in extent of heating surface; 2, the communication of heat from the furnace to the working air at those periods of the stroke when it is not performing work.

The necessary conclusion is, that the more completely we remove those two causes of waste of fuel, the more clearly shall we approximate to the theoretical extent of the economy of the air-engine—an extent far exceeding that to which the economy of the steam-engine is restricted—and the more fully, in short, shall we accomplish that which has hitherto been very imperfectly done *to realise the advantages of the air-engine.*

The *fourth* section describes the improved air-engines of Messrs. James Robert Napier and W. J. Macquorn Rankine. In this engine the heating surface is increased to any required extent by means of tubes employed in a peculiar manner. The waste of heat by its communication to the air at improper periods of the stroke is prevented by a sort of plunger, or combination of plungers, called the *heat-screen*, which prevents any access of the air to the heating surface, except when it is in the act of expanding, and so performing work. The engine may be made of the same size with a steam-engine of the same power, or smaller, according to the degree of condensation at which the air is employed. The air-receivers of an experimental engine, with their various fittings, were completed some time since without practical difficulty, notwithstanding the novelty of their construction; but the erection of the engine has been retarded by delay in the execution of the cylinder, fly-wheel, shaft, and other parts, which are similar to those of a steam-engine.

Independently of the amount and value of the saving of fuel which will result from the introduction of the air-engine, it possesses the important and incontestable advantage, that even should an air-receiver burst (which is very unlikely), the explosion would be harmless, for its force would not be felt beyond the limits of the engine itself, and hot air does not scald.

## HIGH-LEVEL RAILWAY FOR THE LIVERPOOL DOCKS.

Mr. J. Grantham exhibited a model of and explained his plan for a high-level railway for the Liverpool docks, to facilitate the transit of passengers and goods along the whole line, extending at present for four miles. It is unnecessary for us to do more than mention this paper, as a detailed description was published in the *Journal* for 1853, Vol. XVI. p. 460.

## SOLIDIFICATION OF BODIES UNDER PRESSURE.

A paper was read by Mr. Fairbairn, on the solidification of bodies under great pressure, in which he stated the results of further experiments conducted by Mr. Hopkins, Mr. Joule, and himself, on the effect of pressure on melting points, and on the strength of materials. The apparatus by which the bodies operated on were submitted to pressures equal to 90,000 lb. on the square inch, was described in our notice of the meeting of the British Association last year. In the experiments reported to the Mechanical Section at this meeting, the objects kept in view had been to ascertain the exact laws which govern the cohesive strength of bodies in their natural physical conditions, and how far a knowledge of those laws may conduce to the reduction of and the subsequent solidification of the metals under circumstances whereby increased strength and density may be obtained.

The experiments commenced with spermaceti, short bars of which were cast and left to solidify, at the same temperature but under different pressures. The bar that was solidified under a pressure of 40,793 lb. carried 7·52 lb. per square inch more than one submitted to a pressure of 6421 lb.; the ratio being in favour of the more strongly compressed bar, in its power of resistance to a tensile strain, as 1 to 0·876. It appears from these experiments that bodies solidified under pressure have not only their densities greatly increased, but that their molecular structures are also materially affected so as to increase their adhesive power. Still further to elucidate the subject, cubes of exactly one inch were carefully prepared and loaded with weights till they were crushed. The first cube, solidified under a pressure of 6421 lb. was crushed with 213 lb.

Tin was then operated on. A quantity of pure tin was melted and allowed to solidify, first at the pressure of the atmosphere, and afterwards at a pressure of 908 lb. on the square inch. The same quantity taken from the same ingot was subsequently submitted to a pressure of 5698 lb. on the square inch. The bars, after having been solidified and allowed to cool for upwards of fourteen hours, were subjected to the usual tests of tensile strains. From these experiments there was derived, as nearly as possible, the same law or measure of strength as obtained from the experiments on spermaceti; for with the same pressures of 908 lb. and 5698 lb. on the square inch, the breaking weights were respectively 4053 lb. and 5737 lb.; or in the ratio of 1 to 0·706, being an increase of nearly one-third on the crytallised metal when solidified under about six times the pressure.

From these facts it is evident that the power of bodies to resist a strain is greatly increased when solidified under pressure, and Mr. Fairbairn considered it highly probable that the time is not far distant when the resisting powers of metals, as well as their densities, may be increased to such an extent as to insure not only greater security but greater economy by solidification under pressure. He said he was borne out in these views by the fact, that the specific gravities of the bodies experimented on were increased in a greater ratio to the pressure. Spermaceti, solidified under a pressure of 908 lb. on the square inch, had a specific gravity of 0·94859; whilst that solidified under a pressure of 5698 lb., had its specific gravity increased to 0·95495. The specific gravity of tin, solidified under a pressure of 908 lb., was 7·3063, and that solidified under a pressure of 5698 lb. was 7·3154, which gave ·0091 as the increased density from pressure.

There are other experiments in progress to determine the law that governs the increase of specific gravity, and to determine the conducting powers of bodies solidified under severe pressure. Experiments have also been made on clay, charcoal, and on different kinds of timber. From the experiment on powdered dry clay, it appeared that a bar of that substance 3½ inches long by 1¼ inch diameter, after being hammered into the testing cylinder so as to be slightly consolidated, was reduced in bulk, with a pressure of 9940 lb., to 2·958; with a pressure of 54,580 lb., to 2·3; with a pressure of 76,084 lb., to 2·288; and with a pressure of 97,588 lb., to 2·195 inches. Under such enormous pressures, clay and other substances operated on, had acquired the density and hardness of some of our hardest rocks.

## A MARINE BAROMETER.

The Committee of the Kew Observatory having had their attention directed to the importance of obtaining an accurate marine barometer, have, after examining several forms of those instruments, adopted one made by Mr. Adie, who thus described it:—The tube has a diameter of from 0·22 inches to 0·55 inches. About four inches of the tube, near the middle, has a capillary bore in order to produce the contraction necessary to prevent inconvenient oscillation at sea from the motion of the vessel. The degree of contraction is such that, when the barometer is first suspended, the mercury requires about twenty minutes to fall from the top of the tube to its proper level. A pipette, or Gay-Lussac's air-trap, about two inches long, is inserted a little below the contraction, which serves to prevent the entrance of air into the upper part of the tube, or into the capillary portion of it. The lower end of the tube, which is within the mercury in the cistern, is also contracted. With these precautions it is believed that when the tube has been well filled at first it is very unlikely to become deteriorated. The mercury is necessarily boiled in the tube in the process of filling. The cistern of the barometer is a cylinder of cast-iron, the tube being fitted into it mercury-tight by cement; a portion of the upper part of the cistern being covered with strong sheepskin leather firmly fixed by abutting flanges. This leather has been found to be sufficiently porous to permit the free action of the air through it, but not to allow the mercury to pass without considerable pressure, to which it can never, from the construction of the instrument, be subjected. The cistern is filled with mercury to such a height that it can never under any circumstances of temperature or pressure be full, but always sufficiently so to prevent the lower end of the tube being ever exposed either during carriage or when in use. This renders any adjustment of the instrument when being mounted for observation unnecessary. The diameter of the cistern is about 1·3 inch. The barometer tube is protected by a cylindrical case of brass, which is screwed firmly to the upper portion of the iron cistern. The graduation is made on this brass tube, and the vernier moved by a rack and pinion, the index being adjusted to the top of the mercurial column by shutting off the light, as is commonly done in standard and other good barometers; the vernier reads to 0·002 inch. The correction for the relative capacities of the tube and cistern (which is usually applied as a numerical correction varying with the height) is in these instruments included in the graduation of the scale, the scale being shortened by the amount of correction, but divided so as to represent the true measurements. The correction for capacity is obtained by computation from carefully measured diameters of the tube and cistern. The zero point of the scale is determined by comparison with a standard barometer. A thermometer, whose scale is divided on its stem, and having its bulb within the encasing brass tube, gives the temperature of the mercury. In making an observation it is only necessary to set and read off the vernier, and to note the height of the thermometer. The instrument presents much the appearance of a mountain barometer. It is suspended in gimbals from a point a little above the middle of the tube, the rack motion being close to the point of suspension, so that the hand may rest on the supporting arm. The supporting arm is flat, of hammered brass, thin enough to give the elasticity necessary to counteract sudden jars, and is equivalent to the spring gimbals usually employed, while much simpler in its construction.

---

### CYLINDRICAL LENSES.

Professor Sturm, of Vienna, described a method of manufacturing cylindrical lenses, which by insuring accuracy of construction has removed the difficulty attending the use of lenses of that shape, and promises a great improvement in optical instruments. Professor Sturm observed that the superiority of the cylindrical principle is evident from the circumstance, that a perfectly cylindrical lens is free from the defects of spherical aberration, and that the opposite rectangular planes combine in forming ellipses in their intersections, and consequently show a greater precision, distinctness, and luminousness, and less contraction of dimensions; they, therefore, admit of enlarged visual angles. The cylindrical system, moreover, renders it practicable to form curves of all kinds, for instance, paraboles, hyperboles, ellipses, &c., which is impracticable in the spherical system. In the second place, the machine is so constructed that every lens, even for spectacles, is accurately centred, since the cross lines of the two planes pass through the middle, whilst the centralisation of spherical object-lenses is very difficult and imperfect. This defect arises, both in the best spherical and cylindrical lenses, from their being hitherto ground by hand; the imperfection becoming more evident in the latter than the grossest defects in the former; and this is the reason why more attention has not been paid to cylindrical lenses. In the third place he said that two cylindrical planes, intersecting each other at right angles, have the effect of neutralising the defect of spherical aberration; whilst two parallel spherical planes produce the effect of doubling the imperfection; consequently the former are much better adapted for spectacles.

The Abbé Moigno stated that cylindrical lenses were the invention of M. Chambland, a Frenchman, who had described them long since.—M. Sturm explained that he did not claim the invention of such lenses, but only of a means of accurately centering the halves of such lenses, and manufacturing them with strict correctness, which had never been before accomplished.

---

### SUBMARINE TELEGRAPHS.

Several communications were made in the Physical and in the Mechanical Sections in reference to the probability of establishing electric telegraphic communication between England and America, and the difficulties attending such an undertaking. The first paper on the subject was read by Mr. John Brett, who after claiming for himself and his brother Mr. Jacob Brett, the honour of being not only the first inventors, but also the first projectors, of a submarine or oceanic telegraph, proceeded to give an account of the difficulties and prejudices they encountered in establishing the first submarine telegraph, which has now been successfully working for three years between France and England. He then explained some of the difficulties he had encountered in laying down the two submarine lines in the Mediterranean in July last,—especially in passing a depth exceeding, by 100 fathoms, what had previously been ascertained to exist on the route between Piedmont and Corsica. The depths encountered between England and France, and England and Belgium, did not exceed at their maximum 30 fathoms; whereas the submarine cable was laid down in the Mediterranean at a depth of 350 fathoms, exceeding about eight times that of the English Channel. He then explained the difficulties they encountered, when, after the line had been paid out, along the top of a submarine mountain for some miles at a depth varying from 180 to 200 fathoms, it suddenly as he believes, came to the edge of a precipice, making a total of 350 fathoms, where it ran out with frightful velocity; and had the cable been less strong the whole must, of necessity, have been lost. They were compelled to anchor by the electric cable all night, to restore the injury that had occurred; but he felicitated himself upon the experience thus gained, as it had led to many valuable suggestions necessary to successful operations in great depths. Mr. Brett explained his reasons for selecting this line to India, *viâ* Egypt, in preference to the line by the Italian peninsula, which would ever be impeded by the jealousies and restrictions of the petty States; whereas, to the shores of Africa, the Mediterranean telegraph passed through only the States of France and Sardinia, who had encouraged it by liberal guarantees, and had permitted all communications, in whatever language, to pass quite unrestricted through their States. From Africa, he stated, he had two plans in contemplation for its extension to Egypt—one, a line dropped in the Mediterranean in the shallow line near the coast, and another buried in the sand along the shore,—both of which he was satisfied might be laid secure from derangement of any kind. He concluded with a statement of the labour and attention he had given for many years in preparing for the telegraph to America, and of the depth, on the proposed line, as recently ascertained by Lieut. Maury, of the United States, with some estimates of the weight and cost; and stated that a return of 100*l.* to 150*l.* per day would give a fair interest on the necessary capital. His plan comprised several lines of communication.

Mr. Bakewell read a paper in the Mechanical Section on telegraphic communication between England and America, in which he proposed to facilitate such an undertaking by laying down a single insulated wire, sufficiently thick to be self-protective. By that means, he said, the difficulty of paying out the wire would be greatly reduced, as the wire would be comparatively flexible, and need not weigh more than half a ton per mile. Two or three ships laden with such a wire, assisted by a steamer, would be sufficient to convey it from the west coast of Ireland to the United States. The cost of 2500 miles of such wire, estimating it at 30*l.* a mile, would be 75,000*l.*, and allowing 25,000*l.* for the laying down and incidental expenses, a telegraphic communication might thus be formed between the old and the new world for 100,000*l.* A single wire telegraph, he contended, would be sufficient in the first instance, for the transmission of the intelligence between England and America; for even if no quicker instrument was used than the needle, there might be 1400 messages transmitted in twenty-four hours, and that number exceeds the amount of messages transmitted daily through all the wires of the Electric Telegraph Company. Mr. Bakewell exhibited some specimens by his copying telegraph, which, he said, transmits much more quickly than the needle instrument.

Mr. Varley explained in the Physical Section a difficulty which has within the last year been found to exist in the transmission of electric telegraph signals through submerged wires; and he stated the means he had contrived for overcoming it. The first public notice of the peculiar action of submerged wires in the transmission of an electric current was made by Professor Faraday, at the Royal Institution, where he stated that a wire coated with gutta-percha, and immersed in water, resembles in its effect an elongated Leyden jar, the gutta-percha taking the place of the glass, the wire being the inside coating, and the water the outside conducting substance. When an electric current from a powerful voltaic battery, is sent through a wire so circumstanced, a part of the charge is retained in the wire, and is not discharged until upwards of half a minute after contact has been broken. Where, therefore, a telegraphic instrument is used in which the electric current is always passing in the same direction, as in Mr. Morse's telegraph, which is extensively used in the United States, and occasionally in this country, the charge is retained in the wire, and the succeeding signals cannot be distinguished. This is particularly the case where the signals are recorded on paper by electro-chemical decomposition. The needle telegraph is not much affected by this retention of the charge, because the electric current is being continually reversed to produce contrary deflections of the needle, and the electricity in the wire is thus discharged. Availing himself of this action in the needle telegraph, Mr. Varley has constructed an apparatus for working Mr. Morse's telegraph, that overcomes the difficulty by sending reverse currents along the wire, after every signal, for the express purpose of discharging the wire. Mr. Varley stated, that in the submarine and subterranean wires between Holland, London, and Liverpool, Morse's instrument would only work at speeds too slow for commercial purposes; but that by aid of his apparatus these wires are now and have been for six months working at the required speed,—viz., twenty-five words per minute, for which three hundred alternations of current per minute are required. His apparatus, by discharging the wire and reversing the current at every move of the key, produces rapidly alternating currents through the wire, which are quite sufficient to actuate his galvanometer relay, which actuates a local battery to produce the marks. The little arm on the axis of the relay, instead of striking against a dead stop, rubs obliquely against a gold spring, filing off the little film of air which otherwise would prevent the instant completion of the local circuit. After alluding to the mechanical difficulties of laying a cable between England and America, he stated he had come to the following conclusions:—1st. If a wire could be suspended in an unbounded non-conductor or atmosphere, with no conducting body near it, the transmission of an electric current through it would be instantaneous, no matter what the length of wire. 2nd. The approach of any conducting body to this wire would (by induction) reduce the speed of the transmission. 3d. In the case of a wire coated with a non-conducting substance (such as gutta-percha) the induction decreases in the same proportion as the thickness of the coating is increased. 4th. The conducting power of a wire is in proportion to its substance, the induction in proportion to its surface. He then calculated the dimensions of a cable 3000 miles in length, which would transmit twenty-five words per minute. A copper wire one-sixth of an inch in diameter, coated with gutta-percha to the depth of nearly half an inch, would, he said, be found capable by aid of his apparatus of transmitting twenty-five words per minute, 3000 miles. To work the ordinary telegraphs the copper wire must be three-eighths of an inch in diameter, and coated with gutta-percha three-fourths of an inch, making a total diameter of about two inches.

Mr. John Brett stated that he had instituted a series of delicate experiments, with the aid of an eminent scientific gentleman, the results of which were, that they had so completely overcome the difficulty of the retention of the charge, that a working electric current might be transmitted to America through the thin wires now commonly employed in submarine cables, and equally as rapidly as at short distances.

---

### APPLICATIONS OF WATER-POWER.

Mr. Armstrong read a paper on various applications of hydraulic power, referring more particularly to the hydraulic cranes at the Albert dock, and to those recently constructed upon an improved principle at the Stanley dock, Liverpool. He said he first introduced the principle at Newcastle-upon-Tyne, in 1846, and soon afterwards it was applied at the Albert dock in Liverpool. In both these instances the moving power was supplied from the town waterworks, but the variation of pressure in the pipes was found an objection. A comprehensive system of hydraulic machinery, combining the opening and closing of dock gates and sluices, with the cranage of goods, was next carried out at Grimsby new dock, where the pressure was obtained by means of a tower supporting a tank, into which water was pumped by a steam-engine. This arrangement obviated the objection arising from fluctuation of pressure, but in the natural process of improvement he was led to another method of obtaining the pressure, which had proved very efficacious, and had given a great impulse to the extension of such machinery. The apparatus used for this purpose was called an "Accumulator," and consisted of a heavily-weighted press, of large dimensions, into which water was forced by the steam-engine, and which gave out its power by the descent of the weight. The accumulator operated both as a reservoir of power and a regulator to the engine. Since the introduction of the accumulator, water-pressure machines had been applied to a great variety of purposes connected with dock and railway traffic, more particularly at the docks and railway stations in London. The details of the machinery were explained, and the general system was described as one which afforded the means of working a multiplicity of machines, intermittent in their action and extending over a large area, by means of transmitted power produced and accumulated at one central point by a steam-engine.

### PECULIAR INFLUENCE OF RAPID ROTATION.

The subject that excited most interest of any that was brought before the meeting of the Association, was M. Foucault's new mode of showing the rotation of the earth, by an instrument, called the "Gyroscope." This instrument was first exhibited and explained by M. Foucault, in French, to the Physical Section; it was afterwards shown at one of the soirées, when Dr. Tyndall explained its action in English; and it was subsequently exhibited to a select number of members in one of the committee-rooms, on which occasion Dr. Whewell acted as interpreter. The gyroscope is a ring of brass connected with a steel axis by a thinner plate of the same metal, all turned beautifully smooth, and most accurately centered and balanced; in other words, the axis is made to pass accurately through the centre of gravity, and to stand truly perpendicular to the plane of rotation of the entire mass. On this axis was a small but stout pinion which served, when the instrument was placed firmly on a small frame containing a train of wheels, turned by a handle, to give it an exceedingly rapid rotatory motion on its axis. To this frame it could be attached or detached instantly. The revolving mass was only about three inches wide, and four of the gyroscopes were mounted in frames a little differently. The first was mounted in a ring, attached to a hollow sheath, which only permitted the axle and the pinion to appear on the outside, so that it could be laid hold of, or grasped firmly in the hand, if the pinion were not touched, while the mass inside was rapidly revolving without disturbing that motion. By this modification of the gyroscope, M. Foucault afforded a sensible proof of the determination with which a revolving mass endeavours to maintain its own axis of permanent stable rotation; for upon setting it into rapid rotatory motion, and handing it round the room, each person that held it found himself forcibly resisted in any attempt to turn it round either in his fingers, to the right hand or left, or up and down, or in his hands if he swung it round. So that the idea was irresistibly suggested to the mind, that there was something living within which had a will of its own, and which always opposed attempts to change its position. The second modification presented the mass suspended in a stout ring, which was furnished with projecting axles, like the ring of the gymbal. These axles could be placed in a small frame of wood bushed with brass. This small frame, when placed on a piece of smooth board, could be turned freely round by turning the piece of board on which it rested, as long as the gyroscope was not revolving, friction being sufficient to cause the one to turn with the other; but, when the gyroscope was set rapidly revolving, the frame could not be turned by turning the board on which it rested, so determinately did it endeavour to maintain its own plane of rotation, as quite to overpower the friction. In the third modification of the gyroscope it was suspended in gymbals, so exquisitely constructed, that both the gyroscope proper and the supporting gymbals were accurately balanced so as to rest freely when placed in any position in relation to the earth. By this the author showed most strikingly the effect of any attempt to communicate revolving motion round any other axis to a mass already revolving, for, on placing the gymbals in a frame of wood while the gyroscope was not revolving, it remained quite steady; but, when thrown into rapid revolving motion, the slightest attempt to turn the frame round to the right or to the left was instantly followed by the entire gyroscope turning round in the gymbals, so as to bring its axis to coincide with the new axis endeavoured to be given it, with a life-like precision, and always so as to make its own direction of revolution be the same as that of the slightest turn imparted to it. Having thus demonstrated the necessary effect of combining one rotatory motion with another, M. Foucault then proceeded to demonstrate palpably that the earth's revolving motion affected the gyroscope in precisely a similar way. Having, by the screw adjustments, brought the gyroscope, in gymbals, to a very exact balance, it remained fixed in any position when not revolving. But, rapid rotatory motion having been communicated to the gyroscope mass, as soon as the gymbal supports were placed on the stand, the entire apparatus was seen, slowly at first, but at length more rapidly, to turn itself round, nor ever settle until the axis, on which the gyroscope was revolving, arranged itself parallel to the terrestrial axis, in such a sense as to make the direction of the revolving gyroscope be the same as that of the whole earth. He next showed that the determination with which it did this was sufficient to control the entire weight of the instrument, though that amounted to several pounds. He took the ring gyroscope from the side of the ring of which a small steel wire projected, ending in a hook, the wire coinciding with the prolongation of the axis of the gyroscope, and of course, when the ball was not made to revolve, the hook, if placed in a little agate cup at the top of a stand, would permit the instrument, by its weight, to fall instantly, as soon as the support of the hand was taken from it. But, upon imparting to it rapid rotatory motion, it stood up even beyond the horizontal position, so as to bring its axis of rotation nearly to the same inclination to the horizon as the axis of the earth, while the whole acquired a slow rotatory motion round the point of the hook; and so steady was its equilibrium while moving thus, that a string being passed under the hook and both ends brought together in the hand, the whole was lifted by the cord off the stand and carried revolving steadily about the room. Next, to show the motion of the earth sensibly, he placed the gymbal gyroscope suspended freely by a fine silk fibre in a stand with the lower steel point of its support resting in an agate cup; a long light pointer projecting from the ring carried a pointed card which passed over a graduated card arch of a circle placed concentrically with the gyroscope; upon imparting rapid rotatory motion to the gyroscope the index was seen as the earth moved to point out the relative motion of the plane of rotation exactly in the same way: the law of the motion being also the same as that of the well-known pendulum experiment. Lastly, he set the ring gyroscope in motion, and by placing a small pointed piece of brass at the end of the axle on the ring, the instrument went immediately through all the evolutions of a top on the floor, humming loudly.

### LIFE-BOATS.

Colonel Chesney read a long report on life-boats, which had been prepared by a committee appointed at the last meeting of the British Association at Hull, on which occasion there was a long discussion on the subject. A great part of the report was occupied with a statement of the number of life-boats on the coast, and of the loss of life and property by shipwrecks, which might have been in a great degree prevented if a sufficient number of well-constructed boats had been established. Since 1840 the five life-boat stations belonging to Liverpool had saved 1329 lives, and had, during the same period, saved 312 vessels. On the south coast of England, which is about 350 miles from the Land's End to the North Foreland, there are but about 15 life-boat stations. The eastern and western coasts, however, are better provided, there being 49 for the former between the Land's End and Berwick-upon-Tweed, a distance of 448 miles, and 33 boats for the latter, a distance of 700 miles; whilst the eastern coast of Scotland has but six life-boats, and the western only two. The Hebrides and Shetland Islands have not a single life-boat. There are five on the western coast of Ireland, but not one on its eastern shores; so that the Liverpool establishment for the preservation of life exceeds Scotland, and is nearly double those in Ireland. The paper then gave a numerous list of shipwrecks during the last four years. According to the casualties compiled from Lloyd's list, and laid before parliament, there had happened 1236 disasters, varying in magnitude from a total shipwreck to a slight shipwreck. Of these, 204 ships were never heard of again; 517 were driven ashore, and their cargoes totally or partially lost; 2665 cases of collision occurred, by which vessels were brought into port in a sinking state; 2295 were wrecked; 883 foundered; 679 were abandoned by their crews; 87 were burnt by accident, and 51 damaged by ice. The casualties to steam-boats during the same period of four years were—103 driven ashore, but afterwards floated again; 146 foundered; 15 burnt; 2 abandoned at sea; 1 capsized; 1 never heard of; and 7 returned to port in a sinking state. With the exception of 64 large vessels, between 700 and 1500 tons, this loss fell chiefly on the smaller vessels of 90 to 500 tons, and which were economically sailed and badly commanded. As an approximative loss, founded on the scale of four men and a boy to convey 100 tons, it would seem that the annual loss of life reported at Lloyd's averaged about 1250, the gross amount for the last four years being 4298. The tonnage, supposing the vessels to average 250 tons each, would give 100,000 tons of shipping lost, which, at 10*l.* per ton, would be 1,000,000*l.* sterling during the last four years. Colonel Chesney then invited the attention of the section to the tubular life-boat, invented by Mr. Richardson, of Aber Hirnant, Merioneth, which, he said, had already successfully encountered the sea in almost every form. The boat is formed of two tubes of tinned iron, 40 feet in length by 2½ in diameter, tapering at both ends and meeting each other. An iron frame-work, securely rivsted, unites the whole into one mass, the tubes having longitudinal bars of iron and hoops within, and iron keels running from end to end. They are divided into water-tight compartments, occupied by air-proof bags; a cork fender surrounds the whole of the fabric. The rowers and passengers are placed on a platform above the frame-work, which is surrounded by a light gunwale, the height of the rowlocks. A rope passes along under the kelson for the purpose of towing. Sliding keels are proposed to be added to render her more weatherly. She carries two lugsails, topsails, and jib; steers, rows, and sails well. Hitherto, it was stated, it had been found impossible to capsize this tubular life-boat.

### THE BOILERS OF THE ARCTIC.

Mr. Prosser read a paper on surcharged steam, in which he commented particularly on the construction of the boilers of the *Arctic*, which had just left Liverpool on its last voyage. The main object of the paper was to show that the great source of difficulty and danger in the use of steam is to be found in its high temperature rather than in its high-pressure, and that, consequently, all other things being equal, that medium which requires the highest temperature to produce a given pressure is the most difficult and dangerous. In the boilers of the *Arctic* the plan was adopted of giving additional heat to the steam after it was generated, and that plan Mr. Prosser contended is defective in principle and causes a greater consumption of fuel. To accomplish the heating of the steam a portion of it was passed through wrought-iron pipes, which were placed within the furnace of the boilers, and after being heated by coming into contact with it the steam was reunited with the other portion which had not been so heated, and then passed into the steam-chest and cylinder. The tubes of wrought iron, 5 inches in diameter externally, were placed horizontally fore and aft in each furnace, one on each side; the lower ones communicating with the upper ones by other tubes placed vertically of the same diameter, and united by malleable cast-iron elbows. The principle of using heated steam is no novelty, as it had been put in practice by Watt, and abandoned as useless. Numerous other persons had since revived the plan as new, and had endeavoured by fallacious experiments to prove its advantages; but Mr. Prosser contended there is loss, and no gain whatever, in heating the steam. He alluded particularly to the experiments and calculations which had led to the determination of introducing the "mixture" of steam and heated steam into the system of the *Arctic*. The experiments and calculations referred to are detailed in the 'Journal of the Franklin Institute' for the current year. They were compiled by Mr. Isherwood, from the notes of Mr. Martin. The experiments were intended to prove the advantages of "surcharged" over "normal steam," and of the "mixture" over both when applied to steam-engines, whether condensing or not. A very little reflection, however, would show that, if anything at all is proved, it is the exact contrary to the inferences drawn therefrom. High-pressure steam had been limited in its application by a sense of danger, but a far greater one is involved in its high temperature, and in these very experiments it is recorded that the felt covering of the steam-pipe was burned. The *Arctic* had been fitted up with sixteen double furnaces in four boilers. Each double furnace worked into one tube chamber, and had an aggregate recipient heating surface of about 1000 feet through which to transmit about 1000 degrees of heat to the water in the boiler, and thus convert it into steam. The steam heaters in each double furnace exposed about 50 feet to the direct action of the fire, and he had assumed the additional heating surface at 5 per cent. of the whole which the boilers previously had. The average pressure used was about 16 lb. above the atmosphere. The density of the steam would, therefore, be about 1-856th as compared with water, and this addition might increase the density, if applied in the ordinary way, by about 5 per cent., the corresponding increase of elasticity to which is 2 lb., or, in other words, we may calculate upon a gain of about 7 per cent. by a consumption of fuel equal to 5 per cent. only, or four tons per day, taking the ordinary present consumption at 80 tons per 24 hours. It is not, however, proposed to apply the heat thus, but to the heating of the steam. Now, as steam has but about ¼ the specific heat of water, it follows that the same amount of heat cannot be extracted by the steam, or by water, from the additional surface in the same space of time. Even in the impossible supposition of the density of the steam being the same as water, the rate of absorption can be but ¼, or equal to the specific heat of the steam, as compared with water, and requiring, therefore, the combustion of 1 ton instead of 4 tons of coal per day, that being all that the steam will take up. But the density of the steam, if taken only at 1·800 that of water, and half of the whole which is generated is made to pass through the steam heaters, it follows that the velocity must be 400 times greater than would be necessary in the case of water being substituted for the steam to be heated. Mr. Prosser said he had endeavoured to show, first, that these experiments are of no value whatever, because they meet no possible case; and, secondly, that the addition of 5 per cent. of recipient heating service to a boiler will be far more efficacious when applied in the ordinary way to the evaporation of the water and consequent increased tension of the steam, than to the heating thereof. The whole operation in either case is merely mechanical, although many have attached to it a mysterious action, a sort of mechanical catalysis, very difficult indeed to understand, and still more so to explain in any rational manner. The great advantage of using water as the medium consists in its great density as compared with its vapour; and this also, together with the enormous amount of latent heat in its vapour, is a great source of safety, as it avoids the danger attendant upon a sudden increase of heat, by absorbing it without the production of that fearful state of attenuation of the metal which the repeated overheating of it must inevitably produce, to say nothing of the diminished strength by a slight increase over the usual temperature employed in the steam heaters. Steam is instantly condensed by coming in contact with anything colder than itself, and hence arises enormous loss and waste, the avoidance of which appears to have led many to the belief that using heated steam is the proper remedy for this great defect. A remedy it certainly is, and one simple enough, but beset with difficulties and dangers which few are aware of, and far exceeding any other known method of using steam, however high-pressure it may be. In conclusion, Mr. Prosser suggested the use of high-pressure steam, worked expansively, and condensed without a vacuum, for ocean steamers. High-pressure steam, he said, is always dry when worked expansively under ordinary circumstances; and when, in addition to that, the working cylinder has a steam jacket, it is more than probable that far greater economy will be attained, without increase of danger, than by any system of "surcharged steam" it is possible to devise.

---

RAILWAY BREAKS.

Mr. Edward M'Dermott read a paper on an improved method of applying breaks to railway carriages. The invention comprises an apparatus for applying any of the existing breaks to each carriage of a train, and to the means of connecting or disconnecting the same. The source of power is the insertion, below the water line, in the boiler, of an iron tube (say of one inch diameter), and closed at the end most distant from the boiler. The tube becomes filled with water, and has exactly the same pressure on every inch (say 100 lb.) of its surface as the water in the boiler itself. By the insertion of a cock in the boiler the pressure of the steam might be cut off at pleasure. The iron tube, or pipe, is made to enter at one side of a cylinder and out at the other, making the cylinder a part of the tube. Into this cylinder (which may be of 4½ inches diameter and 8 inches stroke) is fitted a solid piston or plug. The tube enters below the piston into the cylinder. The pressure from the boiler is turned on at a force of say 100 lb. to every square inch in the cylinder; and the area of the latter being 15·904, less the piston rod, there would be an effective pressure of 1500 lb. to act upon the piston. As the latter is driven upwards by the pressure, the piston-rod is elevated also, and, being connected with the levers of the ordinary break, they are at once brought into contact with the periphery of each wheel, and kept there as long as the tube remains in communication with the boiler.

---

VARIATIONS OF THE COMPASS IN IRON SHIPS.

The subject of the variations of the compass caused by the mass of iron in iron ships excited great interest at the meeting, and gave rise to much animated discussion. The question was brought forward by the Rev. Dr. Scoresby in the Mechanical and in the Physical Section, and he explained the principles for which he has for some time contended. He observed that since the first promulgation of these views at the British Association in Oxford in 1847, he had to contend with either the denial or non-reception of them from the principal body of scientific men engaged in the consideration of compass adjustment and compass action in iron ships; but they were now admitted to be correct by those who had the best practical means of forming a judgment on the matter. These principles might be thus enumerated:— 1. That the magnetism of iron ships in its action on the compass, may be represented by a vertical and a horizontal iron or magnetic bar swinging round a compass. 2. That changes in the magnetic distribution and compass action in iron ships do take place. 3. That the changes take place in a ship's magnetism by change of magnetic latitude. 4. That there are influences in a ship, derived from the varieties of form and position (relatively to the compass) of particular masses of iron, which may act as natural correctives. 5. That the plan of correcting the deviation on iron ships by fixed magnets (unless in certain places or limited voyages) is unsafe, and in going to southern regions aggravates the error. 6. That the twisting of the iron materials will tend, especially in ships recently launched, to alter the magnetic action on the compass. 7. That it requires time to effect the changes in a ship's magnetic distribution, which ultimately may, in regions very distant from the place of building, be effected. The whole of the results plainly go, he believed, to the establishment of a proposition, of the accuracy of which he has long endeavoured to convince those interested in the navigation of iron ships, that the magnetism of such ships is, in all its qualities, changeable; the most enduring, or apparently fixed, being of a description changeable under severe straining and mechanical violence, which he has denominated retentive magnetism. No large changes may be expected under the following circumstances: 1. In iron ships long in use, and ordinarily pursuing the same voyage, because extreme distribution gets shaken down, as it were, in a medium or average state. 2. Great changes do not take place in the retentive magnetism (by far the greatest portion) in latitudes not farther south than the Mediterranean, because, 3, in ships trading in the channels, or east and west to America, the liability to new or unexpected changes greatly diminishes. In such cases, an intelligent captain, observing the changes, alteration, and allowances, may generally run with great confidence.

Dr. Scoresby concluded by making several suggestions for correcting the errors caused by the deviations of the compass. He recommended that a standard azimuth compass be placed on a high pedestal, where (on the Admiralty plan) a position of small deviation may be found. A compass at mast-head he believed best of all for reference, by which the great body of error will be demonstrated. The wheel-compass required for ships engaged in the home trade, or traversing mainly parallels of latitude not southward of the Mediterranean, if adjusted with magnets and pieces of iron, might not be then unsafe, where reference may always be had to the standard for verification. Care should also be taken in the selection of compasses, so as to have ample directive force. His improvements had trebled the directive force, weight for weight, of the compasses used in the navy up to 1839 or 1840.

Mr. Fairbairn said he had strong reasons for being the advocate of iron ships, and he thought they were the strongest and the best; but there was no doubt that they influenced the compass, and it was most desirable that means should be found of correcting the deviations with accuracy and certainty. He had had some experience of this effect himself, in one of the first trips made in an iron ship, having, in 1830, sailed in a small boat from Liverpool, her plates being only about the thickness of a shilling. They started in a fog from the Floating Lightship for Douglas, in the Isle of Man; but instead of finding the Isle of Man, they found themselves on the coast of Cumberland, owing to the change in the compass by the boat's attraction.

Mr. Grantham denied that there is any more danger of compass deviation in iron ships than in wooden ones; and he contended that the wrecks of the *Tayleur* and the *Birkenhead*, which had been attributed to variations of the compass, were produced by other causes, to which all ships are liable.

Mr. Towson contended that there is a variation of the compass in iron ships. He was convinced, however, that iron ships must progress, and that the existence of their mercantile marine must rest upon that progress; but they could only place them upon a proper basis by guarding against dangers, and instead of iron ships being brought into disrepute by these means, it would only place them upon that foundation which would cause them to progress in Great Britain.

Several other gentlemen spoke on the subject, and it was stated that the Admiralty had paid great attention to the subject, and the mode of adjustment they had adopted and the compasses they used were well calculated to overcome the difficulty.

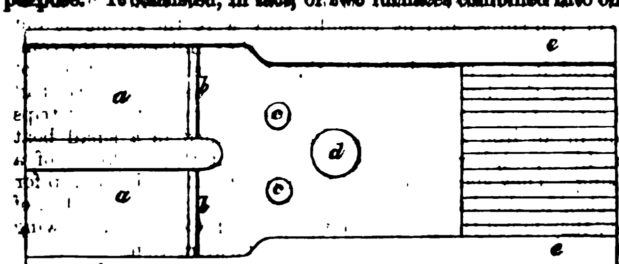
The reading of Dr. Scoresby's papers created a great sensation on the Liverpool Exchange, and he was afterwards requested to deliver a lecture on the subject in the Cotton Sale-Rooms. The rates of insurance on iron ships were raised in consequence.

### A MONSTER FLY-WHEEL.

Mr. Clay described the large fly-wheel at the Mersey Forge, which was stated to be the largest in the world. In rolling boiler plates there is a certain limit to the speed at which the roller should travel—in other words, the number of revolutions made by the roller are very few when compared with the rollers of other descriptions of iron; and it was therefore necessary in a mill where direct action was required, that a fly-wheel should be constructed of sufficient size and weight to have, with a small number of revolutions, sufficient momentum to overcome the ordinary shocks of rolling large plates of iron. This could only be done by increasing the diameter of the wheel to such an extent that the rim should have the requisite momentum. With this view a wheel has been made of 35 feet diameter, and weighing about 60 tons, about 24 tons of which is disposed in the rim, which is intended to run with a velocity of about 4500 feet per minute, in making about 38 revolutions. Great care was necessary, in a wheel of such magnitude, that the various parts should be well and securely fastened together, and after finishing the drawing of the wheel it was submitted to the authority of Mr. Fairbairn, who pronounced it as perfectly safe at a velocity of 14,000 feet per minute—number of revolutions, 120.

### THE PREVENTION OF SMOKE.

Mr. Fairbairn read a paper on the consumption of fuel and the prevention of smoke, in reference more particularly to the construction of boiler-furnaces. He said that the prevention of smoke was practicable in several ways, and it might be effected by using proper care in the furnaces at present employed without any special provision being made to accomplish that object. He referred to the Cornish engines as examples of the perfect consumption of fuel in ordinary furnaces, which is effected by the care used in feeding them, so as not to waste any fuel. If sufficient inducements existed, as in Cornwall, where the engineers are stimulated by rewards to make each pound of coal do its utmost duty, there would be no necessity for any further contrivances to be adopted; but in the absence of such stimulus, it is desirable to construct the furnaces in such a manner as to consume their smoke with ordinary management. The great secret, he said, is to have sufficient capacity in the boiler; and if boilers were made of double their usual capacity, the consumption of smoke might be readily effected. Mr. Fairbairn described a boiler-furnace which he considered to be well-adapted for the purpose. It consisted, in fact, of two furnaces combined into one.



The accompanying sketch is a plan of the furnace as shown by Mr. Fairbairn. The two fireplaces are represented by the letters *a*, *a*; *b*, *b*, are the bridges of the furnaces; *c*, *c*, are large tubes, which conduct the products of combustion into a mixing-chamber *d*, where the gases are mixed, and they then pass through the tubes *e*, *e*, perfectly transparent. The furnace-bars should be kept clean for the admission of air, and fresh air should also be admitted at the bridges to burn the inflammable gases when in a heated state, on the principle of Mr. Williams's furnace.

Dr. Arnott explained the principle on which the combustion of fuel is effected in his stoves. They are founded on the plan invented by Dr. Franklin, of inverting a fire-grate after the coals had been lighted, and thus having the coals at the bottom and the fire at the top. The smoke of bituminous coal may be regarded as evaporated pitch, and by submitting it to the action of heat in ascending through the hot coals at the top, it is completely consumed, and converted into carbonic acid gas and water. It is estimated, that in a common fire with a large open fireplace, five-sixths of the heat passes up the chimney. By contracting the throat of the chimney, the draught becomes so strong as to permit of making an opening into the chimney from the upper part of a room without the risk of its smoking, and by this arrangement a more perfect ventilation is obtained than by any other means.

Mr. Dircks explained Mr. Williams's method of consuming smoke by the admission of jets of fresh air at the bridge of the furnace. In the discussion that ensued, Mr. Jukes's plan of moveable bars was spoken of as the most effective for the purpose of consuming fuel, though difficult to be introduced in furnaces already erected.

### THE SUPPORTING POWER OF PILES.

Professor Stevelly made a communication on the limit of weight which may safely be laid on a pile driven into the ground. He said that the force which resists the penetration of a pile may, under very peculiar circumstances, diminish as the pile is driven downwards; but for the most part it increases, and generally towards the last strokes it receives from the ram the increase is very considerable. He pointed out the following simple test: viz., after the pile had been driven as deep as intended, letting the ram descend on it from a less height than the previous stroke, and carefully comparing the two distances it has been thus driven. If the resistance increase, then the actual load the pile can bear will not be less than what it would be if the resistance were strictly uniform which the pile experienced as it penetrated. This last force admits of a very simple calculation; from which, therefore, a most certain limit to the load or dead weight that can be laid on the pile without its sinking farther may be obtained. He then pointed out the two dynamic principles on which the calculation was founded:—1. When a moving mass W, strikes another W′ at rest, with the velocity $v$, then the velocity, after impact, $v' = v \dfrac{W}{W + W'}$. 2. When a body moving with the velocity $v'$, is stopped by a uniformly acting resistance, that resistance can be compared with the weight that gives the velocity (say to the ram), by the principle that the force or resistance is proportional to the square of the velocity gained or destroyed, divided by the space through which the force acts to give or take it away. The following practical rule is, then, a simple algebraic deduction from these two principles. Let W denote the weight of the ram in tons; W′ the weight of the pile in tons and decimals; $h$ the height in feet and decimals from which the ram is let fall on the final stroke; $d$ the depth in decimals of a foot which the last stroke causes the pile to penetrate. L, the limit of load (in tons) that may with safety be laid on the pile, will then be:

$$L = W \cdot \left(\frac{W}{W + W'}\right) \cdot \left(\frac{h}{d}\right);$$

in which W, W′, $h$ and $d$, can all be had by actual weighing and measurement.

### RAILWAY SIGNALS FROM CHINA.

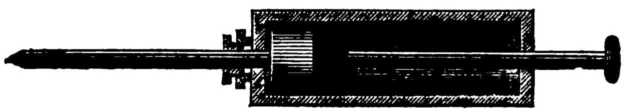
Captain J. Norton described some methods of establishing communication between the guard of a railway train and the engine-driver, one of which he exhibited that had been brought from China, and used there as a signal for different purposes. It consisted of a metal whistle fixed to a short stick, which when thrown through the air made a shrill sound. The faster it is propelled, the louder the noise; and Captain Norton said the most effective way of using it for a railway signal is to push the stick into the barrel of a pistol charged with gunpowder, and to fire it over the engine-driver's head. In this manner he had on several occasions tried its efficacy, for when the train was going at full speed he had sent the missile whistling through the air, and obtained an immediate response from the steam whistle, indicating that the engine-driver had heard it.

### STRENGTHENING CAST-IRON BY MELTING.

Mr. Oldham communicated the results of some experiments on the transverse strain on cast-iron, in confirmation of Mr. Fairbairn's experiments on the additional strength gained by re-heating, as reported at the last meeting of the Association. In these experiments, which were made on bars 2 feet long, the maximum degree of strength was attained at the nineteenth melting.

### BORING ROCKS HORIZONTALLY FOR BLASTING.

Mr. J. Nasmyth described a method of boring holes in rocks for tunnelling purposes. In the ordinary method of boring holes for blasting, by striking at the end of the bar with heavy hammers a great portion of the effect is lost by what is commonly termed the "inertia" of the bar. To overcome this defect, Mr. Nasmyth proposes to convert the bar into a piston-rod, to work in an air-tight cylinder through a stuffing-box. By this means, when the piston is drawn to the end of the cylinder, the pressure of the atmosphere will force it back again with accumulating velocity, and the blow struck will have much greater effect. Mechanical contrivances might be introduced for changing the shape and the directions of the penetrating point. The bar could be drawn to the end of the cylinder by any convenient application of mechanical power.



The annexed woodcut represents the form of the boring-apparatus, as sketched by Mr. Nasmyth.

It was suggested in the discussion that ensued, that a similar effect might be more readily produced by the employment of vulcanised india-rubber springs. Mr. Nasmyth observed, that any elastic medium would answer the purpose, but air suggested itself as affording greater extent of spring.

## FONDES' ROTARY DREDGER.*

This machine consists of a hull of suitable size to carry the machinery. In the middle of the boat athwartships, and near the bow running fore and aft, there is a well-hole about 3 feet wide and 26 feet long. In this hole works a wheel carrying upon its periphery the buckets or scoops, made in the usual manner with a hinged bottom secured with a latch. The wheel has two hubs and two sets of arms, stiffened with diagonal braces to prevent lateral motion; upon each side of the wheel is a segment spur-wheel into which is geared the pinions driven by the engines.

The journals of the scoop-wheel-shaft work in boxes that can be raised or lowered, by a chain and windlass, to suit the depth of the bottom to be operated upon. In a frame at the bow of the boat there are two hinged schutes, one of which, when the machine is in operation, is kept at one inclination; the other, situated above and leading into the first, to which it is hinged, is raised by each bucket as it passes upward; as the wheel revolves, the bucket passes beyond the reach of the schute where the end next the wheel falls beneath the bucket, striking a trigger that open its bottom, leaving the contents free to fall into the schutes, and be conveyed by them into the transporting scows alongside.

The machine, for some kinds of work, must supersede all others where a long stretch can be had, such as a bar of a river, the bottom of a canal, &c., the performance must be admirable. No time is lost, except that spent in replacing the loaded scows with empty ones, and that, by practice, may be reduced to almost nothing. As the material is cut away, the boat is drawn forward by a rope anchored ahead, and passing round a barrel on the wheel shaft; the rate of progress for each kind of cutting being regulated by the proper sized windlass barrel-wheel, can be quickly taken off and replaced by another.

It is said that a machine of the third class, having a wheel 24 feet in diameter with four buckets, has dug 1200 cubic yards of gravel bottom in a day.

## COMPUTED TABLE OF DRAUGHT OF FLUES.*

By Prof. John C. Cresson, C.E.

Having occasion, recently, to prepare a tabulated statement of the effective power of vertical flues under the influence of various conditions of temperature, I have thought it might be made useful to others by publication in the *Journal*, and therefore offer it as a small contribution to the much-neglected arts of warming and ventilation.

The numbers at the head of each column represent the temperature, in degrees of Fahr., of the air within the flue; and those in the first column on the left, that of the air outside. The calculations are made according to the following commonly received formulæ for the expansion, equilibrium, and flow of æriform bodies.

1. Gay Lussac's law showing their increase of volume to be $\frac{375}{1000}$ or $\frac{3}{8}$ in passing from freezing to boiling points of water with equal increments of volume for equal additions of thermometric heat.

2. Fluid columns are in equilibrium when their heights are inversely as their densities, or, in case of homogeneous gases, directly as their relative expansion by heat; and this difference of height, or when heights are equal, their reciprocal densities constitute the effective head creating the draught of flues.

3. By Torricelli's formula, the velocity of flow under the ascertained head is $V = \sqrt{2\,g\,H}$, and the coefficient of actual discharge is assumed as that for a thin plate, which well represents an ordinary damper or flue register, $Q = 0{\cdot}625\ A\,V$, or $\frac{5}{8}$ths the theoretical discharge.

The numbers in the body of the table show the quantity of air in cubic feet per minute that will be drawn through a register, or other similar opening 1 foot square, by a vertical flue of 100 feet effective height at the given temperatures. To adapt these numbers to flues of different heights, multiply them by one-tenth the square root of the effective height in feet.

It is to be understood that the area of cross-section of the flue is not less than that of all the openings for which the flow is computed; otherwise the computations must be based on its area instead of theirs.

| Fahr. | 60° | 80° | 100° | 120° | 150° | 200° | 250° | 300° | 450° |
|---|---|---|---|---|---|---|---|---|---|
| 0° | 1020 | 1167 | 1281 | 1380 | 1500 | 1665 | 1796 | 1896 | 2124 |
| 10 | 940 | 1092 | 1215 | 1320 | 1450 | 1622 | 1760 | 1866 | 2100 |
| 20 | 840 | 1010 | 1145 | 1256 | 1395 | 1580 | 1725 | 1833 | 2075 |
| 32 | 705 | 904 | 1046 | 1181 | 1342 | 1580 | 1675 | 1795 | 2045 |
| 40 | 594 | 826 | 995 | 1125 | 1285 | 1490 | 1645 | 1765 | 2027 |
| 50 | 426 | 723 | 904 | 1054 | 1225 | 1441 | 1606 | 1758 | 2002 |
| 60 | 0 | 581 | 810 | 975 | 1163 | 1394 | 1566 | 1697 | 1980 |
| 70 | — | 415 | 699 | 892 | 1095 | 1342 | 1525 | 1661 | 1950 |
| 80 | — | 0 | 575 | 798 | 1025 | 1291 | 1480 | 1625 | 1925 |
| 90 | — | — | 416 | 688 | 950 | 1238 | 1436 | 1590 | 1900 |
| 100 | — | — | 0 | 562 | 866 | 1178 | 1391 | 1559 | 1874 |

The small table appended below gives the proper factors to be applied as above, for flues less than 100 feet high:—

| Height of Flue. | Factor. | Height of Flue. | Factor. |
|---|---|---|---|
| 10 feet | 0·316 | 60 feet | 0·774 |
| 20 " | 0·447 | 70 " | 0·836 |
| 30 " | 0·547 | 80 " | 0·894 |
| 40 " | 0·632 | 90 " | 0·948 |
| 50 " | 0·7 | | |

## TRINITY NATIONAL SCHOOLS, COVENTRY.

James Murray, Esq., *Architect.*

These Schools have just been completed in one of the improving districts of Coventry, to meet the want which has long been felt in connection with the mother Church. The architect is Mr. Murray, who has produced a picturesque building, and well suited to its purpose. It consists, as will be seen, of two floors, providing large boys', girls', and infants' school-rooms, with convenient class and cloak rooms. The walling is of the red sandstone of the locality, brought to a tooled surface, and irregularly jointed. The roofs are of high pitch, and are open as much as possible in the rooms. The design has been carried out by Mr. Thomas Pratt, of Coventry, at a cost of about 3000*l.* Convenient teachers' residences are immediately adjoining.

## ON THE INLAND NAVIGATION OF IRELAND.*

By H. Hennessy, M.R.I.A.

Public attention has been so much directed of late years to railways as furnishing the most important channels of internal communication, that the more simple means afforded by the physical structure of our country seem to have been forgotten. Railways are undoubtedly superior in many respects to any other system of inland conveyance; but, generally speaking, they can never be considered as forming so cheap a mode of transport as water carriage. This proposition is especially true with reference to Ireland, where most of the products of the country are such as to require economy rather than extraordinary speed in their conveyance, and where certain physical causes seem to present great facilities for lines of water communication.

But if, while the most recent and ingenious contrivances of engineering or mechanical skill are eagerly sought for and systematically applied to the improvement of railways, the state of inland navigation should receive but little comparative attention, the former, even under the peculiar circumstances of this country, would naturally tend to supersede the latter. On the continent, and especially in France, the effect of railways seems to have been to direct attention in a very decided manner to the improvement of the existing water carriage. The results of science and experience have been brought to bear with fresh vigour on the twofold problem of improving the condition of the water ways and the structure of the vessels they convey. In these notes it is my object to briefly examine the natural advantages which Ireland possesses for an extended system of inland navigation, how these advantages have been hitherto availed of, and how they can be more effectually utilised by the aid of recent improvements.

A glance at a good physical map of Ireland shows it to be almost surrounded at its coasts by ranges of high hills or mountains, while a flat district of considerable extent occupies the centre. The principal groups of mountains thus situated are six in number: 1, that on the north-west, occupying the counties of Donegal and Derry; 2, that of the west, stretching through Connemara in Galway and Mayo; 3, that of the south-west, in Kerry and Cork; 4, that of the south, in Waterford; 5, that of the east, in Wicklow and Wexford; 6, that of the north-east, in Down. In the central district there is only one group at all comparable in height and extent with any of these; it lies close to the Shannon, in King's County and Tipperary. The great number of lakes with which the central district of Ireland is covered, and the considerable length of some of her rivers, seem to be natural results of this peculiar configuration. These lakes and rivers are capable of being arranged in several principal lines, some independent and others branching from them. Thus we have:—

1. The line of the Shannon, from Lough Allen to its mouth.
2. The line of the Connaught lakes, running from north to south, comprehending Loughs Con, Cullin, Carra, Mask, and Corrib, between the bays of Killala and Galway.
3. The line from Coleraine, through the Lower Bann, Lough Neagh, the Blackwater, and the lakes of Cavan and Fermanagh, towards the Shannon.
4. An offset from this line, through Lough Erne, towards Ballyshannon.
5. The Foyle and its tidal estuary.
6. The district of the Upper Bann, between Lough Neagh and Newry.
7. The important lines depending on the Shannon, namely, the Boyle water and Lough Key, the rivers Suck and Inny.
8. The Boyne in its course through Meath.
9. The Barrow through Carlow and Wexford.
10. The Suir in its course through Tipperary and Waterford.
11. The Blackwater from Mallow to Youghal.

The Shannon, with the lines of water-way immediately dependent on it, forms by far the most important of these groups. This river may be said, for the purposes we have here in view, to rise from Lough Allen, a navigable basin, 8 miles long from north to south, and on the average 3 miles broad from east to west. This lake is 160 feet above the level of the sea, and possesses a mean depth of 12 feet. It is situated in a district known for its mineral riches, as yet almost unavailable, partly from want of cheap means of transport.

* From the 'Dublin Monthly Journal of Industrial Progress.'

The following is a brief summary of the present condition of the Shannon from Lough Allen to Limerick. A canal extends from the north end of Lough Allen, at Drumshanbo, to Battle Bridge, with two locks, each of 10 feet fall. Thence to Carrick-on-Shannon, a distance of 17 miles from the northern extremity of Lough Allen, the river shoals in some places. At Knockvicar is a lock and weir in connection with the Boyle Water. At Jamestown, Roosky, and Termonbarry, there are three locks, each 120 feet long by 30 feet wide within the chambers, which effectually obviate the influence of the rapids in this portion of the river. In connection with the lock at Jamestown is a side canal, which allows of vessels of 30 feet beam. Below Lanesborough the river expands so as to form Lough Ree, 18 miles long and 3 miles in average breadth. At the south end of this Lough, close to Athlone, a lock has been recently constructed with 7 feet fall, 170 feet long between its upper and lower sills, and 40 feet in breadth within the chamber. From this point to Portumna the river is broad, deep, and sluggish, requiring only one lock at Meelick, 22 miles above Killaloe. This lock has fall of 8 feet, and its other dimensions are the same as those of the Athlone lock. From Portumna to Killaloe the river again expands so as to form Lough Derg, an inland sea, 23 miles long and from 2 to 9 miles broad. Not only has the river channel been made deeper, and its declivity been graduated by locks, but its more easily navigable channels are indicated all along by a series of beacons placed at intervals, depending on the proximity of rocks or shoals. Wharves and landing-places have been recently constructed, and all the bridges on the upper division of the river beyond Killaloe are so arranged with swivels as to allow of the passage of large steamers and other vessels without any displacement of their masts or funnels. In this way 85 miles of navigation above Killaloe are open to steam vessels of 200 horse-power and 150 feet long, while a smaller class of vessels can traverse nearly all the remaining portion of the river up to the northern extremity of Lough Allen, thus opening up nearly 160 miles of direct steam navigation. From Killaloe to Limerick the river has a fall of 97 feet in 15 miles, and is interrupted by rapids and cascades, chiefly at Doonass and Castle Connell. A very imperfect continuation of the navigation is formed by a canal, on which there are 10 locks, of such dimensions as would admit only barges of the size generally used on canals. The advantages thus presented for steam navigation on the Middle and Upper Shannon have been availed of by the City of Dublin Steam Company and by the proprietors of the Grand Canal. Steamers of large size, for the conveyance of goods and passengers have been established by the former company, and run between Athlone and Killaloe; while the latter have introduced steam power chiefly for towing their barges on the river. In this way 5 or 6 tug steamers are continually employed. One of these boats has 50 horses' power, 15 feet beam, and draws 6 feet of water, being thus well qualified to contend against rough weather on the lakes. I have been informed that the company find small boats with powerful engines the most economical for the towing work, and accordingly most of their boats are little more than floating engine houses.

An estuary navigation of 44 miles extends on the Lower Shannon from Limerick to Kilrush; and steamers with a considerable draught of water are admissable. It has been navigated for several years by boats equally adapted for sea or river traffic, belonging to the City of Dublin Steam Packet Company.

The group of Connaught lakes already mentioned might perhaps with some difficulty be converted into a complete line of navigation, extending from Galway to the bay of Killala; but there seems no doubt as to the practicability of forming two distinct lines, one connected with the former, the other with the latter of these arms of the sea. It has been estimated that the southern group, consisting of Loughs Mask, Corrib, and Carra, would require only 3 miles of canal to bring them into communication with the sea and with each other, thus opening a line of navigation at least 40 miles in length. Some progress has been made in the works for connecting Lough Corrib with Galway, but this line of navigation must still be considered as comparatively unopened.

The northern group of Connaught lakes, when properly connected by artificial works, would give a navigable line of 11 miles.

The third line of inland navigation, which has been indicated as extending from Coleraine along the Lower Bann, through Lough Neagh, the river Blackwater, and the lake district of south-western Ulster, towards the Shannon, forms with that river a great system of internal water communication, running nearly in the direction of the longest diameter of the island, from north-east to south-west. It acquires additional importance from its situation in the midst of a populous and industrious division of the country, and it is therefore satisfactory to find that much information can be supplied regarding portions of it from the valuable report drawn up by Mr. MacMahon on the drainage of the Lough Neagh district. The Lower Bann is intersected by trap dykes at certain points, by which steep rapids are produced. The first is at 7 miles from the sea, and the difference of level in the stream above and below it is from 4 to 4½ feet. From this point the water has a depth for some distance averaging 12 feet, the least depth being 9 feet, but it shoals farther on to 3 feet. From Loughan's Island to Gill's Ferry the water varies from 6 to 14 feet in depth. A few miles above this place there are two shoals, having an average depth of 4 ft. 6 in. Nine miles beyond the first rapid is another combined with a shoal having a depth of from 2½ to 3 feet, and an ascent of 8¼ feet. After these shoals come a series of rapids, with 10½ feet ascent in summer, and a depth of stream between 2 and 3 feet. Beyond these rapids the river takes a serpentine course, and is of great depth, to the foot of the Portna rapids, which are the most considerable on its course. These extend for at least a mile; but what are called the falls of Portna do not occupy more than half-a-mile of the bed of the river. During low summer water the total ascent is 18 feet. The acclivity is divided into numerous irregular tables or steps, characteristic of the trap dykes. The stream runs with great force and velocity, and the deepest of the tortuous channels in which it flows are so intricate as to make it dangerous and difficult to guide even a fishing boat through their manifold windings. From Portna, for a distance of 5 miles, to a place called Portglenone, the river has a depth averaging 20 feet, the least depth being fully 16 feet. Above this place shoals occasionally alternate with deep water. The former are usually covered with water to the depth of from to 4½ feet, and in the deep places the depth ranges from 17 to 45 feet. This occurs in one instance for the distance of 8½ miles, but the average depth seems to be from 10 to 20 feet. At the point where the river commences from Lough Beg a sand bank acts as a bar to the down stream entrance of the Lough. This Lough extends 3½ miles in the direction of the sailing course, and is about 1 mile broad. At its entrance is a new cut from 12 to 17 feet deep, and from 120 to 130 broad. There are four bridges on the Bann between Lough Beg and the sea, and another bridge between Lough Neagh and Lough Beg. At the entrance of Lough Neagh is a sand-bank, forming a bar which extends about a mile into the lake. It is 1700 feet wide at the entrance, and in summer is covered to a depth of only 18 inches, except in a narrow channel at the eastern side. The greatest accumulation of sand and gravel is principally on the western side of the Lough, from the debris brought down by the river Moyola.

Lough Neagh, the largest lake in Great Britain or Ireland, extends 17 miles in greatest length from north to south, and 10 miles in average breadth from east to west. Its dimensions as regards direct navigation are thus scarcely of greater importance than those of some of the Shannon lakes. It presents, together with Lough Beg, a surface of 101,379 acres; exclusive of Lough Beg, its surface is 98,235 acres. It is 44 feet above the level of the sea, and in some parts is 100 feet in depth. It presents more than 100 miles of coast belonging to the counties of Antrim, Down, Armagh, and Derry, and it receives from the rivers Blackwater, Upper Bann, Ballinderry, and Moyola, the drainage waters of 1835 square miles of country. The Lough has been already navigated by steam vessels, which have been enabled to touch at different points around its extensive coast.

The river Blackwater is easily navigable between Lough Neagh and Charlemont, for it rises only 2 inches, and its channel is both wide and deep. Maghery Cut, at the opening where there is a bar, allows the passage of large boats in summer. The Ulster Canal, with a course of 48 miles, connects this river with upper Lough Erne, and Lough Oughter. The aggregate coast lines of this lake and both of the Erne lakes amount to 303 miles. They contain many islands, but present no insuperable difficulties to the transit of moderately large steam vessels. Between Lough Oughter and the Shannon is a group of small lakes, which it is proposed to connect, so as to complete the line of inland navigation, extending from the coasts of Clare and Kerry to those of Derry and Antrim.

The lower Lough Erne, being 150 feet above the level of the sea at Ballyshannon, seems to be almost cut off from any practically direct communication with the sea; but there can be no doubt that great advantages would arise to the surrounding districts by its forming a branch of communication from the nearest accessible point on the coast and the great line which has been just described.

The Foyle is navigable for a few miles of its course, and in connection with the tidal Lough into which it flows may yet form an important line of water communication for portions of Derry, Donegal, and Tyrone.

Between Lough Neagh and the Irish Channel at Newry, a line of water communication exists in the district of the Upper Bann. This river is an expansion or arm of Lough Neagh, for a distance of nearly 12 miles, from the Bannwater foot to the White Coast point, where it meets the Newry Canal. It contains a few easily removeable shoals, on which there is a depth of from 2 to 4 feet in summer, and is otherwise well adapted for the application of steam vessels. The canal to Newry is 19 miles long, thus making a line of more than 30 miles of navigation between the tidal estuary of that port and Lough Neagh.

The Boyle Water is a kind of expansion or arm of the Shannon running to the north-west, and is sufficiently deep for steam navigation. It brings a large portion of Sligo and Roscommon into direct communication with the great central line of water-carriage.

The Suck, which flows through Roscommon, and enters the Shannon at Shannon Harbour, and the Inny, which rises among the lakes Cavan and Westmeath, and falls into Lough Ree, are both eminently capable of being used for internal communication. They are free from rapids, sluggish, and comparatively deep. A report on the former of these rivers has been drawn up by Mr. Rhodes, in which it has been clearly shown that its improvement for the purposes of navigation could be effected at a moderate expense.

The Boyne, flowing for the most part through the flat and fertile county of Meath, seems to posses valuable conditions for a channel of internal traffic. In its sluggish course there seems to be few or scarcely any rapids, and its shoals are, no doubt, easily removeable. About twenty-two miles have been already rendered navigable, including the tidal estuary below the port of Drogheda, and there appears to be no serious physical cause to prevent more of it from being used as a channel for commercial intercourse.

The Barrow, running nearly in the direction of the meridian, offers an important line of water-carriage for the counties of Kildare, Carlow, and Wexford. The locks which are used to overcome the declivities of this river are 60 feet long by 13 feet wide in their chambers, and are thus capable of admitting barges, or even small screw steamers, carrying a considerable cargo. Its tidal estuary is extensive, reaching from Waterford up to St. Mullins, and the portion between the former place and New Ross has been navigated by steamers. Combined with the navigable part of the Nore, it brings a part of the county of Kilkenny in contact with the sea, and its connection with the Athy branch of the Grand Canal opens a complete water communication between Waterford and Dublin.

Some of the most fertile portions of Tipperary are traversed by the winding course of the Suir, and the most thriving towns of that county are situated on its banks. It does not seem to present any insuperable difficulties to the introduction of suitably constructed steamers on a portion of its course, although as yet it has been availed of for ordinary canal barges only between Clonmel and Waterford.

The most considerable river in Munster is the Blackwater, draining a basin of more than 1200 square miles, partly in the counties of Kerry, Limerick, Cork, and Waterford. The greatest annual fall of rain being in this part of Ireland, the Blackwater delivers a considerable volume of water into the sea at Youghal, and the rapidity of the portions of its course, rather than an insufficient supply of water, would seem to be the principal obstacle to its forming a complete line of inland navigation from Mallow, or even Newmarket to the sea. The question of its improvement acquires additional importance since it has been crossed at Mallow, by the Great Southern and Western Railway, and it is to be hoped that the enterprising attempts made some years ago to establish steam navigation on a portion of it will be again revived with fresh vigour.

Although the navigation of the tidal estuary of the Lee can scarcely be considered as coming within the scope of this essay, it deserves to be noticed, as its excellent management may well serve as a model. There are at present seven steamers employed for passenger traffic, on the estuary between Cork and the sea, all capable of traversing their course at any time of tide, of which four belong to the Cork and Passage Railway Company, and three to the River Steamers Company. The boats in use present very favourable specimens of the types of steam-boat building of the Thames and Clyde, respectively, but there is good reason to hope that for the future such vessels can be equally well obtained on the banks of the Lee itself. By means of these boats an extensive daily traffic is carried on between Cork and five points on the shores of its harbour and tidal estuary, and it is intended to bring two more in a short time within the circle of their operations. The great success of these boats is, undoubtedly, attributable to their very moderate fares, as well as to their speed and excellent accommodation for passengers.

The foregoing sketch of the natural advantages possessed by Ireland for inland navigation, and the extent to which its rivers and lakes are now available for that purpose, naturally leads us to inquire when, and in what manner, attempts to form systems of water-carriage were made in this country? To give a satisfactory answer to such an inquiry, it will be necessary to glance at the history not only of river improvements, but of artificial canals; a task which is much facilitated by a paper drawn up by Mr. Nimmo, and subsequently published by Mr. Wye Williams. The remarkable preponderance of the number of projects planned over those actually executed, forms a curious comment on the political and social condition of this country.

In the first parliament of Anne, in 1703 a committee was appointed to draw up a bill for rendering the Shannon navigable from Jamestown, in the County Leitrim, to its tidal estuary at Limerick; also for opening a line of water communication between Newry and Lough Neagh, and for improving the Boyne and Barrow.

In 1709 a bill was brought in for the navigation of the Shannon, and for the Newry Canal. A petition was presented in the same year for making the Suir navigable between Thurles and Clonmel, and also to effect certain improvements on the Barrow.

In 1715, some enterprising projectors having undertaken to make the Shannon navigable, a general act was passed for the consolidation of all similar untertakings. This remarkable act is entitled, "For the draining and improving the Bogs and unprofitable Low Grounds, and for easing and despatching the inland carriage and conveyance of goods from one part to another within the kingdom."

The members of Parliament with others were declared commissioners, with powers under this act to appoint competent persons to execute the works, and the following groups of improvements in river navigation, or of entirely artificial canals, were successively contemplated and partly commenced.

1. A line from Dublin by the rivers Liffey, Rye, Boyne, Mungagh, and Brusna, to Banagher on the Shannon. The district which this line was to traverse has since been occupied by the two great canals which run through the central portions of Ireland in such singular proximity to each other. In fact, the Grand Canal may be considered as forming almost the realisation of this project; for it runs very close to some of the above-mentioned rivers and joins the Shannon not far from Banagher.

2. The Barrow navigation, and a junction canal from thence to the Grand Canal at Munroe in the Bog of Allen. To this reference has been already made.

3. Improvements of the rivers Glyn and Bann, from Newry to Coleraine. The portion between Lough Neagh and Newry has been finished.

4. The Nore and Brusna navigation, from the junction of the former with the Barrow to the Grand Canal near the Shannon. Several docks and other works have been made in connection with the Nore, but this line seems to have been soon abandoned.

5. Improvement of the Liffey and Greece from Dublin to Kilcullen and Carlow. The Branch of the Grand Canal known as the Kildare Canal, runs very nearly in the district which this navigation was to open.

6. The Blackwater, from Youghal to Newmarket. It has been rendered navigable from Youghal to Lismore, and a few years ago, a small steamer was plying on this portion of the river, chiefly for passenger traffic; but as yet its capabilities, as a channel for the conveyance of goods, seem not to have been at all brought into operation.

7. The Foyle, Mourne, and Strule, from Derry to Omagh. This has been completed only to Strabane.

8. The river Erne, above Lough Erne, [unattempted].

9. The Maigue, from Limerick to Cork. Some improvements have been effected in this river by the Shannon commissioners, but the proposed line between Limerick and Cork has been long since abandoned.

10. The Boyne navigation, from the Grand Canal to the sea, at Drogheda. This has been effected, as already mentioned, from Navan.

11. From Sligo to Carrick-on-Shannon. This line seems to run nearly in the direction of the Boyle water, and is thus so far partly open.

12. From Galway to Killala, through the lake district of Western Connaught. This line, as already referred to, must be considered as unopened.

13. The Slaney, from Wexford to Baltinglass, [unattempted.]

14. The Suir navigation, from Thurles to Waterford. This has been improved only between the latter town and Clonmel, so as to admit of ordinary canal boats.

15. From Galway to Portumna on the Shannon, [unattempted.]

16. The river Inny, from Lough Sheelin to the Shannon, [unattempted.]

17. The river Suck, from Castlereagh to the Shannon. The Shannon commissioners have turned some attention to this river, but it does not seem to have been as yet rendered completely navigable.

18. The Lee, from Cork to Macroom. A few locks were constructed, but the works were soon suspended, and nothing has been effected since.

19. The river Bandon, from Kinsale to Dunmanway. Ships, such as are used in the coasting and channel trade, can proceed up the tidal estuary of this river as far as Shippool, a few miles below the town of Bandon; and a ship canal was proposed, some years ago, to connect the estuary with the town, for which surveys and estimates were made. This useful project has, however, been abandoned, and is not likely to be resumed, in consequence of the Cork and Bandon railway.

20. The Laune, from Rosscastle to Castlemaine harbour, [never attempted.]

The provisions of the Act of 1715 not having been found sufficiently encouraging, another was passed in 1729, better adapted in some respects to stimulate the carrying out of the several proposed improvements. New commissioners were appointed, and, by the 25th of George the Second, they were incorporated with full powers of improving and extending inland navigation. Certain duties were from time to time imposed, and specific grants accorded, in furtherance of these objects. For many years the commissioners had expended the sums placed at their disposal on the Newry navigation. In 1749 their expenditure amounted to 58,400*l*. After this they commenced other works on the Boyne and Shannon, the expenditure on which, in 1758, amounted to 140,000*l*.

In the 27th of George the Second an act was passed to open a navigation from Belfast to Lough Neagh. This is what is now known as the Lagan navigation; it was commenced in 1755, and received improvements in 1810. A new act was passed n 1843 for deepening it from the first lock towards Belfast, so as to admit vessels of from 50 to 70 tons burthen, and drawing 5 feet of water. This navigation is remarkable from an official testimony to its success, quoted by Mr. MacMahon, from which it appears that it has been but little affected by the Ulster railway, and for all heavy goods it is expected to command a preference. In th s opinion Mr. MacMahon concurs, stating that he has long entertained the conviction that canals and railways in the same locality are not necessarily competing highways.

At the period referred to of the reign of George II., when the entire revenue of Ireland scarcely exceeded half a million, the legislature voted 65,000*l*. for inland navigation. This was done chiefly on the representations of the Tillage Committee, by whom the subject was strongly recommended on account of the great benefits resulting to agriculture.

In 1767 the system of management underwent a change, devised in order to stimulate private enterprise. For, while granting 6000*l*. for improving the Lower Shannon, the condition was annexed that 10,000*l*. should be raised by private individuals, and in conformity with this arrangement the Limerick Navigation Company was duly incorporated. Some years after this the corporation for the general management of inland navigation was dissolved, and several lines of water communication that had been undertaken, were vested in bodies of local commissioners, such, for instance, occurred to the Newry Navigation, the Boyne, the Barrow, the Upper and Middle Shannon, and the Tyrone Coal Canal.

In 1789 the Irish House of Commons resolved to advance one-third of the expense of any new undertaking of this kind, and authority was given to issue debentures at 4 per cent. for 200,000*l.*, the sum raised in one year not to exceed 25,000*l.*

This liberal provision soon caused the following lines of navigation to be carried on, for which public money was allocated to the extent of 189,200*l.*

1. The Shannon, between Killaloe and Limerick.
2. The Grand Canal to the Shannon.
3. The completion of the Barrow Navigation.
4. The Royal Canal, from Dublin to the Upper Shannon at Termonbarry.
5. The Boyne Navigation, above Drogheda.
6. The Newry Navigation.
7. The Erne Canal.
8. The Kildare Canal, to Naas and Kilcullen.

The sum of 33,399*l.* was further appropriated by the 31st of George III. for the following improvements; the Athy branch of the Grand Canal, the Grand Canal docks, the Foyle Navigation to Strabane, and the Collieries Canal. From a report of the commissioners of accounts in 1790, the corporation for promoting inland navigation in Ireland had disbursed of

| | | | |
|---|---|---|---|
| Public Grants ............ | £227,669 | 2 | 1½ |
| Income for Duties ...... | 359,868 | 9 | 6½ |
| | £587,537 | 11 | 8 |

At the Union in 1800, a sum of 500,000*l.* was granted for improving the Port of Dublin, for rendering the Shannon navigable from Lough Allen to the sea, and for the general purposes of inland navigation. Under this arrangement 423,798*l.* were granted partly to the Royal Canal Company, the Barrow Navigation, the Grand Canal Company, for improving the Shannon between Lough Ree and Lough Derry, the Limerick and Killaloe Navigation, the Newry Navigation, the Tyrone Canal, and the improvement of Dublin Harbour. Subsequently by the 57th George III. cap. 34, 300,000*l.* was advanced for different works, no part of this grant going to the Shannon. After so many years of comparative neglect, the capabilities of this noble river were at length destined to be fully recognised, and to be in some measure availed of by the exercise of engineering skill and judicious legislative arrangements. The Shannon Commissioners were duly incorporated, and plans for the improvement of the river were submitted to Parliament every year from 1836 to 1839, inclusive. The entire estimates amounted to 510,750*l.* 15*s.* 9*d.* and the money awarded for compensation to mill owners, land owners, proprietors of fishery rights, &c., reached the sum of 74,054*l.* 2*s.* 0½*d.* The Shannon was thus not only brought to the navigable condition already described, but communication between its opposite banks was further facilitated by the construction of several noble bridges; and it is to be hoped that the prosecution of improvements of every kind of which the navigation of the river has been the object, have not as yet been altogether abandoned.

From this short sketch of the history of inland navigation in Ireland, the liberality with which the subject was entertained by the Irish Parliament is as remarkable as the occasionally injudicious application of the funds so amply provided. Sums comparatively small were appropriated for the improvement of the great natural lines of navigation, while far more encouragement was given to lines entirely artificial, more especially to the two great competing canals which connect Dublin with the Shannon. Thus the general interests of the country are frequently sacrificed to individuals or corporations who may exert an active and interested personal influence on those to whom the conduct of public affairs happens to be entrusted.

We have seen the great natural advantages which the physical structure of Ireland presents for inland navigation, and we have also been able to form some notions as to the way in which these advantages have been applied. Engineering works of great magnitude and solidity have been already executed, yet something still remains to be done in this department; but our observations in the present note will refer chiefly to the improvement in the locomotive arrangements of inland navigation, after a few remarks regarding the improvement of the principal water-ways.

Of these the first which demands notice is the Shannon, both as an independent line from Lough Allen to the sea, and as an important part of the great diametral line extending from Limerick to Coleraine. The condition of this noble river, as already pointed out, is such, that now no very important improvement seems possible, except that of rendering the portion between Limerick and Killaloe navigable, in the same sense as that between Killaloe and Athlone. When the engineering difficulties already surmounted on this river are duly remembered, and when we recollect that several miles of the navigation between Limerick and Killaloe is through the stream, the practicability of such an undertaking will not appear so problematical as many seem to consider it. The construction of a sufficient number of locks of the same magnitude as that at Meelick, or 170 feet long by 40 feet broad within the chamber, seems to form one of the most considerable items of expense. The chief objection to locks with a high lift is the great loss of water during the passage of vessels, but this objection would be scarcely applicable to a series of locks supplied by Lough Derg. If, with Sir Robert Kane* and Mr. Mulvany, we assume the maximum discharge at Killaloe to be one million of cubic feet per minute, and the minimum in the driest summer weather at 100,000 cubic feet per minute, and remember that an admirably-constructed waste weir, 1100 feet in length, now spans the river at this point, it will not need any calculation to be convinced that the supply would be almost inexhaustible for the purposes of navigation. Under these circumstances, the declivity of the river could be surmounted by a smaller number of the large locks than it is at present of the small locks. On the Leeds and Liverpool canal, where the supply of water is comparatively limited, five locks rise together 88 feet, thus giving each lock a lift of 17 ft. 7 in. If we allow to the current an average slope, somewhat less than 1 in 8000, for the 15 miles between Limerick and Killaloe, the lift required to be surmounted by the locks will not exceed 88 feet. The recent construction of floating docks at Limerick, and other improvements in that port, makes its connection with the Upper Shannon more important than ever. The completion of such works as are here referred to would enable sea-going screw steamers to traverse the greater part of the Shannon from its mouth upwards, and would thus establish a direct navigation between the central districts of Ireland, and the principal ports at the opposite side of the channel. In France and in Canada such tendencies of economising transport have been already manifested: the cost of breaking bulk and transhipment of cargoes having led, in the former instance, to the establishment of a screw line direct between London and Paris; and in the other to a very successful attempt to pass vessels of large tonnage over the rapids of the St. Lawrence, thus opening a direct communication between some of the great central lakes of America and the port of Liverpool.

The connection of Lough Erne with the Shannon by Lough Oughter was made the subject of a detailed Report by Mr. Mulvany in 1839. Although he does not seem to have contemplated the adoption of steam vessels on the artificial parts of the line, their introduction throughout might be effected by the use of the screw propeller, and the construction of locks sufficiently long. The moderate original estimate of 170,000*l.* for the entire work, would thus be slightly increased, but if this line of navigation should ever be finished, it must evidently be something better than a canal for conveying ordinary barges.†

The connection of the Shannon with Lough Neagh being thus established, a water communication would be open between the south and centre of Ireland and its north-east coast at Belfast and Newry; while a further opening could be made through the Lower Bann towards Coleraine. From the description already given of this river, it is evident that it presents such a series of levels, regularly descending step-like to the sea, as would present facilities for the establishment of locks, and if suitably improved, it would form a permanent line, adapted to vessels of sea-going dimensions.

* 'Industrial Resources,' 2nd ed. p. 82.

† Since this paper was written we have learned that considerable progress has been made with this canal, which is to connect Lough Oughter with the Shannon, near the southern extremity of Lough Allen, at Drumshambo, passing through the town of Ballinamore. It also appears that Mr. Dargan has, or had, a steamer plying upon Lough Erne, between Enniskillen and Belturbet, thus giving to the former town the advantages of the Ulster Canal. We have not as yet been able to get any data as to the size of the locks, and cannot therefore say whether provision has been made for steam-vessels.

Some important improvements might be suggested in others of the possible lines of navigation, especially in the lines of the Connaught lakes, and in the southern Blackwater, but want of data induces me to defer any further remarks of this nature.

The locomotive question of inland navigation requires the solution of two fundamental problems. 1. What is the best shape and construction of vessels for carrying a large cargo with the least draught of water, and minimum expenditure of tractive or propelling force? 2. What is the kind of motive power best adapted to the requirements of inland navigation?

The greatest immersion with the least vertical depth is evidently secured when the immersed section is a rectangle, in other words, when the bottom and sides of the vessel are flat, and the latter perpendicular to the former. This, therefore, should be the normal section of vessels intended for shallow waters, from which only slight and indispensable deviations should be permitted. Such a shape, combined with lightness of materials and general structure, would entail only a very small draught of water. The principal difficulty consists in combining these conditions with such lines as would present least resistance to the motion of the vessel in a narrow channel, or which would give the smallest value of K, in the formula

$$R = K W A H;$$

where R is the resistance, A area of maximum immersed section, H height due to the velocity of motion, W weight of a cubic foot of water, and K a constant depending on the form of the vessel. The least value of K seems to be that for vessels shaped on what is called the wave principle, for which Mr. Scott Russell states, he has found K = ·08, while the recognised values for ordinary shapes are ·16 or ·18. For canals and the shallow or narrow rivers of Ireland all these conditions should be very rigorously adhered to, and a class of boats totally different from the clumsy barges now chiefly used should be substituted. On this head, Sir John Macneill has addressed the following excellent remarks to the directors of the Grand Canal Company, which would be equally instructive to all who have any control over inland navigation in this country:

"The barges and boats on your canal are much too large, heavy, and unwieldy; they are a heavy load in themselves, and require considerable power to move them, even at a slow rate, when empty; they are also formed as if they were to be employed as sailing barges, similar to those on the Thames and other rivers; this is a great mistake, and quite unsuited to canal navigation. If the boats were built 60 feet long, 6 ft. 6 in. wide, with upright sides and upright sterns and bows, which would admit two of them to enter a lock at the same time, a great amount of saving would be effected on your canal in the power required to haul such boats, as compared with those now in use, for I have no doubt that six of these boats, carrying 35 tons each, would be as easily hauled as two of the present boats, 50 tons each, or in the ratio of 210 to 100."*

Although any future improvements in inland navigation in Ireland must necessarily be made with nearly exclusive reference to goods traffic, an instructive illustration of the manner in which the difficulties presented by shallow rivers may be overcome is afforded by what was done several years ago in France, on the Loire, by the skill and perseverance of a British engineer.

That river being deprived of its usual supplies of water during the heats of midsummer, steam-boats with the ordinary draught of water were found totally unsuitable. A new boat was constructed, 100 feet long, 10 ft. 6 in. broad, 3 ft. 6 in. deep, and 5 ft. 6 in. in height at the part containing the machinery. The material was sheet iron, $\frac{1}{11}$-inch in thickness. She was covered with strong canvas, so as to form a series of cabins, like in a canal passage boat, with small platforms fore and aft. A gangway ran all round, communicating between these platforms. The engine was 24-horse power, with a cylinder 16 inches diameter, and 2 feet stroke. Wrought-iron was employed as much as possible, and every part of the machinery made as light as could be consistent with the required strength. Engine, boiler, shafts, and wheels weighed only 6 tons. The boat and engine complete, was 14 tons. With a ton of coals in addition, she drew only 6 inches of water, possessing, as may be supposed, an almost rectangular cross section. She ran for some time between Tours and Orleans, and when the boats that run from Nantes to Angers were stopped from want of water, she was placed on that portion of the river, and is said to have soon realised the cost of construction. Four or five more steamers of the same kind were subsequently built, of greater dimensions, but not drawing more than 10 inches of water. These would, of course, be unsuited for rough weather, but seem to have admirably fulfilled the object for which they were intended.

The passengers being chiefly under the light canvas deck, the centre of gravity was always kept low during the voyage. It is also probable that when stopping at any of the stations on the river, the ingress and egress of passengers took place by the platforms at the end, and not at the paddle-boxes, according to the absurd and dangerous system generally in use, thereby avoiding the risk of giving so light a vessel a heel over the side, which, in such a case, would be attended with serious results.

Of the several modes of communicating motion to vessels on rivers, lakes or canals, the three most important are direct propulsion by steam, steam towing, and haulage by horses on the banks. The last of these labours under great disadvantages. The line of action is oblique to the direction of motion, whereby force is lost in different ways. If inland navigation is to be brought to any degree of perfection, this method must be entirely superseded. Whether it should be superseded or not, there are certain general principles relative to the motions of vessels in shallow and confined channels, a knowledge of which would very greatly assist in devising such arrangements as to economise the tractive or propulsive power applied to move the vessels. The mathematical and experimental researches of Professor Challis, Mr. Scott Russell, and Sir John Macneill, have added considerably to our information on these interesting questions. The following is a summary of their principal results:

The law of resistance in narrow and shallow channels is entirely different from that in open water. This is caused chiefly by the formation of a wave of considerable length, due to the impelling action of the vessel on the confined fluid, the velocity of which is a function of the depth of the channel. It moves most rapidly in deep channels, and slowest in shallow channels. This wave generally precedes the vessel, sensibly increasing the depth of water, a corresponding posterior depression follows it, which similarly lessens the depth of water. In shallow water, when a boat is behind the wave, an increased abnormal resistance is presented to her forward motion from the mass of water before her head. If by strong impulse she were placed on the wave, she would not only be in deep water, but would meet with diminished resistance. A boat moving in shallow water will sometimes take ground at places where she would float if at rest, and also pass over shallows at a rapid velocity, where she would run aground if her motion ceased or diminished. In the first case, if the vessel moves slower than the wave she will occupy the posterior depression, while in the second, if her velocity is equal to that of the wave, she is supported on it, and floats in a depth of water equal to the normal depth of channel, plus height of wave. Passenger boats on some of the canals of Holland are thus made to float over the shallower parts by giving them a higher velocity of motion. By lowering the velocity, the height and depression of the wave would be also diminished. When two boats are passing each other the effect is most sensible, as the resulting depression is equal to the sum of the depressions that would exist separately. I have frequently observed steamers to lessen their speed at low water in tidal estuaries, in order to prevent either or both taking the ground in the depression produced by their motions.

The practical conclusions are, that in narrow and shallow channels the increase of impelling power has a limit, and there is a certain velocity at which a boat may be impelled with a minimum expenditure of force. This velocity must, however, be attained very rapidly, in order to enable the boat to pass the wave, and a sudden impulse from a low to a high velocity is the best mode of effecting the change. In wide and deep channels the requisite impelling power increases with the velocity, but not in a uniform relation. In such cases, when it is hopeless to attain the same speed as the wave, the least velocity consistent with the requirements of traffic will produce least expenditure of power.

In applying steam power to inland navigation it becomes important to determine the best description of boats for navigating both rivers and canals, as well as the best for either separately. In France a great many boats have been constructed for such objects, moved by paddle-wheels at the stern, or by a single one in the centre, or more recently by screws. Among these is one constructed in 1852, on a principle similar to that pointed out by Mr. Bourne in his 'Essay on the Steam Navigation of Shallow Rivers.' She is capable of being divided into two separate parts, forming two distinct vessels, the forward division containing the

* 'Report on Screw Steamboats Employed on the Grand Canal,' p. 8.

goods and the after portion carrying the machinery as well as goods. The principal advantage gained by this mode of construction is the facility with which the vessel is enabled to pass through locks in separate divisions, for which she would be too long when entire. The project suggested by Mr. Bourne was anterior to this; he proposes a kind of floating train, analogous to the railway train on land. It is intended chiefly for the shallow and winding rivers of India, but as some of its details may be suggestive of improvements in vessels for combined canal and river navigation, we cannot forbear giving it some notice. He proposes to carry the passengers and cargo, not in the steamer herself, but in a succession of shallow barges, so articulated to the steamer and to one another by circular joints, with a single bow to separate the water for the entire train, instead of an independent bow and stern for each of the constituent barges. The steamer or floating locomotive proposed for the Indian rivers would be 220 feet long by 36 feet broad, with an immersion of 15 or 16 inches. The stern barge 160 feet, with less than 12 inches draught. Average draught of barges should be 12 inches, with 50 tons of cargo in each. In favourable cases he expects a speed of from 12 to 15 miles per hour, with a train of five barges. The locomotive, like that on land, carries neither goods nor passengers, she only differs in acting as her own tender. The barges should be so jointed together that only a narrow space would exist between them, at which the plates of the barges mutually overlapping, any intermediate water would be carried as in a tank, and could offer no resistance. Although in this way the resistance of displacement produced by such a train would be comparatively small, the resistances arising from friction and the flexures of the different parts of the train, would be very considerable. The frequent turnings which are requisite in river navigation would be accompanied by differences in the amount of effective resisting section presented by the train, and the midship section would almost always be far less than that representing the resisting surface. It seems probable, therefore, that there is a limit beyond which it would be injudicious to extend the length of such a train, although it must be acknowledged that it possesses great superiority over the system of towing a group of separate barges.

In the first part of these notes I have mentioned that steam power had been applied to the towing of barges on the Shannon, with very useful results. In the experiments made by Sir John Macneill it was found that a much more useful effect was produced in the application of small screw steamers on the Grand Canal by hauling loaded boats, than by carrying goods. But these steamers were essentially tug-boats, and the results obtainable from them cannot fairly determine the relative merits of the two systems of transport. On some of the rivers of France, such for instance as the Rhone, the carrying system has entirely superseded hauling, and cargo steamers of colossal dimensions have been recently introduced for the transport of goods. Some of these are 460 feet long by 22 feet broad, and have an average draught of 4 ft. 3 in. They are worked by engines of about 400 horse power, and move at the rate of from 5 to 6 miles an hour. On the Rhine and Danube the use of cargo steamers seems also to be gradually extending, with a corresponding diminution in the amount of towing.

If the system of jointed vessels already described should not be found to answer, the best application of steam-vessels to the existing canals, would be undoubtedly for towing purposes. I was surprised to learn from an intelligent gentleman connected with one of our principal canals, that the use of tug steamers was not of late regularly continued on the canal. One of the reasons alleged was, that a train of two boats occasioned a great and sudden loss of water at locks. This could be in part obviated by the suggestions of Sir John Macneill; and it should be remembered that the absolute loss would in any case be the same, whether the boats were in a group or separate. Another objection arose from the liability of the sparks from the funnels of the steamers lodging in turf ricks and the roofs of thatched buildings near the canal bank, thereby causing destruction of property. This is no doubt partly due to the lightness of the ashes of the peat, the fuel generally consumed in the canal steamers, but without any change in the description of fuel (which on economical grounds it would be desirable to retain), this evil could assuredly be averted. Spark arrestors are well known, and frequently employed on the chimneys of railway locomotives.

If difficulties of this kind should interfere with the development of inland navigation in Ireland, all the advantages she possesses would be in vain; and it would be long before we could say in the words of M. Gaudry, a French engineer, whose 'Essay on River Navigation in France' I have found both interesting and instructive:*—"Alongside of the best made and most prudently worked railways, each year witnesses, together with increased traffic on our improved water-ways, an increase in the number and power of the steam vessels."

---

## THE MINTS OF THE UNITED STATES.

### By Professor Wilson.†

The transmissions of gold from the new state of California have caused a corresponding increase in the gold currency of the States, and have invested the Mint operations with more general interest than under the previous ordinary circumstances they possessed. The same condition of things exists in this country; and as it is intended to establish a mint in the gold producing colony of Australia, I thought it desirable to obtain as much information as I could in reference to the organisation and working details of those in the United States.

The head establishment is at Philadelphia, and is called "The Mint"; there are also three "Branch Mints;"—at New Orleans, in Louisiana; at Charlotte, in North Carolina; and at Dahlonega, in Georgia, respectively. The Branch Mint in California, and the Assay Office in New York, are not yet completely organised.

At the Mint in Philadelphia, gold, silver, and copper, are coined; at New Orleans, gold and silver are coined; while the branches at Charlotte and Dahlonega coin gold only. At "The Mint," the executive staff consists of a director, treasurer, chief coiner, melter and refiner, engraver, assayer, and assistant-assayer. At the New Orleans Branch Mint the staff consists of a superintendent, treasurer, melter and refiner, and coiner; and at each of the other two branch mints there are but three officers,—superintendent and treasurer (combined), assayer, and coiner. The several duties of these officers, the remuneration they shall receive for their services, and the amount of security they shall give for the due performance of them, are duly prescribed by an Act of Congress supplementary to the Act entitled "An Act establishing a Mint and regulating the Coins in the United States;" this latter act giving all the details referring directly to the coinage of the country.

At the United States Mint at Philadelphia, the salaries are fixed as follows:—Director, \$3500; treasurer, \$2000; chief coiner, \$2000; melter and refiner, \$2000; assayer, \$2000. At the New Orleans Branch Mint the salaries are, to the superintendent, \$2500, and \$2000 each to the other officers; and at the other branch mints the superintendents receive \$2000, and the other officers \$1500 respectively. In each of the establishments the appointment of assistants, subordinate officers and servants, is left entirely in the hands of the chief of the different departments.

In visiting the Mint at Philadelphia I had the advantage of being taken through the several departments by the chief coiner, Mr. Franklin Peale, and the melter and refiner, Professor J. C. Booth, who kindly furnished me with the following details of their operations. As the gold is brought to the Mint in various quantities and in a crude state, it passes necessarily through the department of the refiner before it reaches that of the chief coiner; I therefore give the actual details of the refining operations upon sundry deposits of gold, amounting in the aggregate to \$2,000,000.

The deposits are immediately weighed and a certificate of their gross weight issued. The fires having been lighted in the five furnaces of the deposit melting-room at four or five o'clock, A.M., all the deposits, amounting perhaps to seventy or eighty, are melted before noon; assay slips are then taken off and the assays finished‡ the next morning, after which their values are calculated by the weight after melting, care being taken to include all the grains that can be procured from the flux, pots, &c., by grinding them up under a pair of small chasers, sifting, and washing. There is a clerk and his assistant and one hand wholly engaged in performing all the weighings for the treasurer, such as weighing deposits before and after melting, ingots for coinage, fine bars, and the clippings after cutting out the planchets. There are five men in the deposit melting-room, two of whom

---

† From the Special Report on the New York Industrial Exhibition.

‡ The mode of assaying is according to the "wet process" of Gay Lussac. This is too well known to need description here.

attend to two furnaces each at the same time, one to one furnace and washing grains, and the remaining two are labouring assistants. The whole deposit of $2,000,000 is melted in three or four days in the deposit-room and assayed by from the third to the seventh day.

As soon as the first deposits are assayed, say on the third day (if expedition is necessary), or always on the fourth, they are granulated in the proportion of one part of gold to two parts of silver. The pots contains 50 lb. of gold and 100 lb. of silver, equal to 1800 oz., and each melt requires about an hour. With four furnaces (attended by four melters and two aids), there are ordinarily made thirty-two melts per day, but when hurried forty-eight melts can be made, making from one-third of a million to one-half of amillion dollars per day. Two days' work, or about $650,000 worth of gold, equal in weight to one ton (avoirdupois weight), are granulated for a single setting with acid. The granulated metal is charged into large pots, together with pure nitric acid of 39° Beaumé, between the hours of seven and nine A.M. on the sixth day, and steamed for five hours. The pots made in Germany, are 2 feet in diameter by 2 feet in depth, set in plain wooden vats, lined with $\frac{1}{16}$-inch sheet-lead; a single coil of copper pipe passing around the bottom of the vat blows the steam directly into the water in which the pots are set to about half their depth.

The vats are arranged in a small house in the middle of the room with a large flue connecting with the chimney-stack, so that when in action the odour of nitrous fumes is scarcely perceptible in the building. The $2,000,000 require about sixty such pots; they are stirred about once each hour, say altogether five times, with simple wooden paddles; the next day (seventh), the acid solution of nitrate of silver is drawn off by a gold-syphon into wooden buckets, and transferred to the large vat, in which it is precipitated by salt (chloride of sodium), and fresh acid added to the metals, now containing very little silver. Steaming for five hours on the seventh day completes the refining of $650,000. Early on the eighth one pot is drawn off, washed with a little warm water, and the gold-powder transferred to a filter. Fresh granulations are put into this empty pot, and the acid of the adjoining pot baled over upon them, and thus through the series, the whole being re-charged in from two to two and a-half hours. After steaming for five hours, the acid which contained but little silver from the preceding day becomes a nearly saturated solution of nitrate of silver. By this arrangement 4½ lb. of nitric acid are consumed altogether for each pound of gold refined, and the latter is brought up to 990 at 993 m. fine,—rarely below 990. Thus every two days, 13,000 lb. of nitric acid are used. In the course of the last year 1,000,000 lb. of pure nitric acid, at seven cents per pound, equal to $70,000, were consumed.

The gold is washed with hot water on the filter during the eighth day, and until it is sweet (say by 7 P.M.) The filter consists of two layers of tolerably stout coarse muslin, with thick paper between, in a tub with a false bottom, 2½ feet in diameter and 2½ feet deep, and mounted on wheels. One of the men remains, after washing hours, until 7 P.M., when the watchman of the parting-room continues washing the gold and silver until sweet, *i.e.*, until the wash-water ceases to colour blue litmus paper. Early on the ninth day the wet gold is pressed with a powerful hydraulic press, and the cakes then thoroughly dried on an iron pan, at a low red heat. This process saves wastage in the melting-pot, since there is no water remaining in the pressed metal to carry off gold in its steam. The same day (ninth) the gold is usually melted with a less proportion of copper than is requisite to make standard metal, and cast into bars, which are assayed by noon on the tenth. They are then melted with the proper quantity of copper, partly on the same day, partly early on the eleventh, and assayed and delivered to the coiner the same day. On the fourteenth they are ready for delivery to the treasurer as coins.

The silver solution drawn off from the pots is precipitated in a large wooden vat of 10 feet diameter by 5 feet deep, and the chloride of silver immediately run out into large filters [6 × 3 × 14] where it is washed sweet. The filter is covered with coarse muslin, and the first turbid water thrown back; the filter, which is on wheels, is then run over to the reducing vats, and the chloride shovelled into them. There are four such vats [7 × 4 × 2] made of wood and lined with lead, 1 inch thick in the bottom. A large excess of granulated zinc is thrown on the moist chloride in the vats, without the addition of acid; the reduction is very violent, and when it slackens, oil of vitriol is added to remove the excess of zinc. The whole reduction occupies a few hours, and after a night's repose the solution of mixed sulphate and chloride of zinc is run off into the sewer.

About 2 tons of zinc per $1,000,000 of gold are employed; the silver, however, in this amount, say 10 percent. by weight, should only take, by equivalents, about 2400 lb., so that nearly 2 equivalents of zinc for 1 equivalent of silver are used. This is found to be advantageous, as both time and space are greatly economised by this excess.

The day after the reduction the reduced silver is washed, and the second day it is pressed and dried by heat, the same hydraulic press as for gold being used, but with different drying-pans. The same silver is used again for making fresh granulations, but as it accumulates from the Californian gold, 10,000 or 20,000 ounces are now and then made into coin, great care being taken in this case to avoid getting gold in it when drawing off the silver solution, and in the press.

Such are the actual working details in refining a specified amount ($2,000,000) of gold, the first-third of which is delivered as coin in fourteen days after its arrival, and the third-third in eighteen days.

But as there is a bullion-fund of $5,500,000 allowed by government depositors are paid from the third to the fifth day after an arrival, *i.e.*, as soon as the gold is melted, assayed, and its value calculated. When two heavy arrivals occur in close succession, the time of refining and coining can be shortened from 14 to 10 days.

The number of men engaged in the refining department is 14: 1 foreman, 8 for the parting process, 3 for reducing, and 2 for pressing and drying. In the gold melting-room there are 3 melters and 2 assistants. The total number of hands in the melting and refining departments is 34, including a melting and parting foreman, and 3 in the place for grinding, sifting, washing, and sweeping. This last place or sweep embraces all pots, ashes of fires, trimmings of furnaces, ashes of all wood-work, &c.

The late law for reducing the weight of silver coin necessitated an increase of force, and 15 more were in consequence employed for this purpose. While $50,000,000 in a year have been parted with the above force, they could with the same force and apparatus refine $80,000,000 if it were required.

After many experiments upon anthracite, Professor Booth stated that he had at length fully succeeded in employing it for melting both gold and silver in the same furnaces, slightly modified, in which he had been accustomed to melt with charcoal. This change had been accompanied by great economy in the cost of material and labour, and by greater comfort to the workmen, from being less exposed to heat. The cost of charcoal (of the best quality—hard pine-knot coal) is 16 cents per bushel, delivered at the Mint; and while the cost of this fuel for all their operations in 1852, when gold was chiefly refined and melted, was about $7000, the cost of anthracite will be from $600 to $1000. In using the anthracite he found that a simple draught of air, without a blast, was quite sufficient to sustain combustion.

Californian gold frequently contains the alloy "iridosmine," which is not always detected by the assay. In order to remove it as far as possible without actually dissolving gold, it is allowed to subside, first in the granulating crucibles, and then in the crucibles for toughening (melting fine gold and copper). If the assayers report its presence in the toughened bars, they are again melted, and the iridosmine allowed to subside. By these three, and often four successive meltings, the gold is separated from its troublesome companion as far as practicable. The gold thus refined, and reduced to the proper standard [*Section* 8: "And be it further enacted, that the standard for both gold and silver coins of the United States shall hereafter be such that of 1000 parts by weight 900 shall be of pure metal and 100 of alloy; and the alloy of silver coins shall be of copper, and the alloy of gold coins shall be of copper and silver, provided that the silver do not exceed one-half of the whole alloy,"] is delivered over to the chief coiner in the form of bars or ingots of a certain weight, to be divided and shaped into pieces required for the currency of the country.

The *Coining* department of the establishment is of a power and efficiency sufficient to perform all the mechanical processes incidental to the issue of nearly 70,000,000 of pieces during the past year; and I was assured by Mr. Franklin Peale, the chief coiner, that it could have executed much more if it had been steadily employed, or fully supplied with material during the whole of that period. It is not necessary to go through the whole course of operations in this department, but to notice only such as possess novelty or present special characteristics.

The necessary power for working the machinery is obtained from a large steam-engine of the form usually known as the steeple-engine; it is a double vertical high-pressure engine, with cranks at right angles, the power being carried off by a caoutchouc belt, 2 feet wide, from a drum of 8 feet in diameter; the estimated power is equal to 90 horses. At times, this is all required, at others much less is sufficient, and in uncertain proportions; to meet this irregularity, and to insure that steadiness of motion so necessary in such delicate operations, a governor and throttle-valve of a peculiar construction have been devised which have now been in use for some time, and have produced most satisfactory results, fully effecting the purpose for which they were designed. The rolling mills, four in number, are driven by belts, at the rate of six revolutions per minute; the distances between the rollers being adjusted by double wedges, moved by a train of wheels which are connected with a dial-plate and bands, divided and numbered into hours and minutes, so as to indicate the proper thickness of the strips of metal without the use of gauges. Gold strips are heated in an iron heater by steam, and waxed with a cloth dipped in melted wax, and the silver strips are coated with tallow by means of a brush. The draw bench is used for both metals, and trial pieces are cut from every strip and their weight tested, preparatory to the cutting of the whole.

The cutting processes are very simple and efficient, consisting of a shaft moved by pulleys, and a 2½-inch belt, with a fly-wheel of small diameter but sufficient in momentum to drive the punch through the slip of metal by means of an eccentric of ⅜-inch, at the rate of 250 pieces per minute, which skilled hands can readily accomplish and continue until the slip is exhausted. The annealing during the rolling of the ingots into slips is performed in copper cases, in muffles of fire-clay and brick, heated by anthracite coal, three muffles or hearths being kept at a bright red heat by one fire-grate or furnace, and the distribution and intensity regulated by dampers. These annealing furnaces are recent in their construction and very satisfactory in operation; they are heated by anthracite at the cost of about one-fourth the expense of the wood previously employed.

The whitening of planchets is performed as usual by inclosing the gold in luted boxes, and by exposing the silver in an open pan, to the heat of a simple furnace with wood fuel; the drying and sifting after the action of dilute sulphuric acid, is rapidly and effectually accomplished by a rolling screen—one portion of which consisting of a pair of closed concentric cylinders, between which high-pressure steam is admitted. The blanks, with a sufficient quantity of light wood sawdust (linden or bass wood is the best), being introduced into the interior cylinder, a revolving motion is given to it by the engine for a certain time; the door is then opened and the blanks and sawdust gradually find their way into the wire screen by which they are separated, the movement being continued until the separation is complete, when the blanks are discharged at the end of the machine. An arrangement exists by which a slight inclination is given to the machine so as to direct the motion of the blanks towards the discharging end.

The milling machines are, I was informed, peculiar to this mint, and are in a great measure original, the operation being performed by a continuous rotary motion, with great rapidity and perfect efficiency, varying in rate according to the denomination of the coin, between 200 and 800 pieces per minute, and at the same time separating any pieces that are notably imperfect.

It must be understood that the operation here termed "milling," is merely for the purpose of thickening and preparing the edge, so as to give a better and more protective border to the coin, the ornament or reed, commonly known I believe in this country as "milling," being given to the piece by the reeded collar of the die in which the piece is struck.

The coining presses, 10 in number, and milling machines are worked by a high-pressure horizontal steam-engine, made from the design and under the direction of the present chief coiner, in the workshops of the establishment in 1838.

The presses are three sizes, the largest applicable to the striking of silver dollars and double eagles:—the second to pieces of medium value:—and the smallest to the dime, half dime, and 3 cent. pieces. The first is usually run at the rate of 80 per minute, the last at 104 per minute,—the average rate of the whole is 82 per minute. This rate can be increased if required.

If all the presses were employed in coinage at the usual rate, they would strike in one day (9 working hours) 439,560 pieces; and if employed upon gold, silver, and copper, in the usual manner, and on the usual denomination of coin, they would amount in value to $966,193.

During the past year, on one occasion 8 of the presses were run 22 out of 24 consecutive hours, and coined in that time 814,000 pieces of different denominations of coin.

These presses have been made principally in the workshops of the Mint. They possess in common with the presses of Uhlhorn, in Germany, and Thouellier in Paris, the advantage of "the progression lever," "le genou" or "toggle joint," a mechanical power admirably adapted to this operation; but in almost every other particular they are original in arrangement, being the result of experience, beginning as far back as 1836.

In order to supply these presses various means have been devised; among them and not the least important, is the "shaking box," in which advantage is taken of a disposition observable in similar bodies, or bodies of similar form, to arrange themselves in similar positions. This is a box, whose bottom is constructed with parallel grooves adapted to the size of the blanks or planchets to be arranged. A quantity of them is thrown indiscriminately into the box, which is then quickly shaken in the direction of the grooves, the pieces immediately lay themselves side by side in parallel rows, from which they can easily be lifted in rouleaux as required to be passed to the feeding tubes of the mills or presses.

It is very evident to all visiting the establishment that such a large number of pieces could not be coined and manipulated by such a limited number of hands without the aid of some labour-facilitating arrangements, one of the most worthy of remark of which is the method of counting the pieces coined—if counting it can be called, for in principle it is a measuring machine. The arrangement of this counting frame, or tray, may be understood from the following sketch of its construction.

A board or tray of such dimensions as may be required, is divided by a given number of parallel metallic plates dissected into its plane and slightly elevated above it, the edges of which rise no higher than the thickness of the coin for which it is intended. The board is of such a length as will admit of a few more than the required number of pieces to be laid longitudinally in the rows and is divided across and at right angles with the rows, and hinged at a point opposite to a given number. One of those employed by this department counted 1000 pieces, that is to say, it had 25 parallel grooves or rows sufficiently long to receive 45 pieces. Now, having thrown on this board a large excess of pieces, it is agitated by shaking until all the grooves are filled, and then inclined forwards until all the surplus pieces have slid off, one layer only being retained by the metallic ledge; the hinged division is then suffered to fall, which at once throws off all but the 45 pieces in the length of each row. This operation, somewhat difficult and tedious to describe, is performed in a few seconds, and results in retaining on the board 1000 pieces, each piece exposed to inspection, and the whole accurately counted without the wearisome attention—so likely to result in error—required under usual circumstances.

The very large number of pieces coined during the last year has been counted almost exclusively by two female manipulators, assisted by a man who had the duty of weighing them in addition as a testing check. The same amount of labour by ordinary means could not have been performed with fewer than thirty or forty hands, to say nothing of inferior accuracy. This machine was originally arranged and patented by the late R. Dyler, coiner of the New Orleans Branch Mint, but materially improved in its application and construction by Mr. Franklin Peale.

The balances of the Mint of the United States have received the attention necessary to an instrument of such importance in mint operations. They have been arranged and made generally in the workshops of the establishment, and operate entirely to the satisfaction of the department. It is not necessary to enter into details of their construction, as a full and minute description is given in the Journal of the Franklin Institute for July 1847. I, perhaps, ought to mention that since that appeared, some slight improvements have been made by inclosing all but the stirrups and pans in glass, by these means excluding dust and protecting them from the influence of air currents.

In concluding this brief sketch of the practical working of the two most important departments of the United States Mint, I cannot omit a reference to the very excellent remarks of the chief coiner on the employment of females in some of the operations in his department. This, he informed me, had generally excited the surprise of, and been commented upon, by foreigners, who had visited the Mint. His experience, however, had led him to believe, that in places of trust, where no great physical exertion was called for, but where accuracy and strict integrity were of first importance, the moral perceptions of the female, generally stronger and of a higher standard than in the man, would qualify her as his substitute, and thus, while opening a new field of labour for the occupation of females, would strengthen their claims to it by the superior accuracy and economy of their work.

## LIGHTHOUSE ON THE NEW SOUTH SHOAL, NANTUCKET, U.S.

REPORT *to the Senate of the United States, communicating, in compliance with a resolution of the Senate, a Report, Plans, and Estimates, from* Major HARTMAN BACHE, *in reference to the Construction of a Lighthouse or Beacon on the New South Shoal off Nantucket.*

TO THE HON. C. M. CONRAD, SECRETARY OF WAR.

SIR—In obedience to a resolution of the Senate of the 22nd ult., I have the honour to submit the report, plan, and estimate, in reference to a beacon or lighthouse upon the New South Shoal off Nantucket. The law on this subject is dated March 3, 1849, and is in the following words: "For a screw-pile beacon or other practicable structure on the South Shoal off Nantucket, lately discovered by the survey of the coast, twenty-five thousand dollars, to be expended under the direction of the Bureau of Topographical Engineers."

This shoal—called Davis's shoal, after the officer of the navy who made the discovery and the survey—lies about twenty miles from land, in the broad ocean. I do not know on whose plan or estimate the appropriation was based; but being satisfied that it was utterly impracticable to erect any durable and useful structure of the kind indicated in the law, for the amount appropriated, at such a locality, the bureau has limited its efforts to an investigation of the subject, and to the preparation of plan and estimate. Major Bache was assigned to those duties, and the report now submitted is from him. With his report are numerous and well-executed drawings of his plan, and of its details, and also a model, all of which are now in this office. With the report are sent such of the drawings and charts as he has indicated as necessary to illustrate the views and reasoning of his report.

The direction of the law being "for a screw-pile beacon or other practicable structure." it left the engineer free to the exercise of his knowledge and ingenuity, within the only limits prescribed to him by this office—namely, a beacon or a light-house.

From the estimates submitted, in accordance with the plan which he recommends, it will appear that the estimate for the lighthouse is ................ $322,786 78
For the beacon ................ 234,664 73
And that, for the operations of the first season there will be required, in the first case................ 190,589 20
And in the second ................ 157,530 21

These facts will, I hope, satisfy Congress that the course of the bureau, in reference to this appropriation, has been judicious.

The report of Major Bache exhibits with much force the necessity of some such structure as he recommends upon that shoal, and the bureau is clearly of the opinion that it should be a lighthouse, in preference to a beacon.

Of the appropriation of 25,000 dollars herein referred to, there has been drawn from the treasury, for the purposes stated in this report, no more than 2750 dollars.

J. J. ABERT,
*Colonel Corps Topographical Engineers.*

*Bureau of Topographical Engineers,*
*Washington, April* 14, 1852.

TO COL. J. J. ABERT, CORPS TOPOGRAPHICAL ENGINEERS.

SIR—I have the honour to present the following report, accompanied by plans and estimates, on a beacon for New South Shoal, off Nantucket.

The group known as the Nantucket shoals extends off seaward, from the island of that name, six to twenty miles, between an E. line drawn from Great Point, and a SSE. line drawn from Tom Nevers' Head. It comprises Old Man's, Pochick Rip, Bass Rip, Point Rip, and Old South and New (Davis's) South Shoals, with about forty smaller shoals and shoal spots, single and in clusters, without names, laid down for the first time, within the last few years, by the Coast Survey. These shoals, composed of hard sand, with depths from six to eighteen feet at low water, form an aggregate of about twelve square miles, and are scattered over an area of at least 375 square miles, or in the proportion of 1 to 30 nearly; the soundings between them vary from 3 to 18 fathoms. The direction of the currents through the group is entirely round the compass every successive ebb and flood, one half being occupied by the four "quarters" of the two tides; the flood, the eastern quadrant, from NE. the first, to SE. the last quarter, veering round to the east by the south; the ebb, the western quadrant, from SW. the first, to NW. the last quarter, veering round to the east by the north. Their greatest velocity is $2\frac{1}{2}$ miles; their least rarely less than half a mile, even at the period known in most other localities as "slack-water," and sometimes at that stage of the tide it exceeds a mile. These velocities increase greatly over the shoals, and with their courses are subject, as elsewhere, to be modified by the direction and strength of the winds. The rise and fall of the tide is 3 ft. 2 in.; the extreme rise, 6 ft. 9 in. In common with all parts of the eastern coast, the entire group is enveloped for many days at a time by dense fogs.

The shoals lying seaward of the island, itself separated by a channel of 25 miles from the main land, which there projects beyond the general line, form the most salient point of the coast, north and east of Cape Florida. The course from Sandy Hook to the seaward face of the group is about E. $\frac{3}{4}$ N., and thence due north, or nearly at a right angle to the mouth of Kennebec river; a line drawn between the same points, NE. by N., and cutting across the land, leaving the outer shoal nearly 140 miles seaward. The coast south of Sandy Hook trending less to the westward, the courses from the capes of the Delaware and Chesapeake incline more to the north, and hence lines from those points to the Kennebec cut off, seaward, correspondingly less of the land.

The foregoing account of the character of the bottom, the limited depth of water over the shoals, their number and small size compared with the large area in part out of sight of land, throughout which they are scattered in deep water; the great velocity and ever-changing direction of the currents, in every instance running across the shoals; and the prevailing fogs, coupled with the prominent position of the group, will show at the same time the important relation which these shoals hold to the course of a large portion of the commerce of the country; the great danger to which it is exposed in passing them; the necessity for marking at all times their seaward face, and the extraordinary difficulties which lie in the way of accomplishing so desirable an object. The value of such an aid to navigation can hardly be exaggerated. The advantages flowing from it would certainly not be inferior to those resulting from the marking of any other point of the extended line of the Atlantic coast. What now constitutes a danger and a dread to navigators, and consequently a positive injury to commerce, would in that event become a means of safety, and benefit it. Forming the great point of departure and arrival for that part of the coast, vessels, particularly those engaged in foreign commerce, would no longer approach the shoals under reduced sail or steam, but stand boldly on, and, having made the light, continue confidently on their course for their ports of destination.

The commerce most interested in the proposed measure consists of—

1. The British American and European trades, from all ports south of Nantucket, as far at least as the Chesapeake, and of all other foreign trades from ports north and east of the island;

2. The whale trade, the ports of which are principally in Nantucket and Martha's Vineyard, or on the main in the vicinity of those islands; and,

3. The coastwise trade between ports on either side of Nantucket.

The magnitude and value of the commerce under the first head, and the number of persons connected with it, either as seamen or passengers, will be seen from statement No. 1, appended hereto, condensed from statements A, B, C, D, also appended. It is confined, as sufficient for the present purpose, to the principal ports of New York, Philadelphia, and Baltimore, within the first geographical limits, and Boston, Salem, Portland, Bath, and Eastport, within the second, and shows a grand aggregate of 6177 sea-going vessels of all classes, valued, with their cargoes, at $252,345,286, and paying in duties $26,988,054, and carrying, without taking into account outward-bound passengers, of whom no record is made, 285,558 persons, as passing the shoal in a single year. To what extent the trade of the remaining thirty-two ports within the first, and the twenty-one ports within the second division, as given above, would increase these amounts, can only be surmised in the absence of the records of the respective custom-houses. That these records would increase them considerably, there can be no doubt.

The extent to which the whale trade is interested in pointing out the positions of these shoals, can only be determined with anything like accuracy by tracing the course of each vessel engaged in it, to and from her port. In the absence of this information, it is only necessary to know that this trade is carried on from ports on either side and in the immediate vicinity of the group, to be convinced that it is largely interested in the measure. Thus, of the 606 vessels engaged in this trade, 475 arrive at and depart from their ports by the passage east of Long Island, barely 50 miles wide, and distant at the nearest point not more than 30 miles from the group; 69 belong to Martha's Vineyard and Nantucket, or on the main, back of those islands which, whether inward or outward-bound, are exposed to the shoals; and the remainder, or 62 vessels, are from ports north and east of Cape Cod, which, as the fishing grounds are principally south and in the Pacific, must pass them both going and returning. The relation which the position of the Nantucket shoals has to the usual course of the whale trade being thus shown, it is only necessary to examine the statements herewith numbered 2 and 3, to see the interest which that most valuable trade has in the consummation of the proposed project. The first gives the entire whaling fleet on the 9th of September last, as consisting of 606 vessels of all classes, with crews numbering 14,538 men and boys, and having a tonnage of 189,622 tons, valued at $7,584,850. The second, the arrivals of the trade for 1851, footing up as follows: vessels of the four classes, 239; crews, men, and boys, 5559; value of vessels $2,929,340, and value of *catch* $10,238,784, and total value of vessels and *catch* $13,178,124. That is to say, assuming the correctness of the premises as stated above, the inward-bound fleet of the whale trade, having a value of $13,178,124, and manned by crews numbering 5559, is exposed in a single year to the dangers of these shoals. But this exposure is not confined to the inward-bound trade alone; the outward-bound trade should also be considered. A statement of this trade is not within reach, nor is it absolutely necessary for the purpose of this report; for assuming, as is reasonable, that to keep up the whaling fleet on the fishing grounds, the departures hence must compensate for the arrivals home, a sufficiently near result may be come at by taking the totals under the different heads in the statement No. 2, omitting that under the head of the value of the cargo or *catch*. With this reduction, the footings of the outward-bound whaling fleet per annum will stand thus: number of vessels 239; number of the crews, 5559; and the value of vessels, $2,929,340. For want of reliable data, no note is made of the cost of outfit of the vessels—an item that would add very considerably to the value of this trade.

As the coastwise trade passes for the most part through the Sound, between the island of Nantucket and the main land, that trade is comparatively but slightly interested in the proposed project. Whatever exceptions there may be to its usual course are probably confined to vessels trading between ports north and east of the island and the distant domestic ports of the Gulf of Mexico and the Pacific; and to vessels which, wind-bound by the channel through the Sound, take the risk of the outside passage. It may, however, be confidently assumed that if the outer point of the Nantucket group were at all times distinctly marked, these exceptions would increase, as a consequence of affording greater facilities to this valuable and growing branch of commerce. Of the extraordinary number of the vessels engaged in this trade which pass Nantucket island, either by the Sound or seaward, some conceptions may be formed (in the absence of a true record, which can only be obtained by a laborious search through the "Commercial Lists" of the day) from the fact that during the year ending the 30th of June last, there were *seen* to pass the Cross Rip light-boat, stationed in Vineyard Sound, some 12 or 15 miles north-westerly from Great Point Nantucket, no less than 44,431 vessels of the four classes; a record, let it be remarked, that, in consequence of fogs and the absence of a rigid look-out must fall far short of the actual number that passed that station.

Confining the value &c., of the commerce to the authentic statements under the first two heads—that is, to those having reference to the foreign and whale trades—it appears that 6655 vessels of all classes, carrying in crews and passengers 296,676 persons, and valued with their cargoes at $268,452,750, and paying in duties $26,988,054 (being more than one-half the entire revenue of the country from this source), pass and are exposed to loss by these shoals in a single year. If to these results were added the number of vessels, with their value and the value of their cargoes, and number of persons, of the foreign trades from the 53 inferior ports already referred to, and from ports south of the Chesapeake as far as Cape Florida, and of that portion of the coastwise trade which takes the outside passage at Nantucket; and were also added the value of the precious metals and the number of outward-bound passengers of the foreign trade—the principal statistics of which have been given—it is not unreasonable to believe that a grand aggregate would be shown to prove that property of the value of a million of dollars, and lives to the number of one thousand, are put in jeopardy every day throughout the year by these dangerous shoals.

The foregoing statements and remarks give a general idea of the great importance to commerce of pointing out, at all times, the seaward verge of the Nantucket group of shoals. In other points of view, the subject presents itself in a manner, if possible, still more striking. Between the port of New York alone and Europe, there are, at this time, four lines of steamers. Some of these steamers cost, "all told," to put to sea, about $233 per ton; or, for one of the largest, say $675,000. By the present schedule of sailing, the four lines make altogether 136 trips annually, passing, of course, the Nantucket shoals as often, or at the rate of one steamer for little over every two and a half days throughout the entire year. The cargoes of these vessels hence for Europe—being made up, for the most part, of the bulky products of the country—are not (if the precious metals, of which they carried in the year 1851 $43,673,209, be left out of the account), comparatively, very valuable. On the other hand, those of the inward-bound steamers, consisting mainly, as they do, of the most costly manufactured goods, are generally of great value. This value seldom falls below a quarter of a million of dollars, and at times rises above a million of dollars; and, if the newspaper accounts may be relied upon, in one instance actually amounted to double that sum. As a general rule, it may be assumed that the cargoes of more than one-third of the arrivals are worth over half a million of dollars. From this account it will not be deemed extravagant to set down these vessels, with their cargoes, taking the inward and outward trips, at a value bordering closely on a million of dollars; the destruction of any one of which, if of the American lines, would cause a loss of a like sum to the wealth of the country at large. Again: of the 136 trips in 1851, 67 were homeward passages, at the close of each of which large sums were paid in the form of duties into the treasury. These duties —as often, probably, above as below one hundred thousand dollars—on two occasions, being those on the arrival of the *Franklin*, from Havre, in January and July, actually reached the enormous sums of $311,378 50 and $329,070 80, respectively. Thus it appears that, besides the very heavy loss the wreck of any of these steamers would cause the country, the receipts of the treasury would be seriously affected; in two instances, to an amount that, if the measure be at all practicable, would probably point out, for all time, the position of these dangerous shoals.

To the trade under the first head, the project in hand is of more importance, as involving larger interests than that under either of the other two, and to all of more value in regard to the homeward than to the outward-bound trade. The ratio of equality in the dangers which at present exist between the inward and outward bound trades, so far as these dangers arise from the Nantucket shoals, is owing, it will be remarked, not so much to the intrinsic difficulties of the navigation of the latter (unless, indeed, there are unknown currents in their vicinity, or erroneous estimates of the direction and velocity of those that are known), as to the absence of proper caution in that trade in making an offing. The striking of the steamship *United States*, on her last voyage to Europe, and the total loss, with her crew, during last winter, of the ship *Ivanhoe*, on these shoals, within little more than twenty-four hours' run from their port of departure, New York, would, no doubt, were the circumstances attending these disasters known, prove the correctness of this opinion; and of which the statistics of the losses generally of the outward-bound trade, could they be got at, would probably be a further confirmation. But of all the homeward-bound commerce, to that from European ports is the marking of these shoals a measure of the greatest importance. Fully to understand why this must be the case, it is only necessary to state that the usual course of this most valuable trade is to make Cape Race, the eastern point of Newfoundland, and then run down the coast inside the Gulf-stream, which, by the jutting out into the ocean of Nantucket and its shoals, here approaches nearest the land. The passing of the shoals is hence a proceeding of great peril, causing a corresponding anxiety to all who are engaged in this trade. Nor are the peril and anxiety confined to the navigators of sailing-vessels; they are largely shared, notwithstanding the more perfect means by "dead-reckoning," in the absence of the usual "observations," to determine the vessel's position, by those in charge of steamers, more than one of which, in the short period this class of vessels has been employed in transatlantic navigation, have been involved in the intricacies and dangers of these shoals.

The foregoing remarks upon the value of the commerce, and the dangers of the navigation described, sufficiently manifest, it is hoped, the great importance of the contemplated project. They might be readily extended and supported by further statistics, not only of the commerce proper, but of the losses of property and life. But this more properly belongs to the legislator than to the engineer, whose province it is rather to show in what way and at what cost, the work in hand, so essential to the safety of trade and of human life, may be accomplished.

New (Davis's) South Shoal is the most seaward shoal of the Nantucket group. It lies out of sight of land, south by east-half-east, broad off from the island of the same name, twenty miles distant. It is composed of fine white sand, quite hard and compact; the least depth of water on it at mean low water being 8 feet. The mound is stable, though no doubt subject to superficial variations, as all such alluvial formations are, particularly in situations exposed to the extremes of weather. The extent of the shoal within the two-fathom curve is one and a half mile, by a mean width of about one-eighth of a mile; and within the three-fathom curve two and one-twelfth miles, by seven-twelfths of a mile. The shoal falls off rapidly into deep water on all sides, particularly seaward, in which direction the soundings, in a distance of a mile and a half, increase to fifteen fathoms. As its general course is east and west, the currents, as already described, necessarily run most frequently more or less across it. It is exposed on the land side from north (Cape Cod) to west (Montauk Point), or throughout one-fourth of the circle, to a sweep of the sea varying from twenty miles to one hundred miles; and from the north, round by the east and south, to the west, or for the remaining three-fourths of the circle, from one hundred miles to the extreme reach of the broad Atlantic. The nearest harbours to the shoal by a steam line are Nantucket, 40 miles, Edgartown, 42 miles, and Holmes's Hole, 46½ miles.

There is no reason to suppose that New South Shoal is of recent origin. Like all the shoals forming the extensive group known as "the Nantucket shoals," it is the result of causes which have been in operation from a remote period. Whatever difference in age, if any, exists between it and the other shoals of the group, is wholly due to its greater distance from the land. That it has until late years been confounded with "Old South Shoal," is highly probable. Their size and depth of water, and comparatively near proximity, but, above all, the ever-varying direction of the currents in the vicinage of the shoals, and their positions out of sight of land, would seem to favour the correctness of this opinion. What previously was considered as one and the same shoal, has by the Coast Survey been found to consist of two distinct shoals; a result no less creditable or important from the labours of that great national work, than the discovery and marking of a new shoal.

It is doubtful whether, when its true character is reflected upon, and especially the exposure of the position, the depth of water and nature of the soil at the site, and its distance from land and a harbour, any project in the whole range of maritime construction has ever been entertained which presented so many difficulties in the way of its accomplishment, as the one under consideration. Such was my first impression, when, with only a general knowledge of the circumstances involved in the measure, the bureau thought proper to direct my attention to it; but my early impressions gradually became a settled conviction, under the influence of facts newly-developed, investigations anxiously made, and reflections consequently arising. While under such a persuasion, therefore, it would be affectation on my part, if I were to pretend that I feel no diffidence of my ability to solve so difficult a problem. If I may not recommend the true course to be pursued for consummating so great and important an undertaking, it will be truly regretted by me; but I shall have the satisfaction to know that I engaged in the task with a due sense of my obligations, and a single and earnest desire to do so, free from all bias for or against any particular system of construction.

Instances are not wanting of works founded at positions exposed to the extreme violence of the ocean, which have triumphantly defied its power; and among them may be especially mentioned the Eddystone, Bell Rock, and Skerryvore light-houses. But in all these instances the conditions under which the structures were raised, were widely different from those of the project which is the subject of this report. Those structures were founded upon rock, always or at times exposed above the level of the sea; they were less distant from land and a harbour, and open to the sweep of the ocean through a smaller arc. In these observations, far am I from desiring to undervalue the genius which designed, or the indomitable energy and perseverance which successfully raised, these renowned works. My desire is rather to express more emphatically my appreciation of the serious difficulties and hazards which are to be encountered in carrying out the project under consideration. The accompanying statement, made in the form of a table, will exhibit at a glance the "conditions" of each of the three positions or works just named, side by side, as compared with New South Shoal; extended, for future reference, to the cost and the time consumed in the erection of each work, those for the latter being, of course, only estimated.

No work of a solid character placed on a submerged sand at so exposed a point as New South Shoal, were it possible to found one, could long withstand the power of the ocean. That it would not be overthrown by the direct blow of the waves, the successful resistance of the works just named, at points where the inclination of the bottom and the depth of water are calculated to give greater force to the waves, prove beyond all reasonable doubt; but that its destruction would nevertheless be inevitable, from the rapid and ceaseless process of the wasting of the sands of the shoal, caused by the recoil of the sea from the mass, is no less certain. To provide a base of sufficient size and strength to sustain the necessary superstructure, that shall at the same time offer no very sensible obstruction to the free passage of the currents and the waves, is the great desideratum in founding works on submerged soils exposed to the batter of the ocean. This desideratum the last few years has supplied in the screw-pile of Mr. Alexander Mitchell, of Belfast, and in the pneumatic pile of the late Dr. Lawrence Holker Potts, of London. The next inquiry in order is, whether either of these modes is applicable to the site at New South Shoal. After much reflection, aided in no small degree by the experience acquired in the erection of the light-house on the Brandywine, I am of opinion that the first, being the method of screw-piles, cannot be employed to found a work at that point; and for these reasons:

1. That the screws could not be made to penetrate the shoal to the required depth, by any means applied from a *floating* body, moored in the tide and sea-way at the point in question.

2. That it is not possible to erect a temporary fixed structure during the working season at so exposed a point, at least in time to be available for driving the screw-piles; and,

3. That if it were possible to raise such a structure in time, it is doubted whether any power applied from it could insert the piles, to the necessary depth, into a sand so hard and compact.

The screw-pile has been successfully applied in forming foundations of light-houses on the Maplin Sands, mouth of the Thames; on the North Wharf Sands, mouth of the Wyre; on the shoal ground off Holywood, Belfast bay; and, in this country, on Brandywine shoal, mouth of Delaware bay. The attempt to erect a light-house on the north end of the Kish Bank, in St. George's channel, by means of these piles, failed, from no defect in the principle claimed for these useful appliances in forming submarine foundations, but principally, as it is understood, from the coming up of a heavy gale from the south-east before the piles were properly braced and the diagonal stays attached. The design to raise a beacon of screw-piles on the eastern end of the

Tongue Bank also proved abortive; but, as in the case of the structure on the Kish Bank, from no inherent defect in the piles themselves. This beacon was composed of five six-inch piles, and raised in position by the Trinity House. Shortly after it was put up, it was discovered that an accident had happened to it, and, on examination, it was ascertained that three of the piles were broken off short, and the other two bent. The stumps of the broken piles, and the lower parts of the bent piles, were found perfectly upright, and the sand around them undisturbed; showing the structure failed from no fault of the *hold* they had taken of the ground. Their condition indeed affords the best evidence of the capacity of the screw-pile on this point, as it appears the force that was sufficient to break off three and bend two wrought-iron piles of the size stated, was, at the same time, unequal to the task either of uprooting them or even changing their position in the bottom. As the force of the waves, acting on such small surfaces as these piles presented, was entirely inadequate to produce the effects described, the destruction of the beacon was sought for in other causes. The conclusion arrived at, at the time, and no doubt the correct one, was, that a vessel had passed over it; a conclusion in a measure confirmed by finding the copper of a vessel attached to the top of one of the bent piles. It may be remarked here, incidentally, that accidents from this cause form the only real objection, save the destructible character of the material, either to the screw-pile or the pneumatic-pile, and only then of works founded in navigable depths.

In every one of the instances cited of these constructions in England and Ireland, rafts or pontoons, or boats built expressly for the purpose, were used to receive the power employed to drive the screws. But the circumstances under which this operation was carried on were, in every case, widely different from those which would control it at New South Shoal. In no instance was the exposure as great, and in three much less, and in all the soil afforded greater facilities for penetration. An account of the several localities in question, so far, at least, as to include the characteristics which govern in such operations, compared with that already given of New South Shoal, will at once make this manifest.

The Maplin is on the West Swin channel, at the southeast point of the shoal ground known under that name, and about 4½ miles from the shore, where the Thames expands to a width of 20 miles. The site is bare at the lowest water of spring tides, and the " sand of the bank of an exceedingly soft nature." The soft character of the soil is very evident from the fact stated in the account of the erection of the light-house, that the nine piles, with screws as large as 4 feet in diameter, forming the base of the structure, were driven into the bottom from a raft, by 30 men, to a depth of 22 feet, in the short period of 9 days.—The Wyre light is also situated on a low-water bank connected with the land, from which it is but 1¾ mile distant. Though open towards the sea for a considerable arc, it is protected from its roll by large areas of shoal-ground, which lie off in that direction. One account states that " the bank was found to be sand, but of a much harder description than at the Maplin," and that the screws of 3 feet were " sunk 13 feet into the bank;" another, that the entire penetration was but 10 feet; the first 7½ feet being sand, the rest marl. It is scarcely necessary to remark that a soil may be " much harder" than one described as "exceedingly soft," and yet may not be very hard.—The light off Holywood is in 10 feet at low tide, within a quarter of a mile of a low-water point, and less than a mile of the shore off Belfast bay, where it is little over two miles in width; a position, certainly, of no great exposure. The soil is described as " hard sand and gravel for 7 or 8 feet, then soft tenacious clay." The screws employed were 3½ feet in diameter; but how far they were entered into the bottom the published accounts, as far as these have been met with, do not state. Materials uniform in size and homogeneous in character, form the most compact and impenetrable bodies. This is seen on a large scale in the greater stability of the sea slopes of breakwaters, formed of masses of stone of a uniform size, over those composed of stones of different sizes, and in the greater firmness of the road-bed of M'Adam, of which it is the leading principle, compared with the roads previously made. The same rule applies in a measure also to soils, and will afford the best criterion by which to judge of the facility these screws, or indeed any other form of body, may be thrust into them. Had that composing the site off Holywood been all of sand, or all of gravel of uniform or nearly uniform size, the penetration by the screw would no doubt have called for a much greater power than it is understood was used on that occasion, or, what is the same thing, the same power, if applied afloat, applied from a fixed basis. As it was, the separation of the larger bodies by the smaller ones afforded facilities, by the latter acting as so many minute rollers on the former, not only to enter the screws into the soil, but also to accelerate their descent to the depth required.—The Kish Bank, at the site of the light that was proposed to mark its northern end, is about 11 miles from the main land, with a depth of 13½ feet at low water, and a rise of tide of 13 feet. The bottom is represented as consisting of " sand of an exceedingly hard and dense description." The screws were intended to be planted 12 or 13 feet in the bottom, but it was found impracticable, with the means employed, to penetrate the bank to a greater depth than 9 feet.—The Tongue Bank, or Sand, is at the mouth of the Thames estuary, and hence more exposed than the Maplin, which, besides having the protection of a greater extent of shoal ground seaward, is some few miles further removed from the ocean. The position selected for the proposed beacon was on the eastern end of the bank, in 17 feet water (another account says 9 feet) with a rise of tide of 15 feet. The screws, which were but 2 feet in diameter, it is stated, were sunk into the soil, described as " ground exceedingly hard," to the depth of 17 ft. 9 in. It will be remarked that the exposure and depth of water in the last two instances are much greater than at the positions first named. How it was possible in these cases to apply an adequate power from a floating body (under the circumstances more difficult to maintain in a given position), to insert screws of the size used, to the depths stated, in soils such as those described, it is difficult to conceive. The only way to reconcile what otherwise is inexplicable, particularly to those having any experience in such operations, is to take the expressions applied to the soil, as in the case of that of the site of the Wyre light, in a *comparative* and not a *positive* sense. This probably is the true explanation, and accounts for whatever success attended the attempts to apply the screw-pile at the Kish Bank and the Tongue Sand; an explanation in a measure confirmed by the fact that the piles in the case of the former, though buried up for a depth of 9 feet, could not stand alone, or, in other words, that the soil, under the action of the sea, on even so small a surface as the shaft presented to it, was, from its soft nature, incapable of sustaining them.

It is evident from these statements, that in all the cases mentioned, the soil, if not *absolutely*, was *comparatively* soft, and that this characteristic alone admitted of the employment of floating bodies from which to apply the power in driving the screws. At the Brandywine the employment of the same means would have signally failed. The preliminary examinations of the shoal gave palpable evidence—which, if possible, was more than confirmed by the subsequent operations—that a more stable footing would be required; for so far from being able, with such means, either to give the piles their proper relative positions, or to sink them to a depth which at that point would have secured the stability of the superstructure, it is doubted, indeed, whether they could have been inserted far enough to be able to stand alone. If this be true in regard to the Brandywine, it will hardly be contended that the application of the same imperfect means would meet with better success at New South Shoal, where the circumstances (excepting the character of the bottom, which, judging from the specimens and *feel*, may be considered of the same description) of distance from the land, and a harbour exposure and depth of water, &c., increasing the sum of the difficulties attending such operations, are greatly exaggerated.

The experience at the Brandywine is alone relied upon in support of the opinion contained under the second head. The fixed structure or platform at that point stood 19 ft. 9 in. above the shoal, and was 55 feet square, with a projection at one corner, in all forming an area of 3587 feet, and consumed 74 days of the working season of that locality in its construction. At New South Shoal a structure of the same description, large enough for the intended purpose, would have a floor of about 80 feet square, and an area of about 6400 feet, and would be elevated 38 feet (as will be shown hereafter) above the bottom—that is, it would be about double the area and height, and three and a half times the cubical dimensions, estimated from the surface of the shoal in each case, of the one on the Brandywine. Whether the time required for the erection of two structures of the character of those in question, would, under like conditions of exposure, &c., be as the areas of the floors and the heights from the bottom, or as their cubical contents above that plane, is a question of which the present experience in such operations affords no satisfactory solution. It is enough, however, for the present purpose, in the absence of any definite rule on the subject, to show that—assuming even the most favourable view of the case, and taking no account of the greater exposure and depth of water, and the increase of distance from 13 to 42 miles of a harbour of refuge in the case of New South Shoal, and conceding also that proper skill and due diligence were exhibited in the operations at the Brandywine—it would not be possible to raise the required structure at that point within the season of operations (limited in that latitude to five months, from May to September inclusive, or 153 days), and leave sufficient time either to perform the final operation of inserting the screw-piles, or to make up losses of time contingent upon all similar undertakings exposed to delays from vicissitudes of weather.

Neither is it probable, as stated under the third head, that recourse to a fixed structure, such as was employed at the Brandywine, were it possible to erect such a one on New South Shoal, would prove successful, except in giving the piles their true relative positions, and this for the reason of the great elevation above the point of resistance of the mechanical power, which would be so far spent in the mere torsion of shafts of so elastic a material as wrought-iron of the length required, as to prove unequal to the due penetration of a sand as hard and dense as that which is described to be at the point in question. The elevation at Brandywine shoal was 23 ft. 9 in., made up as follows: 6 feet for depth of water at lowest spring-tide; 7 ft. 6 in. for rise of highest tides observed (12 feet being the rise of storm-tides); 6 ft. 3 in. for height, including 2 ft. 3 in. for thickness of platform above highest tides observed; and lastly, 4 feet for height of the capstan-drumhead employed to drive the screws above the floor of the same. It was the original intention to insert the screws in the shoal for a depth of 15 feet; but it was only after the most strenuous exertions, with a force of thirty men working the mechanical power above mentioned applied to a spur and pinion wheel attached to the shafts of the piles as low down as the water would permit, that they were buried up in the sand for a little more than 10 feet.

At New South Shoal, the measurements that would go to make up the distance between the point of resistance and the point at which the power is applied, considered with the size of the shaft as the governing condition in the case, are greatly increased, as will be seen from the following statement. The depth at low water at the point proposed to occupy on the shoal is 14 feet, the extreme rise of the tide 6 ft. 9 in. A platform beyond the reach of the sea should not be less than 15 feet above the level of the highest water, as the waves, by striking against the many vertical obstructions presented by the wooden piles forming the temporary structure, might, at the limited depth named, be thrown upward against the floor of that platform in such masses as to endanger its safety. Thus, the height of the platform, including 2 ft. 3 in. for the thickness, would be 38 feet; add to this 4 feet for the height of the capstan-drumhead above the platform, and the whole height is increased to 42 feet, being also the least distance between the points of resistance and application of the power, and, as a consequence, the least length of shaft through which the power to drive the screws must be exerted—a length that would seem sufficient, in view of the experience at the Brandywine, to defeat every effort, notwithstanding the increased size of the shaft to 12 inches, to insert them to a depth to insure the safety of the superstructure.

The pneumatic pile of Dr. Potts is of more recent origin than the screw-pile, or, at least, has not been so long known to the public. It has not yet, it is believed, been successfully applied in founding works, such as lighthouses, beacons, harbours, &c., exposed to the sweep of the ocean. That it is practically applicable for the purpose there is every reason to believe. The favourable opinion of those well known in engineering and construction in Great Britain, communicated in the report on the ice-harbours of the Delaware, dated the 28th December last, may be received as conclusive, particularly as it is supported by cases of application already made in other, and in some respects kindred works, on this point. To this testimony and to these cases the bureau is again referred for all the information in possession of this office upon the subject. Of the latter, it is deemed sufficient for the present occasion to recount merely the following instances in which these piles have been used, to show that their size, both length and diameter considered, would seem only limited in their application to the power under the circumstances to handle them. Besides being employed, among other instances, in the founding of the piers of a viaduct in Anglesey over an arm of the sea, the bed of which is of running sand and gravel of great depth; in an experiment on Grain Spit to test the powers of the pile to sustain great weights; in the sinking of a pile of large dimensions in a quicksand in Cornwall; in the construction of a bridge over the Thames at Datchet; and in the foundation of part of a large viaduct on the Holyhead line of railway, a pile of this description, 3 feet in diameter, has been sunk in the Goodwin Sands to the depth of 77 feet, to the chalk formation; and others of the enormous size of 10 feet diameter, as cofferdams, in the construction of the Midland Great Western Railway bridge over the Shannon. To this list may be added the new bridge over the Thames from Putney to Fulham, in which the piers will be formed of four cast-iron cylinders 8 feet in diameter, carried to such a depth as not to interfere with the dredging of the river. It is proper to remark here, that other applications of both the screw-pile and pneumatic-pile either in constructions or in experiments, may have been made and noticed in the publications of the day, particularly in periodicals devoted to such and kindred subjects; but as these, in consequence of the restrictions upon the purchase of books, are only occasionally accessible, and then through private sources, nothing is positively known as to the fact.

The objection to screw-piles for founding a work at New South Shoal does not apply—except as to giving them their true relative position—to pneumatic-piles, which, being sunk into the bottom by atmospheric pressure caused by exhausting the air from the hollow shaft, the erection of a fixed structure, such as that required to apply the mechanical power to drive the former, is dispensed with, and the objection to the great length of the pile through which this power must be exerted, at the same time got rid of. But it must not be supposed, that because a fixed structure is not indispensable, a floating body is deemed sufficient for the successful application of atmospheric piles in the present instance. This is not the case. That these piles may be planted singly in favourable weather at so exposed a point as New South Shoal, by well-devised measures fully matured, from so unstable a footing as a floating body, the sinking of the cylinder on the Goodwin Sands is of itself abundantly sufficient to prove; but that the number of piles required to constitute a foundation for a lighthouse or beacon may, under the circumstances, be made to receive their proper relative positions, so far at least as to render them properly available for the intended purpose, is not believed. The manner in which it is proposed to provide against this objection in the use of the atmospheric pile in the present case, or at other points of equal exposure, will be explained in the project now submitted.

Having premised that though a solid structure at New South Shoal, were it possible to erect one at that exposed point, might withstand the direct assaults of the sea, it nevertheless would be overthrown by the wasting of the sands on which it stands, through the insidious workings of the waves acting on the mass, and that to meet the case, it would be necessary to adopt a foundation; which, while it afforded the necessary area and strength to support the required superstructure, would offer no impediment, practically considered, to the motion of the currents or the waves; having also expressed the opinion that works combining these pre-requisites may be founded on submerged soils by means of Mitchell's screw-pile and Pott's pneumatic-pile—and further, that for reasons which it is conceived are indisputable, the former cannot be applied to that use at New South Shoal—the bureau will already be prepared to learn that, as the practical application of the latter is not open to the same objections, it is recommended for the present design.

The instructions of the bureau calling for a plan and estimate for a beacon on New South Shoal are predicated on so much of the "Act making appropriations for lighthouses, light-boats, buoys," &c., approved March 3, 1849, as is contained in the following words, to wit: "For a screw-pile beacon or other practicable structure on New South Shoal, off Nantucket, discovered by the survey of the coast, $25,000, to be expended under the direction of the Bureau of Topographical Engineers." A plan and estimate for a beacon are accordingly herewith submitted. Considering, however, that a beacon would mark the shoal during the day only, and that the risks and dangers of navigation are more imminent and numerous at night, and especially during the boisterous season, when the nights are longest, it has been deemed advisable, in anticipation of the approval of the bureau, to prepare also a plan and estimate for a lighthouse for the same point. In doing this, less hesitation has been felt, because, in the erection of any work at a position so exposed as the one under consideration, the only real difficulty consists in establishing the foundation; and because the greater cost of a lighthouse, although certainly considerably more than for a beacon, bears no sort of reasonable comparison when the superior and continuous usefulness of the lighthouse is considered. It was also conceived that the plan might be so arranged, that in case the beacon structure should be adopted, and should, when raised, be found competent to resist the shocks of the ocean, the project of a lighthouse might be finally executed. In contemplation, therefore, of that ultimate object, the dimensions of the proposed beacon, in general and in detail, have been enlarged beyond what might be otherwise considered sufficient; but whatever may be the excess thus caused in the estimate for the beacon, it is confined almost wholly to the foundry cost of the structure. In other respects, unless the size of the work should be greatly reduced, the expenses, excepting those in which time enters, would remain nearly, if not quite, the same.

As the two structures, as already stated, are in part common to each other, a description of the lighthouse, as the larger of the two, will, with occasional reference to the beacon, be sufficient for both.

The foundation is composed of iron piles, so grouped together as to form an octagonal prism 50 feet in diameter, and about 42 feet in height. From this prism, as a base, rises a truncated pyramid, composed also of iron piles, which inclining inward 6 on 1, for a further height of 120 feet, fall within the diameter of 10 feet, and are received and secured in a great ring-piece, which, in turn, is surmounted by the watch-room and lantern, making the whole height 185 feet. The piles, one at each angle, and one at the centre of the octagonal prism, are of 12 inches; those of the truncated pyramid in three lengths of 12 inches, tapering to 6 inches. The entire structure, including the prism for the length of the piles, is braced horizontally in seven planes, and diagonally between every consecutive two of these planes, except where the dwelling of the light or cage of the beacon, as the case may be, interferes, when these are in part omitted. The dwelling stands 40 feet above the highest tides, is composed of three stories of 9 feet each, and communicates with the watch-room and lantern above by a spiral stairway in a column of wrought-iron 8 feet in diameter. The two lower stories are 30 feet, and the upper story 20 feet in diameter; the first and third stories, as well as the roof of the dwelling, and the watch-room and lantern, being surrounded by galleries. The watch-room and the lantern are 12 feet in diameter; the former 6 ft. 9 in. in height, the latter about 12 feet, with the roof and ventilator, &c., 20 feet in height. The beacon occupies but two of the three lengths of piles forming the pyramidal frustrum of the larger structure. The cage, the bottom of which is elevated 60 feet, and the extreme top 108 feet above the level of the highest water, is composed of columns arranged in the form of a cylinder, 24 feet in diameter and 24 feet in height, surmounted by a canopy, giving it a further height of 24 feet.

These are the outline or main features of the two structures. The details will be better understood from the drawings communicated herewith, than from the most lengthened and minute description. They consist of an elevation and vertical section of each work on a scale of 4 feet to an inch ($\frac{1}{48}$), and sixteen sheets of details on the same, and double the scale; and will show, not only the manner of bracing proposed, but also the character of the cage, the arrangement and finish of the dwelling, and passage thence to the watch-room and lantern of the latter; and also the arrangements for securing the boat for taking in stores; the position of the fog-bell; the keeping of the oil, water, and fuel, &c.. &c.; and all other particulars, even to the size of the material employed, &c. Talbotypes of the elevation and vertical section of each, reduced in scale to about $\frac{1}{152}$, are also appended to the report.

It is now necessary to explain in what manner it is proposed to establish either work on the shoal. It was stated, when describing the applicability of screw-piles and pneumatic piles for founding the proposed structures, that as the latter required no mechanical force to insert them into the bottom, the employment of a fixed staging, from which to apply such force as was required in the use of the former, would be unnecessary; and that although a floating body might, by well digested measures, in favourable weather, be successfully employed in sinking them singly, it would not be practicable to give the number of piles required to found the work their proper relative positions from so unsteady a footing. The utter hopelessness of constructing a fixed platform, under the circumstances, at so exposed a point as New South Shoal, at least by such time in the working-season as to render it available for the intended purpose, was also shown. What other course, then, shall be adopted in the emergency? It is, in my opinion—not lightly formed—to carry out and deposit on the shoal, by one bold measure, the entire lower or foundation portion of the structure described as the octagonal prism, and by Dr. Potts's process, so simple in its character and wonderful in its results, to sink it in the sand to the required depth. It will not escape attention, that in taking this course, the necessary bracings, down to the very level of the shoal, will be secured to the work; whereas, in putting down the piles separately, the attaching of them is barely possible under the most favourable circumstances, at so exposed a point.

The foundation or lower portion of the structure, already in part described, is formed of nine piles, occupying the angles and centre of the prismatic figure, bound together by two sets of horizontal braces—one 20 feet from the bottom, the other at the top—and by three sets of diagonal braces between these planes. It is necessary to state here, that the lower part of each pile is received by a cylinder having a conical base or foot, through which, by a separate pipe, provided for the purpose, extending to the top of the framing, it is designed to excavate the sand by the pneumatic process. By this arrangement, the advantages of the two systems—of the screw-pile and the pneumatic pile—have been combined; the means, on the one hand, by which the soil may be penetrated to the required depth, and the use, on the other, of a shaft, presenting, with a proper bearing, the least exposure, strength considered, to the action of the sea. For the character of this arrangement, and for all other details, reference is respectfully made to the model of the foundation section, on a scale of $\frac{1}{24}$, which will be deposited in the bureau. The work, as designed, including the cylinders with the conical bases to receive the solid piles, and all necessary appendages, such as air-pump and receivers, and air and sand piles, &c., &c., for sinking it into the bottom, weighs 238 tons. To receive and float this great weight, distributed as it is throughout such large bounds, will require twin-camels, each at least 100 feet in length, 15½ feet beam, and 10 feet depth of hold, or say about 160 tons. These camels, when light, will draw little over 3½ feet water; and when loaded, about 7 feet. Carrying the foundation as proposed, with the lower set of horizontal braces resting on the rail, the cones or shoes of the cylinders will extend nearly 4½ feet below the keels. In this same position, 61 tons of the weight will be suspended below, while the balance, or 177 tons, will stand above the rail. It will be time enough, should the present design be approved and ordered to be carried out, to digest all necessary details, to insure a full efficiency to the camels; to determine whether they shall consist, as now proposed, of two similar vessels of the ordinary model, or of two having, when combined, the general outline of a single vessel; the most perfect way of securing them to each other, and to their burden; the best arrangement for towing, mooring, and flooding; and, finally, the proper mode of removing them from under the framing when it rests in position on the shoal. It is even now evident that it is desirable so to modify the lower framing that a larger proportion of the weight may be carried below the body of the camels than the present arrangement provides for. Again, it further appears, as far as experiments with the model may be relied upon, that to insure the uniform descent of the foundation, it is necessary to have either an air-pump for each pile, or, if one air-pump only is used, to communicate with the soil-receivers by air-pipes of equal lengths. The weight on each pile, when resting on the bottom, is 26·2 tons, which distributed over 19·6 feet, the area of the base of the cones, 5 feet in diameter, gives 1·33 ton for each foot. The entire weight of the lighthouse structure is 640 tons; of the beacon, 466 tons; giving 71·1 tons on each pile, or 3·6 tons on each superficial foot in the case of the first, and 51·6 tons on each pile, or 2·6 tons on each superficial foot, in the case of the second work. To sink the cylinders 19 feet in the sand, the depth proposed, will require the raising in each case of a column of sand of that height, 5 feet in diameter, or 373 cubic feet, or about seven times the contents of the receivers, calculated at 54 cubic feet. As there is, however, a large admixture of water with the sand, raised by pumping, the descent of the cylinders will necessarily call for the filling of the soil-receivers much more frequently.

In recommending the carrying out of the foundation in one body to the shoal, the hazards which belong to the entire proceeding, from the departure of the camels with their burden from

the selected harbour, to their arrival, and the complete establishment of the work at the site, are, it is believed, in no wise underrated. So far from this being the case, it is not improbable that, by dwelling on the subject, I may have rather magnified them. The towing the camels in a sea-way with their load, a large portion of which is, on the one hand, high above their decks, and on the other, far below their water-line; the placing, and then securely mooring them at the selected site; the flooding the camels, and then relieving the foundation, on resting on the bottom, from them, without injury from the heave of the sea to either, particularly the former; and, lastly, the sinking of the piles by the pneumatic process, are all operations, under the circumstances, of much delicacy, liable to great risks, and, as a consequence, involving the issues in much uncertainty. The velocity and ever-changing direction of the currents at the site, and through the group generally; the exposure, and the distance of the shoal from the land; and, above all, if it be possible to draw a distinction where each controlling condition holds so important a place, the distance of the point of destination from

a harbour, all go to show that the difficulties and dangers of the operation are of no ordinary character. As its success depends on the vicissitudes of the weather, that is the true turning-point in carrying out the final design. But in making these observations, I desire also to say, that, in my opinion, the question is not, as in most cases, a mere selection from several plans, but is reduced to the alternative of adopting the plan now suggested as the only one that has a chance of success, or the entire abandonment of the design, to mark the position of the dangerous shoal in question.

The plan of operations for the erection of the lighthouse calls for four and a half years, thus distributed: one year and a half in constructing and setting up and taking down the work at the foundry, and transporting it to the selected harbour of refuge and departure; the first season at the shoal in establishing the foundation section at the site: the second season in raising and bracing the pile-framing, and forming the iron work of the dwelling, &c.; and the third and last season in finishing the interior of the dwelling, &c., completing the lantern, and setting up lighting apparatus, constructing hoisting-davits, &c., putting up fog-bell and striking-machinery, water and oil-tanks, &c., furnishing, painting, &c., and lighting. The plan of operations for the erection of the beacon covers three years, employed as follows: one year at the foundry in forming structures, &c.; the first season at the shoal in fixing the foundation section; and the second and last in building up and bracing the framing and forming the cage, &c.

Conceiving, as already remarked, that the placing of the foundation constitutes the main obstacle to a successful issue to the proposed project, a description of the operations to carry it out will be confined to an outline of what would probably be the course in regard to that measure. It is necessary previously, however, to state, that although there is as little as 8 feet at low water on the shoal, and an area of considerable extent within the two-fathom curve at the same stage of the tide, it has been thought advisable to design the work for a point in a depth of 14 feet on the land-side, and midway of the length of its crest, which standing in the relation somewhat of a breakwater, will afford a partial protection to the work against the deep-sea wave. It should also be stated that as Nantucket, the nearest harbour to the shoal, has but 6½ feet at low water at the entrance, Edgartown, the next nearest, with 15 feet at the same stage of the tide, is selected as the harbour of departure and refuge in the proposed undertaking.

The precise site of the work on the shoal having been marked out by disc-buoys, having mooring anchors laid down, &c., and the double section composing the foundation put together on the camels, a favourable state of the weather, with the wind offshore, should be taken to set out from the harbour—so timing the departure as to reach the shoal, distant, as already stated, forty-two miles, by the dawn of day. The time required to make the trip will depend, of course, on the speed at which the steam-tugs can tow the camels with their burden. This will probably be found to be somewhere between three and a-half and seven miles per hour; but this point should be settled previously, by one or more experimental trips off the mouth of the harbour. These trials may also be found necessary to ascertain how the camels carry in a sea-way, so as properly to adjust the burden on them, &c. As the draught of the foundation structure, as carried on the camels, is less by 2½ feet than the depth at low water at the point at which it is proposed to found the work, the arrival at the shoal need not be governed by the stage of the tide, though high-water is preferable, as all other conditions being the same, the swell of the sea, in consequence of the greater depth is then least. Having arrived at the shoal, the operation of depositing the foundation at the site is one which, in case the weather continues propitious, should require but little time to accomplish. As the plan of the work is based on a regular figure, and may consequently take any position relatively with the shoal, the steam-tugs should tow the camels into place on the direction of the current as it then runs, when the anchors will be let go, and the other appliances prepared for the purpose put in requisition, to moor them as immovable as the circumstances of the case will admit. The next proceeding in course is to flood the camels, and bring the foundation on the bottom, when the former may be drawn by the steam-tugs from beneath the latter. A full and well-instructed force, already occupying the work, will then commence sinking the structure by the application of the steam air-pump, by excavating the sand under the piles through the tones forming their feet, and continue vigorously to prosecute the operation until it descends to the required depth. Twenty-four hours of favourable weather, would, it is confidently believed, suffice for the complete and satisfactory accomplishment of this most novel proceeding; and even half that time to place the work in safety on the shoal against any ordinary contingency of weather, in case the state of it at the time should prevent the sinking of the cylinders. The great breadth of the structure compared with its height, and the absolute regularity of its figure, combined with its enormous weight, and the smallness of the surface exposed to the blow of the sea, all go to warrant a confidence in this belief.

Estimates for the light-house, as well as the beacon, accompany the report. They consist in each case of a synoptical estimate under distinct heads, with references to corresponding subordinate estimates, running much into detail.

It has been earnestly desired, by tracing closely the probable course of the operations, to arrive at the true cost of carrying out the designs submitted. No exigency that seemed likely to arise has failed to be noticed and provided for; and hence the opinion is confidently entertained, that either work, if at all practicable, may be executed for the sum set down for it. It may excite surprise that this assurance should be given, when the aggregate in either case is so large. But when the position and character of the locality, and the extraordinary circumstances under which the operation must be carried on, are fully understood and fairly weighed, this feeling it is believed, will give place to a fixed conviction, that though made up from data as full as the nature of the case would permit, they in no wise exaggerate the probable cost. That the large expenditure called for to consummate the more complete design of the two would be justified by so large an expenditure as that named, the valuable interests that would be subserved by it, as set forth in part in the present report, it is presumed, will generally be admitted.

Of the three great light-houses, Eddystone, Bell Rock, and Skerryvore, the last only was built after the introduction of steam navigation. Mr. Alan Stevenson, the engineer, in his account of the construction of the Skerryvore, says: "From the extent of the foul ground round Skerryvore, and the absence of good harbours in the neighbourhood, it was foreseen at the outset that the operations of landing 6000 tons of materials on the rock could not be accomplished by means of sailing-vessels, with that degree of certainty and regularity which was desirable, in order to obtain the full benefit of the short working-season which the climate of the western Hebrides affords, and the necessity for providing a steam-tender was therefore generally admitted." Again: "The use of a steamer at the very outset of the works would doubtless have proved of the greatest service in the erection of the barrack on the rock, and would have materially lightened our cares and toils; but I am not sure that I should have acquired so thorough an acquaintance with the difficulties and dangers of the Skerryvore, or that I should have been so well prepared for all the obstacles that presented themselves in the after parts of the work, had the first season's operations been conducted under those advantages which are always derived from the use of steam-power. As it was we had much to bear from the smallness of the light-house tender, named the *Pharos*—a vessel of 36 tons, new register—which was all the regular shipping attendance we possessed during this first season; and the inconvenience arising from her heavy pitching was, to landsmen, by no means the least evil to be endured. But the frequent loss of opportunities, of which we might easily have availed ourselves if we had possessed the command of steam-power, and the danger and difficulty of managing a sailing-vessel in the foul ground near the rock, and between it and Tyree, were, perhaps, even more felt by the seamen than by the landsmen; and if the experience of a single year's work can form any ground for an estimate of the length of time required for building the Skerryvore light-house with a sailing-vessel, I should say we must still (even in 1845) have been engaged in the masonry part of the work, which was finished on the 25th July, 1842." The steamer employed at Skerryvore was of 150 tons, with two engines of 30-horse power each, and cost completely fitted (5930*l.*) $29,650. An alteration in the engines by raising the shafts, &c., increased this (423*l.*) $2115. Repairs on the hull and engines during the progress of the work (1057*l.*) $5285. Sailing expenses (6001*l.*) $35,005, or for each of the four years, 1839 to 1842 inclusive, $8751. This includes, it should be remarked,, coals supplied the different departments of the works, and also the smiths' forge.

If, according to Mr. Stevenson, the employment of steam was a matter of economy in time, and, as a consequence, in money, in the operations at Skerryvore, with a harbour of refuge comparatively near at hand, and after the first season a barrack on the "rock" for the accommodation of the workmen, it will not be denied that even a greater pecuniary saving would follow from the employment of the same auxiliary in the operations at New South Shoal, a point 20 miles from the land and 42 miles from a harbour, and no footing on which to establish a residence short of the final structure. The principal duty of the steamer at Skerryvore was to tow the vessels carrying the 6000 tons of stone forming the structure. At New South Shoal the call for transportation, even for the larger work, would be but 640 tons of iron, including the 238 tons proposed to be carried out in one body in the foundation. But, on the other hand, it is necessary to provide a residence for the workmen at the shoal, a position at which can be held not only longer, but be more promptly re-occupied after a storm—the very time, too, when the weather is generally most favourable—by means of steam. A receiving-steamer is accordingly provided for; and that she may not be obliged to leave her station except from stress of weather, a steamer of the smallest class considered safe, to ply as a tender between the shoal and the shore, to carry materials, provisions, water, &c., &c., is also added. These steamers should be propellers, which, besides being less costly to build and to run, are more roomy and have flush decks and sides, and hence better adapted to meet the exigencies of the required service.

Although the range for an elevation of 137 feet (the least height by the design of the focal plane above the level of the sea), and the deck of an ordinary size vessel, is quite within the powers of the second order of lenticular lights, it is deemed advisable, in view of the importance of apprising navigators of the position of the shoal at the earliest moment, to provide in the estimate for one of the first order, which by the increased volume of light may not only be seen under a less favourable condition of the atmosphere, but also be distinguished aloft from ships of the largest class when actually below the horizon. The difference in the first cost of the two orders is about $3000, the difference in the maintenance about $350, annually—confined in the present instance, from the character and isolated position of the light, requiring no larger force, to the greater consumption of oil—say 250 gallons—and the slightly increased cost of the smaller accessaries.

I have been assisted in the preparation of the designs of the two works by Mr. William Dennison, of Boston. Besides very many of the details, the arrangements by which the piles are received in the great ring-piece which encircles the stairway cylinder, thus giving them the character of reciprocal tension braces, and the tapping of the cones at the base of the cylinder-piles, through which and a separate pipe the soil is raised, thus admitting of introduction of the solid piles into them before being inserted into the bottom, are both due to his intelligence. The drawings were also made by him. It will not be expected that the details shall not, to some extent, require modification. These it will be time enough to consider and make on the preparation of the necessary working-drawings in case it be determined to carry out either. The propriety for some changes is even now apparent: among these, for instance, the reduction of the weight of the great ring-piece just mentioned, as far as may be compatible with proper strength, and the removal of the soil-receivers and their pipes within the area of the base. Neither is it at all improbable that further investigation and reflection may induce a change or reduction to some extent, or both, of the diagonal bracings, which, by their number and near approach to each other, may cause the ice to form, particularly in the series just above the level of the sea, in such masses as to endanger the safety of the structure. At present these braces are of three kinds: one set in the faces of the octagonal prism or truncated pyramid, as the case may be, called in the estimate *panel;* another set in planes, whose horizontal projections are as radii of those figures, called *radial;* and a third set, forming an endless rod, taking hold in succession of every third pile and alternating between two consecutive series of spider-web bracings, called *chord*—these last serving both as tension and torsion braces.

Besides the plan already noticed, I beg to call attention also to a small tripod beacon designed to be thrown entire on a shoal. The feet are formed of inverted cones, having discs increasing in size upwards, and so inclined as to be parallel with the horizon, which there is good reason to believe would, under the action of the currents and the waves on the sand, sink not only uniformly, but sufficiently deep into the bottom to give the work, from the small exposure of the superstructure to the same action, the necessary stability. As it is with a view merely to call attention to a measure that may possibly lead to future useful results, and as the present plan is not free from serious objection in the details, no estimate either of the weight or cost has been prepared. The entire height of the beacon above the water is about 70 feet; the size of the cage 17½ feet by 8½ feet.

While on the subject of establishing sea-marks by so summary a process, I trust I may be excused for suggesting the trial of disc-buoys to mark to some slight degree of usefulness the principal shoals off Nantucket. These buoys have been used by me in hydrographical surveys now for some years with the most satisfactory results; among the last occasions at the Tortugas, where, though but of 100 lb. in weight and 21½ inches in diameter, and with a wooden staff, they stood immovably on the outer side of the reefs, exposed to the roll of the sea from the Gulf. Buoys for the experiment should, with the same general form, have greater weight—say 250 lb. to 500 lb., with a tapering iron staff, or one of round iron of diminishing sizes, properly coupled, and surmounted by a flag attached to a light iron, vane-like frame. The first cost of a buoy such as described of 250 lb., would not exceed $25; of 500 lb., about $35. A tracing of a buoy of this kind, with a disc of 500 lb., is forwarded herewith.

In addition to the drawings and papers already mentioned, a coast-survey sketch of the Nantucket group, scale $\frac{1}{400000}$; a coast-survey MS. tracing of New (Davis's) and Old South Shoals, scale $\frac{1}{40000}$; coast-survey charts of Nantucket, Edgartown, and Holmes's Hole, and a chart (Blunt's) of the coast from Absecum Inlet to the Penobscot, showing the general contour of the coast and the relative position of these harbours with New South Shoal, are also forwarded, as necessary to a proper understanding of the report.

I beg to make my acknowledgments to Professor A. D. Bache, Superintendent of the United States Coast Survey, for copies of charts of Nantucket, Edgartown, and Holmes's Hole, and of a sketch in part (MS.) of Nantucket shoals, and for information in reference to them, used in the preparation of the present report. I am likewise indebted to him for facilities, through the steamer *Bibb*, engaged in laying down the group, to examine New South Shoal; and also to Lieutenant Commanding C. McBlair, of that vessel, and his officers, for their attention in furthering the object of my visit; and likewise to Lieutenant Commanding McBlair, for a copy of the weather-journal of the *Bibb* for 1847, 1848, and 1849. It is proper I should also express my acknowledgments to the several collectors of the customs of the ports named in the statements herewith, for their prompt response to the call made on them for the commercial statistics they embody.

The delay in the presentation of this report was occasioned, in the first instance, by other and more pressing duties; and since then, by the time required to prepare the model, drawings, (including the estimates), and to obtain the necessary commercial information which accompanies it.

HARTMAN BACHE.
*Major Top. Eng, Bvt. Major.*

*Office of New South Shoal Beacon,*
*Philadelphia, Dec.* 27, 1851.

[Next month we purpose giving the synopsis of the estimate; the estimate for lighthouse; the estimate for beacon; detailed estimate for materials and labour of both lighthouse and beacon; estimate for patterns and pneumatic apparatus; &c.]

---

*Mr. Samuel Phillips.*—This gentleman, the editor of the 'Hand Book to the Crystal Palace,' died suddenly at Brighton, on the 14th ult., from hemorrhage of the lungs, in his 39th year. Mr. Phillips was a well-known writer in *Blackwood*, the *John Bull*, *Morning Herald*, and other Conservative publications. He had been long suffering from consumptive symptoms, but resolutely persevered in his literary labours to the last. The readers of *Blackwood* are probably aware that to Mr. Phillips's pen they were indebted for 'Caleb Stukeley,' a tale abounding in powerful passages, and displaying genius of no ordinary character. To the *Times* it was generally understood that Mr. Phillips contributed those literary critiques which usually enriched its columns in the winter season. Their greatest merit was the masterly analysis they presented of the mode in which authors produce their effects. In this species of exposition, Mr. Phillips had no superior.

## ADDRESS TO THE ARCHITECTURAL ASSOCIATION,

Lyon's-inn-hall, October 6th,

By Thomas M. Rickman, *President.*

In rising to fulfil the customary duty of your President this evening, I address those who, like myself, engage in the study of our art, not merely with the view of passing a lifetime in its practice, but of deriving pleasure from the pursuit, and, as I trust, satisfaction from some future retrospect of progress.

Those of us who are young desire to advance in knowledge, and also, looking at certain bright examples of architects, as well in times gone by as in our own day, we would find in architecture what we see that they have found—that element which shall become a link between ourselves and all the men of higher aim in the pursuit of truth and beauty, and, while we exercise a calling inseparable from the regular routine of business, shall prove an element enabling us to feed that taste, which, dependent principally on what is set before it for character, is yet possessed of an elective faculty that finds charms in the really beautiful unequalled by any other attraction.

Those who have passed through our stage of study will remember that there was in such aspirations a pleasure which was a relief to their more studious hours, and, while proving a recompence to their labours, became at the same time an incentive to continued exertion.

The present, however, is not the time to address a meeting of the rising members of any profession on the mere sentiment of their occupation. I have no hopes of impressing on the mind of any (if such there be) insensible to beauty or truth, the fact that such exist; but I would call to your remembrance, that all the beauty which is admired for its own sake has a common origin, whether it be the chisel, the square, the pencil, or the pen, that is the instrument employed; and that all the truth which the refined eye or the simplest taste can appreciate, whether it be marble, stone, canvas, or language, that conveys the impression to our senses, is but a reflex through the mind of man of eternal truth, of which all nature bears the impress.

We are all engaged in the study of an art whose practice has, like humanity, its bright side and its dark one, and doubtless our tastes will be shown by the line of study we adopt. We study, for it is our business; and we make our business our pleasure, for we love our art. At the same time, there is another class who study architecture, with whom our relations are somewhat perplexed—the critics. With more or less knowledge of the value of particular instances, they generalise. Their position is not that of our enemy, for they diffuse a love of the art; nor is it that of an ally, for they turn upon us, till in each case they are better informed of the faults, not of ourselves alone, but also of our clients; proving once more, that a little knowledge possesses at times dangerous qualities. Yet are there many among them who have great taste for the art, and can give upon occasion most serviceable hints for our consideration. They shine, however, most when, in criticising a building, they lay open the secret workings of the architect's soul in the design. They ofttimes use an architect's work as a phrenologist would his head, and, judging by their own standard, detect the moral, intellectual, and other faculties which he may possess, thereby causing at times some amusement both to ourselves and others. Are we not, however, responsible in the first instance for the opinions which sound critics may entertain of our work? And may not the reasons which may seem to them to have influenced our mind, have had in reality some effect in directing our design, though other matters at the time had turned our thoughts into a much more tangible form? The most important of architectural criticism has been generally that based on historical principles. The character of architecture is a reflex of the age, and ever has been. There are many circumstances in the position of an architect, which render him the best exponent of the character of his time. He is the tool of the men of power. His own nobility of soul he obtains from studying the ideal of the age. His means he derives from having the good opinion of its leading men. Yet is it in his power to render to posterity the nobility of feeling which he sees around him, or not. The characteristics of his age he must, however, import into his work; and his originality must arise from the fact that some great thought is to be found at work, a witness to the age. This, with the aid of the sister arts, specially sculpture, he finds he must make his own, and to it, even unconsciously, he gives that expression which shall for the time more firmly imprint its footsteps on the public mind, and to future ages more clearly depict its course. Thus, whether it were permanent dynastic power, or acquired power of conquest, that was to be exhibited and adorned, the Egyptian or Assyrian architect devised that arrangement, and gave that expression to his work, which we still recognise in the repose of the temples and tombs on the banks of the Nile, and in the life and action of the palaces on the Tigris. Again, whether it were the refinement of independent mental cultivation, or the amount of conquered wealth, that guided the architect in his designs, on the Acropolis every device was used to produce simplicity of general effect; among the Seven Hills every feature of the building was obliged, beside fulfilling its structural duty, to carry so much ornament as its surface was capable of receiving. Nor can I avoid carrying a comparison into our own architectural styles; for as the grand principle of superposition which gives meaning to all Classic architecture, and is still the cause of much of the beauty of early Gothic art, so was the earlier philosophy, a sound course of reasoning, though carried on by a very few, whose works, or rather whose scattered sayings, still remain the key to our present knowledge. And as that other architectural principle so captivating to the eye—the continuity of line—rose with the ascendant ideas of the art, and gradually overcame all other characteristics, so that in all later Gothic this is still to be found the leading idea, so was the superficial study of the dark ages; for, while destroying the vitality of true philosophy, as of the Gothic style, both seemed, in the perverted view of the time, but the legitimate consequence of their principles.

Now, though we may admit the accuracy of a critical judgment as to the character of an age from that of its buildings, yet this is not the criticism we wish; nor are they the peculiar qualities, good or bad, of those who have provided the necessary funds for a structure that we, as architects, value. Critics should have the power of bringing a great amount of knowledge to bear upon architecture, a knowledge gleaned from extensive study in other arts; and they should find in the principles of construction and of ornamentation which we adopt, truth and beauty analogous to those of other arts. From an article in the 'Quarterly Review,' on Mr. Knight's work on Italy (for March 1845), I may draw an illustration of my meaning. There is towards the end of its pages an illustration of the relation of the structural, formative, and pictorial branches of our art, by reference to the skeleton, muscles, and surface of the human anatomy, which is well worth the attention of the student. It brings to view the true position of architecture, as capable of embracing and expressing in the simplest form the greatest truths—those, namely, of relation. To express these relations of form, colour, cause, and effect, appear to me among the highest aims of the architect; but while, in the one case, unless the client's hand is liberal, nobility cannot be expressed by the building, so in the other, unless higher studies occupy the architect's attention, unless he derive a pleasure from the contemplation of something in nature other than its mere surface, unless his reading and his thoughts be elevated above those of his fellows, unless his aim in life be that of the highest standard, it is impossible that his works should embody those relations and contain those higher principles which he may in his brighter moments recognise in the works of the great architects; erections, which have served to place the perfect arrangement of straight lines, and of most formal curves, on a par with the works of artists who, with their all-embracing pigments, chiaro-scuro, colour, or the press, can bring into relief at will every sentiment, every scene, and all the knowledge which the memory of man can contain.

But in the present day, is it possible for the architect to devote his attention to the mastery of these higher relations? How much time must he not devote to the examination of materials and their qualities, and to the study of styles and their characteristics! Where is he to find opportunity for the examination of all buildings by reference to abstract ideas? Each must in this matter judge for himself: I can only bring forward such reasons as seem to me inducements to the study.

The position of this knowledge of materials is not that of the object of study. The comparison of styles is not, even in his own works, the aim of the architect; nor does the use of the material and the class of minor form best adapted for its disposition, constitute the object of his practical efforts. They correspond but to the grammar and logic which are adopted either by natural refinement or by education, either with or without special study of their technical rules. The abuse of a material, or an anachronism in style, gives to the architectural eye as much pain as the breach of a grammatical rule or the adoption of a non-sequitur in a discourse does to the ear of an attentive listener. Again, accidental irregularities in a curve, or deviations from a right line, which occur in a building, offend, as do false quantities in poetry, or discords in music; and the improper ratios in the features of an order are as detrimental to the effect of a design as would be an inappropriate development in a piece of sculpture. These, and many other instances that might be adduced, tend to show, in the several arts adopted by man to exhibit his advancing taste, what are the parts which harmonise the one with the other; and we shall be led to believe that these analagous contrasts and likenesses tell of a relation subsisting among them all; and to contemplate an all-pervading principle, first in nature, then in our treatment of art; a connection elevating to our view of the former, honourable to our appreciation of the latter, and which presents itself as akin to something of a higher character in our constitution—and for this reason: the different arts tell of the diverse forms under which the mind may assimilate the truth and beauty of nature; and since a work of art does not only represent, but also contains some of these beauties, the unity of nature must lead to an unity in all art labour.

If, then, economy of material and accordance with fixity of style are not the great objects of our study, and hence not our legitimate weapons, what *are* the means at our command which may enable us to express the thought of art, to represent those qualities of nature in which we find greatest delight? and thus to take our stand among the poets, or, to give the word its most extensive meaning, the makers of all ages.

Our materials are matter in any form we may choose. We have to think the thoughts we wish to communicate, and we have next to devise means for their communication. The first set of thoughts unites our minds with all that is noble in mankind, the second confines our attention to the study of our materials and of the works of preceding architects; and as ideas elsewere are valueless till expressed in appropriate language, so in our art we cannot separate the idea from the form of its expression. Hence that constant study which is requisite of the orders and styles which have been at different periods the current language of architecture; on these the architect dwells for the knowledge of a language, and the connoisseur for the sake of the thought they convey to his mind. Our thoughts are not all to be obtained from art, but we must endeavour, by that study of whatever we find true or beautiful, to fill our own mind therewith, so that its expression shall be our natural action.

The architect studies art for his own use—he opens his mind to the Cosmos for his own time and for succeeding ages.

Now, as all language expresses action, and our language is composed of materials, so all we do must tell of the action of which materials are capable, that is, motion. All our forms are those of motion, simple or combined. In practice the simplest forms are those always used. If we refer to nature, it is only on its grandest scale that this simplicity is visible; and even then it is so veiled in a complicated relation of masses, that not till thousands of years had rolled over the heads of attentive examiners of the heavens, one, devoted to the pursuit of astronomy, led on by some higher appreciation of the beauty of nature, detected the existence of the ellipse in planetary motion; nor was it till hundreds of years later that the simplicity of that very curve was exhibited, by proof of the intimate connection of the conic sections in all their qualities. Yet are the beauties which Kepler and Newton have found in the simplest curves present in all our works, and though our thoughts may be straying far enough from such abstract considerations at the time when we adopt them in our designs, yet are those causes of force and motion which retain the unity of orbitual progress reflected wherever we use a curved line, and are one cause of the pleasure we derive from their form, so far as it is a reasonable sensation. As, then, the test of comparison for languages is the form of stating an event, the connection between the subject, the object and the verb, so may we use for our comparison of architectural styles the form of expressing motion. In the Classic order we find this most simply expressed, first, in the entablature, column, and pedestal; and secondly, in the column itself: the cap, collecting the weight of the entablature, the subject; the shaft, conveying the weight to the base, which, as it distributes it to the lower part of the structure, represents the object. Now, though we may not find in the other styles so simple a statement of their object, from the character of action being different, yet may we trace this intention, the conveyance of force upwards or downwards, tangentially or normally, in every moulding which the designer has carefully studied for the position which it has to occupy in the building.

Let us see to what extent this is also found to be the case in those branches of natural form which are said by various critics to have been adopted by architects as the basis of their art.

The form of the human body has been adopted by various authors as the exemplar of proportion and symmetry. Here, every part expresses preparation for action: the arrangement of the lower members, ready to convey the superincumbent weight; the arrangement of the joints throughout, so that long-continued vibratory motion can take place without producing any jarr in the frame. These are instances of a like kind to those we have so often practically to study, while every portion of our frame is fraught with means for its proper movements. The relation of the parts tells of their proper occupation, and their symmetry tells of that arrangement which masters all their complicated functions.

Vegetable forms have been adopted by some as the origin of architectural form, and the imitation of them has ever been one great source of beauty in our works. Are these forms not, many of them, clearly attributable to the action of their growth? The increasing weight of the flower and fruit acting on the lengthening stalk, effects its gradual curvature; the varied strength of the different parts of the leaf, and the arrangement of the masses, tend to the curved form of their profile; indeed, the very growth itself is an action of force: and whether we look at that original action, or on the force of gravity acting on the substance of vegetable form during its growth, we still see in this kingdom of nature the clearest exponent of the laws of force and motion.

The pure geometry of lines and angles, as supplied by the mineral crystals, has led many to dwell on the natural superiority of regular forms for conveying an impression of grandeur to the mind; since here we see most clearly exhibited the power of ratio and proportion, as, whatever be the geometrical qualities of a figure, superficial or solid, these it retains, however varied the value of the modulus,—true representative of the strength of that fancy which has induced many to value figures, and forms, and objects, for a symbolism which they have discerned under their surface.

I trust that I may not be considered fanciful while comparing the forms of art with those of nature, with special reference to the actions which they represent, if I refer to certain qualities inherent in the forms we have been considering.

In mineral form the action is all past, the cause of its progress has passed away, and the law of its movements is to be learned but by its results; while in vegetable form, it is its present action, its present growth, that gives us pleasure—the capability of a stalk or stem to support a mass incomparably larger than itself, and that because of a present life which it enjoys, a life untrammelled by rules, yet active by the agency of law. And in the animal form the adaptation is for a future and external work. The modus of its formation we cannot divine; the arrangement of its means of action are hidden from our sight. Its beauty is its possession of powers to act upon other objects. The elasticity of its surface is that of the dormant energy of every member waiting but an inducement to exercise its special function.

Here, then, are some of those truths of natural form which the architect can use. Thus may nature be found a standard with which to compare our art. In this study we shall judge of details from internal evidences, and not from adventitious circumstances; chiaro-scuro will take its place but as an alembic, a means whereby form is made known to us, not as an object for our contemplation.

So far, we have considered only the mental pleasure that the purpose of architectural form is capable of affording us. And what if it should be maintained that the use of colour is also a means of conveying pleasure more immediately through the senses, but still owing its intensity to the purpose displayed in the colour? Would the proof of this point not lead us to value the beauties of nature more highly than by looking at colour as with reference only to colour? For a long time, colours were thought of but as so many separate substances of pleasing texture to be applied to a surface. Then it was found that colour was but decomposed light, and colours were counted seven. Now, we count three colours and their compounds, and we study their mutual relations and the laws which govern their harmony and their contrast, strongly akin to chemical laws. But will the study under this aspect exhaust the interest we derive from colour?

I believe not; and that when we know thoroughly their relations, we may so study the separate colours as to apprehend something intrinsic in their beauties, and thus make true use of them in the scientific conveyance of thought. And since we see that forms derive not their true explanation from contrast with other forms, but by considering the causes which produced them, the life which is proceeding and the actions they are capable of producing, so in colour may we hope to find a meaning not simply by contrast or harmony with other colours, but in reference to some active proceeding or condition which the study of its peculiarities having once suggested, still recalls to mind.

While artists have used animal and mineral, and, specially, vegetable forms, as exemplars ready to hand of the results which, in architectural form, they were anxious to produce, they have treated these shapes in a great variety of styles, displaying more or less of what we call conventionalism; and the greatest artists have always used much of this modification in their natural forms, thereby calling our attention to some portions only of the beauties contained in the original—those, namely, which are applicable in common to both the substance adopted and that in which the applied form is found. But many designers of architectural ornament seem to think that, in conveying to the mind a more exact image of a natural form, they at the same time fulfil the object of their art in conveying a clearer impression of its beauty. There is, however, one great duty of the artist which is in this manner omitted. There are some talents scattered among mankind of an artistic order; men there are capable of analysing the impressions of beauty conveyed from nature, and of seeing the works of God in an aspect somewhat different from their neighbours. Surely, it is their duty clearly to convey to the mind the knowledge they have thus acquired. It may be that such men will not give to the ignorant eye the pleasure to be derived from more exact copies, but the eye will descend upon the real model, upon the natural leaf, after a study of the conventional, with an enhanced pleasure, an effect worthy of high art.

But, not to detain you too long, I have not dwelt, as my predecessors were wont, on the progress which architecture may be said to have made during the past year. Its advance in some branches has been as decided as in others it has been questionable. Our business, as I take it, is more the formation of a class of students, rather than the assumption of an important position in the profession; and therefore I have addressed myself, as far as my small influence may go, to rest the study of our art on a broader basis. Let us admire the expressions of force, and yet not give ourselves up to mathematics, though we must understand them. Let us love variety both of light and shade and of colour, and use chiaro-scuro and chromatics without being mastered by them. And, lastly, let us value symbolism as one method of arriving at the mind of the architect.

The admission of a symbolism in the parts of a structure, and in the details of its construction, is in favour with many classes. Now, I am not now objecting to the explanations which they give, but they seem too often to have this intention—of forming a study, not upon a broader basis, but accessible only to the initiated, a field whereon they may plant a system of dry facts; instead of, by the assistance of refined analogy, leading us up to a better understanding of the subject. They would show some correspondence between the parts of one science and the parts of another, instead of pointing out that vital principle which actuates both.

If, in the remarks which I have had the honour of addressing to you, a view of form has been recalled to your remembrance different from that mere shape which the material object assumes in the mind and in reference to architectural use, the great importance has been brought before you of the motive of the lines which produce form. If you can, for the moment, look at the three kingdoms of Nature, and see in them the representatives of an action not without a purpose; if you can view colours as emanations, yet for the most part to be understood, from the purity of light; if you will look at conventional form as more expressive of distinct thought than the more natural imitation,—then is there present in your mind a conception of that deeper symbolism which looks at all we see as the representative of something unseen, and which consequently considers all man's mental work, all the operations of our minds, as having for its object, in analysis, the discovery of that inner thing, and, in synthesis—(and, for synthesis, what art so great as our own?)—the demonstration of its connection with external nature.

## ON PLAN-DRAWING, AND THE REPRESENTATION OF THE PHYSICAL FORMS OF GROUND IN TOPOGRAPHICAL MAPS.

By Robert Dawson, late Corps of Royal Military Surveyors.

This kind of drawing has hitherto been regarded in a low light as a branch of art, and accordingly has been practised, mostly, under mechanical methods and arbitrary rules; but, as it requires mental apprehension, and is capable of giving mental satisfaction and pleasure, in connection with natural science,—as well as of conveying much useful information for general demands and purposes,—it should be regarded in a higher and more liberal sense; and therefore it is desirable to bespeak, and obtain for it, the attention and judgment of professed artists, to carry it to perfection. In the meantime, being asked my opinion, as a surveyor and draughtsman, on the subject, I proceed to give it by stating, in the first place, what I think a topographical map is, or should be considered.

By a topographical map, then, I should understand a full-face, *pictural* representation of a place, district, or country, in its natural figuration of mountain, hill, valley, and plain,—with its coast and river boundaries and divisions, and the artificial lines, figures, and tracery belonging to the surface, geometrically described on it;—the whole united harmoniously in one pictural exhibition to the eye. It should be such as to exemplify Dr. Arnold's geographical idea of a country, as recommended in his lectures on the study of history, where he says: "A real knowledge of geography embraces at once a knowledge of the earth, and of the dwellings of man upon it. Let me once understand the real geography of a country,—its organic structure, if I may so call it, —the form of its skeleton, that is, its hills,—the magnitude and course of its veins and arteries, that is, its streams and rivers; let me conceive it as a whole made up of connected parts,—and then the position of man's dwellings, viewed in reference to these parts, becomes easily remembered, and lively and intelligent besides. For the sake of mere beauty and liveliness, if there were no other consideration, it would be worth our while to acquire this richer view of geography." "Conceive only (he says) the difference between a ground-plan and a picture—the mere plan geography of Italy." And then, describing part of Italy by way of example, he calls this, in comparison with a common knowledge of geography, "a giving life and meaning and harmony to what is at present lifeless and confused." "I wished (he says) to give an example of what I meant by a real and lively knowledge of geography, which brings the whole character of a country before our eyes." Now this, I think, a topographical map may do more effectually and gracefully than has hitherto been accomplished or exemplified in the best published maps of the present day.

Drawing, in its application to maps, or plan drawing, is not confined to delineation only, but to the whole expression of form in respect of ground. It is *natural history* drawing of land in full perspective perception—the greatest subject for that kind of description;—and, for its successful accomplishment to satisfy the eye and mind conversant with land in its map aspect, it requires the ordinary graphic qualification of the artist, combined with some knowledge of physical geography and geology, and a clear and perfect mental apprehension of the details of the subject, embodied and harmonised as a whole.

*Pictural effect* in maps is the expression of whole forms, and assemblages of forms to the eye, in one whole imaginative view, which must be taken by appropriate surveying, and drawn with artistic judgment and skill. The drawing will be the same, or a parallel case, to that of bas-relief sculpture in full perspective of the plane surface on which it appears, for land may be apprehended and drawn as a great subject of natural sculpture standing in bas-relief of the surface of the sea; but the apprehension of it must be mental and artistic; and the expression will be in bird's-eye and panoramic perspective of the forms, as they fall directly under the eye. The degree of art that may be used, both in surveying and drawing land in map aspect, is greater than seems to have been thought due to this kind of drawing, and therefore it is not to be found exemplified in the best modern maps, nor are the forms poertrayed in those maps so satisfactory and pleasing to the eye, as the most common natural history drawings of other subjects appear, even in books and prints for popular instruction. Those subjects, it is true, may be more familiar in idea,—better known and understood as objects of the animal and vegetable world,—and may please more immediately by direct resemblance,—and, in shape and colour, may be more attractive. They are also comparatively small subjects, and may be apprehended in single view. But there is an appropriate beauty in the forms of land, contemplated in map view, which a map may express, and which the means and resources of art, in the present day, may supply in a much higher degree than has been hitherto effected.

This higher degree of perfection is required for physiological geography, for topographical description, and for other purposes, professional, economical, and general. It has formed the subject of consideration for committees of the House of Commons, for the Ordnance Survey of Great Britain, and for Commissions under the French government for their national survey; but the principle of natural history drawing has not been proposed by any of them, and though some manifestations of its practical application have been made in England, they have not been carried out to their fullest extent.

The *natural history principle* will require the physical substance, and geological structure and formation of the land to be understood, in order to recognise and express those characteristic indications, which a survey of the land itself would give to the physical geographer and to the painter. To form this mental perception, and to make the drawing after it, is the peculiar and great difficulty of the work; for while in the map the eye embraces the whole field at a glance, it is supposed to travel over the ground, and to be everywhere vertically fixed immediately over every part of it. Geometry must give the guiding points, but the drawing will not be a merely geometrical and mechanical process, though it may admit of, and require mechanical drawing and conventional signs, writing, &c., to be added to it. Yet the whole may be executed in such pictural harmony, as to admit of the map being contemplated as a natural picture to the eye. This seems the proper principle to propose, and the artistic ability to require, for this kind of drawing. Under it, description for all purposes and demands, may be accurately and gracefully executed; and, taken as a rule of appreciation for the best published maps, much will be found wanting to bring them up to the standard.

This will not, however, be thought too difficult a task for the accomplished map-draughtsman to undertake; natural history quality of execution being all that is required, and this is known to employ not a very high pitch of artistic ability. Mountains and hills, in map perspective, are not so difficult to draw in single forms as many other subjects of natural history drawing may be, particularly in oblique perspective; for geometrical perspective is the simplest possible, and, in this respect, presents no difficulty at all of mere delineation. It is the whole expression of a pictural idea—in light, and shade, and colour—that constitutes the artistic difficulty to be mastered.

*Natural drawing* in maps has been objected to, I am aware, as having too much of the painter's art in it, the object of which has been supposed more "to please the eye," than to give, as required in this case of topographical drawing, accurate and useful information; and so, liable to abuse in giving fanciful expression, rather than accurate intelligence; but this is arguing from the abuse of the painter's art, which is no more to be assumed for the topographical describer, than for the naturalist, who has acquired enough of the painter's art to describe his subject, whatever it may be, picturally. The same aims, end, and ability are necessary for both. If it should still be thought, however, and contended, that map drawing of all kinds is necessarily more geometrical than natural, and that neat and accurate delineation is better for it, and more useful, than pictural expression,—it may be answered, that both may be combined, that the eye demands natural drawing for natural subjects, and that it is, in fact, in some way or other, always attempted in maps of this kind; sometimes, indeed, absurdly; sometimes rudely and mechanically; and mostly in defect or exaggeration of nature, and artistic judgment of what is really wanted; yet the attempt which is made, and the demand, growing as it does with experience, and a comparison with the state of natural history drawing for other subjects, seems to show that it cannot be given up, or left uncultivated.

The natural history principle, then, I would propose for the aim and standard of the drawing, and the rule by which it may be appreciated. It cannot be expected that either the geodetical surveyor, or the ordinary land-surveyor, should be an *artistic* draughtsman, though in their proper measure both may add this accomplishment to their respective abilities; yet it seems more properly to belong to the latter profession to cultivate it, than to the mathematical and philosophical ability which is occasionally called into action for geodetic operations. Indeed, the land-surveyor may aspire to the higher branch, perhaps, more consistently than the mathematician and philosopher may undertake the purely practical part of surveying and drawing for topographical purposes; for if the surveyor has talent and industry, he may study and learn to add geodetical surveying to the foundation of his business, as well as topographical drawing or portraiture, so to speak, to its finishing efficacy and grace.

Some geological knowledge of land generally, in its figuration, is necessary to apprehend and understand that of any particular country: the general phenomena which appear in its surface forms; the rising and sinking of land in circular and elliptical areas; its formation under a covering sea, and emerging in volcanic forms out of it; its division by rents and faults; its crystalline and mechanical construction in beds and strata; the shaping and denuding effects of floods and currents, cutting out and exposing its forms and features as we now see them. A map, drawn in advertence to these facts and deductions, must be particularly desirable for geological description and illustration.

M. Boué has shown that "a critical similarity of outward forms, while indicating similarity of producing causes, must also, to a large extent, indicate identity of structure; and therefore, from the external appearance of an unexplored country,"—(and from a map properly representing it)—"its geological structure may be inferred, at least to a certain extent."

"Nature has not wrought after an indefinite number of types or models, but on the contrary, her fundamental types are few, and derived from the action of definite constructive forces on a primary base." This reference to M. Boué is made by Mrs. Somerville in her 'Physical Geography,' 1848.

A great flood over all the northern countries of Europe may be assumed to have acted upon and modified their forms, from the traces of it observed in Russia and Sweden by Sir Roderick Murchison. It may be no less evidenced by the forms and figuration of surface in the British Isles, or perhaps more so, when these have been sufficiently surveyed in relation to this great geometrical problem.

A glance at a geological map of England shows a great curvilinear arrangement of its mineral masses on the east of Wales and Cumberland, which the topographical map, in its description of the symmetrical surface forms, should express comprehensively to the eye. Mr. Hopkins, in his paper on the Lakes District, read before the Geological Society, June 6, 1842, assumes the elevations of those masses to have thrown up the incumbent formations at the same time; hence the ringy disposition in horizontal order, of the mineral masses, and the rib-like forms of their surface structure; the hollows forming the channels by which currents of the northern flood passed over the land in a south and south-west direction. The impinging force of the flood is seen in the coast-like escarpments which front the north, the remarkable figuration of the oolite beds affording a curious example. Mr. Darwin's paper, on the connection of volcanic phenomena and the formation of mountain chains, read before the Geological Society, February 7, 1838, seems to afford ground for assuming that the curvilinear order of figuration in England has been produced by this cause, and that it has been the foundation of coralline rings, of which the oolitic beds are the remains.

A surveyor, seeking to qualify himself for drawing the natural figuration of land in a map, should acquire first, a power of figure-drawing (the human figure) with that truth of form and character which may mark, at least, the physical distinction of natural races. He should apply them to landscape-drawing, in that perspective which approaches nearest to the plan view; and in addition to mere manual skill, in delineation and colouring in relief, he should learn enough of the principles of pictural art for his government and use, and study their application from paintings which furnish examples of expression coming nearest to that for which he wants instruction and guidance. He may draw from solid models, too, which are to be met with in stones, heaps of earth, knots in the stems of trees, the waves of agitated water, and other natural forms which resemble those of land so much, that both are described by a common term of resemblance. Models taken on purpose, and cast in plaster, may be used; but I think natural models, such as I have mentioned, will be suffident, and, indeed, the best. Mathematical solids resembling mountains and hills, as the cone, pyramid, and segments of the sphere and ellipse, with a horizontal plane for their base, may be referred to in idea on the ground, as typical forms, for ready whole apprehension, and nice distinction of the natural forms. A nomenclature for the natural forms of land, founded on their similarity to the preconceived types, will assist the perception of geometrical, under actual perspective, and be of great advantage in description and reference by words.

The table-hills about Bagshot, Chobham, and Farnham, must be familiar to many observers of the late encampment at Chobham; and to some with me, who witnessed that on Bagshot Heath, and the other places south of Windsor Forest, in 1792. The table-hill, divided diagonally by an inclined plane, passing from the higher edge on one side, to the lower on the opposite, gives a wedge-like or shelving form to the lower segment;—its natural type is the running and surging wave; and both are common forms in sand and gravel hills, and other loose earths, from the low shelving banks and beaches of a seacoast, to the highest table and shelving lands of the world. Our *edge* hills, as several are called, besides that of the battle (Edgehill), are of this species. Mountain-limestone hills of the carboniferous system, are bold examples of this form—trap-hills, the silurian and old red sandstone hills, &c. Mr. Nichol describes a range of this kind of hills, extending from St. Abb's Head to near Port Patrick, in his paper read before the Geological Society, January 1848. "The most remarkable physical feature of this district," he says, "is the mountain chain which extends from St. Abb's Head on the east coast, in a west-south-west direction, to the vicinity of Port Patrick on the opposite side of the island, a distance of 140 miles, with an average breadth of 25 to 30 miles. This high land consists less of a single connected chain than a group of smaller ridges, separated by longitudinal valleys, running parallel to the chief direction of the mass. These ridges and valleys are crossed almost at right angles by another system of valleys, in which many of the secondary streams flow. By these two systems of valleys, the high land is divided into huge oblong mountain masses, often with steep declivities and flat, or almost tabular summits. When seen from the low ground, the mountains have thus apparently a very complex or irregular arrangement; but whenever a proper view is obtained from the high grounds (a map view) their disposal in parallel ridges is distinct. The whole eastern portion of this extended mass of mountains is composed of greywacke and clay-slate. In the south of Scotland these formations cover a space of more than 4000 square miles, or the twentieth part of the whole island, and have thus a considerable geographical importance." A general wedge-like shape, as I take it, composed of a series of smaller wedges, and the whole under escarpments more plane than rounded, consequently presenting angular partitions of faces, and natural lines of whole-figure boundary, which, in map-drawing, is commonly the most defective part of their delineation, and yet should be most strongly marked.

This description of land-forms, by words and other descriptions, such as Mr. Hugh Miller's, in his 'Old Red Sandstone,' seems vastly short of the defined and accurate expression which pictural map-drawing can give, expressively and immediately, to the eye. Nevertheless, Mr. Miller expresses, in words, pictural ideas of land most delightfully. "Physiognomy is no idle or doubtful science in connection with geology. The physiognomy of a country indicates almost invariably its geological character. There is scarce a rock among the more ancient groups that does not affect its peculiar form of hill and valley. Each has its style of landscape"—(and plan-shape and style, too),—"and as the vegetation of a district depends often on the nature of the underlying deposits, not only are the main outlines regulated by the mineralogy of the formations which they define, but also in many cases the manner in which these outlines are filled up. The colouring of the landscape"—(and the plan)—"is well-nigh as intimately connected with the geology as with the drawing." The rest on this subject, in the 11th chapter, is highly remarkable for power and beauty of landscape apprehension; and its transposition into map apprehension is a fine lesson for the map-draughtsman to take and illustrate.

Ruskin, in his work on 'Modern Painters,' says, what the map-draughtsman may take as addressed to him, to direct his study of natural form in *ideal* perception: "The task of the painter in the pursuit of ideal form is to obtain accurate knowledge of the peculiar characters of every species of being, down even to the stone; for there is an ideality of granite, and slate, and marble. A bank of loose earth of any kind that has been at all exposed to the weather, contains in it features capable of giving high gratification to a careful observer. It is almost a facsimile of a mountain slope of soft decomposing rock; it possesses nearly the same varieties of character."

"There is an expression about all hill lines of nature, but it is not to be reduced to line and rule."

"Turner's early drawings are singularly instructive in definiteness and simplicity of aim; they are little more than exquisite studies in light and shade."

This, I think, should surely be the draughtsman's aim in expressing the forms of land in a map.

"All forceful shadow and play of colour surrendered for quiet uniform hues of grey, and chiaro-scuro of extreme simplicity," —"proper for architectural drawings in relievo." This, I think, is exactly what I should say for the shading plans of ground in relievo.

The term *form* is not to be applied to the outline of bodies; "it necessarily implies light and shade; no form whatever can be known to the eye without its chiaro-scuro,—that perfect and harmonious unity of outline with light and shade, by which the parts and projections of the body are explained to the eye."

"The eye of knowledge is as a telescope to the common eye, by which more is apprehended than is immediately seen." Thus forms of land are seen in their origin, composition, &c., to the cultivated eye.

"Truths of specific form are the first and most important of all."

Under such guidance as this, the map-draughtsman may both please the eye with pictural expression in grace and elegance; and the mind, which must be his chief object after all, with the information and description it requires. The subject may not be always beautiful in itself, but in reference to circumstances and associations with what is interesting and important in the knowledge of ground, it may call for *artistic* description in a map, to convey it at least agreeably and satisfactorily to the eye; and what is beautiful in a richly varied face of country may be beautifully pourtrayed.

It may perhaps, be remarked, that this view of topographical plan drawing does not advert to military topography, a question which I might be supposed to entertain as a military surveyor. But my object was to consider the subject of topographical drawing as comprehensively as I could, for all services and demands; and natural history description of ground, in geometrical, physical, and pictural quality drawn, seem to me to compass the proposition. The cause of this kind of drawing being behind other kinds which have the same general object is, that it has been practised chiefly for professional uses, and science has been more regarded as necessary for it than art. Accordingly, the artistic education and direction of the draughtsman has not been adequately provided. He has not been prepared and required to address the mind with that knowledge of nature and art which is due to the subject, and to the observer who seeks information and gratification from the map-picture.

The draughtsman's art is to do justice to nature, and the engraver's to do justice to the draughtsman; on neither should rules and methods be imposed, except by superior artistic judgment, in the employment of each respectively.

## VARNISH BRUSHES.*

CHARLES D. THUM, U.S., *Inventor*.

THE Committee of the Franklin Institute report that the improvements claimed by Mr. Thum, consist:

1. In the form of the handle. This is extended below the ferrule, where it is expanded and bevilled into a wedge. This gives a greater elasticity to the brush, and renders it superior in this respect, to any before known to the Committee.

2. In the oval form of the brush. It has been customary to give a bevilled form to the varnish brush by grinding it upon a stone, or by long use upon coarse work, as house-painting. This, however, destroys, in a great measure, the *flag*, and thus impairs the smoothness and evenness of the edge. Mr. Thum gives the bevilled form by the arrangement of the hair, the flag being

* From the 'Journal of the Franklin Institute.'

unimpaired. This gives a clean edge, and brushes thus made are found very convenient for working in corners and along edges.

3. In the use of *elastic hair*. The mode of selecting and preparing this hair is not disclosed by Mr. Thum. It appears on examination to be finer, darker, more glossy and elastic than the ordinary hair, and is flat or oval rather than cylindrical. While a brush composed of this material is more elastic than one of ordinary hair, keeping in better form, the hairs have never, in the experience of the Committee, been known to break or split.

The Committee believe these improvements to be original with Mr. Thum. On the whole, his brushes are regarded by the Committee as superior to any, whether of foreign or domestic manufacture, which have come under its notice. This opinion is founded not upon mere examination, but embodies the result of actual trial during many months by members of the Committee.

In view of these facts, the Committee fully endorse the opinion of the Committee of Exhibitions, by which a first premium was awarded for the specimens of these brushes deposited in the last Annual Exhibition, and further recommend the award of the Scott Legacy Medal and Premium.

## IMPROVED FORM OF SUSPENSION BRIDGE.*

WILLIAM REED, U.S., *Inventor.*

In this invention, a hollow truss-beam of plate-iron, with cast-iron ends, runs the whole length of the span. In this, the wire is suspended from the upper end of each extremity, and passing towards the lower margin near the centre, the cable and tube being well supported by truss braces, which effect the double purpose of bringing the weight of the truss and all the superstructure of the span on to the cables, and holding the truss-beam in proper shape, acting as the ribs to a vessel. The height of the truss-beam and the thickness of the iron of which it is made, is to be governed by the length of the span. The upper part of the truss-beam must contain sufficient material to resist the compression of the superstructure and load, and the two feet of the lower edge of the truss-beams with the cables, are to support the whole tension. Where the span is long, and breadth of beam is required, in order to save material, the top and two feet of the lower edge of the beam may be made of plate-iron, and the intermediate space filled in with wrought-iron bars, riveted from the top to the bottom, crossing each other, forming a lattice so as to preserve the stiffness of the tube or beam. Where footways are wanted, the floor-beams can be extended out for that purpose. By this arrangement, the whole amount of the tension of the wire can be obtained, while the peculiar form of the truss-beam will cause any weight that may be brought on any part of the bridge to communicate to all parts of the span.

## REVIEWS.

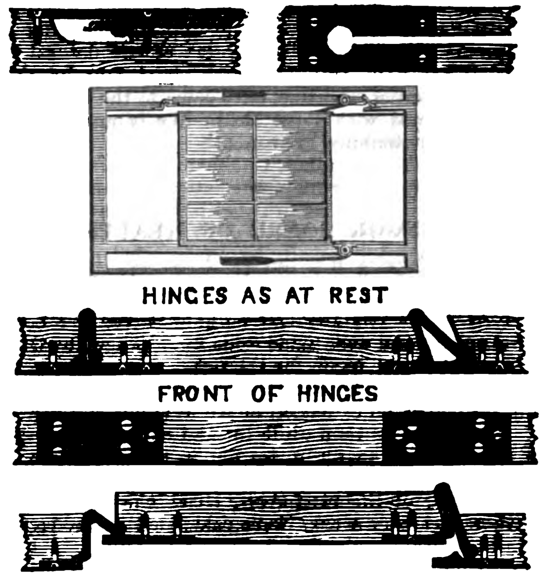
*Manual for Practical Surveyors; containing Methods indispensably Necessary for Actual Field Operations.* By E. W. BEANS, Norristown, U. S. Philadelphia: Moore. 1854.

This little work proposes to assist the practical surveyor, and help him out of his difficulties in the field; but as it is principally devoted to the use of the *circumferenter*, it is not of that value in England as it may be in the United States, for very few surveyors now use that instrument, the theodolite and pocket sextant being considered so far superior to it. However, many useful hints may be gained by the perusal; such as the easiest methods of measuring ponds, rocks, rivers, or inaccessible objects. The following extract may be as well applied to this country:—

"The irregularity of the variation or declination of the magnetic needle in causing uncertainty in retracing old lines of survey, is well known. A step towards obviating the errors attending the old method of finding the difference of variation or declination, and thereby obtaining the present magnetic bearing of the lines of survey, has been taken by the legislature of Pennsylvania, by enacting that meridian lines should be established in the different counties of the commonwealth, and that surveys hereafter made should be returned according to the true, and not the magnetic bearings of the lines."

* From the 'Journal of the Franklin Institute.'

## GRIBBON'S PATENT SASH-MOUNTINGS.



THE object of this invention is to allow the removal of a sash without unfixing the beads. This is accomplished by having half the pulley-stile on one side made loose vertically, and hinged at the top and bottom in the peculiar way shown in the above engraving, the pulley being fixed on the hinged stile and moved with it. When the sash is required to be taken out, it is pressed to the side prepared, when the stile recedes sufficiently to allow the sash to pass the bead on the opposite side. The sash is then drawn out, and the lines, having knots at their ends, are taken out of holders screwed to the edges of the sash, and fitted into others in the pulley-stiles.

## INSTITUTION OF CIVIL ENGINEERS.

THE Council of the Institution of Civil Engineers have awarded the following Premiums for Session 1853-54:—

A Telford Medal, to Nathaniel Beardmore, M. Inst. C.E., for his "Description of the Navigation and Drainage Works, recently executed on the Tidal portion of the River Lee."

A Telford Medal, to Andrew Henderson, Assoc. Inst. C.E., for his paper "On the Speed and other properties of Ocean Steamers, and on the Measurement of Ships for Tonnage."

A Telford Medal, to John Pigott Smith, Assoc. Inst. C.E., for his paper "On Macadamised Roads for the Streets of Towns."

A Telford Medal, to Alfred Charles Hobbs, Assoc. Inst. C.E., for his paper "On the Principles and Construction of Locks."

A Telford Medal, to James Yates, M.A., F.R.S., &c., for his paper "On the Means of attaining to Uniformity in European Measures, Weights, and Coins."

A Council Premium of Books, suitably bound and inscribed, to John Thornhill Harrison, M. Inst. C.E., for his paper "On the Drainage of the District South of the Thames."

A Council Premium of Books, suitably bound and inscribed, to Daniel Kinnear Clark, Assoc. Inst. C.E., for his "Description of the Deep-Sea Fishing Steamer *Enterprise*, with Ruthven's Propeller."

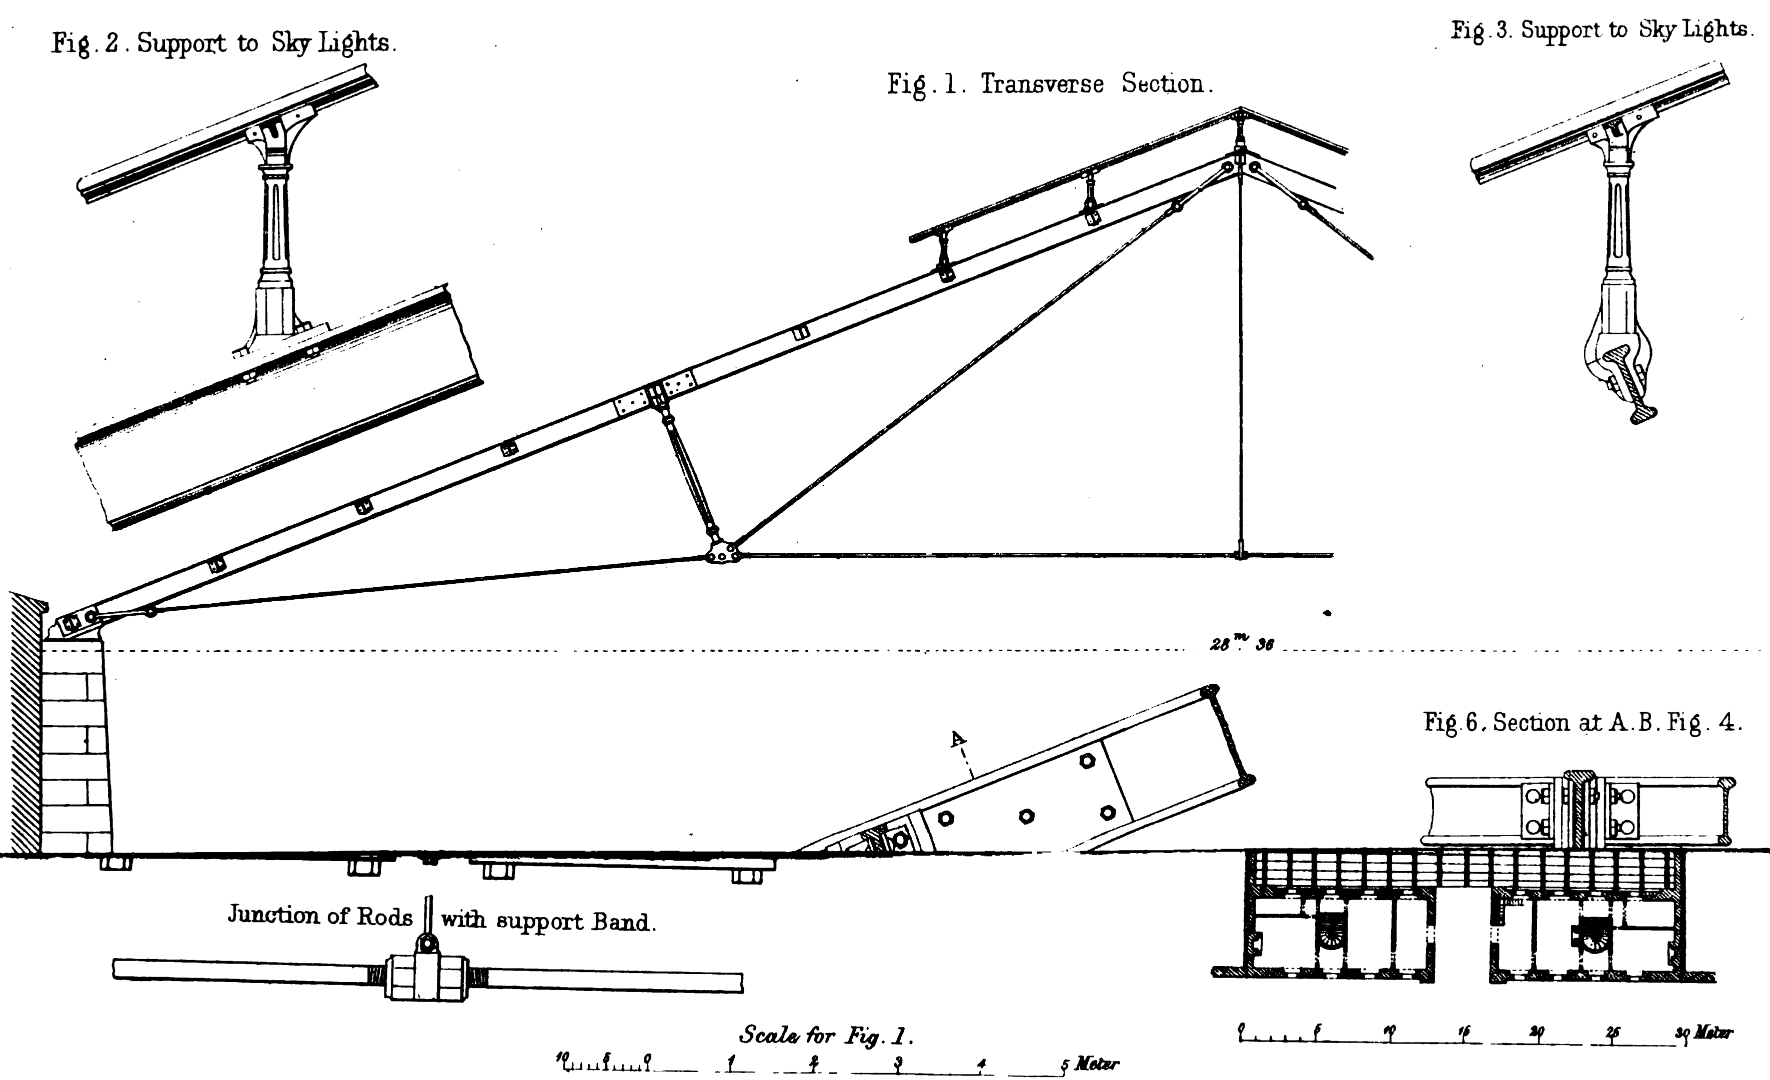
A Council Premium of Books, suitably bound and inscribed, to James Simpson, jun., for his paper "On the Prevention of Smoke in Engine and other Furnaces."

A Council Premium of Books, suitably bound and inscribed, to William Michael Peniston, M. Inst. C.E., for his paper "On the Casualties of Tunnelling, with examples."

A Council Premium of Books, suitably bound and inscribed, to David Chadwick, Assoc. Inst. C.E., for his paper "On Water-Meters."

The Meetings for Session 1854-55 are appointed to take place on the following Tuesday evenings:—In 1854, November 14, 21, 28; December 5, 12, 19 (the Annual General Meeting for the Election of the Council and Officers, and for the Distribution of Premiums). In 1855, January 9, 16, 23, 30; February 6, 13, 20, 27; March 6, 13, 20, 27; April 3, 10, 17, 24; May 1, 8, 15, 22, 29; on the last-mentioned day the President's Conversazione will take place.

# IRON ROOF OVER THE PROVIDENCE MAGAZINE AT PARIS



J R. Jobbins

## PROVIDENCE MAGAZINE, PARIS.

M. Kaulek, *Engineer.*

(*With an Engraving, Plate* XXXIX.)

The roof has been examined with great care by the most competent authorities, and they have come to the conclusion that it has been erected with great skill. We intend giving a full description of the building next month.

## BANGOR BOARD OF HEALTH.

Report *on an Inquiry into certain Allegations against the Proceedings of the Local Board of Health of Bangor.*

TO SIR BENJAMIN HALL, PRESIDENT GENERAL BOARD OF HEALTH.

Sir—Applications were made some months ago, by the Local Board of Health of Bangor, for the General Board's sanction for further mortgage to the extent of 1000*l.*, for the purpose of meeting the cost of an extension of the works of drainage in that town. A request was then made to the Local Board for particulars of this increased expenditure; but in the mean time, certain complaints were made by Dr. O. O. Roberts, purporting to come from a meeting of the ratepayers, as to the injurious effects which these drainage works were calculated to produce in the town.

Examination and inquiry which were then made were sufficient to show that the main statements, as to the levels of the drainage upon which Dr. Roberts's complaint had been founded, were erroneous.

Subsequently, however, Dr. Roberts again addressed the General Board on the subject; and his letter of March 13th contained this statement: "Several cases of fever have recently appeared, and bowel complaints have been indicated in various localities within these districts. Notwithstanding what has been done under the supervision of the Sanitary Board during the past three years and a-half, Bangor is at this moment, with regard to its sanitary prospects, in a worse situation, and in a position more favourable for the reception and propagation of cholera, fever, or any other pestilential epidemic, than ever it has been known to be during the last twenty years."

This statement being calculated to produce considerable alarm, was forwarded to the Local Board. They adopted the judicious course of addressing all the most respectable medical men of the district on the subject, and their replies, which were forwarded to the General Board, certainly bore out the observation of the clerk, that there was "not a word of truth" in Dr. Roberts's statement, and that the district under the control of the Bangor Local Board was generally healthier than it had been for years.

It was thought advisable, however, for the satisfaction of all parties, that a local inspection should be made by an officer of the General Board before sanction was granted for the additional mortgage.

A memorial, dated the 21st ult., having been subsequently addressed to you on the subject from certain inhabitants of Upper Bangor, and an urgent request made, on behalf of the Local Board, that the earliest decision should be come to in respect to the required loan, I had the honour to receive your instructions to attend at Bangor on the 4th instant; and I now beg to submit to you the following report of my examination and inquiries.

Having conferred very fully with the surveyor, Mr. E. Johnson, on the plans and sections, and on the mode in which the works had been carried out, I inspected the district, and examined the main line of sewer at various points.

With the exception of a small portion of the district called Hirael, which lies on the low level, the town of Bangor is very favourably situated for drainage; and I can safely say, that the works have been laid out in a very judicious manner; that they appear to have been extremely well executed, and have been carried out within the original estimate.

With respect to the low district, it is possible that the addition of a very small tank may be found necessary, with self-acting valves, at the junction of the lines of sewer from this part with the main, in order that the action of the drainage may not be impeded at periods of high tide. Some additional work will be necessary, also, for complete surface drainage, and in the removal of old objectionable drains, which will be no longer of use; and when this work shall have been completed, the private works of house drainage carried out, and the whole brought into operation, I believe that there can be no case in which the full advantage of the works will be more likely to be realised.

The complaints which have been raised against them by Dr. Roberts are not founded upon any actual experience of defects, but upon the merest apprehensions of failure, which the ratepayers will be glad to know have not the slightest foundation in fact.

Having made my examination of the works, I attended a meeting of the Local Board, to which the public was admitted, and afforded these explanations. Dr. Roberts, however, then reiterated his objections. His main allegation is founded on the fact, that the actual mouth of the outlet sewer is closed ten hours each day by the tide. Admitting this to be the case, it does not in the least degree affect the drainage of the river, for the junctions of the main, with the exceptions already alluded to, will all be above high-water mark.

Dr. Roberts disputed this, and stated that the sewer would be filled with the tide for three-fourths of its whole length, and that he was prepared with forty witnesses, to prove that the tide had risen nearly up to the bishop's palace.

The bed of the river opposite the bishop's palace is upwards of 20 feet above the highest spring tide level, and if the sea had ever risen to that point, it would actually have reached the roofs of the houses in Hirael, and Dr. Roberts was not prepared with evidence of this. His own statement of the extreme flood level in Hirael is only that of "knee deep."

It is impossible to reconcile this discrepancy, but it would apppear to be probable that the waters alluded to, as having been witnessed at this high level, were those of extraordinary land floods which are said to come down in great violence on rare occasions.

I failed to satisfy Dr. Roberts that this question of floods in no way affected the efficiency of the drainage of the town, but the inhabitants will be glad to know that his conclusions on this point are entirely erroneous.

Dr. Roberts's next complaint was, that the refuse from the gas works should have been allowed to drain into the new sewer. This gas refuse previously drained into the river, and was an intolerable nuisance. It is now no nuisance whatever; but Dr. Roberts contends that at high tide it will be driven into the houses. As no tide will ever reach there, no fear need be entertained on this point. But Dr. Roberts with singular perversity, contends that this drainage of the gasworks into the public sewer is in direct violation of the Water Works Clauses Act, which inflicts a penalty for fouling the streams belonging to waterworks companies, or drains communicating therewith.

Dr. Roberts appeared to have very great complaints to make against the gas and waterworks of the town, and as to the mode in which the waterworks were being executed. These works belong to a company, and as neither the General nor Local Board have any jurisdiction over them, I declined to enter into allegations on subjects with which I had nothing to do. Dr. Roberts could not comprehend this course of conduct, and bitterly complained of it.

A further cause of complaint had reference to the audited accounts. The grievance appeared to be, that these accounts had not been deposited at the right place.

Another of Dr. Roberts's allegations was, that the local surveyor had rendered himself liable to a penalty, for illegally entering into a contract with the Local Board. The facts appear to be these:—Mr. E. Johnson was originally engaged to prepare a survey of the town, and to lay out the plan of drainage, and superintend the execution of the works as engineer, at a per centage on the amount of his estimate. The Local Board, however, subsequently finding that other concurrent professional services were necessary, appointed Mr. Johnson their local surveyor, at a salary of 100*l.* per annum, with the view to his performance of these additional duties; and there can be no doubt that it was perfectly competent to the Local Board to adopt this course.

The memorial from certain inhabitants of Upper Bangor is, for the most part, a repetition of Dr. Roberts's unfounded complaints, but, as it is alleged also, that the Public Health Act had been forcibly extended to that part of the district, and prayed that steps might be taken to put a stop to further progress of works, I felt it my duty to enquire into the circumstances, and to inspect the locality.

So far from any forcible proceedings having been adopted to extend the Act to this part of the district, it appears that no statement whatever was received in opposition to it, on deposit of the report, except from one individual.

On inspection of the locality, I find that it is, for the most part, quite a new district, and although there is no great extent of nuisance there, yet, great complaints are already made of effluvium from bad drains, and it is precisely that kind of place from which the worst consequences must be expected, if neglected much longer. The property has been laid out without any system, the houses being huddled together with small confined back premises, in many of which ventilation is an impossibility.

The chief objection set forth at the meeting to the proposed extension of the works to this spot, was, that the new drains would either pollute the well water, or would deprive the locality of this supply; while the fact is that the sewers will be above this water, and therefore cannot reduce its level, and the very evil which is apprehended by its pollution must very shortly occur unless sewers are constructed for the removal of the refuse.

The Local Board would seriously fail in the performance of their duty, if they did not turn their very early attention to the works required in this part of the district.

I have now remarked on the chief allegations which have been made against the proceedings of the Local Board. Under ordinary circumstances, Dr. Roberts's complaints would scarcely have warranted so much notice, but he has been enabled to excite some dissatisfaction among the poorer class of the inhabitants, and I have been anxious, therefore, to show how entirely they have been deceived.

These works now appear only in the shape of a burden on the town, the rate-payers being necessarily called upon to pay towards their expense before they derive any advantage from them. In a few weeks, however, a better supply of water will be available, when the house drainage may be fully carried out, the surface drainage completed, and all nuisances removed, and the inhabitants will, I feel sure, only congratulate themselves that the Local Board, in the midst of great and undeserved obloquy, have proceeded steadily in discharge of the duties thrown upon them by the Act, and have carried out a system of works which is a credit to the town.

The sum of 1000*l.* to which the Local Board's application for sanction of mortgage was originally limited, is required for the payment of outstanding claims for extension of the drainage works, of which full particulars have been furnished. Some additional works will still be necessary, and the Local Board have therefore now applied for 1200*l.*, instead of 1000*l.*, and I beg to recommend that the General Board's sanction for mortgage be granted for this amount.

*September* 24, 1854. H. AUSTEN.

## LUNATIC ASYLUMS.

The following are the rules issued by the Commissioners in Lunacy to be observed with reference to the selection of the site of an asylum, additional asylum, or accomodation for pauper lunatics.

1. The site of an asylum should be of a perfectly healthy character. A chalky, gravelly, or rocky subsoil is most desirable, but if a clayey subsoil only can be obtained, an elevated position is indispensable, and the foundations must in that case be sufficiently low not to be affected by the variation of the temperature.

2. The asylum should be as central as possible to the mass of the population in the county or district, for which it is to be erected, and should be convenient with respect to its easy access by public conveyances, as well as for the supply of all necessary stores.

3. The site of the building should be moderately elevated, as respects the immediate vicinity, and (if to be drained) undulating in its surface, and cheerful in its position with regard to the surrounding country.

4. It should not be near to any nuisances, such as steam engines, shafts of mines, noisy trades, or offensive manufactories: neither should it be surrounded or overlooked, or be liable to be inconvenienced by the neighbourhood of public roads or footpaths.

5. The airing courts, pleasure grounds, gardens, and fields, annexed to the asylum, should be of such an extent as to afford the patients ample means of exercise and recreation, as well as of healthful employment out of doors; and should be as far as possible in the ratio of at least one acre to ten patients.

6. The site should possess the means of affording a constant supply of a sufficient quantity of good water, and facilities for obtaining a complete system of drainage.

## NOTES OF THE MONTH.

*Architectural Exhibition.*—The Exhibition will be open to the public at the Suffolk-street Galleries on the 11th December next, and will be closed about the 24th February 1855. Two rooms, as before, will be set apart for manufactures, patents, &c., connected with architecture. All drawings, models, &c. must be delivered at the Gallery between the 1st and 5th December. It is suggested that all drawings submitted in the competition of the year should be exhibited.

*Mr. John Dobson, jun., Architect.*—This gentleman, son of Mr. Dobson, architect, of Newcastle, perished in the recent conflagration there. He was a pupil of Mr. Sydney Smirke, and had been a student in the Department of Applied Sciences at University College, London.

*District Surveyor for Deptford.*—An adjourned general quarter sessions for the county of Kent will be held at Maidstone, on the 10th November, when the appointment of district surveyor for the district comprising the parishes of St. Paul, Deptford, and St. Nicholas, Deptford, will be made in the room of Mr. Robert Smirke Martyr, deceased.

*County of Flint Surveyor of Public Works.*—At the last quarter sessions for this county the magistrates appointed Mr. T. M. Penson, of Chester, their surveyor, upon the resignation of their late surveyor.

*Grimsby Cemetery Competition.*—The designs of Messrs. Maugham and Fowler, of Louth, have been selected for the premium of 10*l.* from those of eight competitors. The designs were exhibited for one day in the Town-hall.

*The Elliptical Gun.*—The object of boring the Lancaster gun into an ellipsis is to prevent the ball from taking a rotary motion. It is applicable to small fire-arms as well as large. As tried against the Minie rifle at Woolwich arsenal, the results have thus been officially reported:—With the Minie rifle, at 500 yards, one out of four shots hit the bull's-eye; at 400 yards, one out of three shots hit the bull's-eye; at 200 yards, the whole six struck the target. With Lancaster's smooth-bored patent rifle, same day, at 500 yards, two out of every three hit the bull's-eye; at 400 yards, two out of four hit the bull's-eye; at 200 yards, six shots hit all round the bull's-eye. The practical question now is not that of superiority in force and precision of projection, but in safety. Has the elliptical ball, in passing through the elliptical bore, a tendency to seek a rotary motion? and, being prevented, does it rend the fabric of the gun, or has it a dangerous tendency so to do? If not, what is the cause of those guns bursting so frequently?

*The Sunken Ships at Sebastopol.*—Messrs. W. G. Armstrong and Co., patentees of the hydraulic crane, who have extensive works on the river Tyne, near Newcastle, are busily employed executing an order from the Admiralty for the construction of apparatus for blowing up the sunken Russian ships of war at the entrance of the harbour of Sebastopol. They are twenty-five in number —thirteen large and twelve smaller—and each consist of three concentric water-tight cylinders, placed one within another. The innermost cylinder will be filled with fine gunpowder, and the space between it and the next with ordinary blasting powder, and the outer one left vacant. A galvanic wire inserted in the innermost cylinder will be placed in communication with the battery at the surface. We understand that the order will be completed some time next week, and that prior to their being shipped off to Sebastopol, the effect of one of them will be tried upon a sunken wreck at Tynemouth. The larger ones will weigh three tons each, and when charged four tons.

*Great Guns.*—The large ironworks at Low Moor are fully employed. Last week an order from government was received for 100 guns of immense calibre, we believe Lancaster oval guns, which will throw a ball weighing 94 lb. Besides this, the company have another large order for cannon, which they are executing at the rate of eighteen guns per week.

*Bangor Water and Gas Company.*—An Act for the amalgamation of the Water and Gas Companies, established in this city was passed in July last. The directors report that the line of water-pipes is complete from the proposed service-reservoir at Bangor to the proposed reservoir at the Gaseg (above Bethesda), and that the formation of those reservoirs was being proceeded with as rapidly as possible; pipes had been ordered, and a great portion received, for a 4-inch main into Hirael, and the directors expect to have that main laid and the water turned on in the course of three weeks; and when the service-reservoir was in sufficient forwardness, it was their intention to lay a 4-inch main to Upper Bangor.

*Self-Regulating Gas-Nipple.*—At a recent meeting of the Franklin Institute, U. S., Dr. Rand exhibited Mr. A. Mayer's self-regulating gas-nipple. This is a small cylinder, screwed on the branch, and to which the burner is attached. It contains metallic valves or washers, so arranged that only a certain quantity of gas can pass. It is varied in size according to the capacity of the burner, so as to allow the maximum quantity to pass to attain an economical effect, after which no increase of pressure causes any additional flow of gas.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated May* 31.

1209. J. Bernard, Club Chambers, Regent-street—Improvements in the manufacture or production of boots, shoes, and other protectors for the feet, and in the materials, machinery, or apparatus employed in such manufacture

*Dated June* 9.

1289. J. Bernard, Club Chambers, Regent-street—Improvements in stitching and sewing-machines, and in machines for securing and ornamenting parts of garments and other materials

*Dated August* 16.

1782. W. C. Forster, Hatton-garden—Manufacture of gas for illumination and heating from materials not hitherto employed for such purpose

1788. W. Burgess, Newgate-street, London—An improvement in or addition to reaping and mowing-machines

*Dated August* 21.

1832. R. Brisco, Low Mill House, Saint Bees, and P. S. Horsman, St. John's Beckermet, Cumberland—Improved machinery for preparing flax, hemp, and other fibrous substances for spinning

*Dated August* 30.

1897. B. Meyers, Savage-gardens, Tower-hill—Improvements in walking-stick guns. (A communication)

*Dated August* 31.

1909. G. Eden, Norwood, Surrey—Improvements in cooking-utensils

*Dated September* 4.

1926. J. Fish, Livesey, and J. Thompson, Witton, near Blackburn—Improvements in the mode or method of picking warps

1928. G. M. Miller, Dublin—Improvements in axle-boxes and parts working in connection with axles of carriages and other vehicles in use upon railways

1930. W. Hill, Congleton, Chester—Improvements in doubling or twisting net or raw silks

1932. W. H. Mitchel, Brooklyn, New York—Improvements in means for distributing type

1934. F. A. Skidmore, and J. Belton, Coventry—Improvements in the manufacture of cast-iron pipes

*Dated September* 5.

1937. W. Brownfoot, Leeds—A new or improved instrument or apparatus for raising, lowering, and adjusting Venetian blinds

1938. F. X. A. Fauvelle, Paris—Improvements in cleaning dressing-combs. (A communication)

1939. H. Trappes, Manchester—A process for the preparation of leather to be used in the manufacture of a new flock, and for the manufacture of the same, to be used and applied in lieu of flock made from pounded or ground wool and woollen materials, heretofore commonly used in the manufacture of painted, printed, and dyed decorating papers, carpets, oil-cloths, and other things, and also to be used as a paste or pulp for the manufacture of all kinds of paper, parchment, and pasteboard, of toys, of ornamental, and other picture-frames, of mouldings, architectural and sculptural ornaments, and other things. (A communication)

1940. S. Stocker, Brighton—Coverings for various parts of the human body, with a view to the preservation of health

1941. W. Barnes, Royal Exchange-buildings—Improvements in fastening rails of railways

1942. J. H. Pape, Paris—Improvements in wind musical instruments

1943. I. P. Trimble, New York—Improvements in regulating the temperature in conservatories and other apartments, or in ventilating the same

1944. J. H. Pape, Paris—Improvements in pianofortes

*Dated September* 6.

1945. J. Eden, Lytham, Lancaster—Improvements in apparatus for drying fabrics

1947. J. Westwood and R. Baillie, Poplar—A method of protecting iron ships and vessels from corrosion and animal and vegetable matters

1948. W. Newbould, Derby—Improvements in the manufacture of busks for stays

*Dated September* 7.

1949. E. Calvert and W. Mitchell, Walton-le-Dale, Lancaster—Improvements in looms for weaving

1950. G. P. Wheeler, Bellevue-place, Mile-end-road, and S. Bremhead, Holford-square, Pentonville—The production of new fibrous materials capable of and suited for the manufacturing of string, rope, matting, and various fabrics, with or without the combination of cotton, wool, or flax, or for pulp for the manufacturing of paper, papier-maché, millboard, &c

1951. P. A. Garnaud, Paris—Improvements in certain gasogene apparatus used for the production of aerated liquids

1952. W. Johnson, Lincoln's-inn-fields—Improvements in coating iron and steel wire with other metal or alloy. (A communication from A. D. E. Boucher and A. Muller)

1953. H. Lund, the Temple—Improvements in propelling and steering vessels, and in the steam-engine applied to these purposes

1954. R. Adams, King William-street—Improvements in breech-loading fire-arms. (A communication)

*Dated September* 8.

1955. J. T. Manifold and C. S. Lowndes, Liverpool—Improvements in windlass fittings

1956. J. Burns, Manchester—Improvements in ventilating ships

1957. J. Youil, Burton-upon-Trent—Improvements in the mode or method of fermenting liquors, and in the machinery or apparatus employed therein

1958. J. Jones, Sheffield—Improvements in metal dinner and desert forks

1962. R. Macallister, Glasgow—An improvement in fitting or applying screw propellers to ships and vessels

1963. W. P. Sharp and W. Weild, Manchester—Improvements in the production of raw and thrown silk, and in machinery and apparatus to be used for the purpose

1964. E. Travis, Oldham—Improvements in apparatus for measuring water and other fluids

1965. J. Atherton, J. Kinlock and J. Swainson, jun., Preston—Improvements in machinery or apparatus for sizeing or dressing yarns or threads

1966. J. Bernard, Club Chambers, Regent-street—Improvements in the manufacture of boots and shoes or other coverings for the feet

1968. B. Hustwayte, Hockley-street, Homerton—An improved construction of metal roofing

1969. H. R. Ramsbottom and W. Brown, Bradford—Improvements in preparing to be spun cotton, wool, hair, tow, and other fibrous materials

*Dated September* 9.

1970. A. Guyarding, Paris—The use of a certain fibrous matter for the manufacture of paper and pasteboard

1971. J. W. Hackworth, Priestgate Engine Works, Darlington—Improvements in steam-engines, and in gearing connected therewith

1972. W. Bowler, Southwark-bridge-road—Improvements in hats and other coverings for the head

1973. T. Hodson, Manchester—Improvements in machinery or apparatus for doubling yarn or thread

1974. T. Clowes, Beverley, York—Improvements in muzzles for horses, or apparatus to prevent horses from biting or sucking their cribs or mangers

*Dated September* 11.

1975. P. R. Jackson, Salford—Improvements in the manufacture of wheels

1976. J. Rigby, Dublin—Improvements in fire-arms and guns, and in waddings to be used therewith

1977. E. Palmer, Southampton—Improvements in propelling vessels

1978. J. Norton, Cork—Improvements in the manufacture of ropes, bands, and cordage

1979. J. Worrall, jun., Salford—Improvements in the method of treating and printing such fustian goods or fabrics as are called "cords" and "thicksets," or "velveteens"

1980. S. Szontagh, Paris—Improvements in sewing-machines

1981. J. C. Purnelle, Tachbrook-street, Pimlico—Improvements in obtaining and applying motive power

*Dated September* 12.

1982. M. Billing, Birmingham—Improvements in manufacturing and ornamenting castors for furniture

1983. E. Gillman, Twickenham—Obtaining filaments from certain vegetable substances and applying the same to various manufacturing purposes

1985. C. W. Forbes, Bartley, Hants—An improved rest for fire-arms

1986. E. Morewood and G. Rogers, Enfield—Improvements in baths or receptacles for melting and containing certain metals for the purpose of coating other metals

1987. J. Williams, Liverpool—Improvements in propellers

*Dated September* 13.

1988. W. Nash and J. Jewell, Islington—Improvements in window-sashes and frames

1989. W. M. Campbell, Glasgow—Improvements in furnaces or fire-places, and in the prevention of smoke

1990. A. E. L. Bellford, Castle-street—Improvements in electro-magnetic clocks. (A communication)

1991. J. Brookes, Birmingham—A new or improved waistcoat

1992. A. H. A. Durant, Tong Castle, Salop—A new or improved axle and axle-box, to be called the anateiros or antifriction axle, which said axle and axle-box may be used for wheel-carriages and for a shaft or axle, and bearings for machinery in general

1993. J. Betteley—Improvement in giving elasticity to ships' standing rigging

1994. H. Crosley, Camberwell-grove, Surrey—Improvements in the manufacture of paper, millboard, and felt from materials not hitherto so used

*Dated September* 14.

1995. J. Hossack, Manchester—Improvements in machinery or apparatus for measuring the flow of water, or other liquids and fluids

1996. C. F. Stansbury, Cornhill—Improved machinery for making screws. (A communication)

1998. C. F. Stansbury, Cornhill—Improvements in punches and dies. (A communication)

1999. A. Wilson and G. Wilson, Nottingham—Improvements in knitting machinery

2000. R. Adams, King William-street—Improvements in machinery for boring and rifling the barrels of fire-arms

2001. W. B. Hayes, Manchester—Improvements in looms for weaving

2002. J. Bernard, Club Chambers, Regent-street—Improvements in the manufacture of boots and shoes or other coverings for the feet

2003. T. Purdon, Hull—Improvements in safety lamps

2004. R. Rawlinson, Westminster—Improvements in valves or adjustable thoroughfares

2005. G. F. Evans, Hanover-lodge, Kew-bridge, and F. J. Evans, Gas-works, Horseferry-road—Improved apparatus to be used in the distillation of coal and other bituminous or resinous substances

*Dated September* 15.

2006. F. Fontenau, Paris—An improved mode of preventing mud from touching or adhering to carriages

2007. J. W. Perkins, Poplar-terrace, Poplar—Improvements in purifying gas, the residuum arising from which forms a new artificial manure

2008. A. Barclay, Kilmarnock—Improvements in refracting and reflecting telescopes

*Dated September* 16.

2009. S. Collins, Birmingham—A new or improved castor for furniture

2010. J. Harrison, J. Oddie, J. Eaves, and H. Graham, Blackburn—Improvements applicable to machines for warping, sizeing, or otherwise preparing yarns or threads for weaving

*Dated September 18.*

2011. W. Simpson, Birmingham—An improvement or improvements in beams or girders for bridges and other structures
2012. J. Ashworth, Bristol—Improvements in sizeing and stiffening textile materials or fabrics
2013. N. Thompson, jun., New York—Improvements in life-preserving seats
2014. G. Thorne and S. Lemon, Fore-street—Improvements in facia-boards, sign-boards, or name-boards
2015. W. E. Newton, Chancery-lane—Improvements in tuning-keys for piano-fortes and other stringed musical instruments. (A communication)
2016. O. D. Smal. Huy—A new system of oven for metals
2017. S. Crabtree, Bradford—Improvements in machinery for combing wool, hair, and other fibrous substances
2018. T. Lewis and A. Bartle, Birmingham—Improvements in apparatus for purifying water

*Dated September 19.*

2019. W. H. Dawes, Handsworth, Stafford—An improvement in the manufacture of iron
2020. G. Piercy and G. Collins, Judd-place West, New-road—Improved apparatus for heating and supplying heated liquids to baths, useful also for supplying heated liquids for other purposes
2021. J. Cunningham, Beith, Ayr—Improvements in the preparation or production of printing surfaces
2022. J. Porter, Salford Screw Boltworks, Manchester—Improvements in machinery for cutting, punching, forging, and forming nuts, bolts, screws, and various other articles in metal
2023. J. Kershaw, Bury, Lancaster—Improvements in looms for weaving

*Dated September 20.*

2025. W. Gee, Birmingham—An improvement or improvements in the manufacture of braces used for boring, driving screws, and other such like purposes
2026. M. Billing and W. G. Whitehead, Birmingham—A new or improved waterproof paper
2027. J. Robinson, Huddersfield—Improvements in apparatus for generating steam and gas, and consuming smoke
2028. W. Garnett, Low Moor, Lancaster—Improvements in and applicable to machines for warping and sizeing yarns or warps
2029. V. A. Pierfet, Paris, and Old Compton-street, Soho—Improvements in watches and clocks
2030. J. H. Johnson, Lincoln's-inn-fields—Improvements in ovens or furnaces for melting or manufacturing glass. (A communication from P. Hutter and Co., Rive de Gier, France)
2031. J. B. E. Savary and J. F. Hazard, Paris—Improvements in pumps
2032. A. E. L. Bellford, Castle-street, London—Certain improvements in machines for drilling stone. (A communication)
2033. A. E. L. Bellford, Castle-street, London—Improvements in machinery for washing paper stock. (A communication)
2034. A. E. L. Bellford, Castle-street, London—A new and improved governor for engines and machinery. (A communication)
2035. A. E. L. Bellford, Castle-street, London—Improvements in sewing-machines. (A communication)
2036. A. E. L. Bellford, Castle-street, London—A new mathematical instrument, to be termed the "horometer," for the purpose of solving problems in plain and spherical trigonometry, one feature of which invention is or may be applicable in the construction of other mathematical instruments. (A communication)

*Dated September 21.*

2037. H. Hudson, Flint Glass Works, South Shields—Improvements in the manufacture of vessels for measuring fluids
2038. W. P. Sharp and W. Weild, Manchester—Improvements in machinery for winding, cleaning, doubling, spinning, and throwing of silk
2039. J. A. Passet, Paris—Improved machinery or apparatus for pressing or calendering fabrics
2040. M. Moneyment, Lamb's Conduit-street, Holborn—Improvements in hat, bonnet, and other boxes
2041. W. Hodson, Kingston-square, Hull—Improvements in apparatus for the manufacture of bricks, tiles, and other articles from plastic materials

*Dated September 22.*

2042. W. Crofts, Derby-terrace, Nottingham-park—Improvements in the manufacture of fringes and other plain and ornamental fabrics
2043. J. E. A. Gwynne, Essex-wharf, Essex-steeet, Strand—Improvements in machinery for lifting, forcing, and exhausting
2044. J. H. Johnson, Lincoln's-inn-fields—Improvements in machinery or apparatus for manufacturing cards employed in the preparation of fibrous materials. (A communication from F. P. Morel, Tarare, France.)
2045. H. Holland, Birmingham—Improvements in the manufacture of umbrellas and parasols
2046. T. Lawrence, Birmingham—Improvements in machinery or apparatus to be employed for the purpose of shaping and finishing certain parts of bayonets
2047. P. Spence, Pendleton, Lancaster—Improvements in obtaining sulphur from iron pyrites and other substances containing sulphur
2048. G. Collier, Halifax, and S. Thornton, Rochdale—Improvements in looms for weaving
2049. W. J. Brown, Bristol—Improvements in a composition or combination of materials to be used for sizeing yarns and other articles

*Dated September 23.*

2050. T. Garnett, Liverpool—Improvements in steam-engine and other governors
2051. P. Feloj, Fleet-street—Improvements in the manufacture or construction of a knife and fork
2052. T. Banks, Derby, and H. Banks, Wednesbury—Improvements in apparatus for retarding and stopping railway trains
2053. S. E. Hoskins, Guernsey—An improvement in the manufacture of paper
2054. J. H. Johnson, Lincoln's-inn-fields—Improvements in the generation of steam. (A communication from P. J. C. Montety, France)
2055. R. Pinkney, Long-acre,—Improvements in stoppers, corks, or valvular apparatus bottles or receptacles for liquids, and in the machinery or apparatus employed for making the same
2056. G. M'Naught, Glasgow—Improvements in saddle-trees
2057. G. Danré, Marseilles—Improvements in gas-burner
2058. H. A. Genetreau, Paris—An improved system of carriage-shafts, poles or beams

*Dated September 25.*

2059. W. Marshall, Wachinghem, Pas de Calais—An improvement or improvements in metallic wheels for railway and other purposes
2060. R. M'Connel, Glasgow—Improvements in locks
2061. P. J. Chabot, Spitalfields—Improvements in supplying air to furnaces
2062. H. H. Bigg, Leicester-square—Improved apparatus for curing deformities of the human frame
2063. H. C. C. de Ruols and A. L. M. de Fontenay, Paris—Improvements in the treat- of certain metals for producing an improved metallic alloy
2064. W. P. Surgey, Hackney—Improvements in cigars, cigarettes, and cheroots

*Dated September 26.*

2065. J. B. Halsey, Norfolk-street, Strand—An improved machine or apparatus for crushing and pulverising ores, and for separating the gold therefrom by amalgamation
2066. L. Cornides, Trafalgar-square—A new mode of manufacturing a transparent medium, plain, printed, and coloured, of gelatine, in combination with other substances
2067. J. Boulton, Coppice-row, Clerkenwell—Improvements in dry gas-meters
2068. G. Spencer, Alpha-road, New-cross, Deptford—Improvements in the external coverings of roofs and walls of buildings and sheds, and in the windows of such buildings and sheds
2069. W. F. Sadler, Tooley-street, Southwark—A machine or apparatus for using up all the smoke of furnaces and other fire-places
2070. T. Clayton, Oldham, and R. Harrop, Lowside, near Oldham—Improvements in ornamenting wood, and in the machinery or apparatus connected therewith
2071. The Honourable J. Sinclair, commonly called Lord Berriedale, Hill-street—Improvements in treating, cleansing, and ornamenting paper and other surfaces

*Dated September 27.*

2073. J. S. Holland, Woolwich—Improvements in large and small firearms, and in the preparation of their charges
2074. W. K. M'Minn, Robert-street North, Liverpool—Letting go and heaving up ships' anchors, which he calls a double acting anchor purchase
2075. C. Barraclough, Halifax—Improvements in machinery or apparatus for the manufacture of clog soles and patten soles by power
2076. J. Edge, Bolton-le-Moors—Improvements in pistons
2077. J. Chambers, Manchester—Improvements in washing fabrics, and in machinery employed therein
2078. R. Hoyle, Whitehead-bridge, Bury, Lancashire—Improvements in preventing incrustation in steam-boilers
2079. R. Renfrew, Glasgow—Improvements in bobbins

*Dated September 28.*

2080. F. Clark, King-street, Westminster—An improved spindle and bush for door-knobs, and other similar uses
2081. A. Y. Crosse, Blackheath—Improvements in the manufacture of buttons
2082. J. Rogerson and J. Brimelow, Bolton—Improvements in certain parts of steam-engines
2083. J. Simpson, Rochdale—An improvement in the manufacture of printers' blankets
2084. A. V. Newton, Chancery-lane—Improvement in the rigging of sailing vessels. (A communication)
2085. W. Hutchinson and W. Barlow, Salford—Improvements in steam boilers
2086. W. B. Johnson, Manchester—Improvements in lamps and other apparatus used for illumination
2087. G. Crux, Manchester—Improvements in the production of bonnets, children's hats, and similar coverings for the head
2088. J. Woodward, Barnet, Hertford—Apparatus for stopping shot and other holes in ships and vessels
2089. C. W. Lancaster, New Bond-street—Improvements in fire-arms, and in cartridges to be used therewith
2090. M. Poole, Avenue-road, Regent's-park—Improvements in cylinder paper machines. (A communication)
2091. L. Beer, Elbeuf (Seine Inférieure,) France—Improvements in machinery for shearing piled, terry, or raised fabrics

*Dated September 29.*

2092. T. F. Griffiths, Birmingham—Improvement or improvements in lamps
2093. T. Mohan, Aclint, Louth—Improved churn
2094. W. Sneath, Derby-road, Nottingham—Improvement in sewing-machines
2095. J. N. Gamewell, Camden Kershaw district, South Carolina—Improvements in instruments for relieving the wires of the electric telegraph of atmospheric electricity
2096. J. H. Johnson, Lincoln's-inn-fields—Improvements in machinery for removing the points from the hairs of rabbit and other skins employed in the manfacture of hats, and similar articles. (A communication from P. D. Chaumont)

*Dated September 30.*

2098. J. Bradbury and J. Bradbury, Denton, Lancaster—Improvements in machinery or apparatus for manufacturing or producing piled goods or fabrics
2100. G. Filhon, Paris—Improvements in glass chimneys for gas-burners or lamps
2102. A. Boyle, Birmingham—Improvements in making umbrella and parasol stretchers
2104. G. F. Wilson and G. Payne, Belmont, Vauxhall—Improvements in the manufacture and application of rosin oil

*Dated October 2.*

2106. T. Gray, St. Clement's-lane, Strand—A new and improved method of preparing and bleaching raw and fabricated fibrous substances now used in the manufacture of paper, or which are applicable to be used in such manufacture
2108. W. W. Cook, Rumforth, near Bolton—Improved method of weaving or manufacturing woven fabrics suitable for petticoating, or similar purposes, where thick and thin parts of the same fabric are required
2110. W. Partington, Bonhill, Dumbarton—Improvements in bleaching
2112. C. B. Hare, Bristol—Improved mode of manufacturing printing blocks
2114. J. Penn, Greenwich—Improvement in the bearings and bushes for the shafts of screw and submerged propellers
2116. J. Stephens, the Temple—Improvements in apparatus for supplying purified air to rooms or buildings

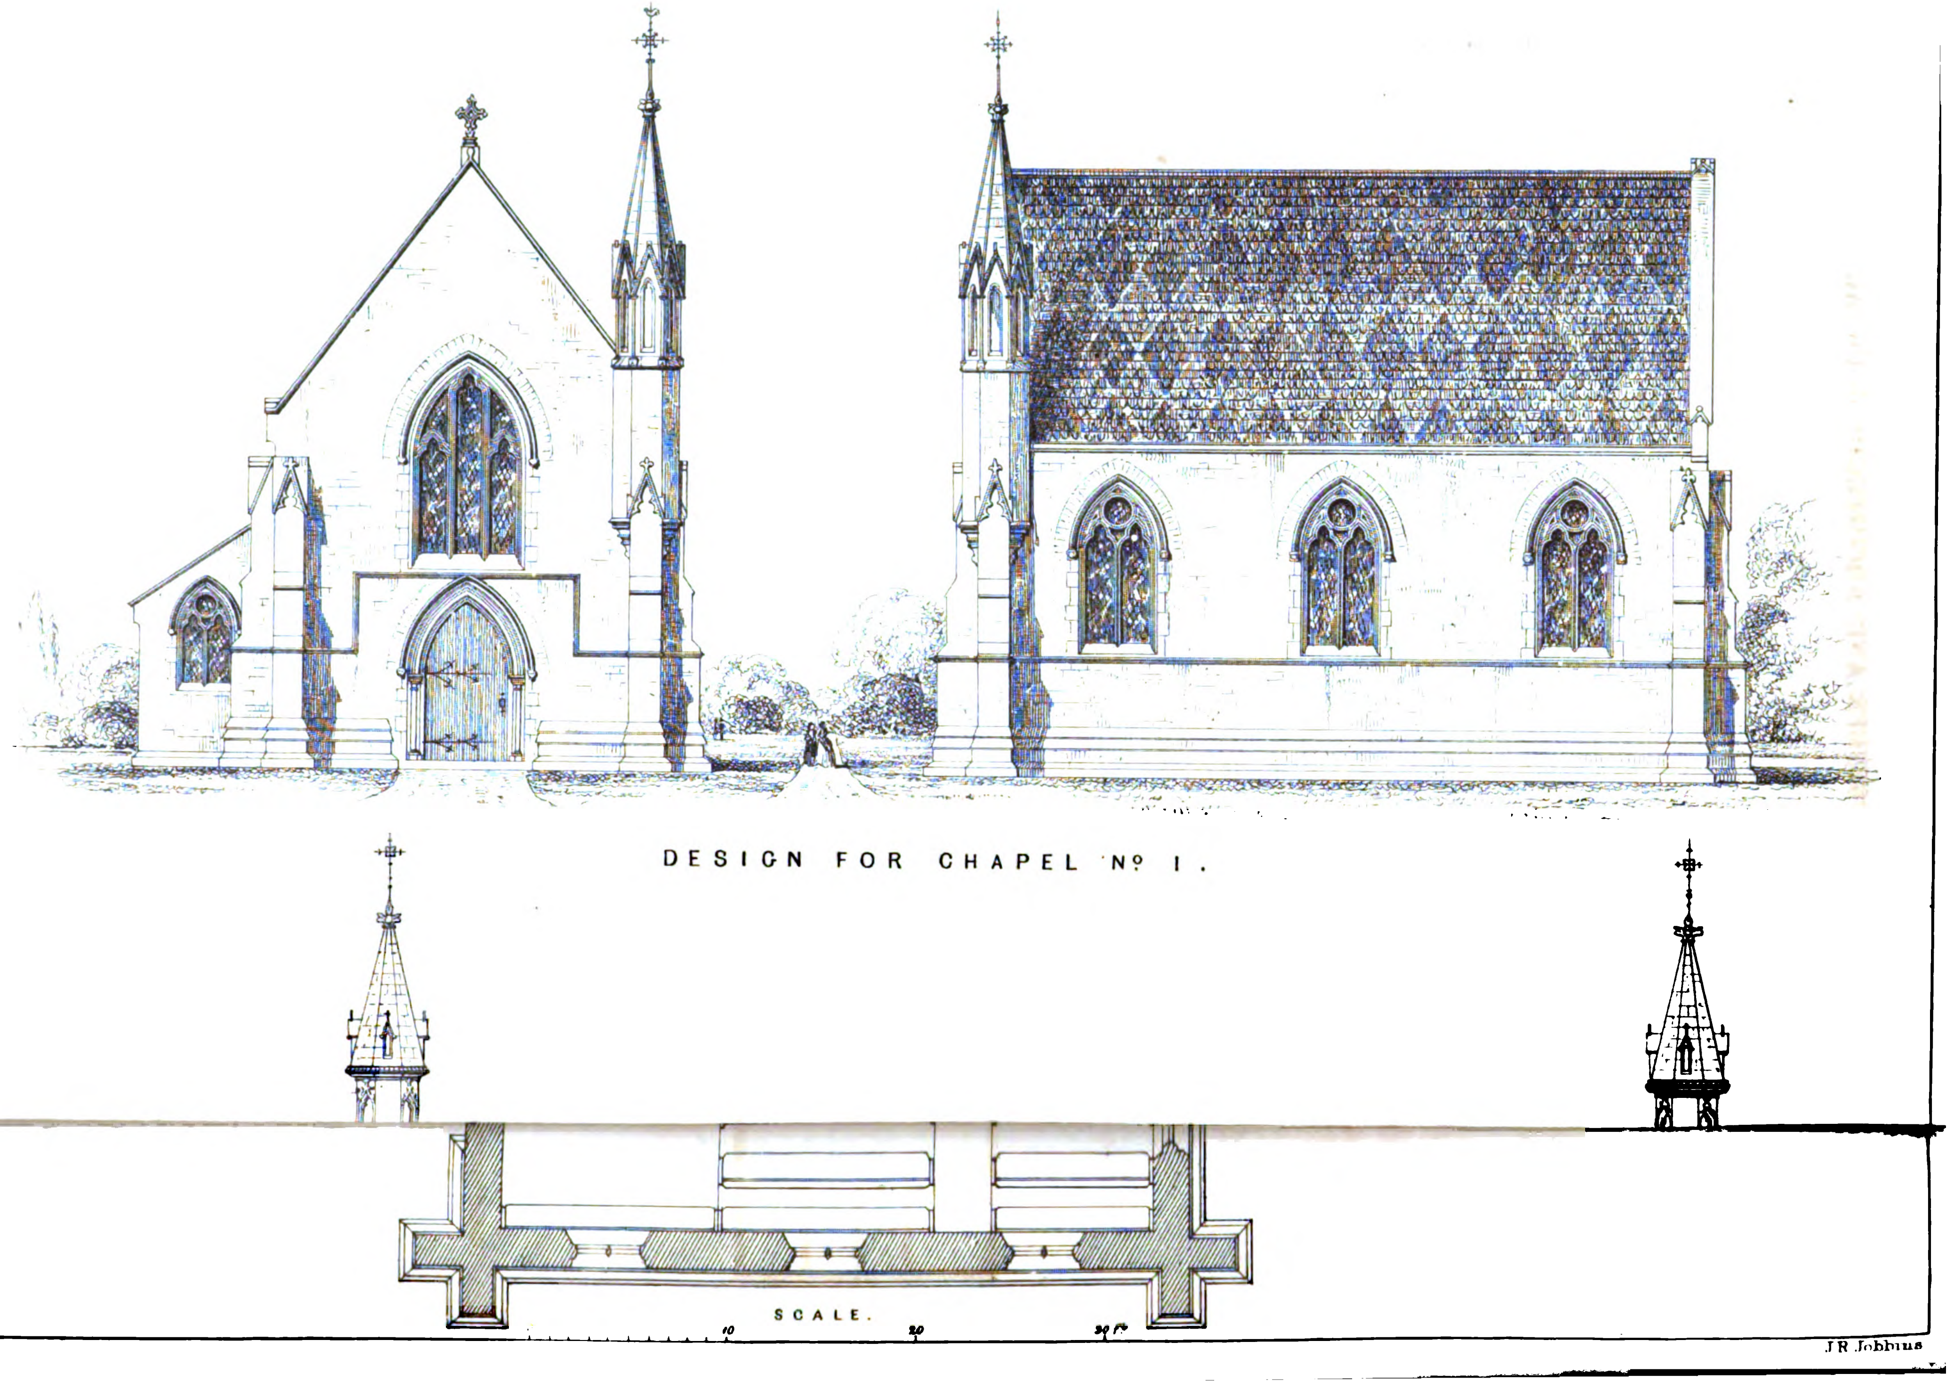
*Dated October 3.*

2120. J. Jeyes, Northampton—Improvement in the manufacture of paper, threads and yarns
2122. W. E. Newton, Chancery-lane—Improvements in the construction of locks. (A communication from L. M. Eiler, Copenhagen)
2124. C. Nickels, Albany-road, Surrey, and J. Hobson, Leicester—Improvements in apparatus used when weaving piled fabrics by the aid of wires
2126. T. Cooper, Isle of Wight—Improvement in the manufacture and in the mode of joining earthen pipes

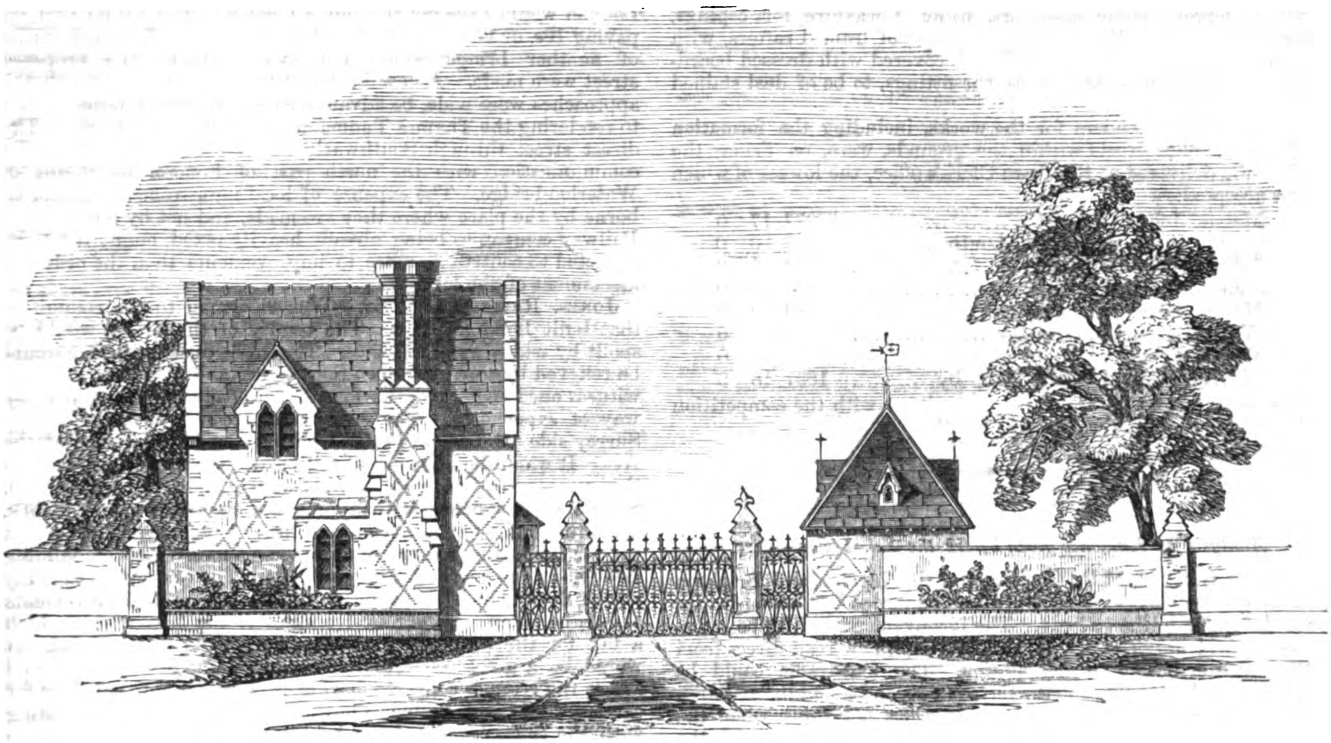
## PATENTS APPLIED FOR WITH COMPLETE SPECIFICATION.

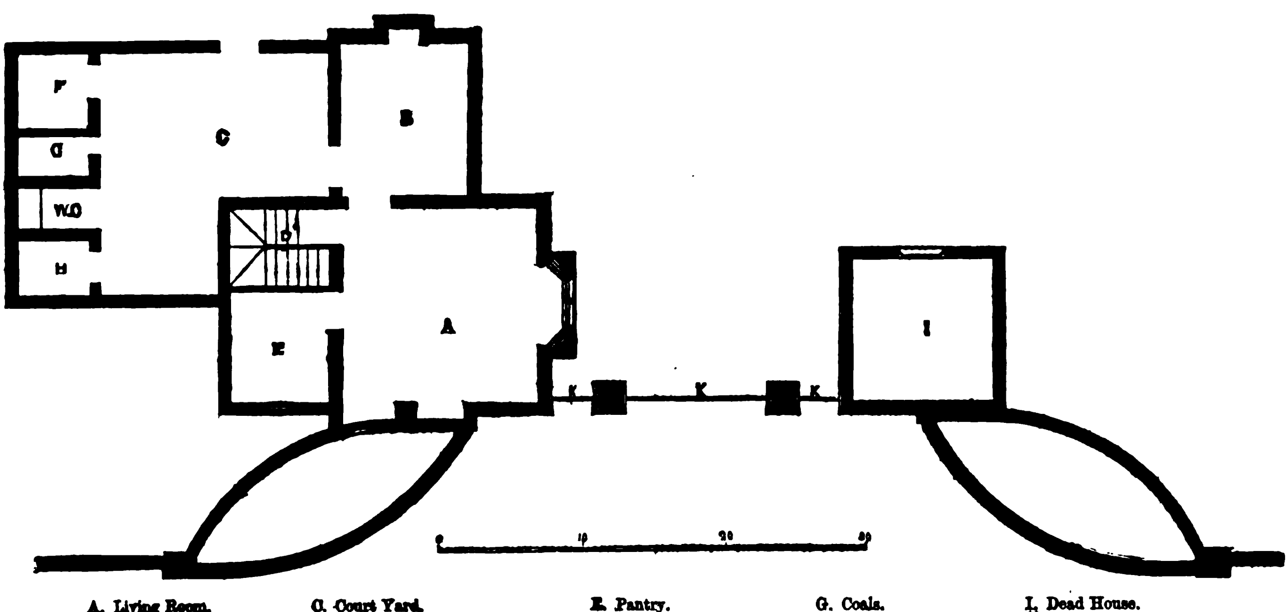
2173. P. E. Proust, Orleans, department of Loiret, France—A new system of apparatus for greasing or lubricating axles and other rotating portions of carriages and of machinery—October 11
2174. J. F. J. A. Boullet, La Chapelle St. Denis, near Paris—Improvements in the manufacture of steel—October 11
2196. A. B. Baron Von Rathen, Wells-street—Improvements in bakers' and confectioners' ovens, and in furnaces or fireplaces connected therewith, parts of which improvements are applicable also to other ovens, furnaces, and stoves—October 14
2223. R. J. Chippindall, Rue de la Rochefocauld, Paris—An improved pencil-case—October 17

# CHAPELS FOR GRIMSBY CEMETERY.



DESIGN FOR CHAPEL Nº I.





A. Living Room. B. Kitchen. C. Court Yard. D. Staircase with Closet. E. Pantry. F. Tool House. G. Coals. H. Ashes. I. Dead House. K, K. Iron Gates.

## GREAT GRIMSBY CEMETERY.

(*With an Engraving, Plate* XL.)

In reply to the advertisement of the Town Council of Great Grimsby, offering to architects a premium of 10*l.* for the design of which the Council should approve, for the intended new cemetery at that place, a great number of drawings were submitted by ten competitors for their consideration. The designs were sent in under motto, and having been exhibited for a short time in the Town-hall, the one by Messrs. Maugham and Fowler, architects, of Louth, marked "Necropolis," was unanimously adopted, and the authors (as stipulated in their sealed communication) appointed by the Corporation to superintend the works.

The ground selected for the site, about eight acres in extent, formed a portion of the Corporation estates, and is conveniently situated on the south side of the town, adjoining the East Lincolnshire Railway; it is quite flat, of a strong clay subsoil, with the exception of a small mound of sand in the south-east corner. The whole is to be inclosed with a dwarf-wall and iron pallisade boundary fencing, eight feet high, in conformity with the Grimsby Improvement Act.

The design comprises two chapels, with sexton's lodge and dead house. The Episcopal chapel, which has received the approval of the Bishop of the diocese, is Curvilinear in design, of the best period of that style, with four-light windows of double-planed flowing tracery at each end, and two-light windows on the sides. The bell-turret forms the apex of one of the gables. The Nonconformist chapel is of Geometrical character, with bell-turret on one angle of the building above the buttresses. The entrance-lodge, &c., which is of simple character, is in corresponding style. The whole of the buildings are to be executed in red stock bricks (the neighbourhood not affording suitable walling-stone), with Ancaster stone dressings, using Yorkshire for copings, weatherings, &c. The roofs to be formed of framed rafters, with arched ribs in the Episcopal chapel, covered with dressed boarding, and the whole, as well as the fittings, to be of deal stained and varnished.

The following tenders for the works, including the formation of the intended roads within the grounds, were, on Friday the 17th ult., delivered at the Town Clerk's office, the lowest of which was accepted:—

| | | | |
|---|---|---|---|
| Messrs. Johnson, Laceby | £2377 | 17 | 0 |
| George Emerson and Co., Louth | 2287 | 0 | 0 |
| John Dales, Louth | 2274 | 0 | 0 |
| James Miller, Tetney | 2200 | 0 | 0 |
| Messrs. Brown, Grimsby | 2089 | 0 | 0 |
| William Johnson, Grimsby | 1953 | 0 | 0 |
| Messrs. Friue and Thompson, Brigg | 1945 | 0 | 0 |
| William Hollingsworth, Grimsby | 1897 | 18 | 0 |

The estimate of the architects, submitted with the competition design, for the same works, was 1885*l.*

## METROPOLITAN BRIDGES.

***Analysis of Evidence given before the Select Committee.****

Laing, Samuel, M.P., Chairman of the London and Brighton Railway Company—Insufficient space is afforded by London-bridge for the traffic to the railway. The inconvenience might be remedied by widening the bridge, and making a new road direct from Westminster-bridge to the station. The foot-traffic could be relieved by better piers on the Surrey side, and an additional arch to supersede crossing on the bridge. Does not think when the West-end Railway is opened, which is to communicate with the Crystal Palace, it will give great relief to the traffic to and from the London-bridge terminus, because the whole of the East-end of London, the most crowded and populous part of the metropolis, will still naturally go to the London-bridge station as the nearest; whatever traffic to the Crystal Palace we get at the London-bridge station will be in addition to the present traffic, the amount of which is quite enormous. The total number of passengers travelling on the Brighton Railway, which in 1848 was only 2,485,778, had increased in 1853 to 4,491,561; that is irrespective of the vast numbers travelling by annual or periodical tickets. Taking the different lines of railway, the lines of the South-Eastern Company, and the lines of the Brighton Company, the total number of passengers crossing London-bridge annually, to and from, may be taken at nine millions and a half; that would give an average of upwards of 25,000 a day for the whole year; but of course that number is by no means uniformly distributed; and on particular occasions, and during the summer season, you have twice that number very often. And in addition to that, the trains go at certain hours, so that the stream of passengers is not regular, but is much larger at certain hours than it is at others. It would not improve matters to make Southwark and Waterloo bridges free, as long as the route was so intricate through Southwark. The bridge funds should be made available for improving the bridge. His impression is that London must be considered as one great whole, and that there ought to be some large central body, however elected, who should control and superintend all great improvements, whether roads or bridges, or sewage or drainage, or other great public purposes; and that the funds for those purposes should be levied by rates within the metropolis, and not imposed upon the country; and that probably the adjustment of the rates for particular districts might be made according to some sort of approximate estimate of the extent to which particular districts might be benefited in comparison with the whole. Considers that if the coal duty is carried to the extent of an area of twenty miles, it is an unjust and harsh tax upon the inhabitants of the country; but if it is confined within the fair area of the metropolis, is not then so sure, if the money must be raised, that it is a worse mode of raising it than by a system of direct taxation; but it should be confined to the district benefited. There would be no injustice in making the bridge funds bear the expense of the suggested improvements. Assuming it to be the fact, as shown by the reports of the various railway companies, that 650,000 tons of coals were brought into London by the different railways for the consumption of the metropolis, thinks the consumers of coal in London would have got through a portion of last winter without paying 10*s.* or 20*s.* a ton higher than they did. The construction of another bridge would not avail without the proposed street were made. A new bridge at Charing-cross might, if the approaches were wide, be advantageous. There are impediments to rendering the Thames Tunnel more available for traffic. The direct street through Southwark would probably facilitate the communication with the north part of London by means of Waterloo-bridge. The expense of local improvements should be borne by the place where they are made, and not by the country. Railway companies being already heavily taxed, ought not to be expected to contribute more to improvements than the ordinary assessment of the locality.

Jones, Richard Lambert—Was chairman to the committee that built London-bridge. The beauty of the bridge would be spoilt by widening the surface. The traffic over the bridge would be relieved by throwing open Southwark and Waterloo bridges; witness once suggested the former being opened for a year by way of experiment. The erection of steam-boat piers on the Surrey side of London-bridge would be an infringement of the Act. It would be useless to throw open Southwark-bridge unless the communication with the railway station were improved. Suggests a new bridge with approaches starting from St. Paul's. The inhabitants of the city are not likely to approve of any direct tax for facilitating the traffic over the bridges. Cost of building London-bridge was about two millions. The coal-tax is the only source from which the expense of the proposed improvements should be taken. Ten or twelve miles is the area within which a tax for the proposed improvements ought to be levied. It would be a great relief to the traffic coming from the Strand across the river to convert Charing-cross-bridge into a bridge for carriages. It is desirable to have a direct street communicating with the Surrey ends of the bridges. Has a great objection to any tax for building a new bridge. The throwing open Vauxhall-bridge would not be any advantage in relieving the city traffic.

Tyrrell, Edward—The inhabitants of the metropolis are strongly opposed to the imposition of any tax upon them alone for purchasing or throwing open the bridges. It would be considered as a contrivance for relieving those who had entered into a bad speculation. There would be a stronger indisposition to buying up bridges than for building a new one, although the latter would be viewed in an objectionable light. Does not concur in Mr. Laing's suggestions. The coal-tax, or any tax raised within the twenty mile area, would be the fairest manner of freeing the bridges.

Brand, Ferdinand, Comptroller of the Bridge-house Estates—The Bridge-house Estates consist of land, houses, wharves, warehouses, and other buildings which are held by the mayor, and commonalty, and citizens of the City of London, in trust for the maintenance and support of London-bridge. They were derived originally from gifts and grants from the Crown, and gifts from different individuals, and purchases made out of the surplus income arising from those estates, and other portions have been purchased with the produce of property sold at different periods under the authority of various Acts of Parliament for effecting public improvements and other purposes. There is a portion of the property situated at Stratford, in Essex, which is also liable to the support of two bridges there, called St. Michael's-bridge and Peg's-hole-bridge, and a portion of the roads adjoining. The specific trust is confined to the maintenance and support of London-bridge. The Corporation have the option of either widening the present bridge or building a new one. The existing incumbrances on the Bridge-house Estates will prevent any further expenditure in repairing Blackfriars-bridge. Reports were made on the state of Blackfriars-bridge by Messrs. Walker and Burges, and by Sir William Cubitt and Mr. Brunel, and on the reference of them to the Court of Common Council they concurred in the necessity for rebuilding the bridge. The Bridge-house Committee are at present considering a plan for widening London-bridge. Negociations have been opened by the committee with the directors of Southwark-bridge for the purchase of the bridge. The directors ask 300,000*l.* for the purchase. It was intimated to the Bridge-house Committee, that unless that sum was immediately given, in all probability a larger sum would be asked. There seemed to be an impression amongst the directors that the bridge must be purchased for the benefit of the public, and that they would therefore have a chance of getting their own price. Witness finds from the reports of the company that the

* For Report of Committee, see *Journal*, ante p. 350.

average annual amount of the net dividends of the Southwark-bridge Company, for the fourteen years ending 1848, is about 2,270*l*. He has no means of going lower than 1848. Now, supposing that be taken at thirty years' purchase, it would be 68,000*l*.; taking it at forty years' purchase, it would be 91,000*l*. The preference shareholders are the only persons who receive any income whatever. The preference shareholders have a right to 7½ per cent, and until the 7½ per cent. is paid to the preference shareholders, the other shareholders do not get anything. The tolls of the Southwark-bridge appear to fluctuate a good deal. They are rather decreasing than increasing; but thinks probably they may now increase, as the City has been opening New Cannon-street. There are impediments to throwing open the bridge for a year as an experiment. The Bridge-house Committee do not propose to pay for Southwark-bridge in the event of a reasonable offer from the directors, but to press the necessity of the purchase being made by the government. Witness proposes an improvement to the steam-boat landing at London-bridge. The arch suggested by Mr. Laing at the Surrey end of the bridge is already there. The Common Council are willing to contribute liberally to the purchase of Southwark-bridge. It would not be advisable to defray any improvements by a rate, on account of its unpopularity.

BUNNING, JAMES, Architect to the Corporation of London—Prepared the model now before the committee for the widening of London-bridge. Had it in his mind for some years, but owing to the immense mass of business he has had to attend to for the corporation, has postponed it till it appeared to him that the traffic had increased to such an extent that he thought no more time should be lost. The design was made with the intention of projecting parapets over the sides of the bridge, and constructing the footways by means of iron cantilevers, bolted down to the voussoirs of the bridge. Of course the traffic for foot-passengers does not require so stable a construction as that for the carriage-way; and by this system the entire solid part of the bridge would be thrown up for the carriage traffic. The parapet is intended to be of wrought-iron, and the cantilevers of cast-iron, and will be painted to agree with the stonework of the bridge, so that as little as possible of the architecture of the bridge should be destroyed. Feeling a good deal of delicacy in altering Sir John Rennie's work, witness suggested to the Bridge-house Committee that he should be consulted. They kindly agreed to that; and not only did they think it necessary that Sir John should be consulted about the architectural effect, but that he should also be satisfied that it was not intended to put a greater weight upon the bridge than it could bear, for there has been a settlement in the bridge. They not only sanctioned Sir John Rennie being employed, but they coupled with him Mr. Page. Those two gentlemen witness had the pleasure of meeting. Soundings are now being taken, and there is no doubt that the report will be made shortly. The extent of the addition proposed to be given is a pathway of 9 ft. 6 in. or 10 feet on each side. The centre line or division upon the model along the middle of the bridge was an idea for facilitating the traffic. If the vehicles passing north and those going south were divided into two separate lines, it would increase the facility greatly. The estimate was 30,000*l*.; but the rise of material has been exceedingly great since then; he should think 20 per cent., and that it would cost now 36,000*l*., including the new road. Independently of the footpaths, the roadway will be very nearly 50 feet; it is now 30 feet. This addition would be carried out in iron. The scheme, he admits, would not improve the bridge. But the question is, whether, circumstanced as London-bridge is, utility is to give place to architectural effect, or appearance and beauty is to give place to utility. He should certainly prefer the bridge remaining as it is in an architectural point of view; in fact, that was one point upon which he was exceedingly desirous that Sir John Rennie should be consulted, that if he had any objection to make to the committee he should be at liberty to do so, because it appears very wrong to interfere with gentlemen's works without consulting them. It would rather lessen the pressure than otherwise, because there are some very heavy granite parapets which would be removed. At the present moment, Sir John Rennie and Mr. Page are confining themselves to the soundings of the river. Sir John Rennie certainly does not appear to like the scheme at all. Cannot say what his report will be to the committee. There is no difficulty in making a passage through the end of the bridge on the south side, so that persons coming by the steam-boats might be able to pass from one side of the bridge to the other without crossing the main line of traffic. The widening of the bridge would not render it unnecessary; the design is quite a distinct thing altogether, to enable a person instead of crossing over the bridge to pass through it. The plan originated with Mr. Dawson.

BENNOCH, FRANCIS—Is the projector of the plan for a bridge across the Thames from St. Paul's. Sometime since calculated the expense of the actual bridge, and the approaches to that bridge from the level on the City side to the level again on the Surrey side. The estimate at that time was 120,000*l*. for the construction of the bridge, and 24,000*l*. more for the approaches on both sides of the bridge from level to level, making a total of 144,000*l*. Since that time, materials as well as labour have risen considerably, and if an estimate were to be given now it would be probably 20 to 25 per cent. higher than it was then. The width of the proposed bridge was 60 feet; but is now of opinion that instead of being 60 feet, it would be a wise economy to have it 80 or 90 feet wide—almost to have two bridges in one—because the traffic at this point would immediately be immense. It was proposed that the piers should be stone, with wrought-iron girders. Considers that a bridge could be built at that part of the river cheaper than anywhere else, because the property from St. Paul's-churchyard to the river side is property of comparatively little value; the streets are narrow, contracted, and ill-adapted to great commercial operations; so that warehousemen who require a considerable amount of room for their wagons avoid them. When you come to Thames-street, the property is necessarily very valuable, because of the number of wharves in that immediate neighbourhood; but it singularly enough happens, that just at that particular point the property is of less consideration than any other property which could be touched upon between the Temple and the Tower; this happens to be an iron wharf, where plain sheds are required to protect it from moisture and corrosion, and this could be done much better by the dry arches of a bridge on girders carried upon columns, and would form altogether a much better wharf than the owners now have. Then, on the Surrey side, thinks it would be almost impossible for the imagination to conceive a condition of society more fearful than that of the population through which the approach would go on that side from the point at which it touches the bank until it reaches the junction of the Southwark-bridge-road, near the Elephant and Castle; it is impossible for language to describe the condition in which the people are there, not living, but festering. It would be a great improvement to clear that neighbourhood away for the purpose of making an approach to the bridge; also as advantageous in a sanitary point of view as the construction of the bridge would be to the traffic. This line happens to come between two great thoroughfares, Blackman-street on the one side, and Blackfriars-bridge-road on the other side, and there is no other main street running through the district excepting the crooked approach to Southwark-bridge. The people have got crowded together, and the alterations made in other parts have driven the poor into this particular locality in great numbers. Thinks it would be an excellent plan to take advantage of such an opening to construct a large series of dwellings for the poor in that particular locality, where they are needed, near the river side, and sufficiently near their work to enable them to go to and fro without much fatigue or loss of time. Has had many designs and suggestions from people desirous of bringing their plans before the public. His attention has been directed to one of the most gigantic kind, which for elaboration, beauty, and adaptability, not only to the present necessities, but to all that may hereafter be required, surpasses every structure hitherto conceived; and witness has been told it can be executed for much less than the corporation believe would be required for an ordinary bridge. The scheme is this: the government have some notion of bringing the railways into connection with the Post-office, and if that be considered necessary for postal communication with the north of England, it is of course infinitely more required with regard to the continental postal arrangements, and that could be effected more easily from the southern than from the northern side. A railway is projected to come to the southern side of the river, and by a bridge at this particular point, with arrangements for a railway underneath, through which the mail-trains might pass, and enter a tunnel as soon as it reached the City side of the river, and come up to the Post-office, where the bags could, without labour or loss of time, be deposited. That has been provided for in connection with this bridge referred to. The name of the designer is Mr. Sang. Witness's bridge would not interfere with New Cannon-street; that street would form necessarily one of its approaches. New Cannon-street comes into St. Paul's-churchyard at the south-east corner of the cathedral; the street should spring from Watling-street if the new bridge is to be constructed; and one must be constructed in the course of time, since more bridges are really required, and that is perhaps of all positions about the best that could be chosen for the erection of the first new bridge. Starting from Watling-street and crossing New Cannon-street, it is about fifty or sixty yards to Old Fish-street, and that would be the point from which the new bridge would take its rise upon the dry arches, and be continued at a dead level till it reached the Surrey side of the river. There is a new street projected here to go to Earl-street, Blackfriars, in order to give relief to Ludgate-hill. The only object of this new street from this point at Bow-lane to Earl-street is to relieve Ludgate-hill of the traffic of this quarter that desires to cross the river. Here there is a large amount of expenditure proposed, merely for the purpose of accommodating the traffic from this point to Blackfriars-bridge. His opinion is, that Blackfriars-bridge is not sufficient, but that a new bridge must be made somewhere, and without loss of time. These new approaches to Blackfriars by Earl-street would cost at least from 180,000*l.* to 200,000*l.* Has no hesitation in saying that more than half the new bridge and its approaches could be constructed for the cost of this one new street; then not only a new line for traffic is got over the water, but the taking of the expensive property which the Earl-street extension would cross diagonally, is avoided. Is aware that this new street is proposed to be constructed for the purpose of taking off the traffic which comes over Blackfriars-bridge; but it so happens that Blackfriars-bridge is probably the worst position for a bridge that there is in the metropolis. They have chosen the lowest part on each side of the river as the place from which the bridge should spring. Now seven-eighths of all the traffic over Blackfriars-bridge comes from a high level, so that both on the Temple-bar side and on the St. Paul's side of the valley of the Fleet they are obliged to descend a hill to get down to the point from which the bridge springs. Then they must ascend a hill to get over the water, and Blackfriars-bridge hill is nearly as bad as Holborn-hill. Any wagon coming from any part of Southwark south of Blackfriars-road would never come over Blackfriars-bridge, but over the new bridge, and would save the double hill. Produced a table showing how the traffic arranges itself. Has gone into the question with reference to this improvement, and the statement shows the traffic of vehicles passing from Ludgate-hill over Blackfriars-bridge, and *vice versâ*, and from Earl-street over Blackfriars-bridge, and *vice versâ*, from 9 a. m, to 6 p. m., on Wednesday, February 8th, 1854. The Ludgate-hill portion of the traffic going over Blackfriars to and from the Old Bailey is as follows:—Islington and Kennington omnibuses 128; all other vehicles, 985; making a total of 1113. The vehicles that go over Blackfriars-bridge to and from St Paul's Churchyard are, 29 South-Western Railway and City omnibuses, and 405 of other vehicles; making 434. The vehicles going along Earl-street are, cabs, 83; all other vehicles, 502. Presuming that those 83 cabs have probably come from St. Paul's Churchyard down to Earl-street to avoid Ludgate-hill, I have therefore added them to the 434 vehicles to and from St. Paul's Churchyard; making a total of 517. Thus we have 517 vehicles going down Ludgate-hill to pass over Blackfriars-bridge, while we have 1113 going along the Old Bailey, and so over the bridge. The other vehicles, to the number of 502, consist of wagons, &c., which do not come from or go to the upper level towards Cheapside, except in rare instances, and therefore cannot enter into any calculation with reference to the new street. So this new street, if constructed, would only accommodate 517 vehicles during the day; and if you suppose that they would go at the rate of three miles an hour, it would leave each vehicle in this distance eighty-eight yards apart, instead of crowding upon each other as they do at present on Ludgate-hill. An omnibus starting from the Post-office to go to Kennington would be at the Elephant and Castle before it at present gets to Blackfriars-bridge, in consequence of the perpetual crowd and crush at various corners. Blackfriars-bridge will never be good for much until rebuilt. When brought down to 20 feet headway it may become a good bridge. There is a scheme afloat to adapt the river to the bridges by artificial dams, instead of adapting the bridges to the river. How this is to be done may perhaps be gathered from witnesses versed in City affairs. Now, in considering the best way to relieve the traffic in the street, of course the first question is in reference to the bridges. In fact, it was noticing the crowding of the bridges that led witness to devote his time to considering the question how we should best relieve the traffic of the streets. Finds that the traffic in the streets increases very rapidly, perhaps in a proportion that we can hardly believe; but taking the calculation for four years, finds that the traffic over London-bridge increases year by year from 5 to 7½ per cent. Has taken it for four years. Considers that it has increased in four years 30 per cent. at least. If Southwark-bridge be taken as about the centre of the City at the present moment, half-way between London-bridge and Blackfriars, and if a line be drawn from north to south, finds that there is all that enormous population lying south and east of the Elephant and Castle and the Clapham-road, which must come over London-bridge. And all that enormous population lying north-east of the Thames, east of Goswell-road, and the Angel, Islington, embracing the district of Finsbury, the Tower Hamlets as far as Limehouse and Stepney, and the whole of Hackney, Hoxton, Clapton, and Tottenham; and the wagons along the Docks have no other means of getting across to Rotherhithe or the railways on the other side than by London-bridge. Take, for instance, Mr. Torr, the animal charcoal-burner in Rotherhithe. He supplies the sugar-refiners on the Middlesex side with charcoal with which to refine their sugar; he employs some forty or fifty horses; witness believes he has ten wagons constantly employed; they are obliged to traverse three miles on the Surrey side, and three-and-a-half or four miles on the Middlesex side, to carry materials from one place to another, which are not a mile apart if they had a direct communication across the river. Taking the population on both sides, London-bridge supplies a population of at least a million; that is to say, a million of people requiring bridge accommodation have only London-bridge to give them that accommodation. Finds that in 1801, when the population was only 958,000, there were three bridges. In 1811 the population was 1,138,000, but we had no addition to the number of bridges. In 1821 the population was 1,378,000, and we had two additional bridges completed, which were found to be essential, making five in all. In 1831 we had one bridge widened; still we had only five bridges, although the population had risen to 1,654,000; the bridge widened being New London-bridge, which was opened in that year. In 1851 there was another bridge added, the Hungerford foot-bridge; making six bridges in all. But at the last census the population was 2,361,640, and yet we have no more bridge accommodation than we had when the population was 800,000 less. However rapidly the population has increased since the last bridge was opened, it has been trifling when compared with the increase of wagons, carts, carriages, cabs, and omnibuses, the latter being unknown before 1828, demanding wider streets and more bridges. There has been no toll taken off or changed since that period. The toll was taken off Blackfriars-bridge during the last century. Taking the population in 1821, and supposing that the population at that period demanded two new bridges, and got two new bridges, it would then give about 250,000 as the number of the population to be supplied by one bridge. If that be taken as the proper mode of ascertaining the necessity for bridge accommodation, we ought at the present moment, in London, instead of five bridges, to have at least ten bridges to accommodate the public. One of the reasons why the streets are so crowded in the City is, that almost all our leading thoroughfares converge at London-bridge. There is a large quantity of traffic from the west going to the South-Eastern Railway, and a large quantity of traffic from the north going over the water, and they prefer the high level of London-bridge to the low level of Blackfriars; so that all from that area, between Goswell-street, round by Hackney and Limehouse, come up to London-bridge; and there is a tremendous crush in Fenchurch-street. On the other side of the river we have them coming from Rotherhithe, Bermondsey, Greenwich, Camberwell, Clapham, and Wandsworth, all crowding to London-bridge. Now the question is, how to get rid of this traffic that is every day increasing. Thinks it would fall within the scope of the inquiry of this committee to see what is done in other great cities; for instance, in New York, over the East River, and over the North River, which is four miles wide, there is a continual supply of steam ferry-boats, starting every five minutes, sufficiently large to convey ten wagons and 1000 men, if required. If there was something of that kind at the river-side, say, for example, about the lower part of the Tower, and crossing over to Dock-head, there would be a continual traffic across, and relieve London-bridge of nearly one-eighth of its present traffic. It would not interfere with the traffic up and down the river. In

New York a very light toll is levied; where the city claims the river-side, they let the ferries to parties who are disposed to take them, and permit a small toll to be levied. The number of barges coming up the Pool during a flood-tide would cause some difficulty to a steam-boat crossing the river at such a time; but that would not be insurmountable. There might be a guiding chain underneath, to enable them to go very nearly in a straight line. There is always plenty of opportunity for crossing. Was prepared to offer securities to construct the bridges which he proposes in a way that should be satisfactory to the City and to the government for 500,000*l.*; including the whole of the approaches and the whole of the land from St. Paul's Churchyard to the level of Union-street. The corporation are very anxious he believes to carry out this improvement; their only difficulty is money. London-bridge cost—removing the old bridge, 35,600*l.*; building the new bridge, 680,232*l.*; and the approaches, 1,840,436.: making together, 2,566,268*l.* Mentioned to the committee two or three points with respect to the necessity for more bridges. Any man who comes over London-bridge twice a day, must be satisfied that at least two bridges are wanted to relieve the traffic; there is quite enough traffic there for two bridges. Produced the following table of the traffic taken by twenty-four men, who were employed on all the bridges on one day last year:

*Table showing the Traffic of the Bridges.*

| | | 982 | 1301 | 1531 | 1424 | 1239 | 1295 | 1330 | 1602 | 1511 | 12,215 |

When in Paris, witness took pains to ascertain the exact amount of bridge accommodation there, and finds they have, in fact, ten times more bridge accommodation in Paris, a pleasure-taking city, than there is in London, where there is a large amount of business conducted. Thinks the principal manufacturing city in France comes nearer the point, because we find there, as in London, a large population upon one side of the river, and another large population upon the other side of the river; at Lyons, in five miles, there are twelve bridges over the Saone, and in three miles and a-half, seven over the Rhone, making nineteen altogether. At Lyons, the population is only 350,000, or about one-seventh of ours; and if population be taken as the criterion for the number of bridges required to place Loudon on a level with Lyons in that respect, there ought to be 132 instead of seven bridges over the Thames. At Glasgow, they have opened two bridges within a very short time; they opened one last year, and they are now setting to work to get another, in order to have sufficient accommodation; there we find an example worthy of being imitated. Those bridges are paid for, to a certain extent, by money borrowed upon the tolls, but there is now a movement to have them entirely free. The parties on either side of the river are to pay a small rate, and it is proposed to keep them free in perpetuity. They have three stone bridges and a suspension foot-bridge; two of the stone bridges are 60 feet wide each, and the other 40 feet wide. Now, if three bridges are required for 385,000 people in Glasgow, then for London, with a population of 2,400,000, we ought to have at least eighteen bridges to have the same amount of accommodation. The four bridges at Glasgow are within half a mile; it is not quite half a mile from the lowest to the highest. While in Glasgow they have four bridges within a space of half a mile, in London we have only five within two miles; to equal Glasgow in this respect London should have twelve bridges. It is important to know that our streets are much crowded in consequence of wagons creeping along the river side instead of getting across the river at the most convenient point. In Glasgow the aggregate width of the bridge accommodation is 160 feet; in London, from Westminster-bridge to London-bridge, we have only 220 feet of bridge accommodation. In Glasgow there is 1 foot of bridge accommodation for every 2380 persons; in London we have only 1 foot for 11,363; in other words, the population of Glasgow enjoys five times the amount of bridge accommodation provided for the people of London. London-bridge provides accommodation for at least 1,000,000, which, being only 54 feet wide, gives only 1 foot for 18,000 persons designed to be accommodated by that particular bridge; so that, whether you take it as regards population or as regards traffic with reference to the bridge accommodation enjoyed by other cities and towns, London is the worst accommodated of any city in Europe. Witness produced the following table, which, he believes, is not to be found anywhere else; had considerable difficulty in obtaining the facts, which are gathered from various sources (*see Table on next page*). At Glasgow one of the stone bridges cost 42,000*l.*, another cost 36,000*l.*, and the third cost 28,000*l.* The difference between the width of the Clyde at Glasgow, and the width of the Thames at London is about one-half. The average water-way of the five bridges in London is 800 feet, and in the Clyde it is a fraction over 400 feet. None are at present free; there is an agitation for the purpose of making them all free. Twopence pontage is levied for each cart of goods, and one penny for coals; twopence for each cab with one horse, fourpence for the carriages with two horses. Has turned his attention to the question how the expense of the proposed new bridge could be met. From the evidence given

*Table showing the Proportions, Cost, and other Particulars relating to the several Bridges.*

| Name. | Length. | Width. | Height above High water. | Arches. | Span of Centre. | Begun. | Finished. | Waterway. | Material. | Architect. | Cost of Bridge. | Cost of Approaches. | Total. | Gradients, Surrey Side |

Average Width of Waterway, 800 feet.

by Mr. Brand, it appears that the Bridge-house Committee have now at their command about 230,000*l.* They have borrowed 431,000*l.*, and rather more than one-half the time of the annuities has expired, and that amount might be considered a very fair contribution for the City of London. Does not think that there is any body in existence at present that could be trusted with the levying of a rate; thinks it would be proper to have in London, as they have in Glasgow, a river trust, which, he believes, is composed partly of gentlemen and merchants, who use the river; a certain portion of the corporation form another part of the trust, and other persons appointed by the counties form another part; the whole being twenty-four persons in number; they form the river trust, to whom the management of the banks of the river, and the bridges, and everything of that kind is entrusted. Something of that sort might be done in London; the Corporation of the City of London, and the counties of Surrey, Kent, and Middlesex, might each delegate a certain number of members to form a certain trust, a bridge commission, for the express purpose of conducting these matters, and be vested with powers to levy a rate upon the population which they represented; or, if we have before long the whole metropolis divided into corporations, as has been elsewhere suggested, the thing would be easier done. As part of his scheme, suggests that a street should be carried straight to the Elephant and Castle. His belief is, that properly managed, the property so taken, being comparatively valueless at present, would increase so largely in value, that the ground-rent would, to a large extent, pay for the compensation given for the land. A wide street on the south side of the river, from Westminster to London-bridge, into which all lateral traffic would fall, if made wide enough—70 feet at least—could not fail to be of immense advantage. Thinks that a new road passing along the Surrey side is an exceedingly good plan for accommodating the traffic to the railways; but it would be still better if the South-Western Railway were to come to the point of the new bridge, opposite St. Paul's, and if the South-Eastern should have a branch to the same point for the accommodation of persons seeking that quarter of the city, and still more for the economy and convenience of our continental and colonial postage. By such an arrangement the mail-train might start an hour earlier every night, and the distance between London and Paris be shortened by an hour.

Walker, James, V. P. Inst. C. E., Consulting Engineer to the Navigation Committee.—The existing bridge accommodation of the metropolis is less than is requisite; the immediate remedy is to make those bridges that are now toll-paying bridges free. His reason for saying so is, that the collective width of road of all the free bridges over the Thames is 138 feet; and if a reference be had to the capabilities of the present bridges, and also to the alterations that are about to take place in them the collective width of thoroughfare might be increased 150 per cent. of its present amount, that there might be 323 feet. A favourable opportunity is now offered of purchasing the toll-paying bridges. A rate levied within a radius of ten or twenty miles of St. Paul's would be the best method of raising the purchase-money. Considers it more expedient to purchase Southwark-bridge than to build a new bridge to compete with it. The fairest manner of assessing the sums to be paid for the different bridges, would be to throw them open for a year, to ascertain the traffic. A bridge coming near or through Northumberland House, opening into Trafalgar-square, is much to be recommended; there is a greater distance of the river between Waterloo and Westminster bridges than anywhere else lower down; the distance between them by water is three-quarters of a mile, and one mile by the Strand. Thinks the Cannon-street improvements will give very great facilities to the communication over Southwark-bridge. Presumes that to consider what the bridge companies make now is a narrow way of looking at it as the purchase price; as the population increases so does the value of the property. The limited navigation of the Seine renders the erection of bridges easier than over the Thames. The width of bridges over the Clyde at Glasgow, one of which is just finished, is greater than that of free bridges over the Thames. London-bridge could not be widened as suggested without destroying its architectural beauty; he has no doubt that it could be done as regards solidity. The throwing open Southwark-bridge will relieve the inconvenience more than that of Waterloo. The approaches to Southwark-bridge might be made better at a comparatively small expense. To effectually improve the approach would be to make an archway as was done at London-bridge, and pass the traffic under it, but that would be a very expensive affair, now the inclination on the Middlesex side is too steep. The approach on the Surrey side is much better, being 1 in 30½. On the Middlesex side, thinks the inclination could not be improved without a considerable outlay; it is now only 1 in 20, not much steeper than Westminster, which is 1 in 22; a length in the approach to London bridge is 1 in 25; Ludgate-hill is 1 in 27, Vauxhall-bridge only 1 in 35. Does not know any improvement more desirable than an improved communication between the Surrey side of Waterloo-bridge and Union-street, Borough, there would then be a good communication all the way from Westminster-bridge to London-bridge.

McClean, John Robinson, C.E.—The only way to improve the bridge accommodation is to divert the traffic as much as possible. Widening the bridges will not alone accomplish the object of facilitating the course of traffic. Proposes to build two bridges, instead of rebuilding Westminster-bridge, one commencing at Charing Cross, close to the Duke of Northumberland's, and terminating in the Westminster-bridge-road at its junction with St. George's road. The second to be placed at the south end of the Houses of Parliament, near the end of Great College-street. The expense would be 1,500,000*l.* for the two, including the approaches. Would prefer a new bridge at Charing-cross to purchasing Waterloo-bridge. The funds for erecting the bridges could be raised by a rate on the counties of Middlesex and Surrey. A rate of two-pence in the pound would provide the means of building the two bridges and throwing open the money-paying ones. More bridges are preferable to widening existing ones.

Bateson, Samuel, C.E. and Architect.—Has particularly considered Blackfriars-bridge. Was led to thinking of it by having made a design for Westminster-bridge. Was led to that by having made previous designs for bridges. The subject was given by the Society of Arts some time ago, and witness sent in a design to them which he afterwards endeavoured to adapt for Westminster-bridge, and submitted it to the committee; but the design having been decided upon for that, he has endeavoured to adapt it to this. Retaining the three arches on either side, the expense would be 125,000*l.*, but calculating the whole bridge it would come to about 300,000*l.* Proposes two plans, one for widening the old parts of the bridge and the renewal of the remainder, the other a new part altogether. In the first increases the width from 42 feet to 70 feet, at an expense of 125,000*l.*, retaining three arches on either side. Is informed that three of the arches on either side are defective, and in consequence has designed an entirely new bridge of iron on stone piers, on a plan which would make the width 100 feet, and give two roadways of 35 feet each.

## MUNICH INDUSTRIAL EXHIBITION OF 1854.*

The building appeared appropriate to its purpose, and was generally admired. It was in the form of a cross, and was constructed of iron, glass, and wood, from the design of the architect, M. de Voit, of Munich, by the contracting builder, M. Cramer-Klees, of Nuremberg. The site chosen was the northern side of the Botanical Garden. The length of the main edifice was 800 Bavarian feet,† and that of the main transept 280 feet. The greatest height was 87 feet. The following is a correct statement of the space which the building afforded:—

| | | |
|---|---|---|
| | | Square feet. |
| Superficies of the glass hall (main building) | | 216,800 |
| Superficies of the adjoining engine-room | | 23,210 |
| Superficies of the adjoining room for agricultural implements | | 17,204 |
| | | 257,214 |
| Deduct for offices and staircaises | | 23,210 |
| Space for the Exhibition | | 244,814 |
| | Square feet. | |
| Of which the floor took | 64,556 | |
| the tables | 60,672 | |
| the passages | 119,586 | |
| | | 244,814 |
| The walls or sides took | | 48,927 |

The average space allotted to each exhibitioner (taking the number of exhibitioners at 6800) was calculated at about 18 square feet of flooring and tables, and 7 square feet vertically, making in the whole somewhat more than 25 square feet. The general effect upon the observer from within was undoubtedly good; but the pillars being of wood, not iron, was a circumstance which rather detracted from its general elegance and lightness. The entire of the cost of the building is stated to have been 180,000 florins, or about 88,000*l.* sterling.‡

* From the report of Consul-General Ward to the Earl of Clarendon.
† 100 Bavarian feet are equal to 95⅔ feet English measure.
‡ 1 florin of 60 kreuzers is equal to about 2*s.* sterling.

*Appointments, &c.*—Mr. John Whichcord, F.S.A., F.R. Inst. B.A. has been elected by the Justices of Kent, District Surveyor of Deptford. The following gentlemen were also candidates:—Messrs. Williams (second), Henry Jarvis, Edwin Nash, George Barnes, Legg, and Pring.

## THE NEW NORTH BATTERY, LIVERPOOL.

The new battery which has been built to the front of the river north-west of the Huskisson Dock, from designs by Captain Westmacott, is ready for the reception of the guns and Ordnance stores. It has been constructed by Messrs. Arthur and George Holme, of Liverpool; the principal material employed being Runcorn stone. It is a square building, occupying about 3000 square yards, and having been erected in the castellated style of architecture, it presents from the land side a handsome and substantial appearance. The battery fronting the river is completed, and ready for the reception of ten 32-pounders, with which it is to be mounted. At either end, and also facing the river, is placed a tower of solid masonry, on each of which will be mounted a 68-pounder, so arranged as to sweep the river in every direction. The steps by which access is obtained to the guns are of Irish granite. The parade is a fine open area, almost square, enclosed by the various accessory buildings requisite in connexion with a defensible construction, entrance to which is obtained from the east side by means of a drawbridge, suspended in the usual manner over a deep ditch or artificial fosse. On either side of the arched entrance are a series of apartments, to be used as quarters for the officers and men, a school-room, magazine, &c. These buildings are protected by a roof of great strength, covered with Seyssel's asphalte, and made bomb-proof. The battery is capable of defence in every direction, facilities being provided for mounting guns on all sides. It is capable of holding a garrison of 500 men, and, as a protection against privateers, will be found to answer the purpose for which it has been constructed. Beyond that it would be but of little use. The chimney-pieces, shutters, racks for the guns and cutlasses, and, indeed, nearly all the fittings, are of wrought iron. In the centre of the parade there will be two large tanks; and a lightning conductor will be placed near the magazine, which is protected by a brick arch, of great strength, made bomb-proof.

## THE DRAINAGE OF TOWNS.

### By Robert Rawlinson, Assoc. Inst. C.E.

[*Paper read at the Institution of Civil Engineers.**]

The Drainage of Towns is so comprehensive a subject, that its full and complete treatment, within the limit of a communication to be read at one evening meeting would be a useless attempt; the object of the present paper therefore is restricted to furnishing topics for a discussion, during the course of which it may be anticipated that the merits and demerits of the different systems of sewerage will be fully developed and freely canvassed.

Town drainage may be considered historically, politically, and socially. The historical portion of the question need not be entered into further than to say, that remains of what appear to have been drains are found in the long buried cities of Syria, and the sewers of ancient Rome partake of the fame of "The Eternal City;" indeed, the Cloaca Maxima is asserted by some authors to have been the work of a people older than Romulus. Livy, however, gives the reign of Tarquinius Superbus as the date of its formation.

Politically, the question of the best system of town sewerage and house drainage is very urgent, and at no period has it ever been of greater importance than at the present time. It may be clearly shown that the progress, if not the permanence, of civilisation is dependant upon a correct appreciation of its merits; as the healthy existence of town populations must ever be influenced by their sanitary condition. Misery, pauperism, vice, and crime find a forcing-bed in the unsewered parts of towns, and amidst the foul air of undrained houses.

This may not be self-evident on a cursory consideration, but facts and figures which will not admit of contradiction, can be brought in aid of the assertion.

The tendency of modern civilisation has been to congregate the human race in masses, and in Great Britain the extension of towns is unprecedented. In 1841, the population in one hundred and seventeen districts, comprising the chief towns, was 6,612,958 souls. In 1851, in the same districts, the number was 7,795,882, being an increase of 1,182,924 in ten years. When it is remembered that the greater portion of the area thus populated is comparatively low and flat, such as in seaports, on the banks of inland rivers, or in valleys intercepted by canals, it is not surprising that this crowding should produce disease, as is proved by the almost constant presence of fever, and a recurrence of the more deadly cholera. It is quite true that disease, in some terrible form or other, has ever been associated with man when thickly congregated,

*Excerpt 'Minutes of Proceedings of the Institution of Civil Engineers,' Vol. XII. Session 1852 53. Edited by Charles Manby, F.R.S., M. Inst. C.E., Secretary.

whether in cities, in towns, or in armies—but it may also be shown that much of the disease has been of that class which, by due precaution, might have been averted. A full elucidation of this portion of the subject belongs rather to the medical department than to that of engineering; it may, however, be stated that the averages of mortality, though much higher in town than in country districts, do not reveal the worst feature of the case, as the annual number of deaths in the most unhealthy parts of a town are frequently as ten to one, compared with the better parts of the same town. That is, if ten out of each thousand die annually in one district of a town, one hundred out of each thousand perish in another quarter of the same place; so that a statement of any given average of deaths per thousand would be liable to mislead. The average number of deaths in English towns ranges from twenty to thirty per thousand. In country districts the average does not exceed seventeen or eighteen per thousand; and amongst the well-regulated classes only about ten to fifteen deaths per thousand occur annually. In the convict prison, on the Isle of Portland, the annual average of deaths is only about five per thousand. There are, however, in that establishment neither infants nor very old people to swell the mortality.

This portion of the subject may be closed by a quotation from a valuable report on cholera in England, recently issued by the registrar-general, in which he says:—"A large portion of the next generation of Englishmen will be born in town districts, some of which are high and healthy, while others, low, insalubrious, subject to inundations, and to the incursions of cholera, present many of the circumstances in which a degradation of race is inevitable. In the dense districts of Lancashire, where the health of parents is depressed, and the circumstances are often so prejudicial to their offspring, that of the coming generation five, instead of two, of every ten born are destroyed in the first five years of life, and the survivors, with a few happy exceptions, are left with shattered, feeble, febrile, and disorganised frames—degeneration is as inevitable as the degeneration of horses, oxen, and sheep in circumstances equally unfavourable." The might of a nation consists in the health and strength of the people; therefore the supremacy of a country is, in a degree, dependent upon its general sanitary condition.

It is, however, to the social effect of town drainage that the attention of civil engineers will be most naturally directed, as under that head the leading principles of actual practice, and those modifications which have been proposed for adoption, must be brought forward and discussed. So much has been recently said and written upon town drainage, that it will be quite impossible to strike out either a new or an independent course, nor is it advisable to do so, as to study precedent, to learn from experience, and to correct from practice, are the chief duties of an engineer.

The much-disputed question of, "In what good town drainage consists?" can only be answered by the exhibition of actual works which do fully answer their intended purpose. The forms and dimensions of sewers, the materials of which they may be constructed, and the depths below the surface at which they should be laid, admit of some moderate difference of opinion, but certainly not to the extent now permitted in practice. In one position a brick sewer 5 feet high by 3 feet wide will be constructed at about 2*l.* 10*s.* per lineal yard, whilst in a similar situation there will be laid down an earthenware tube 1 ft. 3 in. diameter, at an expense of 8*s.* or 10*s.* per lineal yard. There must be something positively wrong in such discrepancy of practice as this, and the sooner the truth is discovered and proclaimed the better will it be for all parties. If that man is a benefactor to his race who makes two blades of wheat grow where one only grew before, he is likewise so, in a degree, who constructs two lineal yards of effective sewer for the price that has before been expended upon one yard; if the cheaper sewer performs its functions more or even as perfectly, then is the achievement so much the more worthy; but if it does not perform so well, then the innovation becomes an injury.

It has been asserted that no street sewer ought to be less than will allow a man or a boy to pass along it. The legislature has passed an Act to prevent boys being sent up chimneys, and, better arrangements being made for providing water for flushing, it may some day be inclined to pass an act to prevent men from entering sewers. The latter will be more humane than the former, as it is asserted that more lives have been destroyed in foul sewers than ever were lost in crooked chimneys.

In town drainage there are three primary considerations:—

1. The line for the outlet sewer or sewers, if more than one such be necessary.
2. The dimensions of these outlet sewers and their form.
3. The materials of which sewers may best be made.

The position of the outlet or outlets will in some measure be governed by natural conditions. They must be in such a relative position as shall least endanger health; and wherever it is practicable only one outlet should be formed, as the refuse will then be concentrated, either for natural removal or for agricultural use.

The size of outlet-sewers must be fixed by the number of houses to be drained, and the extent of the area upon which they stand.

The site to be drained may consist of flat alluvial land, impervious mud, or pervious gravel shingle; or the town may stand on the banks of a tidal river, the surface being very little above the high-water line, or it may be actually below the level of high-water of spring tides. Then there are inland cities and towns, through a part of which flow rivers liable to excessive land-floods, and the waters may be impeded by locks for the purposes of navigation, and by weirs for mills.

The site to be drained may be partially a flat plain and partially rising land inland, showing a tolerably straight front, or being convex towards the plain. The land may rise on both sides, as in a creek or bay, or may consist of several such creeks, with natural watercourses passing through each, bringing down the surface waters of suburban areas much larger than the town itself; these and other innumerable combinations, which need not be specified, are all questions, for the treatment of which no fixed rules can be given; each individual case will demand especial study, and must have local knowledge and care.

That the question may, however, be discussed, certain rules relative to town sewers will be assumed, which may or may not be established.

1. They cannot receive the excessive flood-water even of the urban portion of the site.
2. They ought not to be combined with the natural watercourses which drain large areas of surburban land previous to entering the urban portion.
3. They should be adapted exclusively for removing all the liquid and soil refuse from the houses in such a manner as to cause the least possible nuisance to the inhabitants.

Where the site of a town is a plain, only little elevated above the tidal water-line, the delivery of the refuse from the sewers must either be by pumping to render it constant, or it must be intermittent, and therefore leaving the refuse for a time stagnant in its channels of conveyance. Sewers and drains are frequently required in situations where high tides, land floods, or both combined, cover to a considerable depth the surface beneath which such sewers must be laid; or if the area is embanked, the waters rise above the level of the land and the outlet. These circumstances frequently serve as excuses for not attempting the formation of any sewers or drains, and most certainly it is much safer to the inhabitants that there should be no sewers, than that there should be sewers of deposit. That towns so situated may, however, be perfectly and even economically drained, is proved by the condition of Holland, where the land is almost all below the level of the sea, and yet it is the most densely-populated country in Europe. In England, great portions of Lincolnshire, Cambridgeshire, and other counties, with large areas of agricultural land only worth from one hundred to two hundred pounds per acre, are drained either by intermittent action or to a great extent by pumping-machines, designed by and erected under the direction of members of this Institution.

That which is done profitably for agricultural land may assuredly be carried out for town sites, where the intrinsic value of the land and of the property placed upon it (exclusive of the importance of preserving human life) is in many instances as one hundred to one, or even more.

Inferentially, it may therefore be stated that town sites may be profitably drained by pumping, independently of any commercial value attached to the sewage refuse.

Where a town site is partially a plain and partially rising ground sloping towards the level or low portion, the formation of intercepting lines of sewer to receive the contents of the sewers and drains of the higher portion, and to prevent their falling into the lower level, will save much pumping.

The sewers formed in level or low districts should be of minimum dimensions; they should be laid as near the surface as is consistent with their safety, and should be constructed of a material capable of bearing external pressure without crushing, and internal pressure without leaking or bursting. If sewers connected with a pumping establishment are much larger than corresponds with the lifting power employed, the current through them will be sluggish, and deposit will take place. It will be evident that such sewers should not be unnecessarily deep, in order that the artificial lift should be as little as possible; and they should be capable of resisting hydraulic pressure, as they will be liable to be filled above the crown, either through an extraordinary rise of tide or through heavy land floods. This latter consideration involves the question of sluices and valves, which, however, need not be entered upon in this paper.

Another reason why sewers in flat districts liable to surface flooding should be of minimum dimensions is, that maximum volumes of water in such places cannot be provided for in sewers. The river Eden, at Carlisle, rises about 20 feet, and the river Ouse, at York, rises about 18 feet above summer level, laying under water areas of many miles square. Large sewers in such districts would give no relief at such times, and in dry weather they would be a nuisance.

The assertion that "town sewers should not receive suburban waters or excessive suburban rain-fall," requires some explanation. The area drained by natural streams may be much larger than the urban area, and therefore any arched channel or sewer to convey away safely the flood waters of such a district must be in proportion to such area; the cost of course being in proportion to the sectional dimensions of the tunnel or sewer formed. Another consideration which ought also to have great weight is, that the flow of flood waters is intermittent, whilst the flow of sewer waters should be constant—that is, the sewers should be as much as possible self-cleansing, by the daily action of the fluids passing through them. This cannot be the case if a small body of water is spread out over a wide bottom or invert. There must in such a case be a deposit, which will be increased by such obstructions as stones, sticks, road-sand, gravel, &c., which will be carried from the open watercourses into all sewers or tunnels receiving the flood waters of a suburban district, because the channels leading to the sewer and the end of the sewer itself must be open. The stagnation of sewage refuse in such places will also be greatest during the driest period of the year, when the evaporation will be most injurious.

Several reasons may be given for the assertion that "sewers, other than main outlets under particular circumstances, should not be calculated to contain the flood-water of an excessive rain-fall," though one only ought to suffice—namely, that the waters of an excessive rain-fall cannot be passed through any ordinary gully-grates into the sewers. In Birmingham, on the evening of Sunday, the 6th July 1845, there fell 1·945 inch of rain in little more than half an hour. This was equivalent to 9·091 gallons upon each square yard of surface, or 44,000 gallons to each statute acre. This is no doubt such a flood as is seldom met with, but equal volumes of rain have fallen in the metropolis and in other places in England. Those who have any given area to drain for town purposes, taking these figures as multipliers will ascertain about the maximum if they premise that sewers ought to be of sufficient capacity to receive the storm waters and to retain or pass them off below the level of the cellars. In many cases the storm waters will pass over the surface after the formation of sewers just as they flowed away before the construction of any artificial conduits.

The dimensions of sewers ought in some measure to fix their depth below the surface, as there ought to be a fall of not less than one in sixty from the deepest house or cellar drain to the highest water-line to which a sewer can safely be allowed to be filled.

In arranging a system of town drainage an engineer must consider the following questions:—

1. How has the flood water hitherto passed away, seeing that there never has been such a work as a sewer in the district?
2. What has been done on the surface, in the formation of quays, roads, or streets, or in any other way to impede the free escape of the surface water?
3. What are the effects experienced during land floods?
4. Is it practicable to construct sewers large enough to pass the whole volume of a maximum rain-fall at such a level as shall not inundate the cellars with back-water?
5. What additional length of outlet will be involved to secure the fall required for large and deeply-laid sewers?

These are all questions of the utmost importance, involving economy and efficiency, but there are other minor questions which an engineer should settle before finally deciding on a system of town drainage.

There are sites upon which houses ought never to have been built, and cellars have been dug where the natural outlets upon the surface have been contracted or destroyed, instead of being preserved and improved. In such cases an engineer should constitute himself nature's journeyman, and by carefully observing the natural features of the locality, and using them as much as possible, attain his end more readily than by attempting any forcible control.

There are cases in which it is the province of an engineer, in some degree to oppose nature, but this must ever be a costly and dangerous undertaking, and nothing short of actual necessity will justify the attempt. The greatest men in the profession have shown, by their works, that they never undertook an opposition course, when they could accomplish their purpose in an easier manner.

In town drainage, nature must first be consulted, and effective assistance may then be given to her operations at the least cost. Where there has never been a sewer, it may not be considered necessary to construct one 5 feet deep by 3 feet wide, at a depth of some 15 feet, or 20 feet below the surface of the street, to the great danger of all the adjoining property, and, in many instances, to the certain destruction of the natural outlet.

If it shall be decided, the town sewers are not to convey away the drainage waters of suburban districts, and if it shall further be granted, that they cannot be made of sufficient capacity to contain even the urban waters, during maximum rain-floods, it may naturally be asked, of what dimensions should town sewers be constructed? and this may be partially answered by considering the principal intention in constructing town sewers.

If it be for house and yard drainage, then to these they should be adapted, —and there will be reliable data from which to calculate their dimensions. The sewers and drains will be of minimum size, and will, consequently, not require either very wide or very deep excavations to be made, and the cost of the work will also be reduced to a minimum.

It will be admitted, that many large sewers were not originally constructed to serve the purpose to which recent practice has adapted them —namely, to receive and convey away the contents of water-closets for an entire population.* The assertion may sound strange to the dwellers in this metropolis, where the practice of water-closet drainage has prevailed for some time; but few even of the metropolitan sewers were designed solely with reference to house-drainage. This duty has been subsequently imposed, but even now there are miles of sewers which do not receive the drainage of one-tenth of the houses in the district.

In Paris the contents of water-closets are generally excluded from the public sewers, and it is only recently that the law has been repealed in Liverpool, forbidding the turning of water-closet refuse into the sewers. The architect of St. George's Hall was obliged to arrange for the construction of large cesspools beneath the foundations, to receive the contents of the water-closets proposed to be erected in that building.

There are, in many towns in England, great lengths of sewers, which do not receive the adjoining house-drainage.

In discussing the best form for sewers and drains, it is necessary to consider carefully their dimensions, and the materials of which, under all local circumstances, they can most advantageously be made. The nature of the subsoil must first be well ascertained, before either the form or the material can finally be decided upon; that is, the engineer will frequently have to modify both the form and the material, in order to overcome some natural difficulties which could not be foreseen, but which will induce more or less alteration from the first design, and not unfrequently occasion even partial failure in the works of the ablest and most watchful engineer.

In existing sewers and drains may be found almost every sectional form, of which such constructions are capable; they are V shaped, square, oval, and circular, and also partake of every intermediate combination of these figures; V bottoms have been defended; flat floors, or inverts, have been advocated, and the egg shape has been insisted on, even down to drains of 4 inches in diameter. There have been as varied assertions, relative to diameters; but that question need not be discussed here, as actual works, the great test of engineering, can alone give a practical solution to this question. Beyond all dispute, there are many miles of sewers in existence, very much too large, and there may be some too small.

Rules have their use, and that man who works without rule will seldom be right; but he who works by rule alone may also sometimes be wrong.

Rules for the diameters of sewers and drains, to remove, not only the ordinary flow, but also the storm-water of districts, have recently been published,* and, as these rules are within the reach of every member of this Institution, more need not be said relative to them, at present.

If the materials of which sewers may be constructed, are to be subjected to local contingencies and conveniences, the sectional forms may be more definitively settled.

Sewers, having a transverse sectional width of more than 2 feet, should have a circular invert, in order that the minimum flow of water may be concentrated.

For sewers, less than 2 feet in diameter, the strongest form is the circle, whether they be constructed of pipes, tiles, or bricks. There may be an advantage in the egg shape, when sewers exceed 2 feet in diameter, but practically that form possesses none for lesser dimensions, and should not in practice, be adopted for small sewers or drains.

The best material for the construction of main sewers, is a question only to be determined by practical results. Brick, stone, and cast-iron, either used singly or variously combined, have each their partisans; recent practice has however indicated earthenware pipes as (apparently) the most economical and effective, for all sewers and drains, under ordinary circumstances, and within the capacity of the material. They have been made from 3 inches up to 30 inches in diameter; the former are too small for any drain,—the latter are too large for the material of which they are made.

It is self-evident, that theory alone cannot be followed in determining the sectional area of house-drains; if it were they might be reduced, in some cases, to the size of a quill, as more water will pass through such an aperture in the course of twenty-four hours, than is used in a cottage; but drains are devoted to other uses than the mere passage of fluids through them, and their sectional dimensions must be adapted accordingly. It will probably be eventually shown, that 4 inches in diameter is the minimum sectional area to be given to house-drains, and that they should not be laid at a less gradient than one in sixty.

This question of size may, however, now be left to be settled by practice; discussion rarely makes converts; but facts are stubborn things, when they can be arrived at without any colouring of prejudice.

The theory of pipe-sewers has been recently much agitated, and without undue advocacy of extreme views it may be asserted that no discovery of modern times is more fraught with benefit, if properly applied, than the use of pipe-sewers for town and house drainage. Streets have been effectively sewered, and houses efficiently drained, by earthenware pipes, where neither sewer nor drain would have existed, if costly brick constructions had alone been available.

Earthenware pipes cannot, however, be beneficially used as sewers, beyond certain limits, which can only be settled by practice; temerity will lead to failure, and failure will correct theory. The engineer who is anxious after truth will not denounce a system, because some men push it to extremes, and hence he will use the mistakes of others as his beacons.

* The Cloaca Maxima was designed and used by the Romans for conveying away both fluid and solid sewage.

* Vide "Minutes of Information on Sewerage and Cleansing of the Sites of Towns;" General Board of Health Reports. 1852. Page 67.

Various forms and modes of jointing earthenware pipe sewers have been tried; there are plain ends or "butt-joints," rebate-joints—full-socket joints—and half-socket joints. There are also both circular and egg-shaped sections. About fifty miles of pipe sewers are laid in Manchester, the majority of which are egg shaped, with plain or "butt" joints finished with clay. These pipes range from 4 inches to 30 in height and are laid with the narrow side down. In twenty-five miles of main sewers also laid with pipes, there has not been a single case of failure, and in the lateral drains, wherever a few failures occurred their causes were easily discovered; indeed at Manchester, the pipe sewer system may be said to have proved most successful, and in a recent report of the town council it is stated, "The economy effected by the use of tubular sewers is palpable, and the result will be, no doubt, a great extension of the practice of draining and consequent improvement of the public health."

The maximum dimensions of pipe sewers must be governed, in some measure by contingent circumstances. At present 15 inches or 18 inches diameter is the extreme size to be recommended for socket-pipes, and in laying these great care must be taken, or through unequal bearing, the pipes will break each other at the the joints.* Pipes with plain ends may be laid of as large dimensions as the material of which they are made will allow; care being taken to secure fair fitting and equal joints. Full-socket or half-socket pipes of 12 inches in diameter and under, may be used with advantage; where they are restricted to these dimensions, the pipes are much more uniform in shape, the relative strength of the material is much greater, and there is little danger of such pipes fracturing each other. The difficulty in moulding, drying, and burning pipes increases probably as the squares of the diameters. If large pipes are moulded too thin the finished sewer is liable to be crushed, and if they are moulded of extra strength the wet pipe collapses by its own weight in drying.

The side-junctions as moulded by the best makers are a great improvement upon the direct entrance of brick sewer branches, at right angles with the mains. A well-made pipe-junction increases the velocity of the current, by passing the sewage into the main in the direction of the flow, and all side junctions should have a quick descent for the last 3 or 6 feet before reaching the main.

Good and cheap sewers may be made with either solid or hollow radiated bricks, having their beds in the radius line of the curve. Bricks of this description cost very little extra; they may now be moulded of such dimensions as are required; for instance, sewers of 2 feet diameter may be made with bricks 4½ inches on the bed; those of 2 ft. 6 in. diameter, with 6 inches on the bed, and those of 3 feet diameter with 7 inches on the bed, and so on upwards; the limit being the capability of moulding the bricks with economy and of the workman handling them with facility. Hollow bricks may be used advantageously for the external ring of sewers constructed of more than one brick in thickness; the horizontal perforations forming channels for the land drainage.

Sewers of radiated bricks set in cement are cheaper than large pipes; that is, a brick sewer of 3 feet in diameter is cheaper than one of pottery 20 inches in diameter; the capacity of the sewers being as the squares of the diameters. There is no reason why brick sewers may not be made as smooth and as impervious to wet, as pottery pipes—either by selecting bricks of peculiar quality or by having the surfaces prepared with asphalte. It is difficult to arrange perfect side junctions in brick sewers, as every inlet should curve in the direction of the sewage flow: but pottery junctions may be worked into the brick sewers or in some cases cast-iron inlets may be used.†

In a system of sewers and drains, man-holes, at intervals will be of great service. These may be simple shafts of brickwork 2 ft. 6 in. or 3 feet in diameter, carried up over the line of sewer; if placed at intervals of one or two hundred yards apart, they enable the engineer to examine the action of the sewers, and should a stoppage take place, the exact spot is more readily indicated and discovered. They are especially useful at street junctions.‡

Street gullies are generally trapped, and there is a receptacle for the heavy detritus of the roads. Here again local contingencies will affect the application of rules. Small towns with paved streets where there is little wear and a good fall for the sewer, need not have any elaborate gully arrangements; the surface water may pass at once into the sewer, or into a well, or receptacle for the grit, out of which a plain bent pipe passes to the sewer, which latter will be all the gully arrangement required. Gully-grates should be tolerably fine, that is, the apertures should not exceed ¾-inch, and if there is a kerb-stone the grate may dish towards it and be continued up the side; so that, should the surface become choked, the water will pass off by the vertical side. Large openings into pipe sewers should not on any account be permitted.*

Sewers which require trapping are either faulty in construction or their action in use is imperfect. House-drains may be trapped by a plain bent pipe; mechanical traps of every kind ought to be avoided, they are a delusion and a snare; hinged traps impede the flow of sewage and do not prevent the escape of foul gases.

There should be full and free ventilation of the sewers at all the highest and most convenient points of a town, and where any escape of foul gas will be the least nuisance. Ventilating chimneys may be of much service in flat districts of great extent, or the steam jet may be applied; but furnaces should be used with caution, as the gases of a foul sewer are liable to explosion.

In some districts cast-iron pipes may be used for sewers with great advantage, as for example, where there is partial flooding by land-floods or by tides; or, in heavy ground in quicksands, and to cross intervening spaces, where towns stand upon alluvial shingle within tidal influences. Externally they may be laid in clay,—internally the metal will be protected by the fatty matter of the sewage.

The question of town sewerage or drainage, has of necessity been very briefly and imperfectly treated in this paper. Each branch of the subject might be made a text, which would require an entire essay, with many diagrams for its illustration; but as the author's principal object has been to elicit opinions in a discussion, he has merely ventured to treat generalities.

Certain rules may, however, be given for town drainage:—

Sewers should be below the level of cellars, and they should be adapted to the especial work they have to perform.

Rivers, brooks, and natural streams should not be made a part of a system of sewers, and the sewers themselves, in low districts, should be capable of resisting internal pressure.

Wherever it is practicable, the sewage of high districts should be intercepted, so as to preserve a free outlet at all times for this portion of the system.

Small sewers and drains should be circular; large ones should be oval, or egg-shaped.

The longest practicable radius should be adopted in laying out curves on lines of large sewers, and there should be an extra fall in the curve, especially at a junction with a main sewer. All sewers and drains should be impervious to water, and should present even and smooth surfaces; special arrangements being made for land drainage.

The gradient, or fall of large sewers, in steep ground, should be modified; that is, the gradient should be interrupted, or the sewer should be made of such material as will resist the tendency to rapid wearing away.

Wherever it is practicable, the outlet, or delivery of sewers should be free, and in every case there should be full and free ventilation.

Cesspools within a town, and either beneath or attached to houses, are subversive of sewerage and drainage; indeed, no town or city can be considered as drained, in which cesspools are pérmitted to exist.

Cesspools, or manure tanks, at or near an outlet, are nevertheless admissible; care being taken that such outlet or delivery of the sewage refuse is not blocked or impeded, and that there is no in-draught or back-draught through the sewers.

The true purpose of town sewers is the instant removal, from the vicinity of dwelling-houses and from the sites of villages, towns, and cities, of all refuse liable to decomposition, and which is capable of being conveyed in water. The more fully this is accomplished, the more perfect will be the system. Efficiency, durability, and economy should never be lost sight of, and though the drainage of towns may not, at first, appear to be an attractive occupation, yet if the works are well designed and executed, it will neither be the least noble nor the least useful pursuit of the Civil Engineer.

Mr. Rawlinson admitted that his paper might be considered loose and discursive, but he had written it chiefly for the purpose of eliciting opinions on a question of great social importance, and he was ready, in answering the questions put to him, to afford any additional information in his power. It might be said that there were some positions unduly assumed; if so, they would be overthrown, and the erroneous conclusions would be pointed out.

Perhaps the best method of opening the discussion was to state a few facts in connection with the drainage of a town, where, from local circumstances, only earthenware pipes had been used. He alluded to the town of Hitchin, where upwards of 60,000 feet of pipe sewers, from 20 inches down to 4 inches diameter, and 2 ft. 6 in. long each, had been in action for four months with perfect success; the average depth below the surface was 8 feet, and the outlet of the main sewer, which was 5000 feet in length and only 20 inches in diameter, was laid in part beneath the bed of the river, at an inclination of one in eight hundred. This was designed for the sewerage of one thousand houses, of which only two hundred were at present connected, and for eleven hundred acres of urban and suburban drainage. He admitted that some of the pipes laid

* In recent practice, the author has discontinued the use of full-socket pipes, above 9 inches in diameter, and has either adopted half-sockets, or used butt-joints laid on earthenware chairs. Unequal bearing at the joints has chiefly caused the fracture of the pipes, which has been so much complained of, and which should be specially guarded against.

† Since this paper was written the author has used stone inlets. The beds of the stones are worked to suit the radius of the brick sewer, and the inlet for the pipe drain is formed out of the solid stone. Messrs. Doulton have since made a pottery inlet, which must supersede the use of stone.

‡ In all the work done since this paper was prepared and read, the sewers, whether of brick or of pipes, have been laid in straight lines, from point to point, in lengths as great as were practicable. At the change of direction or of gradient, there is a man-hole, or hand-hole, to allow of examination, so that the light is never lost through a sewer.

* A gully grate has been invented and used by the author, which effectually traps the drain, and yet allows a direct communication with the sewer. It enables the drain or sewer to be flushed with the full force of any water at command, as a hose-pipe can be passed direct into the drain leading to the sewer.

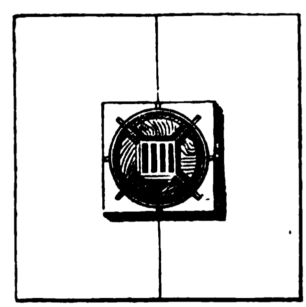

Fig. 4.—Plan of top of Lamphole, showing the Cover.

to a pumping-engine had been broken from being laid in bad ground, but after being relaid in wooden troughs no further fractures ensued. He was aware that the system of pipe sewerage had been, and must be, modified in practice to adapt it to certain localities; that in a rocky uneven bed improperly loaded pipes would break, and if of large dimensions, they were very liable to split longitudinally or be fractured transversely, as it was very difficult to get them accurately made and burned, and the false bearing at the sockets caused breakage. If in the case of Hitchin the rule laid down in Mr. Roe's tables had been followed, the outlet must have been 5 feet diameter, instead of 20 inches diameter.

No attempt has been made to divert the natural flow of the surface water, the street gullies being connected directly with the pipe sewers. In this, as in the arrangement for all towns, an engineer must modify his practice to meet local circumstances. He was satisfied with the general results at Hitchin; and as the earthenware pipes supplied by Messrs. Doulton, and put together with clay joints both of the full and half socket forms, had supported an internal pressure of a head of 4 feet, there was not much reason to find fault.

Pipe sewers had been in use at Manchester for seven or eight years, and Mr. Francis had expressed his satisfaction with the result; the only difficulties had arisen from a few cases of the choking of some of the smaller-sized pipes. In that instance where a great extent of oval pipe drains 25 inches by 18 inches had been laid with success, it should be explained that they were 2¼ to 3 inches in thickness, and were laid with great care in strong ground. The maximum size at which even these thick pipes were preferable to brick sewers was 30 inches by 24 inches. The smallest size made for small streets was 12 inches by 9 inches, and for foul water 6 inches by 4 inches. The largest area draining into a pipe sewer was about fifty acres.

On the authority of Mr. Harper, and quoting from a communication relative to some houses in Back King-street, Bury, he stated that though they had formerly been in so bad a state as to be untenantable, in consequence of fever constantly raging there, they had been rendered perfectly habitable by being drained with earthenware pipes, and that the experiment had been quite successful as regarded the general amelioration of the district.

[We next month intend giving an abstract of the discussion which took place at the Institution upon the subject of the above Paper. At present, however, we append some remarks made by Mr. Rawlinson towards the conclusion of the discussion, upon the subject of man-holes and lamp-holes.]

Man-holes and lamp-holes at short intervals, he said, were requisite on lines of pipe sewers, and each intermediate length should be quite straight, in order that they might be examined and cleansed, if and whenever it should become needful. At each manhole there should be an arrangement for flushing; and, in some instances, a depth of seven inches of deposit had been flushed out of a pipe of 15 inches diameter,

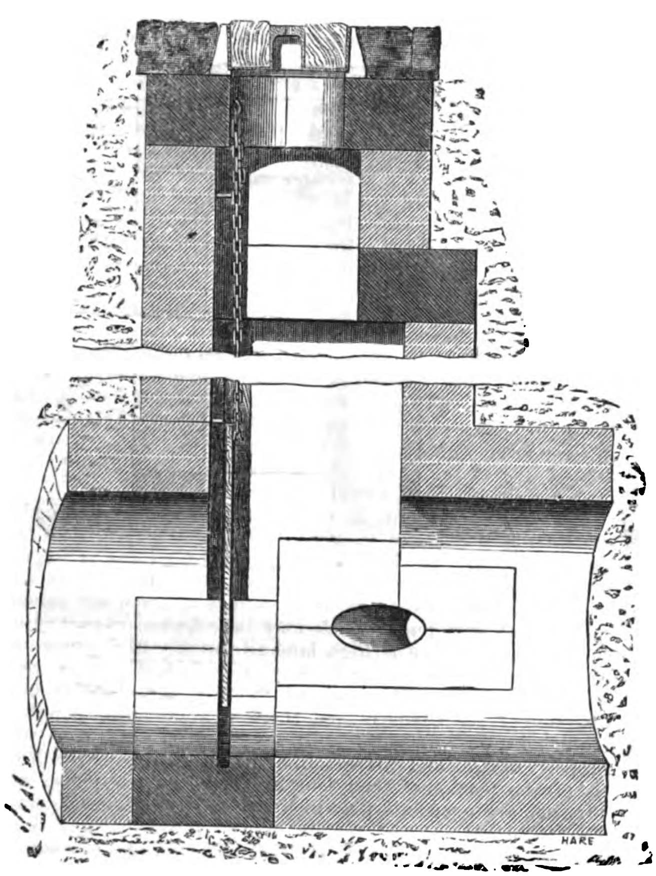

FIG. 5.—Manhole and Flushing Chamber, with Junctions on Brick Sewer. Section on the line A A, of Plan, Fig. 6.

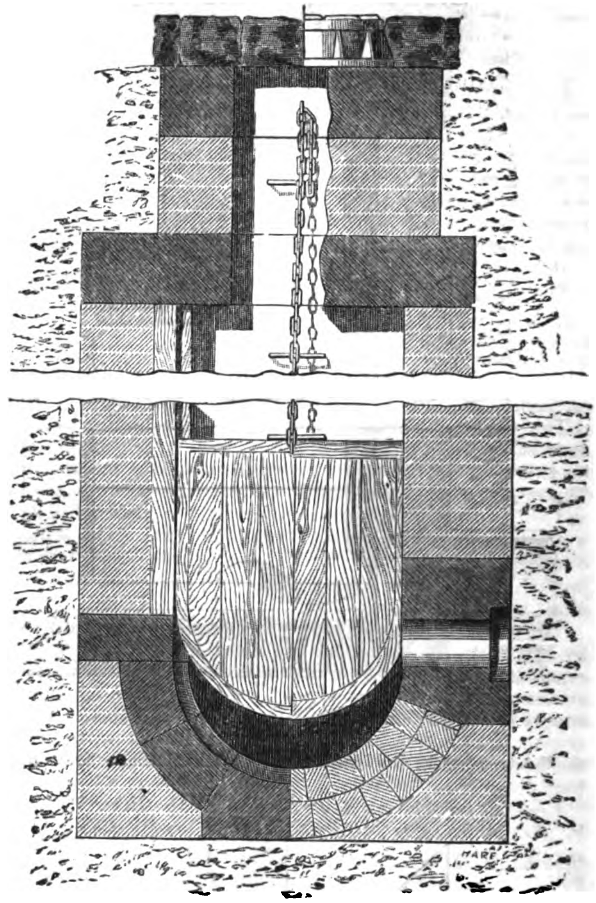

FIG. 7.—Section on the line B b B of Plan, Fig. 6.

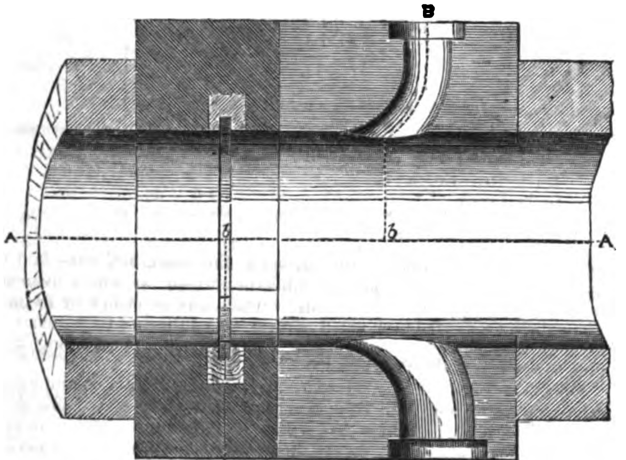

FIG. 6.—Plan of Invert.

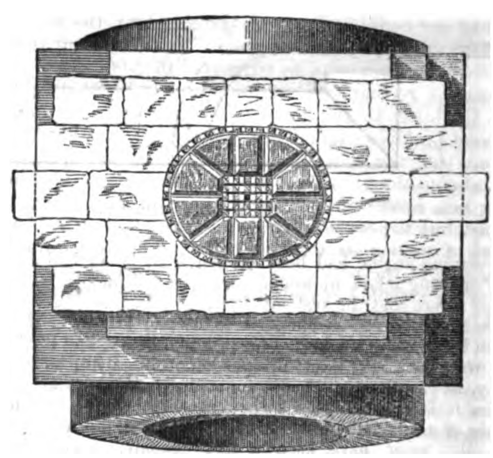

Fig. 8.—Plan of top of Man-hole, showing the Cover.

in ten minutes, leaving the pipe-drain perfectly clean. Precautions also were necessary to prevent sand, mud, or rubbish being introduced into the pipes whilst they were being laid; and the surfaces of roads, streets, and yards should be kept well cleansed, in order to prevent the dirt from being washed by heavy storms into and being deposited in the pipe sewers.

The annexed engravings exhibit the details of a manhole in a brick sewer, with side junctions from pipe-drains; and with a loose flushing-board fitting into a groove sunk in masonry. The manhole-cover could be lifted off by means of a key, in order that the sewers might be examined. Step-irons were fixed in all the manholes. All side junctions of pipe-sewers or drains, with brick sewers, were made with stone. Junctions were also now made of earthenware, and were preferable. The lamphole-cover was removable, so that a lamp or light might be lowered opposite the end of the sewer, in order to discover any stoppage.

## WATER SUPPLY AND SEWERAGE OF SWANSEA.

By Robert Rawlinson, C.E.

*First Report to the Swansea Local Board of Health.*

In accordance with a request contained in a letter from your clerk, Mr. Edward Strick, dated 20th April, 1854, that I would meet the Board in Swansea, on Thursday, the 25th April, I left London for that purpose, and at an interview with the committee, it was arranged that I should examine the water supply and sewerage, for the purpose of reporting thereon at the earliest possible period. A copy of Mr. Scott's report was placed in my hands, and I carefully examined the general and detailed survey of the town.

The committee are aware it was their wish that I would report, first upon the water supply, and especially as to the best means of making the existing works available to the uttermost. For this purpose, I made an inspection of the reservoir from which water is now drawn to supply the lower part of the town; as, also, a new upper reservoir not yet completed.

The existing works do not supply the higher parts of the district, neither can they, in my opinion, ever be made available for this purpose; they may, however, admit of some improvement. The area of land above the old and new reservoir is too limited, and the springs and streams too small, to yield a full supply of water for a large and rapidly increasing town. The water is also comparatively hard; and, as stored in open reservoirs, must be impure. At the time of my visit there were numerous tadpoles; at all times there will be conferva and animalculæ.

The question of water supply has been tolerably fully discussed by Mr. Scott, in his report of 1852. I have looked over that report, but consider it quite unnecessary to repeat published evidence, to prove that the existing works are not such as will supply the inhabitants of Swansea with good water in abundance, or even in moderate quantity. The works are now the property of the Local Board, and the only course to adopt is to make the best possible use of them.

I cannot recommend any extension of the Bryn Mill reservoir. It should however be kept in order,—well cleansed, and the spring supplying it opened out, to prevent waste which now takes place. The water from these springs may, with considerable advantage, be conveyed to the reservoir through earthenware pipes, properly laid, jointed, and covered. A considerable addition may be made to the present supply, if all the water at command is collected, as suggested.

The new reservoir may be finished, and the pipes now on the ground may be laid to convey water into the town; but before making any connnection with the old plant, the state of the pipes and taps ought to be ascertained. This reservoir may ultimately be used for new works, as suggested in this report.

I cannot recommend engine power to be used for lifting water from the lower to the new higher reservoir, as there should be the least possible expenditure on the present works; for I am of opinion that the water question, in Swansea, requires to be taken up and considered, in one respect, as though nothing had been done; not, however, for the purpose of neglecting the existing supply, but to prevent further mistakes, and an imprudent expenditure of money on works which are not as comprehensive and expansive as the requirements of the town demand.

Having satisfied myself that the district wherein the existing works are situated, will not yield the quantity of water at present required (and which will unquestionably be required), in Swansea, even should pumping be resorted to, I inquired if there were not other sources, at moderate distances; and several were named. I was informed that an Act of Parliament had been obtained to take water from Cwmgelly; as also that the river Llan had been proposed, and other minor streams in the district. Mr. Strick and Mr. Glasbrook also named the river Clydach. On the 26th and 27th of April I went, in company with the mayor, Mr. Strick, and Mr. Glasbrook, and examined Cwmgelly, the river Llan, several smaller streams near Swansea, and the river Clydach. Samples of the waters were obtained, and were subsequently submitted to Dr. Robert Angus Smith, of Manchester, for analysis, the results of which will be found in this report. As it will be necessary to obtain full information on the subject before any new works can be commenced, and as to obtain such information will be a work requiring much time, the expense may (at this stage) be avoided. It will be sufficient for the purpose of this report if I confine my remarks more to generalities than detail.

The present works I consider cannot be relied upon for the supply of water to Swansea. The reservoir is at an elevation too low, and the volume of water too small. Engine power would raise the water to a sufficient elevation, but I do not consider there is area or water at command, to warrant such an outlay; or, indeed, any costly permanent extension.

The several springs and streams from Cwmgelly to Swansea I also consider too limited, and otherwise objectionable. The Cwmgelly site, in my opinion, must be abandoned. During my visit, not more than ten thousand gallons of water per day was flowing down the valley. It would be most expensive, and I also consider, in some degree dangerous, to make storage reservoirs so near to the town. The water in such reservoirs would at all times be vapid, and more or less tainted, especially during very dry weather.

The river Llan would yield a sufficient volume of water even in dry weather, but the whole supply from this source would have to be pumped and forced through several miles of main. This river flows through ornamental grounds and fish-ponds of J. D. Llewelyn, Esq., and I am informed there is a mill or mills below the point from which the supply would be taken. Compensation, in some form, would have to be given for this water, besides the annual cost of pumping, which, from the length of main and height of lift required, would be most expensive.

The river Clydach is, in my opinion, the source to which the inhabitants of Swansea should direct their attention for a future supply of water to the town. The drainage area is large, the water abundant and singularly pure, the valley is but thinly populated, and almost free from minerals; there are numerous springs also very pure, which may be collected at any required elevation, and there is high land all the way to Swansea, along which conduit pipes of earthenware may be laid up to a covered service reservoir. The town of Swansea is extending in the direction of the Clydach, and there is a numerous population, requiring water, up to the junction of the rivers. Any works, properly devised and carried out, may be made productive through the greater portion of their length. There is mill power on the Clydach, arrangements for which will require due consideration. The following are the results of Dr. Robert Angus Smith's analyses of the waters of the district. The samples of water were taken on the 26th, 27th, and 28th of April, 1854, after ten or twelve weeks' dry weather. Mr. W. Roberts, and Mr. Strick (who owns and works the coal on the valley of the Clydach), stated they did not remember ever having seen the water so low:—

| | | | |
|---|---|---|---|
| River Clydach | 2·9 | degrees | of hardness. |
| Spring in the valley of the Clydach | 1·9 | do. | do. |
| Do. do. do. | 3·0 | do. | do. |
| | 7·8 | | |

or an average of 2·6 degrees of hardness.

| | | | |
|---|---|---|---|
| River Llan | 4·4 | degrees | of hardness. |
| Glanbrane Brook | 2·1 | do. | do. |
| Birchgrove Brook | 2·1 | do. | do. |
| Gelly Brook | 2·6 | do. | do. |

The river Llan, being the hardest water, contained most sulphate of lime. The total quantity was found to be 7·1 grains per gallon. All these waters are excellent—(the samples were remarkably clear). They are all soft, and contain chiefly sulphate of lime, a minute quantity of magnesia, and a little common salt. The water marked Glanbrane was least palatable.

The following table gives the quantitative analysis of the Clydach waters:—

| | Grains in a gallon. |
|---|---|
| Sulphate of lime | 1·6045 |
| Carbonate of magnesia | ·1542 |
| Sulphate of potash | ·0613 |
| Sulphate of soda | ·3113 |
| Chloride of sodium | ·75 |
| Silica | ·12 |
| | 3·0013 |
| Organic matter | 1·4 |
| | 4·4013 |

This water was tried with lead, and was found not to act perceptibly upon it; but a much harder sample in the same time gave a distinct amount of lead to the water. I thought it right to look for metals in the Clydach waters, but the tests did not give a trace.

(Signed) R. Angus Smith.

On comparing these analyses with those made by Professor Brande, and given by Mr. Scott in his report, it will be seen that the Clydach water is the purest in the district.

*General Remarks.*—Estimating the population of Swansea at thirty thousand, to provide twenty gallons per head will require six hundred thousand gallons of water per day. Any increase in the population, if provided for on this scale, will require, of course, a proportionate addition in the daily quantity to be supplied.

In establishing works of water supply, it is of primary importance to obtain the best source. The water should be the purest to be found in the district. The area from which it is to be drawn should be large, and free from works the tendency of which would be to taint the supply. If there are springs, they should be collected at the respective sources, and be conducted by means of earthenware pipes into covered fountain reservoirs. That source is the best which not only enables an engineer to secure such conditions, but which will enable him to supply the quantity required, or likely to be required, at such an elevation as will give high pressure without pumping, and volume without flood-water storing. Any moderate cost of additional distance in length of aqueduct main may safely be incurred to secure works which will yield such a supply.

The Clydach district is the only place within reach of Swansea where the advantages enumerated can be secured. The minimum volume of water in the river is several millions of gallons per day. The district, as is proved by the analysis of the water, is free from mineral impurities; the land, from its slope, mountain character, and isolation, is not likely to be more highly cultivated or more densely inhabited, and there is an elevation sufficient to give any required level above the town, with high land the whole distance, round which a comparatively cheap earthenware pipe conduit may be laid to service reservoirs above the town. Another advantage, and the greatest, consists in the district abounding with springs of singular purity, most of which are at elevations to render their waters available. Fully one-half the water required by the town may be, as it were, created; that is by collecting the springs, and by preventing evaporation and waste, water will be obtained which at present is lost on the mountain side, never reaching the river or the mills.

It is evidently one of the plainest maxims of prudence to select such a source, and such water for the supply of a town, in respect of quantity and quality, that no removal or alteration is likely to be subsequently required. When a wrong choice is made, every after expense, in extending such works, is but an aggravation of the first error.

The advantages of a supply of soft water are numerous; for instance, in the saving of soap, in the saving of tea, in the saving of clothes, in preventing furring or deposit in steam boilers, &c. One degree of hardness represents 2½ ounces of soap to be wasted with each one hundred gallons of water used for washing. Thus, one hundred thousand gallons of water, of one degree of hardness, will require the use of about 132 lb. of soap, which at 6*d*. per lb. represents 3*l*. 6*s*.. The Clydach water has an average hardness of 2·6. If, therefore, any harder water be used, and fifty thousand gallons of water are consumed daily for washing purposes, the cost to the town will be 1*l*. 13*s*. per day for every degree of hardness above 2·6, or an annual cost of 602*l*. 5*s*. Five degrees in excess of 2·6, will therefore cost 3011*l*. 5*s*. per annum more than Clydach water, for soap alone.

*Proposed Works of Water Supply.*—Sketch of works necessary to render the waters of the Clydach available:—The springs should be collected at the respective sources, and be conducted through earthenware pipes into a fountain reservoir, which must be covered. The line of aqueduct main will contour the land as far as possible. Valleys or water-courses may be crossed by light aqueducts, continuing any given gradient; or cast-iron syphon pipes may be adopted. Small covered service reservoirs may be constructed at the most convenient points where a supply is required, for populations situate on the line of the main; and one or more service reservoirs will be required for the town, at such elevation as will command every house within the borough. From these service reservoirs the mains, sub-mains, and branches will proceed into the town, and conduct the water into each street and every house, preserving it pure and cool, as collected from the springs.

*Proposed Works of Sewerage.*—During my short stay at Swansea, I could not enter into details necessary for a full report on the sewerage of the town. I examined the present outlet, as also the general features of the place; and, with the exception of that portion within tidal influence, I can say there will not be any work to execute either peculiar, difficult, or costly. Brick outlet sewers will be required in the low and level parts of the town; but in the higher parts, and along streets of steeper gradients, earthenware pipes may be adopted with advantage and economy.

*Summary.*

Having examined the existing waterworks, and having further considered the question of water supply, for the present and future requirements, I arrive at the following conclusions:—

That the existing works cannot be relied on for a full supply of water to Swansea.

That the water is comparatively hard, and is at present impure.

That the most economical expedients should be immediately resorted to, in order to make the present works available to the fullest extent.

That a full supply of pure and soft water will be of the greatest benefit to the inhabitants of Swansea, and the adjoining district, for domestic and other purposes.

That the water of the river Llan must be pumped, and the waters of Glanbrane, Birchgrove, and Gelly brooks must be stored, if used; all of which I consider objectionable.

That the river Clydach, and the springs having their source in the valley of the Clydach, yield pure waters in great abundance, sufficient not only for the present wants of the inhabitants of Swansea, but sufficient for any future requirements of the borough and surrounding district.

That accurate information is required relative to the existing works, the state of the mains, house service pipes, fittings, &c.

That the present reservoir should be preserved clean, the springs opened out, and the water prevented from wasting, either by absorption or evaporation.

That the new reservoir be completed, the pipes on the ground laid, and that the water available be put to its fullest use.

That accurate sections of the streets, &c., are required, to enable an engineer to devise and lay down a proper and comprehensive system of sewers and drains.

That surveys, sections, and gaugings, are required to enable an engineer to report fully on the proposed source of water supply, and to prepare estimates.

I beg therefore to recommend that the Board authorise the employment of a surveyor to put the present works to their full use, to complete the new reservoir, &c., and to make such surveys and sections, and obtain such general information, as will enable me to report fully, and to furnish the Board with detailed estimates for the necessary works of sewerage and water supply.

APPENDIX.

The following I submit as approximate estimates for works of water supply and sewerage:—

*Water Supply.*—The distance from the Clydach to Swansea is about seven miles; that is, an aqueduct main winding round or contouring the high land will be about seven miles in length. An earthenware pipe may be laid complete, capable of conveying one and a half million gallons of water in 24 hours, at a cost not exceeding 10*s*. per lineal yard. This would make the cost of such a main about 6000*l*. The necessary works on the Clydach for collecting springs, &c., need not cost more than 4000*l*., making in the whole, for collecting the water and conveying it to Swansea, 10,000*l*.

Service reservoirs, service mains, sub-mains, and branches, within the town, will not cost more than 15*s*. per head, making, for a population of 30,000, a sum of 22,500*l*. Add for land, compensation, engineering, incidental expenses, and other contingencies, 10,000*l*., and the estimate will be as under:—

| | | | |
|---|---|---|---|
| Works on the Clydach ..................... | £4,000 | 0 | 0 |
| Aqueduct main to Swansea ............... | 6,000 | 0 | 0 |
| Plant within the town, service reservoirs, pipes, &c. .......................... | 22,500 | 0 | 0 |
| Compensation, land, engineering, and incidental expenses and contingencies | 10,000 | 0 | 0 |
| Total ..................... | £42,400 | 0 | 0 |

I find Mr. Scott estimates the cost of waterworks, (for an increased population of 55,000) as under:—

| | | | |
|---|---|---|---|
| Works on the Western district............ | £91,000 | 0 | 0 |
| Works on the Cwmgelly district ......... | 55,000 | 0 | 0 |

The works, as projected for the Clydach district, will serve for a population of 100,000, and may, at any time, be increased to serve a population of half a million, without the loss of one pound of the money expended on the projected works.

*Sewerage.*—The sewerage of Swansea I have said will not be difficult. There are peculiarities to be considered,—in outlet, in contour, and in sub-soil. These will, in a degree, alter any general estimate, but not to an extent of 10 per cent. I have estimated in detail, works of sewerage, complete, for a similar population (30,000), and I consider that a sum of 25,000*l.* will most completely sewer and drain the borough of Swansea.

| *Springs Gauged in the Clydach Valley*— | | Gallons in 24 hours. |
|---|---|---|
| White well, Clydach | about | 45,000 |
| Cefn Parc spring | about | 40,000 |
| Ffynon Las spring | about | 35,000 |
| Two small springs | about | 40,000 |
| A third small spring | about | 10,000 |
| | or a total of | 170,000 |

These, as Mr. Strick and Mr. Glasbrook can verify, form only a small portion of the whole, and yet it will be perceived there is nearly one-third of the 600,000 gallons required for present purposes.

*June 5th*, 1854. Robert Rawlinson, C.E.

*Second Report to the Swansea Local Board of Health.*

On the 5th June last, I reported briefly on the water supply and sewerage of Swansea. Since that period, one of my assistants has thoroughly investigated the existing "plant," and I now beg to suggest such alterations, and additional works, as appears best calculated to make the existing water supply available to the uttermost.

*Waterworks.—Suggested Extension and Improvements.*—The waterworks at present consist of an open reservoir at Bryn Mill, from which a cast-iron main leads to the town of Swansea, and there are branch pipes through certain streets in the lower part of the town. All the springs flowing into the reservoir pass through open channels, and consequently the water is liable to contamination, from disturbance by cattle, and otherwise; as also during heavy rain. It is proposed to lay earthenware conduits from the springs down to the reservoir, so as to preserve the water comparatively pure at all times. Some of the springs now flowing down to the Bryn Mill reservoir may be taken to the Cwmdonkin reservoir, giving all the additional pressure obtained from the latter site.

The service pipes within the town have been examined. They are sound, but deposit and rust have diminished the water way, by partially choking them. A portion of this deposit may be cleared out, and the pressure from the Cwmdonkin reservoir will render the pipes more serviceable, by quickening the flow. The street mains will, I believe, bear the additional pressure. House service cocks, of the common low-pressure construction, must be replaced by high-pressure screw-down taps. This need not cost more than from two to five shillings per house, including material and labour.

*Cwmdonkin Reservoir.*—It is proposed to make this reservoir water-tight. At present, with 37,000 gallons of water per day flowing in, not less than 19,000 or 20,000 gallons are lost by leakage, with an average depth of four feet. The depth, when full, will be about 18 ft. 6 in.

It is also proposed to conduct the waters from Fynone and Carn Glas springs into Cwmdonkin reservoir; thereby adding to the volume of water which may be delivered at high-pressure.

A portion of the 12-inch pipes will be laid from the reservoir, and all the 7-inch pipes at present in store (with such additional length of new pipe as may be required), will be laid along the new road, to Mansel-street and Cradock-street. This main will also supply Brunswick-street and Brunswick-place.

The new mains will be connected with a portion of the old mains, giving additional pressure, and consequently making them more efficient.

All existing street valves on the water mains require casings to protect them.

New fire cocks or hydrants are required. These, with the water from Cwmdonkin reservoir, will do the work of many fire engines. Streets may also be watered, and channels cleansed, by means of the hose and jet.

The water in Cwmdonkin reservoir will be 206 feet above datum, or medium tide level. This will give about 100 lb. pressure on the inch at the docks and wharves. If hydraulic cranes and lifts are used, they may be worked by this pressure.

The works, as proposed, will bring in an immediate rental far more than equivalent to the outlay.

The whole of the works proposed below the Cwmdonkin reservoir, new mains, repairs to old mains, valves, and hydrants, will be serviceable should the Clydach scheme be accomplished.

The entire expenditure now proposed for these works will be as under:—

| | | | |
|---|---|---|---|
| Cwmdonkin reservoir to be made water-tight, say... | £250 | 0 | 0 |
| Covering in Cwmdonkin stream | 60 | 0 | 0 |
| Diversion of Carnglas stream | 275 | 0 | 0 |
| Diversion of Fynone stream, &c. | 150 | 0 | 0 |
| Providing and laying new mains to town | 750 | 0 | 0 |
| Putting casings on old valves | 35 | 0 | 0 |
| New hydrants or fire cocks | 150 | 0 | 0 |
| Fixing ditto ditto | 50 | 0 | 0 |
| Stand-pipes and hose | 50 | 0 | 0 |
| Altering old mains, cleansing ditto. | 150 | 0 | 0 |
| New mains in side streets | 2000 | 0 | 0 |
| Contingencies | 90 | 0 | 0 |
| Total | £4000 | 0 | 0 |

This expenditure will furnish to the town about double the present volume of water supplied by the works as they now exist; and will ensure the water being free from surface contamination, both to the Cwmdonkin and Bryn Mill reservoirs.

The present minimum volume of water supplied by the old works is 120,000 gallons per day. The Cwmdonkin reservoir, completed as proposed, will supply an additional 120,000 gallons in the driest season.

*Sewerage.* — The whole question of Sewerage cannot be laid before you at present, as the requisite plans are not completed. Attention has however been directed to the east side of the river, as also to the Town Ditch and Mysydd Fields district. The works proposed to be executed in these districts, will form part of any general scheme. They may at once be carried out, giving immediate relief in places where fever prevails, and the new outlet sewer will be brought more fully into use. The particulars of the works proposed to be undertaken immediately, are as under :—

East side of river:—

1230 Lineal yards of main sewer.
15 Manholes and covers.
28 Street gullies.
1 Tidal cast-iron outlet, with flap, &c., complete
Estimated cost, £600

Town Ditch and Mysydd Fields district:—

2880 Lineal yards of main sewers.
30 Manholes and covers.
50 Street gullies.
Estimated cost, £2000

Summary:

| | | | |
|---|---|---|---|
| Waterworks | 4000 | 0 | 0 |
| Sewerage of Mysydd Fields district | 2000 | 0 | 0 |
| Sewerage east side of river | 600 | 0 | 0 |
| Total | £6600 | 0 | 0 |

It is proposed to expend 4000*l.* in improving the water-works; this, at 5 per cent., represents 200*l.* per annum: for depreciation, and to provide a sinking fund to repay the principal in thirty years, say 100*l.* additional. The annual charge will thus be 300*l.*, and the probable income may be stated as—

| | | | |
|---|---|---|---|
| 1500 Houses, at 10*s.* each per annum | 750 | 0 | 0 |
| Trade purposes | 150 | 0 | 0 |
| | £900 | 0 | 0 |
| Deduct Annual charge for interest and depreciation | 300 | 0 | 0 |
| Clear gain | £600 | 0 | 0 |

In addition to which the principal, or proposed outlay of 4000*l.*, will be paid off in thirty years.

The Board will be enabled to judge as to the benefit to be derived from the proposed expenditure on the waterworks. It will be bringing into use much property now absolutely waste; and the additional houses supplied will be benefitted far more than the rental proposed to be charged. The existing works are in a very neglected and ruinous condition. As stated, all the water collected is liable to surface and other contamination. The sluice valves within the town are absolutely without any casings, and the brass spindles, in some places, project through the roadway several inches, exposing the valves to ruinous concussions from cart wheels and endangering the feet of horses. There are no fire cocks on the mains which can be used; neither are there any wash-out valves. The cost of these improvements and additions is included in the estimate given.

ROBERT RAWLINSON, C.E.

*Westminster, Nov.* 4, 1854.

## NEW MANUFACTURE OF SHOT.

PROFESSOR WILSON, in his special Report on the New York Industrial Exhibition, describes the following new process for the manufacture of shot:—The building, of the height of an ordinary house, was arranged so that a cylinder or large shaft in iron or wood should connect the upper story where the melting-furnace and dropping-pan were fixed, with the lower story in which the water receiving-tub was placed. This cylinder or pipe constituted the air-shaft, and communicated at the bottom with a blower driven by steam power. When in operation, the metal was melted at the top in the usual way, and dropping down this shaft encountered a powerful blast of cold air being driven up it, the divided metal or shot finally falling into the water-receiver at the base. The advantages of this over the ordinary method of making shot, show themselves in two or three points. In the first place, the expense of building a high tower is avoided; the effect obtained by letting the molten lead fall through a long column of air in a quiescent state, is equally secured by its descent through a shorter column driven rapidly in an opposing direction. The saving in power required to lift the lead to the lesser height will go far towards furnishing the power required to drive the blast. In the practical part, he was informed a very decided advantage was shown over the ordinary method. In dropping lead from a high tower, it is necessary to keep the lead at as low a temperature as possible, consistent with its fluidity or capability of being poured, in order to counteract the tendency which the shot (the divided metal) has to burst while falling at a high velocity, owing to the unequal resistance of the air, and thus become useless except as metal.

In the old method a considerable proportion of waste shot is thus incurred, and in dropping large sizes, a greater or less proportion of smaller sizes are always made, and, indeed, a certain quantity falls of so small a size as to be fit only to be melted up again. By this new method, the metal is dropped at a higher temperature, its fluidity enables it to drop more rapidly, and the falling shot are cooled so rapidly and so equally by the blast, that no loss is sustained by bursting, and each dropping made varies but in a small proportion from the sizes worked for.

The process was invented in 1848, by David Smith, of the firm of T. O. Leroy and Co., of New York, who commenced the manufacture of shot in 1849, and have carried it on successfully up to the present time, having made and sold upwards of 5000 tons in that period. The process is patented in the United States, and also in this country.

## IMPROVED STEAM TRAVELLING-CRANE.*

(*With an Engraving, Plate* XLI.)

THE economy of manual labour in working travelling-cranes is a subject of great importance to the builder and contractor for heavy works, and much attention has been given to the subject for several years. Steam power has been employed for some time for the lifting and removal of heavy weights, and the amount of saving in wages effected by a steam travelling-crane, compared with the ordinary hand-labour machine, has been sufficiently proved during the last four years.

The crane which is the subject of this paper, the construction of Messrs. Dunn, Hattersley, and Co., of Manchester, closely resembles the general appearance of the ordinary travelling-crane used by masons and contractors, as shown in the Engraving, Plate XLI. The longitudinal way, transverse carriage, and crab, are arranged in the usual manner. The steam-engine and boiler with its driving-gear is supported upon a platform at one extremity of the transverse carriage, being fixed thereto and travelling with it, in a longitudinal direction, whenever so required.

The advantages sought by this crane are, that the steam power travels with the traversing carriage, and does not require any longitudinal shafts or bearings, which is the case when a fixed engine is employed; the lubrication and friction of the longitudinal shafting being also saved. It was found from the great length of the longitudinal travel in the remarkably extensive works for the viaducts and bridges of the Grand Trunk Railway of Canada, that the introduction of such modes of driving was too expensive. The saving of these shafts and bearings in the first cost was not the only consideration, the wear and tear, and lubrication being a further source of expense, and the repairs very inconvenient.

The steam travelling-crane was designed for the construction of the above works, for the contractors, Messrs. Peto, Brassey, and Betts. It was intended to work to a distance of three-quarters of a mile, by extending the framing and traversing rails. The first crane was completed, but not yet at work; it was intended for setting the stones of the piers in the Great St. Lawrence Bridge, and several more were being constructed. The cost of the whole was 550*l*., including the engine and boiler, but exclusive of the timber-work for the frame of the traveller and platform and the shed over the engine, which was not sent out, and would be supplied in Canada; and it is thought would not exceed a total cost of 650*l*. including them. The crane was intended for lifting 10 tons, and moving it into any position; it would take more, but was constructed to take that load in regular work. The engine and boiler weighed 2¾ tons; a pair of cylinders, with cranks at right angles, was employed to give uniform motion without a fly-wheel, and the boiler was tubular, 2 ft. 4 in. diameter and 8 feet long, with 2-inch copper tubes; the fire-box casing was lined with fire-bricks, and had to be adapted for burning green wood, the fire-bricks retaining the heat for the fresh charge.

A pair of small direct-acting horizontal high-pressure steam-engines A, A, are secured to the two main timbers B, B, of the traversing-carriage. The boiler C, is constructed for burning wood; the tubes are made of solid copper, without seam or joint, so that the acid from the wood cannot corrode them.

The engine and boiler with the driving-gear are protected from the weather by a cabin D, D, constructed of light framework, and covered with a corrugated iron roof. The power of the engine is transmitted by a spur-pinion E, upon the middle of the crank-shaft, through a spur-wheel placed on the horizontal main driving-shaft F, which communicates the motion for hoisting, lowering, traversing, and moving the crane longitudinally. Each motion can be used independently of either of the others, or simultaneously, when required. The communication of the power to the various motions is effected by the three sets of mitre-wheels upon the main-shaft, which are engaged or disengaged at pleasure by means of three handles G, H, I, that move the sliding clutch-boxes as required by the attendant. Three mitre-wheels are furnished to each motion, so that whilst the engine revolves continually in one direction, the reversing of any motion can be effected by the intermediate wheels, as in the ordinary manner.

The motion for moving the carriage longitudinally is conveyed through the wheels at I, at the extremity of the driving-shaft furthest from the boiler. The middle one of the three handles H, engages or disengages the motion K, for hoisting and lowering; and the handle G, next to the boiler belongs to the motion L, for traversing the crab with its weight. The arrangement for moving the crane longitudinally by means of spur-gearing driving the travelling-wheels T, T, is similar to the plan adopted to a hand travelling-crane. The travelling-wheels run upon rails M, M, which are fixed at 54 feet gauge, centre to centre.

The hoisting and lowering motion is transmitted to the chain-barrel K, of the crab, by means of an endless chain N, which is placed in the longitudinal direction of the traversing-carriage, and is driven by a pulley fixed upon the counter-shaft O, parallel to the main shaft; the motion is communicated by a pair of mitre-wheels through the short intermediate shaft at right angles. This endless chain is connected to a pair of mitre-

J.R.Jobbins.

wheels fixed at the lower end of the crab-carriage, which give motion to a worm-wheel, the latter being keyed upon the chain-barrel.

The transverse motion of the crab is obtained by another chain P, placed in a parallel position on the opposite side of the main timbers of the traverser-carriage; this chain is attached to the four-wheeled crab, and passes over a pulley on the axis of the worm-wheel L, which is driven by the bevil-gear.

An additional handle R, is provided for the purpose of throwing out of gear the chain N, of the hoisting motion, by means of the clutch-box U, at the time of the transverse motion of the crab; and the chain N, then runs with the crab; the pulley at U, turning loose on the shaft.

A simple apparatus for adjusting the requisite tension of these chains is provided at the furthest extremity of the two main timbers of the traversing-carriage, at the opposite end to the engine, consisting of a tightening-pulley S S, sliding in grooves, and drawn back by a screw.

This crane is constructed to lift at the rate of 6 feet per minute. The longitudinal motion works at the rate of 30 feet per minute, and the transverse motion at the rate of 20 feet per minute. The engines are 6-horse power collectively. A wrought-iron water-tank is placed under the engine, the top-plate of which formed the bed-plate for fixing the cylinders.

The motions can be worked altogether or separately, as desired; and the clutch-box levers are so arranged that the man in attendance can work all the motions from one place.

## WATER SUPPLY OF BIRMINGHAM.

*Report of* THOMAS CLARK, C.E., *to the Public Works' Committee.*

HAVING on the 5th of August last been favoured with a copy of a resolution passed by your Board, directing Mr. Pigott Smith to call in my aid, to ascertain the quantity of water that could be collected at Digbeth, and made available to supply the town of Birmingham, with an estimate of the probable costs; after conferring with Mr. P. Smith on the subject, and making a general survey of the suburbs of the town, I found that to have anything like an adequate supply, the quantity to be obtained must be a very large one indeed. A careful consideration of the requirements of the place, induced me to write to you on the 16th of the same month, soliciting you to favour me with your estimate of the probable quantity of water you deemed it necessary to obtain. This led to my being favoured with an interview with the committee, when the subject of the supply was brought fully under the attention of the committee, and I was directed to examine the locality, and report to you what supply, in my opinion, it would be practicable to obtain—how it could be obtained and made available—and the probable cost of the same.

I beg leave now to submit to you my report, accompanied with drawings, illustrative of the mode of constructing the works which I shall recommend to your consideration, for effectuating the object you have in view, as to procuring the supply, raising it, and distributing the same.

As regards the place where the supply should be procured, it appears to me that the best that could be selected would be the piece of vacant ground in Park-street, partly belonging, as I am informed, to the corporation, and partly to Mr. Dadley.

The situation of the ground, renders it, as it appears to me, the most fit place for the waterworks. I, therefore, made an experiment to ascertain the nature of the strata, and the probability of obtaining a good supply. The experiment was made by boring down to the depth of 137 feet, which proved so successful as fully to justify the selection of the place. This experimental boring, or testing the supply, yielded a flow of water at the rate of 115,200 gallons of water per day of twenty-four hours, and of a quality most unexceptionable, as the chemical analysation to which it has been submitted, and to which I shall hereafter have occasion to allude, will clearly show.

The survey I have made, together with the results of the experimental boring, satisfy me that a supply of excellent water, to the extent of 1,008,000 gallons of water per day of twenty-four hours, or 700 gallons per minute, may be relied upon.

I recommend the following plan to be pursued, for the purpose of obtaining a supply, and to make it available for the town.

That four shafts each 8 feet clear in diameter, should be sunk; that a communication by tunnelling, or adits, constructed of an oval shape, should be made from the others to the shaft, which on the plan No. 2, is represented as the pumping shaft. That the depth of the pumping shaft should be 90 feet, and 10 feet diameter. All the shafts to be steined with 14 inches brickwork laid in Roman cement, and that a boring of 15 inches diameter should be made in each of the shafts, to the depth of 140 feet from the surface of the ground, and in all the borings to fix a cast-iron pipe of 12 feet in length, and securely drive the same 8 feet below the bottom of the respective shafts, as shown on the section accompanying this. That all the tops of the shafts should be covered with wrought-iron chequered plates, fixed to strong iron girders, at the surface of the ground, to afford free access at any time to the shafts. If you should be pleased to adopt this mode, I feel no doubt whatever but that the supply I have mentioned, viz., 1,008,000 gallons of water per diem of twenty-four hours will be obtained.

To raise the supply, I advise that a double set of three-throw pumps should be fixed in the pumping shaft; the pumps to be 16 inches in diameter, and have 2 ft. 6 in. stroke. The barrels and fittings to be gun-metal, and the buckets to be fitted with butterfly valves, and the lower boxes also. The suction pipe to be cast-iron, 12 inches in diameter, and faced; above the barrels a false main cast-iron pipe, 17 inches in diameter, to be carried up the shaft above the surface-line of the water. This false main pipe to be fitted with flanges and faced. The joints to be connected by wrought-iron bolts and nuts. Cast-iron bonnets, with proper stuffing-boxes faced with gun-metal, with a copper piston-rod to work through each. The whole of the pump work to be supported by strong cast-iron girders, and wrought-iron tie-rods The pump-rods to be $1\frac{3}{4}$ inches in diameter, and the joints secured by proper couplings and strong bolts. Should a tank as subsequently mentioned, be erected, then a 12-inch cast-iron main pipe, to be carried to the tank, and an air vessel fixed to the same.

And that the pumps should be worked by a steam-engine of 45 horse power. To have a spare boiler; each boiler to be 53-horse power, with two safety-valves to each, all to be of the best manufacture.

I beg also to recommend that a tank should be erected, as shown on one of the drawings accompanying this. The tank to be 120 feet long, 60 feet wide, and 5 feet deep. To be constructed of cast-iron plates, $\frac{7}{8}$-inch thick, upon strong cast-iron girders, to be fixed on brickwork. The top of the tank to be covered over with a light iron roof glazed.

In speaking of the height of the tank, I must beg the favour of your attention to a map of the town of Birmingham, upon which drawing there are several parts, designated by particular colours. In order to distribute a supply of water over the parts of the town indicated on the drawing by the colour green, it is necessary that the water should be raised to the height of 25 feet. To distribute it over the part coloured pink, that it be raised to the height of 35 feet; and to distribute it over the part coloured blue, that it be raised to the height of 45 feet.

Entertaining the fullest confidence that the quantity of water I have stated could be obtained, I felt the importance of being able to satisfy you as to the quality of that from the experimental boring. I therefore carefully took samples of water from the experimental boring at Digbeth, from the waterworks main pipe, and from Park-street pump, and took them myself to Mr. Professor Brande, of her Majesty's Royal Mint. The following is a copy of his report upon the analysis, which I have much pleasure in adding.

*Copy of Mr. Brande's Report.*

I have carried the examination of three samples of water from Birmingham, sent to me by your order for analysis, as far as time has allowed, and herewith send you such particulars respecting them, as will, I trust, be sufficient for your present purpose.

There is nothing objectionable in the *physical characters* of these waters. They are *bright, colourless, tasteless*, and well aërated, but they all of them come under the denomination of *hard waters*, and the sample from the Park-street well is so hard as to be quite unfit for any purposes in *which* soap is used.

The total solid contents, in *one imperial gallon*, of each of the waters, were determined by careful evaporation, and perfectly drying the saline residue at a temperature of 212°. The following are the results.

I. WATER FROM THE EXPERIMENTAL BORING.—The imperial gallon leaves 34 grains of solid matter, or 1 in 2058. The *hardness* of this water, as indicated by the soap test, is from 16° to 17°; pure distilled water being the standard of *unity*.

II. Water from the Birmingham Waterworks.—The imperial gallon leaves 37·2 grains of solid matter, or 1 in 1881. The *hardness* of this water is between 24° and 25°.

III. Water from the Park-street pump.—The imperial gallon of this water leaves 159·5 grains of solid matter, or 1 part in 438. With these very impure waters, the indications of the soap test becomes somewhat equivocal, but the *hardness* of this sample may be placed somewhere between 90° and 100°.

The substances which are contained in these waters are soda and lime (with traces of magnesia, potassa, silica, oxide of iron, and a very slight indication of organic matter), together with chlorine, carbonic acid, sulphuric acid, and nitric acid.

The salts derived from the above constituents appear to exist in the respective waters as follows:

| | |
|---|---|
| Chloride of sodium,<br>Sulphate of soda,<br>Sulphate of lime,<br>Nitrate of lime,<br>Carbonate of lime,<br>Traces of magnesia,<br>Traces of potassa,<br>Traces of oxide of iron,<br>Traces of silica,<br>Traces of organic matter,<br>Traces of phosphoric acid, | 34 grains in the water of the Boring, equal to 1 in 2058.<br>37·2 grains in the Waterworks, equal to 1 in 1881.<br>159·5 grains in the Park-street pump, equal to 1 in 438. |

The quantity of *chloride of sodium* (common salt), contained in a gallon of water of the experimental boring, is 7·60 grains; in that of the Birmingham waterworks, 4·26 grains; and in water from the Park-street pump, 31·36. The quantity of *sulphate of lime* in the same water is, for the boring, 8·82 grains; for the waterworks, 2·08 grains; and for the Park-street well, 46·48 grains; in this latter water also, the proportion of *nitrate of lime* is very large; the same salt is contained, though in much smaller relative proportion, in both of the other samples. It is therefore evident, that although each of these waters appear to contain the same saline substances, their relative proportions to each other are very different.

William Thomas Brande.

*Royal Mint, November* 13, 1852.

---

I have now to solicit the favour of your consideration to this report, with the drawings and plans illustrative of the same. I do so in the hope that I have executed the directions you were pleased to give me, in a manner that will be satisfactory to you, and that should any of the recommendations I have humbly submitted to you be adopted that I shall be further favoured by your orders to execute the same. Permit me to add, that should the works be entrusted to me, no effort shall be wanting on my part to secure your satisfaction.

I estimate the cost of executing the whole of the works, every part thereof to be done in the best manner possible, and all materials used to be of the best quality of their respective kinds, will amount to the sum of about 27,500*l.* Say twenty-seven thousand five hundred pounds.

Thomas Clark.

4, *Furnival's Inn, Holborn, Nov.* 15, 1852.

---

Report of Robert Rawlinson, C.E. F.G.S., and J. Pigott Smith, Assoc. Inst., C.E.

*To the Chairman of the General Purposes' Committee.*

In accordance with instructions contained in a resolution of your committee, we have examined most carefully and fully into the question submitted to us. The question of "water supply" for so great and important a town as Birmingham is of the utmost importance, and demands all the attention which can be given to it. Few places are so fortunately situated as to have a full supply of water at command, so unexceptionable and so advantageously situated, as to leave no room for dispute as to which is the best mode of supply. Birmingham is not so situate. It therefore becomes necessary to consider the several features of the case, as they may be presented to the committee. There may be three forms of supplying a town with water, or there may be a combination of these.

1. Water may be pumped from wells, sunk into the stratification upon which a town stands, or from wells sunk near to a town.

2. Storage reservoirs may be constructed to reserve the excessive rain-fall, and thus eqalise the water of a limited area as also to provide compensation for mills and water rights generally.

3. Springs which appear at the surface, and rivers may be made available; the water being brought in by aqueduct mains, should there be elevation sufficient at the source, or pumped if too low.

Birmingham having a midland position, and standing on the highest land of the district, renders it imperative that pumping be resorted to in order to supply the whole of the houses within the borough. Water might be introduced by gravitation it is true, but on so limited a scale as to preclude this means of supply being resorted to.

A public supply of water from wells sunk into the subsoil in or near the town has been suggested, and borings having been made, as also analyses of the water, we will not trouble the committee further on this head of the subject than to point out the uncertainties and inconveniences likely to arise from adopting this mode of supply.

*Local stratification.—Uncertainty of a full supply of water being obtained from wells.*—The town of Birmingham stands upon the new red sandstone foundation, which consists of marls, shales, and beds of sandstone rock of vast thickness; the whole formation is broken by faults and fissures, or dykes, vast walls of igneous rock which have been protruded from unknown depths. Some of these fissures are open, and contain water; the rock also contains water to a limited depth from the surface. Many of the faults or dykes are impervious to water, isolating areas of limited extent, and there are intervening beds of clay, shale and marl, which are as water-tight as a continuous plane of sheet lead would be.

Faults and dykes are for the most part vertical. Beds are generally horizontal. Few "dykes" are, however, perfectly "vertical," neither are "beds" always level or "horizontal." Beds "crop" to the surface, as "dykes" rise to the surface. It is important fully to understand these facts, because they must ever make sinking or boring for water a question of speculation.

The fresh water found within the crust of the earth, or which issues from it in springs is the result of rain fall, or condensation from vapour. The whole must have passed from the surface, and as a rule, the deeper the well the more mineral matter the water will contain; and further, the more nearly a well in the new red sandstone is exhausted, the harder the water becomes, by reason of a waste of the solids forming the stone. Many of the wells in Liverpool, when hard pumped, yield water having a milky tinge, by washing out the gypsum of the stone.

That wells can be exhausted, however powerful the springs apparently are when first opened, is proved by all mining operations. That wells in the new red sandstone form no exception has been proved in many places, New York, in America, Manchester and Salford, Liverpool and Wolverhampton. In Liverpool, besides the vertical shaft of the wells there are many miles of headings, and many deep borings. As the wells are pumped these are added to, and so uncertain is the present limited supply that the corporation are constructing extensive storage reservoirs at thirty miles distance. The Manchester corporation have also constructed large works of a similar character, and within this week the corporation of Wolverhampton have passed a resolution to call in some engineer, to advise as to the waterworks, &c.

*Artesian Boring.*—Many persons having read or heard of artesian wells, come to a conclusion that it is only necessary to bore deep enough and water will be obtained. The conclusion is not true neither in theory nor in fact. There must be a peculiar configuration of strata to give facilities for the formation of an artesian well. That which in geology is known as a basin formation, and even in a geological basin, there must be a peculiar order of strata,—impervious clay above, and sand or other highly porous water-bearing strata below. If a town or city, as London, Paris, &c., stand on such a basin, water may be obtained by deep boring, and is so obtained, but not to an extent anything equal to the supply of large populations. The deep wells and artesian borings in London are only used for private and commercial purposes, brewing, &c. (and generally only for cooling in these establishments), yet all the wells in the metropolis are in course of exhaustion. *The water line is reduced year by year.* Upwards of fifty millions of gallons of water are poured into the metropolis daily by the several companies, independent of any wells or springs, from the New River, from the Thames, and from other sources.

As a proof that deep sinking or boring will not answer in the new red sandstone, we may instance the experience with two deep mines sunk through it, and situate wide apart,—the Pendleton Colliery, near Manchester, the Monkwearmouth Colliery, near Sunderland. After a depth of 900 feet vertical had been obtained, the strata was found to be comparatively dry, and water had to be passed down into the workings to water the roads, they were so intolerably dusty. The water obtained at the deepest points to which it was found to penetrate was impregnated with mineral as strongly as brine. Both these shafts yielded water in profusion in the upper beds to the depth of several hundred feet. This had to be "tubbed" out by a casing of cast-iron.

That water may be obtained from wells sunk in or near Birmingham we do not deny, but we wish to impress upon the committee all the facts within our knowledge bearing on this question, and from these facts (the experience of other places similarly situated, and where the experiment has been tried and abandoned) we deduce the following rules:—

1. No large town or city can be permanently supplied from wells sunk into the strata upon which it stands. The experiment was tried in ancient Rome, in New York, in America, in Manchester and Salford, in Liverpool, and in Wolverhampton. London and Paris, notwithstanding that they stand in the most favourable situation for artesian wells, do not obtain more than a limited supply by these means.

2. The water for the supply of a large town should be visible, and should be of such extent as to preclude any possibility of failure.

3. The source of supply should be the least objectionable the district will afford, and the works should be established in such a position as to be available for any future extensions required.

*Remarks as to Pumping from Wells*, &c.—The vertical lift of water by the company is about 240 feet. Blythe Mill, near Coleshill, is about 60 feet below the pumping station at Birmingham, and allowing 4 feet per mile as an available head to overcome friction in the main, the entire lift at Blythe Mill should be about 90 feet. This would necessitate an entire lift to supply the upper portions of Birmingham of about 330 feet, the water being at the surface.

*Probable Depth of Sinking.*—Wells to be available for a large supply must be deep. The wells in Liverpool vary from 300 to 600 feet vertical, and this is probably the depth to which wells in or near Birmingham must be sunk. The entire depth of any well or wells would have to be added to the existing lift from the surface. The annual cost of pumping will be in proportion to the depth from which water is raised.

Should wells in or near Birmingham be sunk, the following table will show the relative proportion of depths:—

*Probable Depths of Wells if Sunk in or near Birmingham.*

| | Feet. | Feet. | Feet. | Feet. |
|---|---|---|---|---|
| Assumed depths | 300 | 400 | 500 | 600 |
| Company's lift added | 240 | 240 | 240 | 240 |
| Total lift required | 540 | 640 | 740 | 840 |

*Known Lift of Water, if taken from or near Blythe Mills.*

| | Feet. |
|---|---|
| Lift from proposed pumping station into fountain reservior, near Coleshill | 90 |
| Company's lift added | 240 |
| Total lift required | 330 |

Or a saving of 210 feet, should the shallowest wells indicated be found sufficient, but a saving of 510 feet lift should the deepest wells be required.

The cost of wells and headings is as uncertain as the results. The Green-lane well, near Liverpool, with engines and reservoirs, has cost about 100,000*l.*, and this is considered an eminently successful case, the well yielding about one million gallons of water each twenty-four hours, but at the cost of the surrounding district, as most of the private wells have been drained, and compensation has had to be paid.

*Proposed Source of Supply.*—Having carefully examined the water shed of the following rivers south of Tamworth, viz:—the Tame, Bourne, Cole, Blythe, Avon, Dene, and Alne, together with their tributaries within a circuit of 105 miles east and south of Birmingham, bounded by the following places:—Erdington, Sutton, Coldfield, Tamworth, Polesworth, Baddesley, Ensor, Baxterley, Fillongley, Meriden, Berkswell, Kenilworth, Stoneleigh, Warwick, Barford, Wellesbourne, Stratford-on-Avon, Wootten Wawen, Henley-in-Arden, Tanworth, and Moseley, comprising an area of 450 square miles, or 288,000 acres. We propose, out of this large district, to select for the supply of Birmingham, the water shed of the rivers Blythe and Cole, taking the combined waters of these rivers a little below their junction, in a direct line 9½ miles from the centre of Birmingham, and about 60 feet below the pumping station of the present company. There is one feature peculiar and most favourable in this case About eleven hundred yards below this point is the junction of the Tame, down which is brought the entire sewage of Birmingham, so that no heavy compensation for loss of water can be sustained, as the supply would be taken and returned into the same stream within eleven hundred yards of its point of abstraction.

*Volume of Water in the River Blythe in Dry Weather.*—We gauged the Blythe at the point stated, and (after twelve months of unusually dry weather) we found about twenty-five million gallons of water passing per day of twenty-four hours; it was clear, colourless, and tasteless, and well adapted as a supply for Birmingham. On examining the rivers Blythe and Cole, as also their tributaries, we found the water-shed free from limestone, or lime-bearing strata, and particularly favourable, the entire district being of a true agricultural character, and likely so to continue, the subsoil being composed of alluvium gravel and sand principally, or varying combinations of these. There is an area of about 144 square miles or 92,160 acres. There is no other source of supply within reach of Birmingham in any respect so eligible as the one referred to. The water is only about 9½ miles from Birmingham, and may be pumped from within a few yards of the spot to which it is again returned by gravitation, after having done its work and been purified at the sewage works now in course of construction. The next source of supply is the Avon, a Kenilworth or at Stratford; the latter place would be most eligible, but water would have to be lifted 522 feet, or 192 feet higher than that required on the Blythe. The distance from Birmingham is also greater, being twenty miles; and as it could not be returned to the Avon except at enormous expense, compensation to a ruinous amount would be exacted.

*Area of District from which the Waters of the Rivers Cole and Blyth flow.*—About one hundred and forty-four square miles, or ninety-two thousand statute acres, producing a minimum volume of water equivalent to twenty-five million gallons in each twenty-four hours. Birmingham at present requiring about six million gallons each twenty-four hours.

*Geological Character of District.*—For the most part new red sandstone. There is a small portion of coal in the Trent Valley, east of Tamworth and Coventry; but no portion of the drainage falls into the water proposed to be taken, or even can be turned into these streams. The stratified rocks are covered by alluvium sand, gravel, clay, marl, more or less separate, as also varying mixtures of these. The whole district is agricultural, and is likely to remain so, there being no manufactures carried on in the district, nor is there one town larger than Coleshill.

*Recommendations.*—We recommend that the combined waters of the rivers Cole and Blythe be taken at or about Blythe Mill. Blythe Mills consists of two small undershot water-wheels, having an available fall of about 4 feet. Three pairs of stones can be driven when in full work; for a considerable portion of the year two pairs only are worked, and for many weeks during the present year there has only been water sufficient to drive one pair of stones. On September 19th, 1854, the miller stated that he never remembered so dry a season, and consequently never saw the water so low.* That a storage or settling reservoir and filter-beds, with pumping-engines, be established at this point; that the water be raised into a covered fountain-reservoir, situate in or near Coleshill, which is about one mile distant; and that from this reservoir an acqueduct main be laid up the valley of the Tame, to or near the pumping establishment of the Birmingham Waterworks Company. The Birmingham and Derby line of railway from Coleshill may be adopted, or an independent route up the valley may be taken. The lift will only be about one-third that of the elevation from the company's engines to the service-reservoir, situate at Aston, and consequently one third of the power now used by the company, if added at the proposed Blythe Mill Station, would supply Birmingham with the same amount of water the present company can furnish. Any future addition to the power would have to be in this proportion.

*Remarks as to the Advantages of the Proposed Supply.* — The advantages of the proposed supply consist:—1. In the large area at command, upwards of ninety thousand acres, and the abundant supply of water in the driest seasons.† 2. The favourable cha-

* See *Journal*, *ante* p. 384.

† The drainage area of Liverpool is about 17,000 acres, for Manchester 27,000 acres; out of these acres one-third of the water stored is given as compensation.

racter of the subsoil (new red sandstone), and the favourable character of the surface (agricultural), free from large towns and manufactures. 3. The nearness to Birmingham (about nine and a-half miles), the moderate elevation and comparative light lift required (about 330 feet), as also the favourable gradient afforded by the valley for an aqueduct main.

*Estimate.*—For works to be capable of delivering six millions of gallons of water in each twenty-four hours at the present pumping-station, Birmingham, 111,880*l*. Engine power to the extent of 300-horse power will be required. Three engines—two working, and one in reserve.

*Remarks.*—We beg to apologise for the brief character of our report. We did not, however, feel justified in causing the delay necessary to draw up a lengthened statement. Having, by making a full examination of the district, discovered that which we consider to be a good and sufficient supply of water for the present and future wants of the inhabitants of Birmingham, we thought it to be our duty to inform the committee at the earliest possible period of this fact; and should the scheme suggested be approved, we would ask the committee to allow us to prepare a more full report, with map and estimate complete.

Robert Rawlinson, C.E.
J. Pigott Smith, C.E.

*Birmingham, September* 23, 1854.

---

Appendix.—*Report of* Dr. Robert Angus Smith.

After inspecting the whole district of the drainage ground of the Birmingham water supply, I came to the following conclusion. The Birmingham water was tolerably clear in appearance when seen in a glass at the time when I went there to examine it in April last. In the reservoir it was somewhat milky; by no means inviting in appearance, but not presenting to the eye any decidedly bad features. I got a specimen of it in April, and had only time to look generally at what it contained: it was 20 degrees of hardness, and contained 80 grains of solid indigenous matter per gallon, besides organic matter, the amount of which I did not ascertain. These 20 degrees of hardness are sufficient to condemn the supply. It is needless to enter into all the evils connected with very hard water—they are well known; the great expense in washing is one of the prominent evils, and the fact that more water is needed in order to wash is another.

Every million gallons of water must require at least a ton of soap, needlessly, in washing, on account of the hardness; this is equal to 40*l*. The amount of solid matter per gallon is made up of various sorts, alkaline chiefly; such an amount is of itself a great objection to water, independent of the hardness; the taste of the water is very much injured by them, and so it happens that the water at Birmingham is most unpleasant to drink: any one accustomed to pretty good water must perceive this at once. The use of water as a beverage can never be popular at Birmingham when there is so little to encourage it: water with so many salts in it is never fresh; it feels insipid, and even nauseous. To compare it with other towns, the Manchester supply has only about 3 grains in a gallon, and is less than 2 degrees of hardness; it used to be 12, but the new waterworks were undertaken at the expense of about a million pounds, in order to improve it. The water of Glasgow has about 13 grains in a gallon, and is 6 degrees of hardness; but they are going to spend as much as Manchester, in order to improve the supply. Even London has only about 18 grains in a gallon in its supply, so much complained of, except in the very worst cases, now no longer existing, when the amount rose to 24. Liverpool is being supplied with water nearly as soft and pure as that of Manchester; and many other towns have followed, or are about to follow their example. To perpetuate such a supply as that of Birmingham, would be to ignore all that the late important inquiries into the subject have so completely established.

If we inquire what is the nature of the substances in solution, and what injury they do, we have only to go from the reservoir of the Waterworks' company at Aston a little higher into the river Tame, in order to ascertain the cause. At Sunday Bridge the stream is still less pure than at the reservoir; this is after depositing an immense amount of filthy matter in its course. There I took a specimen of the water No. 7. On examination it contains in a gallon:—

| | |
|---|---|
| Organic matter.................................. | 2·52 grs. |
| Inorganic matter, soluble .................. | 15·4 |
| Inorganic matter, insoluble ............... | 9·8 |

Going still higher to one of the nearest brooks to Birmingham (at Oldbury Green), we find a stream converted into an open sewer, in no respect differing, but having all the qualities of sewage water. I here took another specimen. This is one of the supplies of the Tame; another at Tividale, in no way different; another at Bilston, and at West Bromwich, Wednesbury, and Great Bridge.

All these places send their sewerage into the Tame, where, after running about ten miles, it is pumped up into the water-pipes and sent into Birmingham houses without change, excepting the deposit of solid matter. Now, although I have not analysed all these specimens, it is well enough known what sewage water contains. Some sewage is soluble in water, and some is insoluble; although the water is clear therefore, it is by no means on that account purer, some of the most disgusting ingredients being soluble in water.

In flood time the insoluble matter comes down, and the brook courses to some extent are purified, the solid matter being in these cases more or less carried into the reservoir.

Now, it is possible for soil to purify water from a considerable amount of sewage, as water from purely pastoral land shows, when the water sinks into the ground and comes out purified; but here the matter has no such chance, it never sinks into the ground to be purified. The sewers run directly into the river without concealment.

There is no doubt therefore that the Tame contains the sewage water from a population of at least a quarter of a million; this population covers all the ground on the banks of the river between Birmingham and Wolverhampton: there is scarcely an acre of ground not covered with works, buildings, roads, or rubbish from works of various kinds.

These villages and scattered houses are many of them in a wretched condition, as far as their sanitary arrangements are concerned. They are generally or altogether without sewers; the streets are lined with open drains: in many places these lie stagnant, and deposit green offensive matter before the houses. In all of them the flow is interrupted, and the inhabitants must suffer from them. Now, it seems quite essential that these places should at once be put in proper order. When this happens, the streams will carry away much more of their refuse, and by clearing the towns more the streams will become still more impure. Some of them are now applying to be put under the Board of Health.

At present the stream which fills the Birmingham reservoirs is the washing of fifty miles of land inhabited by a population living, to say the least, in a state so far from being conducive to health, that the whole country has been appalled by the severity with which epidemics have attacked them. Bilston itself is drained into the Tame, and even in the time of cholera sends its polluted water to be drunk at Birmingham. There is no portion of England, not even in the streets of London, so unsuited for collecting the water from as this portion; there can be no doubt whatever of this.

Besides that the river contains the washings of such a population, and the washings of so many iron and chemical works, it contains the water also from numberless coalpits which cover the district from one end to the other in perfectly marvellous numbers. Water from coalpits is never good, it contains salts of various kinds and in great variety, subject also to considerable changes. Even a coal district is often unfavourable to the water, even when it is not pumped up directly from the pit.

The rain in a busy manufacturing district is always impure, as is well known, from the blacking of the water from the house-tops, and the general blackness of rain water, however collected, in manufacturing districts; besides its blackness, we know that its taste unfits it for drinking, so that however the soil may be in the district in question, rain from such a quarter would be unfit for use.

I can only conclude by saying that in every respect the water of Birmingham is absolutely unfitted for domestic use, and for many mercantile purposes, whether calico printing, dyeing, or mere use in a boiler, and that I know of no city or town which has a supply at all to be compared with it, and the inference of course is, that the health of the inhabitants must suffer, as we know it has done in other cases not so bad, and that it becomes a matter of the greatest importance to obtain a better supply.

R. A. Smith.

## ESTIMATE FOR LIGHTHOUSE AND BEACON ON NEW SOUTH SHOAL, OFF NANTUCKET, U.S.

SYNOPSIS *of Estimate for the erection of a Pneumatic Iron Pile Lighthouse on New (Davis's) South Shoal, off Nantucket, Massachusetts. Time, four and a half years.*

| | | |
|---|---|---|
| Cost of structure: materials and labour | (a) | $89,175 50 |
| Cost of patterns | (b) | 1,000 00 |
| Expenses at foundry, offices, &c. | (c) | 18,195 00 |
| Expenses of building up and taking down structure at foundry | (d) | 7,017 50 |
| Cost of receiving and tender steamers and camels | (e) | 55,000 00 |
| Cost of pneumatic apparatus, including steam air-pump | (f) | 4,084 74 |
| Expenses of receiving-steamer first season at the shoal | (g) | 10,316 20 |
| Do...do...second...do... | (g) | 10,941 20 |
| Do...do...third...do... | (g) | 12,191 20 |
| Expenses of tender-steamer first season at the shoal | (h) | 6,620 85 |
| Do...do...second...do... | (h) | 6,995 85 |
| Do...do...third...do... | (h) | 7,745 85 |
| Expenses of workmen, &c., first season at the shoal | (i) | 10,519 95 |
| Do...do...second...do... | (i) | 10,519 95 |
| Do...do...third...do... | (j) | 9,663 75 |
| Miscellaneous expenses of construction | (k) | 6,823 75 |
| Miscellaneous expenses of dwelling | (l) | 5,522 87 |
| Cost of lenticular lighting apparatus | (m) | 8,850 00 |
| Amount | | 280,684 16 |
| Contingencies 15 per cent. | | 42,102 62 |
| Total amount | | 322,786 78 |

| | | |
|---|---|---|
| Required for first year and a-half at the foundry, &c. (n)... | $190,589 20 | |
| Do...for first year at the shoal (o)... | 40,947 76 | |
| Do...for second year......do......(p)... | 37,249 07 | |
| Do...for third year ......do... ..(q)... | 54,000 75 | |
| Total amount | | $322,786 78 |

*(a.)—Synopsis of estimate.—Materials and labour for lower or foundation section (common to beacon.)*

| | | |
|---|---|---|
| Cost of wrought-iron (r) | $16,875 65 | |
| Cost of cast-iron (s) | 4,613 79 | |
| Cost of material | | $21,489 44 |
| Labour on wrought-iron (t) | 3,721 20 | |
| Labour on cast-iron (u) | 927 00 | |
| Cost of labour | | 4,648 20 |
| *Second (double) section (common to beacon).* | | |
| Cost of wrought-iron (v) | 18,044 83 | |
| Cost of cast-iron (w) | 1,342 20 | |
| Cost of material | | 19,387 03 |
| Labour on wrought-iron (x) | 4,834 20 | |
| Labour on cast-iron (y) | 651 00 | |
| Cost of labour | | 5,485 20 |
| *Third (double) section (common to beacon).* | | |
| Cost of wrought-iron (z) | 8,201 08 | |
| Cost of cast-iron (aa) | 168 72 | |
| Cost of material | | 8,369 80 |
| Labour on wrought-iron (bb) | 1,547 20 | |
| Labour on cast-iron (cc) | 132 00 | |
| Cost of labour | | 1,679 20 |
| *Third (double) section.* | | |
| Cost of wrought-iron (hh) | 1,606 20 | |
| Cost of cast-iron (ii) | 792 00 | |
| Cost of material | | 2,398 20 |
| Labour on wrought-iron (kk) | 1,534 40 | |
| Labour on cast-iron (ll) | 400 00 | |
| Cost of labour | | 1,934 40 |
| *Fourth (double) section.* | | |
| Cost of wrought-iron (mm) | 5,483 61 | |
| Cost of cast-iron (nn) | 904 61 | |
| Cost of material | | 6,388 22 |
| Labour on wrought-iron (oo) | 1,630 56 | |
| Labour on cast-iron (pp) | 436 00 | |
| Cost of labour | | 2,066 56 |
| *House, &c., third (double) section inclusive.* | | |
| Cost of wrought-iron (qq) | 4,487 55 | |
| Cost of cast-iron (rr) | 4,035 84 | |
| Cost of material | | 8,523 39 |
| Labour on wrought-iron (ss) | 4,707 86 | |
| Labour on cast iron (tt) | 2,098 00 | |
| Cost of labour | | 6,805 86 |
| Total amount | | 89,175 50 |

### ESTIMATE FOR LIGHTHOUSE—CONTINUED.

*(c.)—Expenses at foundry, offices, &c.*

| | | |
|---|---|---|
| Agent at foundry 1½ year, 548 days, at $3 50 | $1,918 00 | |
| Books, &c., on construction, 4½ years, at $100 | 450 00 | |
| Stationery, office and drawing, 4½ years, at $75 | 337 50 | |
| Office rent, 1 office 1½ year, 2 offices 3 years, at $125 | 937 50 | |
| Office fuel at $72 each per year | 540 00 | |
| Office attendance at $48 each per year | 360 00 | |
| Clerk 4½ years, or 54 months, at $75 | 4,050 00 | |
| Draughtsman 3 years, or 36 months, at $75 | 2,700 00 | |
| Quarters and fuel for 1 major 4½ years, at $579 | 2,605 50 | |
| Quarters and fuel for 2 lieutenants 4½ years, at $313 50 each per year | 2,821 50 | |
| Transportation of baggage of 3 officers U. S. A., 4½ years, at $50 each per year | 675 00 | |
| Model of structure | 800 00 | |
| Total amount | | $18,195 00 |

*(d.)—Expenses of building up and taking down structure at foundry. Time, 7½ months of 26 days, or 195 days.*

| | | |
|---|---|---|
| 1 rigger in charge, 195 days, at $3 | 585 00 | |
| 6 machinists, 195 days, at $2 each—$12 | 2,340 00 | |
| 4 labourers, 195 days, at $1 50 each—$6 | 1,170 00 | |
| 1 blacksmith, 195 days, at $2 | 390 00 | |
| 1 striker, 195 days, at $1 50 | 292 50 | |
| 7500 feet lumber for scaffolding | 150 00 | |
| 15 spars for scaffolding, from 12 inches to 5 inches at butt | 90 00 | |
| Derrick | 500 00 | |
| Tools—drills, stocks and dies, jack-screws, rollers and bars, clamps, hammers, saws, chisels, axes, adzes, crowbars, &c., including steel for cold-chisels | 1,000 00 | |
| Blocks and falls, rigging, lashings, &c. | 500 00 | |
| Total amount | | 7,017 50 |

*(e.)—Cost of receiving and tender-steamers and camels.*

| | | |
|---|---|---|
| 1 receiving-steamer, 130 feet in length | 25,000 00 | |
| 1 tender-steamer, 90 feet in length | 15,000 00 | |
| 2 camels, 100 feet in length, at $7500 | 15,000 00 | |
| Total amount | | 55,000 00 |

*(f.)—Materials and labour for pneumatic apparatus, including steam air-pump (common to beacon).*

| | | |
|---|---|---|
| Cost of wrought-iron | 73 42 | |
| Cost of cast-iron | 2,176 32 | |
| Cost of material | | 2,249 74 |
| Labour on wrought-iron | 63 00 | |
| Labour on cast-iron | 572 00 | |
| Cost of labour | | 635 00 |
| Cost of steam air-pump | | 1,200 00 |
| Total amount | | 4,084 74 |

*(g.)—Current expenses of receiving steamer, &c., first, second, and third seasons at the shoal.*

| | | |
|---|---|---|
| 1 master .. 6 months at $100 per month | 600 00 | |
| 1 first mate .. do. 40 do. | 240 00 | |
| 1 second mate .. do. 30 do. | 180 00 | |
| 1 pilot .. do. 60 do. | 360 00 | |
| 1 first engineman .. do. 60 do. | 360 00 | |
| 1 second do. .. do. 40 do. | 240 00 | |
| 2 firemen .. do. 25 do. each | 300 00 | |
| 2 coal-heavers .. do. 20 do. do. | 240 00 | |
| 4 hands .. do. 20 do. do. | 480 00 | |
| 8 boatmen .. do. 20 do. do. | 900 00 | |
| 1 steward, 1 cook .. do. 25 do. do. | 300 00 | |
| Subsistence of 24 persons, 183 days, at 35 cents each | 1,537 20 | |
| Fuel, 3 tons coal per day, 549 tons, at $6 | 3,294 00 | |
| Repairs, 2½ per cent. on $25,000—cost of steamer | 625 00 | |
| Expenses in ordinary, 6 months, at $100 | 600 00 | |
| Total amount | | 10,316 20 |
| Second season same as the first | 10,316 20 | |
| With an additional 2½ per cent. for repairs | 625 00 | |
| Total amount | | 10,941 20 |
| Third season same as the second | 10,941 20 | |
| With an additional 5 per cent. for repairs | 1,250 00 | |
| Total amount | | 12,191 20 |

*(h.)—Current expenses of tender-steamer, &c., first, second, and third seasons at the shoal.*

| | | |
|---|---|---|
| 1 master, 6 months, at $75 per month | 440 00 | |
| 1 mate do 35 do | 210 00 | |
| 1 pilot, acting also as second mate, 6 months, at $60 per month | 360 00 | |
| 1 first engineman, 6 months, at $50 per month | 300 00 | |
| 1 second do. do. 30 do. | 180 00 | |
| 1 fireman .. do. 25 do. | 150 00 | |
| 1 coal-heaver .. do. 20 do. | 120 00 | |
| 2 hands .. do. 20 each | 240 00 | |
| 6 boatmen .. do. 20 do. do. | 720 00 | |
| 1 steward, 1 cook .. do. 25 do. do. | 300 00 | |
| Subsistence of 17 persons, 183 days, at 35 cents. | 1,088 85 | |
| Fuel, 1½ ton coal per day, 274½ tons, at $6 | 1,647 00 | |
| Repairs, 2½ per cent. on $15,000—cost of steamer | 375 00 | |
| Expenses in ordinary, 6 months, at $80 | 480 00 | |
| Total amount | | 6,620 85 |
| Second season same as first | 6,620 85 | |
| With an additional 2½ per cent. for repairs | 375 00 | |
| Total amount | | 6,995 85 |
| Third season same as second | 6,995 85 | |
| With an additional 5 per cent. for repairs | 750 00 | |
| Total amount | | 7,745 85 |

ESTIMATE FOR LIGHTHOUSE—CONTINUED.

| | | |
|---|---|---|
| *(i.)—Current expenses of workmen, &c., first or second season at the shoal.* | | |
| 1 superintendent of work, 183 days, at $5 00 | $ 915 00 | |
| 2 foremen do. 2 50 each | 915 00 | |
| 8 machinists do. 2 00 do. | 2,928 00 | |
| 2 riggers do. 2 00 do. | 782 00 | |
| 2 carpenters do. 2 00 do. | 732 00 | |
| 1 blacksmith do. 2 00 | 866 00 | |
| 1 striker do. 1 50 | 274 50 | |
| 10 labourers 6 months 25 00 each | 1,500 00 | |
| 1 steward, 1 cook do. 25 00 do. | 300 00 | |
| Subsistence of 29 persons, 183 days, at 35 cents each | 1,857 45 | |
| Total amount | | $10,519 95 |
| Second season at the shoal same as the first | | 10,519 95 |
| *(j.)—Current expenses of workmen, &c., third season at the shoal.* | | |
| 1 superintendent of work, 183 days, at $5 00 | 915 00 | |
| 2 foremen do. 2 50 each | 915 00 | |
| 5 machinists do. 2 00 do. | 1,830 00 | |
| 2 riggers do. 2 00 do. | 732 00 | |
| 5 carpenters do. 2 00 do. | 1,830 00 | |
| 1 blacksmith do. 2 00 | 366 00 | |
| 1 striker do. 1 50 | 274 50 | |

## ESTIMATE FOR BEACON.

SYNOPSIS *of Estimate for the erection of a Pneumatic Iron Pile Beacon on New (Davis's) South Shoal, off Nantucket, Massachusetts. Time, three years.*

| | | |
|---|---|---|
| Cost of structure: materials and labour | (a') | $66,159 05 |
| Cost of patterns | (b') | 425 00 |
| Expenses at foundry, offices, &c. | (c') | 12,045 50 |
| Expenses of building up and taking down structure at foundry | (d') | 4,945 00 |
| Cost of receiving and tender-steamers and camels | (e') | 55,000 00 |
| Cost of pneumatic apparatus, including steam air-pump | (f') | 4,084 74 |
| Expenses of receiving-steamer first season at the shoal | (g') | 10,316 20 |
| Do. do. second season do. | (g') | 10,941 20 |
| Do. tender-steamer first season do. | (h') | 6,620 85 |
| Do. do. second season do. | (h') | 6,995 85 |
| Do. workmen, &c., first season do. | (i') | 10,519 95 |
| Do. do. second season do. | (i') | 10,519 95 |
| Miscellaneous expenses of construction | (k') | 5,483 00 |
| Amount | | 204,056 29 |
| Contingencies, 15 per cent. | | 30,608 44 |
| Total amount | | 234,664 73 |
| Required for first year at foundry, &c. | (n') | 157,530 21 |
| Do. do. at the shoal | (o') | 40,446 07 |
| Do. second year at the shoal | (p') | 36,688 45 |
| Total amount | | 234,664 73 |

## ESTIMATE FOR BEACON.

| | | |
|---|---|---|
| *(a'.)—Materials and labour for lower or foundation section (common to light-house).* | | |
| Cost of wrought-iron (r) | $16,875 65 | |
| Cost of cast-iron (s) | 4,613 79 | |
| Cost of material | | $21,489 44 |
| Labour on wrought-iron (t) | 3,721 20 | |
| Labour on cast-iron (u) | 927 00 | |
| Cost of labour | | 4,648 20 |
| *Second (double) section (common to light-house).* | | |
| Cost of wrought-iron (v) | 18,044 88 | |
| Cost of cast-iron (w) | 1,342 20 | |
| Cost of material | | 19,387 08 |
| Labour on wrought-iron (x) | 4,834 20 | |
| Labour on cast-iron (y) | 651 00 | |
| Cost of labour | | 5,485 20 |
| *Third (double) section (common to light-house).* | | |
| Cost of wrought-iron (z) | 8,201 08 | |
| Cost of cast-iron (aa) | 168 72 | |
| Cost of material | | 8,369 80 |
| Labour on wrought-iron (bb) | 1,547 20 | |
| Labour on cast-iron (cc) | 132 00 | |
| Cost of labour | | 1,679 20 |
| *Third (double) section.* | | |
| Cost of wrought-iron (dd) | 728 49 | |
| Cost of cast-iron (ee) | 3,150 49 | |
| Cost of material | | 3.878 98 |
| Labour on wrought-iron (ff) | 882 20 | |
| Labour on cast-iron (gg) | 339 00 | |
| Cost of labour | | 1,221 20 |
| Total amount | | 66,159 05 |
| *(c'.)—Expenses at foundry, offices, &c.* | | |
| Agent at foundry, 1 year—365 days, at $3 50 | 1,277 50 | |
| Books, &c., on construction, 3 years, at $100 | 300 00 | |
| Stationery, office and drawing, 3 years, at $75 | 225 00 | |
| Office rent—1 office, 1 year; 2 offices, 2 years—at $125 | 625 00 | |
| Office fuel, at $72 each per year | 360 00 | |
| Office attendance, at $48 each per year | 240 00 | |
| Clerk, 3 years, or 36 months, at $75 | 2,700 00 | |
| Draughtsman, 2 years, or 24 months, at $75 | 1,800 00 | |
| Quarters and fuel—1 major, three years, at $579 | 1,737 00 | |
| Do. do. 2 lieutenants, 3 years, at $313 50 each per year | 1,881 00 | |
| Transportation of baggage of 3 officers U. S. A., 3 years, at $50 each per year | 450 00 | |
| Model of structure | 450 00 | |
| Total amount | | 12,045 50 |
| *(d'.)—Expenses of building up and taking down structure of foundry.—Time, 5 months of 26 days, or 130 days.* | | |
| 1 rigger, in charge, 130 days, at $3 | 390 00 | |
| 6 machinists, 130 days, at $2 each—$12 | 1,560 00 | |
| 4 labourers, 130 days, at $1 50 each—$6 | 780 00 | |
| 1 blacksmith, 130 days, at $2 | 260 00 | |
| 1 striker, 130 days, at $1 50 | 195 00 | |
| 5000 feet lumber for scaffolding, at $20 | 100 00 | |
| 10 spars for scaffolding, from 12 inches to 5 inches at butt | 60 00 | |
| Derrick | 500 00 | |
| Tools—drills, stocks and dies, jackscrews, rollers and bars, clamps, crowbars, hammers, saws, chisels, axes, adzes, &c., including steel for cold chisels | 700 00 | |
| Blocks and falls, rigging, lashings, &c. | 400 00 | |
| Total amount | | 4,945 00 |
| *(e'.)—Cost receiving and tender-steamers and camels.* | | |
| 1 receiving-steamer, 130 feet in length | 25,000 00 | |
| 1 tender-steamer, 90 feet in length | 15,000 00 | |
| 2 camels, 100 feet in length, at $7500 | 15,000 00 | |
| Total amount | | 55,000 00 |
| *(f'.)—Materials and labour for pneumatic apparatus, including steam air-pump (common to light-house).* | | |
| Cost of wrought-iron | 73 42 | |
| Cost of cast-iron | 2,176 32 | |
| Cost of material | | 2,249 74 |
| Labour on wrought-iron | 63 00 | |
| Labour on cast-iron | 572 00 | |
| Cost of labour | | 635 00 |
| Cost of steam air-pump | | 1,200 00 |
| Total amount | | 4,084 74 |
| *(g'.)—Current expenses of receiving-steamer, &c., first and second seasons at the shoal.* | | |
| 1 master, 6 months, at $100 per month | 600 00 | |
| 1 first mate, 6 months, at $40 per month | 240 00 | |
| 1 second mate, 6 months, at $30 per month | 180 00 | |
| 1 pilot, 6 months, at $60 per month | 360 00 | |
| 1 first engineman, 6 months, at $60 per month | 360 00 | |
| 1 second do. 6 months, at $40 per month | 240 00 | |
| 2 firemen, 6 months, at $25 per month each | 300 00 | |
| 2 coal-heavers, 6 months, at $20 per month each | 240 00 | |
| 4 hands, 6 months, at $20 per month each | 480 00 | |
| 8 boatmen, 6 months, at $20 per month each | 960 00 | |

## ESTIMATE FOR BEACON—Continued.

| | | |
|---|---|---|
| 1 steward, 1 cook, 6 months, at $25 per month each | $300 00 | |
| Subsistence of 24 persons, 183 days, at 35 cents each | 1,537 20 | |
| Fuel, 3 tons coal per day, 549 tons, at $6 | 3,294 00 | |
| Repairs, 2½ per cent. on $25,000, cost of steamer | 625 00 | |
| Expenses in ordinary, 6 months, at $100 | 600 00 | |
| Total amount | | $10,816 20 |
| Second season same as the first | 10,816 20 | |
| With an additional 2½ per cent. for repairs | 625 00 | |
| Total amount | | 10,941 20 |
| *(h'.)—Current expenses of tender-steamer, &c., first and second seasons at the shoal.* | | |
| 1 master, 6 months, at $75 per month | 450 20 | |
| 1 mate, 6 months, at $35 per month | 210 00 | |
| 1 pilot, acting also as second mate, 6 months, at $60 per month | 360 00 | |
| 1 first engineman, 6 months, at $50 per month | 300 00 | |
| 1 second do. 6 months, at $30 per month | 180 00 | |
| 1 fireman, 6 months, at $25 per month | 150 00 | |
| 1 coal-heaver, 6 months, at $20 per month | 120 00 | |
| 2 hands, 6 months, at $20 per month each | 240 00 | |
| 6 boatmen, 6 months, at $20 per month each | 720 00 | |
| 1 steward, 1 cook, 6 months, at $25 per month each | 300 00 | |
| Subsistence of 17 persons, 183 days, at 35 cents each | 1,088 85 | |
| Fuel, 1½ ton coal per day, 274½ tons, at $6 | 1,647 00 | |
| Repairs, 2½ per cent. on $15,000, cost of steamer | 375 00 | |
| Expenses in ordinary, 6 months, at $80 | 480 00 | |
| Total amount | | 6,620 85 |
| Second season same as first | 6,620 85 | |
| With an additional 2½ per cent. for repairs | 375 00 | |
| Total amount | | 6,995 85 |
| *(i'.)—Current expenses of workmen, &c., first and second seasons at the shoal.* | | |
| 1 superintendent of work, 183 days, at $5 | 915 00 | |
| 2 foremen, 183 days, at $2 50 each | 915 00 | |
| 8 machinists, 183 days, at $2 each | 2,928 00 | |
| 2 riggers, 183 days, at $2 each | 732 00 | |
| 2 carpenters, 183 days, at $2 each | 732 00 | |
| 1 blacksmith, 183 days, at $2 | 366 00 | |
| 1 striker, 183 days, at $1 50 | 274 50 | |
| 10 labourers, 6 months, at $25 each | 1,500 00 | |
| 1 steward, 1 cook, 6 months, at $25 each | 300 00 | |
| Subsistence of 29 persons, 183 days, at 35 cents each | 1,857 49 | |
| Total amount | | 10,519 95 |
| Second season at the shoal same as the first | | 10,519 95 |
| *(k'.)—Miscellaneous expenses of construction.* | | |
| Freight of structure from foundry to harbour of departure and refuge, 466 tons, $1 75 | 815 50 | |
| Wharfage at harbour of departure and refuge, 2 years, at $500 | 1,000 00 | |
| Temporary wharf-house on wharf at harbour of departure and refuge | 250 00 | |
| Paints, and paint-oils, &c., and paint-brushes, for ironwork | 300 00 | |
| 6 disc-buoys, 500 lb. each, at $32 50 each | 195 00 | |
| 6 do. 350 lb. each, at $27 50 | 165 00 | |
| 5000 feet lumber for scaffolding, including freight, at $27 50 per thousand | 137 50 | |
| Derrick for the work at the shoal | 500 00 | |
| Blocks and falls, rigging, lashings, &c. | 800 00 | |
| 2 portable forges, at $36 each | 72 00 | |
| Blacksmiths' tools for do., at $64 each | 128 00 | |
| 200 bushels of blacksmiths' coal, at 25 cents | 50 00 | |
| 4 boats— 2 of 8 oars, 2 of 6 oars—at $250 | 1,000 00 | |
| Freight of derrick, blocks and falls, forges, &c. | 70 00 | |
| Total amount | | 5,483 00 |
| *(n'.)—Expenses of first year at foundry, &c.* | | |
| Agent at foundry | 1,277 50 | |
| Books, &c., on construction; stationery, office and drawing | 175 00 | |
| Office rent, office fuel, office attendance | 245 00 | |
| Clerk and draughtsman | 1,800 00 | |
| Cost of structure, materials and labour | 66,159 05 | |
| Cost of patterns and model of structure | 375 00 | |
| Cost of pneumatic apparatus, including steam air-pump | 4,084 74 | |
| Expenses of building up and taking down structure at foundry | 4,945 00 | |
| Cost of receiving and tender-steamers and camels | 55,000 00 | |
| Freight of structure from foundry to harbour of departure and refuge | 815 50 | |
| Temporary store-house at harbour of departure and refuge | 250 00 | |
| Quarters and fuel for 1 major and 2 lieutenants | 1,206 00 | |
| Transportation of baggage of 3 officers U. S. A. | 150 00 | |
| Total amount | | 136,982 79 |
| Contingencies, 15 per cent. | | 20,547 42 |
| Total amount required for first year at foundry, &c. | | 157,530 21 |

## *Detailed Estimate for Materials and Labour of both Lighthouse and Beacon (a).*

| | | |
|---|---|---|
| LOWER OR FOUNDATION (DOUBLE) SECTION, COMMON TO BOTH LIGHT-HOUSE AND BEACON. | | |
| *Material—wrought-iron.—(r.)* | | |
| 9 12-inch piles (hammered scrap), 13,347 lb. each, at 7½ cents, $1001 02 each .. .. .. .. | 9,009 18 | |
| 2 centre collars for spider-web braces, 3228 lb. each, at 6 cents, $193 68 each .. .. .. .. .. | 387 36 | |
| 16 periphery collars for spider-web braces, 1353 lb. each, at 6 cents, $81 18 each .. .. .. .. | 1,298 88 | |
| 48 spider-web braces (16 periphery, 16 radial, 16 chord), 6 by 4 inches, 101,871 lb. at 4 cents .. .. | 4,074 84 | |
| 48 diagonal braces (16 panel, 16 radial, 16 chord), 3-inch round iron, 43,762 lb. at 3½ cents .. .. .. .. | 1,531 67 | |
| 96 turn-buckles for diagonal braces, 9863 lb. at 4 cents | 394 52 | |
| 4480 lb. bolt and bar iron, assorted sizes, for bolts, nuts, straps, &c., for section, at 4 cents .. .. .. | 179 20 | |
| | | 16,875 65 |
| *Material—cast-iron —(s).* | | |
| 9 cylinders with cones, 11,745 lb. each, at 3 cents $352 35 each .. .. .. .. .. .. .. .. | 3,171 15 | |
| 9 sleeves or couplings, 3896 lb. each, at 3 cents, $116 88 each .. .. .. .. .. .. .. .. | 1,051 92 | |
| 16 periphery collars for spider-web braces, 187 lb. each, at 3 cents, $5 61 each .. .. .. .. .. | 89 76 | |
| 24 diagonal brace clasps (8 panel, 16 chord), 54 lb. each, 1296 lb. at 3 cents .. .. .. .. .. | 88 88 | |
| 16 diagonal brace clasps (radial chord), 1344 lb. at 3 cents | 40 32 | |
| 16 spider-web brace clasps (chord), 4192 lb. at 3 cents .. | 125 76 | |
| 16 spider-web brace clasps (radial and chord), 3200 lb. at 3 cents .. .. .. .. .. .. .. | 96 00 | |
| | | 4,618 79 |
| *Labour on wrought-iron.—(t).* | | |
| 9 12-inch piles (hammered scrap), turning each 5 feet, 45 feet, at $6, $270; and turning to lengths, at $6, $54 | 324 00 | |
| 2 centre collars for spider-web braces, planing, turning, chipping, boring bolt holes, riveting bolts, &c., at $85 | 170 00 | |
| 16 periphery collars for spider-web braces, turning, chipping, boring bolt holes, riveting bolts, &c., at $42 .. | 672 00 | |
| 48 spider-web braces (16 periphery, 16 radial, 16 chord), forging, chipping, and boring bolt holes, &c., at $12 each all round .. .. .. .. .. .. | 576 00 | |
| 48 diagonal braces (16 panel, 16 radial, 16 chord), 3-inch round iron, welding, heading, cutting screws, &c., $7 50 each all round .. .. .. .. | 360 00 | |
| 96 turn-buckles, forging, turning, cutting screws, &c., at $15 .. .. .. .. .. .. .. | 1,440 00 | |
| 4480 lb. bolt and bar iron, assorted sizes for bolts, nuts, straps, &c. for section, at 4 cents .. .. .. .. | 179 20 | |
| | | 3,721 20 |
| *Labour on cast-iron.—(u).* | | |
| 9 cylinders with cones, boring each 3 feet, 27 feet, at $6 | 162 00 | |
| 9 fixtures, &c., for attaching collars, pipeing, &c, at $15 | 135 00 | |
| 9 sleeves or couplings, boring each 4 feet, 36 feet, at $6, $216 and turning for attaching collars, &c., at $10, $90 | 306 00 | |
| 16 periphery collars for spider-web braces, planing, &c., at $8 .. .. .. .. .. .. .. .. | 128 00 | |
| 40 clasps (8 panel, 16 chord, 16 radial and chord), at $2 50 | 100 00 | |
| 32 spider-web clasps (16 radial, 16 chord), at $3 .. | 96 00 | |
| | | 927 00 |

ESTIMATE FOR MATERIALS AND LABOUR—CONTINUED.

| | | |
|---|---|---|
| SECOND (DOUBLE) SECTION, COMMON TO BOTH LIGHT-HOUSE AND BEACON. | | |
| *Material—wrought-iron.—(v).* | | |
| 1 12-inch centre pile (hammered scrap), 14,300 lb. at 7½ cents .. .. .. .. .. .. .. .. | $1,072 50 | |
| 8 periphery piles, from 12-inch tapering to 10½ inch (hammered scrap), 12,636 lb. each, at 9 cents, $1137 24 each | 9,097 92 | |
| 24 spider-web braces (8 periphery, 8 radial, 8 chord), 6 by 4 inches, 36,985 lb. at 4 cents .. .. . | 1,479 40 | |
| 80 diagonal braces (32 panel, 32 radial, 16 chord), 3-inch round iron, 62,874 lb. at 3½ cents .. .. .. .. | 2,200 59 | |
| 24 spider-web braces (8 periphery, 8 radial, 8 chord), 6 by 4 inches, 45,421 lb. at 4 cents .. .. .. | 1,816 84 | |
| 160 turn-buckles for diagonal braces, 16,438 lb. at 4 cents | 657 52 | |
| 1 centre collar for spider-web braces, 3228 lb. at 6 cents | 193 68 | |
| 1 cap of centre collar, floor of house, 805 lb. at 6 cents .. | 48 30 | |
| 16 periphery collars for spider-web braces, 1353 lb. each, at 6 cents, $81 18 each .. .. .. .. .. | 1,298 88 | |

| Skerryvore ...... | 133 | Atlantic ocean | 227 | 10½ to 103 | 10½ | 10½ | Rock ... | 17 | ......... | 12½ | 2½ to 4½ | ‡449,086 | 6 |
| N. South Shoal | 270 | Atlantic ocean | 90 | 20 to 103 | 20 | 42 | Hard sand | ......... | 8 | 4 | 1½ to 2½ | §322,787 | §3 |

* £37,800. † £61,331 9s. 2d. ‡ £89,817 6s. 11d. § Estimated.

*Eddystone.*—1756 to 1759 inclusive. The mean height of the rock above low water is given. Light first exhibited 16th of October, 1759.

*Bell Rock.*—1807 to 1810 inclusive. Light first exhibited 1st of February, 1811.

*Skerryvore.*—1838 to 1843 inclusive. Light first exhibited 1st of February, 1844; surveys, 1834 and 1835; opening quarries, &c., 1836 and 1837. The nearest harbour is Hynish bay, which being open through a large arc, others about the islands of Coll and Mull, in some instances forty miles distant, were used. Two thousand tons of stone were cut off the rock before building.

*New South Shoal.*—One year and a half in addition in the preparation of the structure. Nantucket is forty miles distant; but this harbour would not always be available, from the limited depth at the entrance (six and a half feet) at low water.

OFFICE OF NEW SOUTH SHOAL BEACON,
*Philadelphia, Dec* 27, 1851.

HARTMAN BACHE,
*Major Topographical Engineers, Brevet Major.*

## INSTITUTION OF CIVIL ENGINEERS.

SUBJECTS FOR PREMIUMS—*Session* 1854-55.

The Council invite communications on the following, as well as other subjects, for Premiums; and which are to be forwarded to the Institution on or before January 30, 1855:—

1. On the principles upon which the works for the improvement of river navigation should conducted, and the effects of the works upon the drainage and irrigation of the district.

2. The construction, improvement, and maintenance of natural or artificial harbours and docks, with the forms and action of large sluices, for clearing away deposits by the use of backwater, or by directing the natural currents.

3. The selection of sites for the construction of docks on the course of tidal streams, with reference to communication with railways and with inland navigation.

4. The selection of sites for, and the principles of, the construction of breakwaters and of harbours of refuge, illustrated by examples of existing works.

5. The forms and construction of piers, moles, or breakwaters (whether solid or on arches), sea-walls, and shore defences, illustrated by examples of known constructions, such as the Cobb-wall at Lyme Regis, &c.

6. On the chemical constitution, the method of preparation and the use of artificial cements, to be employed either as "beton") for forming foundations under water or on dry land, and for stuccoing the exterior of houses.

7. The best system of forming artificial foundations, showing the ratio of pressure to surface, and the soil best calculated to sustain heavy structures, illustrated by the best examples in modern practice, and by accounts of the failure of large works.

8. The history and practical results of timber and iron piling for foundations and for wharf and dock walls, with notices of mechanical modes of driving.

9. The relative value of various kinds of natural stone available in Great Britain for the purposes of construction, with experiments on the law of increase of the crushing force of short blocks of stone, with their diameters.

10. On brick and tile-making, and the capability of introducing new forms for engineering and architectural purposes, with the processes most useful to emigrants and settlers.

11. The laws of the strength of cast and wrought iron under the various conditions of tensile, compressive, transverse, tortional, impulsive, and other strains, with examples illustrative of the coefficients employed by eminent practical authorities in the construction of works.

12. The forms and dimensions of journals of machine-shafts, axles, &c., with the best composition for the linings of bearings, and the most approved methods of lubricating.

13. The construction of girder-bridges, whether of trussed timber or wooden lattice; of cast-iron trussed or plain, or combined with wrought-iron in simple or compound triangulation; of wrought-iron lattice-work; or of plate-iron riveted sides with cellular top and bottom.

14. The construction of suspension-bridges with rigid platforms, and the modes of anchoring the stay-chains.

15. The comparative advantages of iron and wood, or of both materials combined, for the construction of steam-vessels, with drawings and descriptions; the methods for preventing corrosion; and details of the arrangement for the compasses, and for their adjustment in iron ships.

16. On the changes that have been introduced within the last fifteen years in the lines of ships and steam-vessels; and an examination of the effects produced by the new law of measurement for tonnage.

17. An examination of the circumstances which appear to limit the maintenance of higher speeds than are now attained by steam-ships in deep-sea navigation; and an inquiry into the causes which have hitherto prevented the asserted high speeds of steam navigation on the American rivers from being arrived at in England.

18. The results of the use of tubular boilers, and of steam at increased pressure, for marine and other engines, noticing particularly the difference between weight and speed in proportion to the horse-power and the tonnage; with details of the most successful means for avoiding smoke in furnaces of all descriptions.

19. The best methods of reducing the temperature of the engine and boiler room of steam-vessels, and of preventing the danger arising from the over-heating of the base of the funnel.

20. The relative efficiency of the screw-propeller and paddle-wheels when applied to vessels of identical form, tonnage, and steam-power, independent of the use of sails.

21. The results of the application of steam-power and screw-propellers to the conveyance of coal, compared with the system of sailing-vessels.

22. The arrangement and distribution of the workshops at the principal repairing-station of a railway, for the repairs and maintenance of the locomotives, passenger, and other carriages, &c., derived from existing examples.

23. The construction of locomotive engines, specially adapted for steep inclines, with accounts of experiments demonstrating the comparative value of large and small engines under various circumstances.

24. Improvements in the manufacture of iron for rails and wheel-tyres, having special reference to the increased capability of resisting lamination and abrasion.

25. On the cost of maintenance of the permanent way, noticing the principal systems in use for the last ten years, and the depreciation of the rolling stock of railways.

26. Improvements in the construction of railway carriages and wagons, with a view to the reduction of the gross weight of passenger trains, also of railway wheels, axles, bearings, and breaks, treating particularly their ascertained duration and their relative friction.

27. The results of a series of observations on the flow of water from the ground, in any large districts, with accurately recorded rain gauge registries in the same locality for a period not less than twelve months.

28. On the construction of catch-water reservoirs in mountain districts, for the supply of towns, or for manufacturing purposes.

29. The laws governing the velocity and discharge of currents of water, whether in pipes or in open channels, receiving tributary accessions at various points of their course.

30. The comparative duty performed by the various descriptions of steam engines for raising water for the supply of towns, or for the drainage of mines; noticing the depth and length of the underground workings, the height of the surface above the sea, the geological formation, the contiguity of streams, &c.

31. The drainage and sewerage of large towns, exemplified by accounts of the systems at present pursued with regard to the level and position of the outfall; the form, dimensions, and material of the sewers, the prevention of emanations from them, the disposal of the sewage, whether in a liquid or solid form, and of the arrangements for connecting the house drains with the public sewers.

32. The precautions adopted for guarding against accidents by fire-damp in mines.

33. The results of contrivances for facilitating the driving of tunnels or drifts in rock.

34. Descriptions of various kinds of machinery in use in the principal shipping ports, for the shipment of coal, noticing particularly those in which the greatest expedition is combined with the least amount of breakage of the coal, and also accounts of the means of unshipping, and measuring, or weighing the coal on its arrival in port.

35. Descriptions of the ovens, and of the best processes used in Great Britain and on the continent in the manufacture of coke for railway and other purposes, with the comparative values of the products.

36. Improvements in the system of lighting by gas; the results of the use of clay-retorts; of large ovens (for producing a better quality of coke); of exhausters, condensers, and modes of purifying, and the precautions for the economical distribution of gas.

37. A mathematical or geometrical demonstration of the advantages of flat sails for ships over those of different degrees of curvature, when exposed to direct and slanting winds, with practical examples.

38. On the application of machinery combined with mechanical power, and the means of transporting manure and produce on large farms and agricultural establishments; and on improvements in the plan of the works and buildings and the "plant" employed.

39. The most effective arrangement and form of centrifugal and reciprocating blowing apparatus.

40. The chemical analysis and the application to economic purposes of the gases generated in iron blast furnaces.

41. An investigation of the causes of "red" and of "cold-shortness" in malleable iron, and other chemical characteristics which affect the physical properties of cast or of wrought iron.

42. Description of cast or wrought iron cranes, scaffolding, and machinery employed in large works, in stone quarries, hoists or lifts on quays, in warehouses, &c., especially where either steam or water is used as a motive power.

43. On the improvements which may be effected in the buildings, machinery, and apparatus for producing sugar from the cane in the plantations and sugar works of the British colonies, and the comparison with beet-root with regard to quantity, quality, and economy of manufacture.

44. Accounts of the improved systems of storing corn, and of producing flour.

45. Description of the machinery adapted for the preparation of Indian cotton.

46. Improvements in flax machinery, and in the processes for preparing the flax for manipulation.

47. Notice of the principal self-acting tools employed in the manufacture of engines and machines; also of moulding-machines and wood-working machines, and the effect of their introduction.

48. The construction of lighthouses, their machinery and lighting apparatus, with notices of the methods in use for distinguishing the different lights.

49. Memoirs and accounts of the works and inventions of any of the following engineers:—Sir Hugh Middleton, Arthur Woolf, Jonathan Hornblower, Richard Trevithick, William Murdoch (of Soho), and Alexander Nimmo.

## THE DISTINCTION BETWEEN ILLUMINATION AND PAINTING.

### MR. RUSKIN'S LECTURES ON DECORATIVE COLOUR AT THE ARCHITECTURAL MUSEUM.

MR. RUSKIN commenced by stating that he was not going to read a paper or to speak from notes, and it was a mistake in the advertisement to say that he intended to deliver a lecture. It was not a lecture, but a talk; and his object was to address himself to the students present, and place before them, in a familiar way, things which were useful.

Before entering upon his subject, however, he wished to glance at one or two historical points, with the view of explaining the examples he proposed to set before them. In these days it was a very common practice to laugh at the middle ages, and hold them up to ridicule. Truly, they were ridiculous in many senses, but certainly they were not ridiculous in their way of writing. They did not write in those days so much as we do now, but they wrote much better when they did write. Even so far back as the seventh century, the Saxon writing began to acquire character and dignity, though the writing of that period differed materially from anything that we did now. The specimen he now submitted (an initial letter) was written as an ornament to a psalter belonging to a lady who died in the year 656, St. Salaberga. It would be perceived that the colours employed in writing in that day were simply black, yellow, and red. The design in the example was a continuous scroll, beginning in a bird's beak, and terminating in a sort of yellow dragon. It never encountered itself at a turn, but it glanced off and met again in some different part of its progress, and never doubled simply upon itself. Such was the general character of the MS. of that century. It was not very easy to imitate. He had himself tried it, but found it difficult, and to do it well considerable practice would be required. He wished, however, to draw attention to the fact, that there was a character and a finish about this writing which was not found in common penmanship.

From these yellow and black scrolls they went on improving until the time of Charlemagne, when the art of illuminated writing received a great impulse. Then more and more colour was introduced in the finish, and greater variety in the outline. It had been frequently said that Charlemagne could not write; true, he could not write in what would be called writing now, for what we now understand as writing would not have been called writing in the days of Charlemagne. Here was an example of the writing of that age. This (the specimen exhibited) was written in the eighth century, and it was the beginning of one of the books of the Gospel. It would be observed that more colour was introduced about this time; and they would notice how it was stolen in, as it were upon the gold. But though it was said Charlemagne could not write, though he could not write as we write now, yet he could write after a fashion. He always carried tablets about with him, upon which he from time to time put down anything he desired to remember. He could not, however, write like the specimen the meeting were now examining; but he employed those who could, and paid great respect to them. Immense respect was paid to to the writers of those days. He (the lecturer) would much like that respect paid to the art of writing now. As showing the kind of respect which this art commanded in the middle ages, he would read an anecdote respecting an eminent writer who lived in the time of Charlemagne. "There was in the monastery of Arnisberg a writer named Richard, an Englishman, who had with his own hand copied a great number of books, hoping to receive in heaven a recompence for his labours. When he quitted this life, his brother monks buried him in a place of honour. Twenty years afterwards his tomb was opened, and his right hand was found in as perfect a state of preservation as though it were alive, and appeared to have been recently cut off from an animated body, while all the rest of the corpse was dust. This hand is shown as a great miracle to this day in the monastery of Arnisberg." This showed the honour with which a good writer was regarded at that period; and not only was the art honourable and profitable to those who practised it, but its effect was profitable and valuable to others. We had an instance of this in the history of one to whom we were indebted for all our English literature—he alluded to King Alfred. Alfred himself was honoured in France for his writing; and the best writing of that period came from France. It was well known that the French princess Judith, who was Alfred's stepmother, took great pains to teach him; but it would seem that he had naturally no more taste for study than other children, for it was recorded of him that he lived to twelve years old before he was taught to read. How he was induced to learn was, according to Mr. Sharon Turner, in this wise. "When Alfred was twelve years old, she [Judith] was sitting one day surrounded by her family with a MS. of Saxon poetry in her hands. With a happy judgment she proposed it as a gift to him who would the soonest learn to read it. The whole incident may have been chance play, but it was fruitful of consequences. The elder princes—one then a king, the other in mature youth or manhood—thought the reward inadequate to the task, and were silent. But Alfred, captivated by the prospect of information, and pleased with the beautiful decoration of the first letter of the writing, inquired if she actually intended to give it to such of her children as would the soonest learn to understand and repeat it. His mother repeating the promise with a smile of joy at the question, he took the book, found out an instructor, and learned to read it. When his industry had crowned his wishes with success, he recited it to her. To this important though seemingly trivial incident we owe all the intellectual cultivation and all the literary works of Alfred, and all the benefit which by these he imparted to his countrymen." In this case the beautiful initial letter was the attraction—a letter probably like that which he (the lecturer) had just exhibited as characteristic of the date of Charlemagne. This was the first inducement to study with our English Alfred, and he was not quite sure whether it would not be better generally that children should remain until they were twelve years of age, and then be tempted to read by such inducements as these, rather that we should go on impressing upon their minds in infancy the enormous fallacy that "A" ever was, or under any circumstances could become, an apple-pie.

The main idea of the age of which he was now speaking, however, was that a book was a noble and a sacred thing, to be respected and revered. It became precious because it was written with so much labour and with so much beauty: and then came the idea of its sanctity. It was noble, inasmuch as it was the means of making human thought—the most transient and evanescent of all things—the most permanent of all things. Well, this being the idea of books, which then obtained in men's minds, they worked, and worked on, to attain greater excellence in their writing, by systematizing their colour more and more, until they arrived at a perfect system, which, however, they might have found out long before they did, and which it was strange that we ourselves had not discovered. It was strange that those who were familiar with the Bible, wherein they were told that the colours directed to be used for ornamenting the tabernacle, were gold (or yellow), and blue, and purple, and scarlet, as being those calculated to form the basis of the richest, most harmonious, and glorious combinations, should not have adopted them in all cases where such results were required. The thirteenth-century people, however, had not, it appeared, derived their knowledge from the Bible; they went on working and experimenting until they found it out. Here (exhibiting it) was a Bible of the year 1220: it was but a common example, but worth exhibiting, on account of the clerkly manner in which the letters were written. He now came to the middle of the thirteenth century, when an immense development of the art took place. It was well known that the whole spirit of the middle age was to be found in the writings of Dante: there it must be sought. Dante was the prophet of the middle ages. In his "Purgatory" he introduced a description of certain people suffering the penalty of pride. He represented them as being crushed under great stones, in the position of which we have so many examples in the architectural decorations of that period, as in figures bearing corbels, brackets, &c. It was curious to see what Dante appeared to think most calculated to create the feeling of pride in the human breast. It was not valour, nobility, or success in battles, but excellence in writing. These were his words:—

> "Listening, I bent my visage down, and one
> (Not he who speaks) twisted beneath the weight
> That urged him, saw me, knew me straight, and call'd,
> Holding his eyes with difficulty fix'd
> Intent upon me, stooping as I went,
> Companion of their way. 'O!' I exclaim'd,
> 'Art thou not Oderigi? Art not thou
> Agobbio's glory?—glory of that art
> Which they of Paris call the limner's skill?'
> 'Brother,' said he, 'with tints that gayer smile,
> Bolognian Franco's pencil lines the leaves,
> His all the honour now—my light obscured.'"

The line which is given by Cary (for this is his translation)—

> "Which they of Paris call the limner's skill,"

is not properly translated. The word which in the original is "*alluminare*," does not mean the limner's art, but the art of the illuminator—the writer and illuminator of books. The passage gave a peculiar interest to the illuminated works of the date in which Dante wrote. This period—the middle of the thirteenth century—was marked also by the career of St. Louis, and the next example which he (the lecturer) had to produce, was from a psalter, which was peculiar in having, in addition to the names of the saints, the names of the members of St. Louis's family, with the date of their death, but not of that of St. Louis himself. First, there was the name of Count Robert of Artois, St. Louis's brother, who lost his life while charging the Saracens at Mansourah—just as our light cavalry had charged the Russians at Balaklava. There was thus a note of his death which was put down as a sort of martyrdom. Then there were the names of King Philip II., then that of Louis VIII. the father, and of Blanche of Castile, the mother of St. Louis, but not his own. Now Queen Blanche died in 1252, and St. Louis himself in 1270, so that it was evident this psalter was written between those two periods, and the different portions of it at some distance of time from each other. The leaf exhibited was one of the common leaves taken from the beginning of the book. The flourish of the initial letter he had enlarged, in order to show more clearly what sort of a thing it was. The prevailing colours were blue, purple, and scarlet, with gold: leaves were introduced, and the ornament, it would be perceived, was constantly changing in form and in the curve and lie of the leaf. If there were no change there could be no life. That might be taken as the great rule of art.

He might, while upon this point, remark, that one of the great evils of the day was an intense love of symmetry. Nothing in nature was perfectly symmetrical. No two sides of any animal, tree, or other natural object, were exactly alike. Try to brush your hair exactly alike on both sides, and you will find it could not be done. A statue to be graceful must not have the arms and legs in the same action on both sides; they must be in different actions. In nature they always *were* in different action. In sculpture, in painting, as in everything else, in art as in nature, without dissimilarity there could be no grace. The next specimen he would present to their notice was a capital letter at the beginning of a psalm. In this they would observe, that animals, as well as natural leaves, were introduced. Up to this period nature had not been followed in writing to the same extent, but had been treated in the manner represented in the previous examples. The little Bible he had in his hand, in which the initial capital, of which the letter he exhibited was an enlargement, occurred, was a good example of the style of writing of the year 1230. Here, they would observe, the prevailing colours were the same, blue, purple, and scarlet, with white introduced at intervals, like beautiful pearls. It was a great point in the arts—which many did not seem to be aware of—to know how precious white was. Here were two of the introductory leaves of a psalter which he wished to bring to notice, on account of the human faces introduced in the ornament of the letters. One of these illuminations represented Solomon, having been named David's successor, being made to ride upon the king's own mule, and the burial of King David. Both of these examples were remarkable for the beauty of the faces. Outline and colour were, however, the principle of these examples; beyond that there was no imitation of nature. But from this they began to enrich their MSS. more and more: the systematization of colour went on until they reached a point of enormous luxury. With that luxury of ornament and colour came carelessness, and the gradual degradation and decline of the art. The MS. now produced, one given to Queen Blanche, in the sixteenth century, exhibited that carelessness and degradation in a marked degree. The art having reached its culminating point about the middle or towards the close of the thirteenth century, from that period began to decay, the principles of it having been lost sight of in the attempt to attain greater luxuriousness of drawing and effect, those principles which he insisted upon as the fundamental principles of the art being clearness of outline, and simplicity of colour, without the introduction of light and shade. He had said that writers were not reverenced sufficiently in these days—he said also that neither were painters reverenced as they ought to be. It was a very difficult thing to paint well—much more so than most people imagined, and to lay on light and shade properly, to realise and to convey upon canvas a thorough impression of the varying effects of sunshine and shadow, in the colour of the air, and in the tints given to every object in nature, was a far more difficult thing than most men were capable of accomplishing. This was the reason why we had so few really good painters, and so many bad paintings. There had been never more than three or four really good painters in the world in any one age, and no wonder, for it required talent of a very rare order to be a painter in the higher sense of the term. It was as difficult, and required a natural capacity as extraordinary, to be a good painter, as it did to be a Duke of Wellington; but though it was necessary to possess a first-rate capacity, and talents of the highest order to be a painter, it was not so to enable persons to outline truly from nature, and to lay on simple colour beautifully. This also was a peculiar gift not possessed by every one; but it was a gift which hundreds of persons possessed naturally. Amongst dressmakers there were many who instinctively, as it were, evinced an aptitude at arranging flowers and putting on colour, so as to throw in depth or light as required, for the purpose of producing harmonious combinations, and the instinct to arrange bouquets of flowers so as to combine in harmony the various hues was common. But the mischief was, that when young people were found to possess the talent of outlining or arranging colour in more than an ordinary degree, they were pressed to learn to draw, though they might not have brains enough ever to draw well. He would urge upon those of his audience who had the gift of colour, not to allow it to be checked or run away with by pursuing that which it was more than doubtful that they would ever succeed in. There might be first-rate art exhibited in the pursuit of colour only. The field was narrow, no doubt; but if a man made up his mind to be an illuminator—if he possessed the gift of arranging colour, and his opportunities and time did not admit of his making himself a good painter, then let him take up this principle, that every form he drew must be in pure colour, without shadow. He might use what colours he pleased, but let him not resort to shadow in any shape—the object should always be represented in gradated pure colour, with true outline. The first step was to be perfect master of outline. Outline was susceptible of great beauty and infinite variety; but it must be firm and true; not thickened on the side opposite to the light, with a view of showing something like a shadow. It must not be shadowed at all. Nothing could be more absurd than to attempt to throw in shadow by thickening the line, for if the outline was ever lost, it would oftener be on the dark side than on the light side. Besides, the veracity of the line would lie within the compass of a hair. It must be right or wrong. If right, the thickening of the line destroyed the correctness, and the thickness must be removed before the outline could be true, the truth lying somewhere within the thick line.

The first thing to practise was perfectly faithful outline, and an important thing to know was how much could be expressed by it. Here was an example of the fourteenth century, containing nothing but outline. They would observe that there was a blue bird in the composition, which appeared all but animated, because it was as far as it went so beautifully drawn. This example, and some of the others, would however appear to those who were close to them somewhat coarse, in consequence of their having been considerably enlarged from the original MS. But there might be as much perception of nature in working out these mere outlines as in working out a fully shadowed drawing, like one he now exhibited (a bunch of leaves very far inferior as a work of art to either of the examples of MS. shown), and it was much better that they should possess, for the purposes of decorations generally, the daring conventionality of colour shown in other specimens he submitted to them with pure outline, than that they should be imitators of the spurious examples produced by painters who could not paint, and which violated the eye wherever they were seen. He had said that the peculiar character of the decorative work of the thirteenth century, was the introduction of nature, and that was the circumstance that would make it especially agreeable to those who pursued this art now, if it could (as he hoped) be revived amongst us. In practising it, they need not limit themselves to birds and leaves, as in the examples before them, but might avail themselves of every natural object. As soon as they could trace an outline correctly, he wanted them to watch closely every living object around them—groups of children in the streets, leaves, trees, birds, and the animals in the Zoological Gardens; but he would warn them against introducing too much; and when they were painting, let them never introduce the same letter twice, or the same figure or animal twice in the same composition.

Now, what were the fields for an occupation of this kind?

This was a serious question, and unless the change took place which he was now striving to bring about, he found himself wedged in between two difficulties. He frequently received letters from persons who said to him, "Build us a house, or paint us a room in this way." The reply he was compelled to make was, that he had not the workmen who could do it; and then it was said, naturally enough, that he was a humbug. He went to the workmen, and they said, "We cannot devote our time to that kind of work; there is no demand for it, and we could not earn our money by it." Now, he had asked the students and workmen to come together there that day that they might aid him in the attempt to revive the art to which he had been directing their attention, by recommending to those by whom they were employed to introduce this kind of decoration wherever opportunity offered. There was a great field for it in ornamenting the interiors of churches. There was the lettering of the Commandments, and the writing over the communion-table, the windows, and other ornamental work, where illuminated letters might be introduced with great effect. The patterns might be perpetually varied, and animals, birds, leaves, trees, and other natural objects might be made to give life and diversity to them. But he would urge upon them, whenever they were required to paint anything in a church, to do it as well as they could, and to introduce as much of nature as they could in a graceful manner. Then there was the decoration of rooms—though upon that point he confessed he saw considerable difficulty. He liked pictures and prints in rooms, and would, as far he could, induce people to buy them, and the examples he had exhibited certainly would not look well with those. He would say nothing further upon this point therefore, except that he should like to receive the advice and suggestions of workmen themselves upon it. In the lettering on the outside of shop-fronts, illuminated letters might appropriately be employed, and would form a pleasing change from the dingy appearance which many of the shop-fronts, especially in the metropolis, presented. He would urge upon them, when they had shop-fronts to decorate, to endeavour to induce the shopkeeper to allow them to introduce such letters. He believed the effect would be good, but he was not over-sanguine when he looked at that unhappy thing in Leicester-square, which was abominably ugly, in spite of its colour.

Another, and a most important field for the exercise of this art was the decoration of books. He did not say that every book should be illuminated; some books, as the Bible, should, he thought, be as simple in lettering as possible; but books of poetry or art, which might be very appropriately decorated as suggested. He was anxious to see a taste for decorating books in this manner, because he believed we were falling into a very careless way of regarding our books. It might be that we had so many books now as compared with what persons in similar positions in life formerly possessed. It had been said that it was better to have a few books than many; he could not say that that was his feeling; he considered it a most delightful thing to have a library; at the same he should like people to value and love their books more than they did. The feeling that prevailed in the middle ages with regard to books was, that they were holy things, and those who were employed upon them felt that they were engaged upon a holy work. He would like to bring back something of that feeling, and he would also like to bring back for the workmen the employment of illuminating books, for he thought it must have been a most happy employment. He did not know at what cost now an illuminator might be able to produce a finely-illuminated page. That was a subject on which he was anxious to obtain information. He wanted to have the data, and if the workmen would furnish him with that, he would endeavour to bring the subject before the public. What he wanted was, the information to enable him to say, when asked, what would be the cost of illuminating some beloved book which it might be desired to preserve as a valued work in a family. He thought very many would gladly avail themselves of the opportunity, if it were offered them, to have books of this character so decorated to be preserved as heirlooms. For his own part, he would rather have an illuminated book in his library than a picture. He would like to have a book of which every page was a picture.

The great point was to make this art of book illumination fashionable; if that were done, it would go on as a matter of course. A new school of art would be introduced; the eye for colour would become disciplined; the perception of truth and form in outline would become disciplined; and the art of painting would be more and more appreciated. A Titian could only be appreciated by those who understood harmony of colour. It was not the extraordinary effects of the light and shade—beautiful though they were—that marked the true Titian, so much as the beautiful harmony of his colours; and by disciplining the eye to those harmonies a feeling would be created in the public mind which was now almost dead. There was another advantage that would result from the revival of this art to the student and the illuminator. He could not imagine a happier life than that which would be led by any person of quiet and studious habits with something like the disposition of the old monks who were the illuminators in past times, while following this occupation. If it were cultivated, a totally new impulse would be given to art in every direction, and possibly also to literature, for people would feel that it was better to have a monument in the shape of an illuminated book than in that of an illuminated window; and many a man engaged in writing a book would feel more interest in his work, and take more care in its composition, if he knew that it was to be beautifully illuminated, to be placed in a library as a beloved thing, to be handed down from father to son, and from generation to generation, than if it were printed in the ordinary way, tossed about by printers' devils, and thrown aside as soon as read.

As showing the kind of life he would encourage, he would ask permission to read a passage from Longfellow, describing the Friar Pacifico transcribing and illuminating the Gospel of St. John:—

"It is growing dark! yet one line more
And then my work, for to-day is o'er;
I come again to the name of the Lord,
Ere I that awful name record,
That is spoken so lightly among men,
Let me pause awhile, and wash my pen;
Pure from blemish and blot must it be
When it writes that word of mystery!
Thus have I laboured on and on,
Nearly through the Gospel of St. John.
Can it be that from the lips
Of this same gentle Evangelist,
That Christ himself perhaps has kissed;
Came the dread Apocalypse?
It has a very awful look,
As it stands there at the end of the Book.
Ah me! when I think of that vision divine,
Think of writing it line by line,
I stand in awe of the terrible curse.
Like the trump of doom in the closing verse.
God forgive me! if ever I
Take aught from the Book of Prophecy;
Lest my part, too, should be taken away
From the Book of Life on the Judgment-day."

Then notice the change of feeling—how natural!

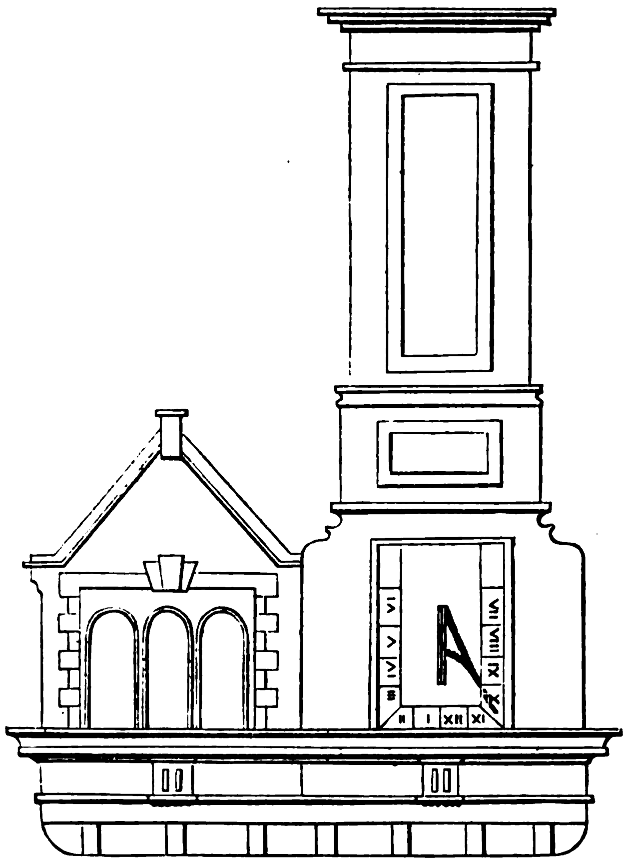
"This is well written, though I say it!
I should not be afraid to display it,
In open day, on the self-same shelf
With the writings of St. Thecla herself,
Or of St. Theodosius, who of old
Wrote the Gospels in letters of gold!
That goodly folio standing yonder,
Without a single blot or blunder,
Would not bear away the palm from mine,
If we should compare them line by line.
There, now, is an initial letter!
King René himself never made better!
Finished down to the leaf and the snail!
Down to the eyes on the peacock's tail!
And now, as I turn the volume over,
And see what lies between cover and cover,
What treasures of art these pages hold,
All ablaze with crimson and gold,
God forgive me! I seem to feel
A certain satisfaction steal
Into my heart, and into my brain,
As if my talent has not lain
Wrapped in a napkin, and all in vain
Yes, I might almost say to the Lord,
Here is a copy of thy word,
Written out with much toil and pain;
Take it, O Lord, and let it be
As something I have done for thee."

He looks from the window:—

"How sweet is the air! How fair the scene!
I wish I had as lovely a green
To paint my landscapes and my leaves!
How the swallows twitter under the eaves!
There, now, there is one in her nest;
I can just catch a glimpse of her head and her breast;
And will sketch her thus, in her quiet nook,
For the margin of my Gospel Book."

This was the kind of life he wished the students of this art to follow. He proposed to leave the various examples he had exhibited in the Museum, that those who desired to do so, might come in if they pleased, and work from them between then and the next lecture. In the next lecture he proposed to explain the general principles of outline, and to exhibit examples; and in the third lecture he intended to explain the principles of colour.

## DORMER WINDOW, HILL HALL.



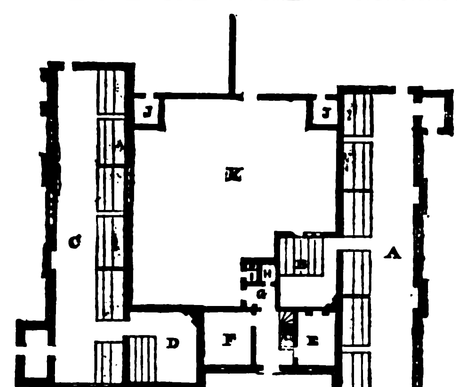
Our engraving represents a Dormer window and chimney shaft with sun-dial, from Hill Hall, drawn to a scale of ¼-inch to the foot, by our correspondent, Mr. Horace A. Alexander, of Stratford, architect. The chimney-shaft is in brickwork.

## THE COAL MINES OF FRANCE.

About a year since, the French government, alarmed for the industrial classes by the rise in the price of coal, resolved to avoid a position which might have materially interfered with their commercial and industrial prosperity. To attain this end, it at first reduced the import duty on English coal, but soon perceived that the remedy applied was insufficient. It became evident that the consumption of coal throughout France was taking such rapid strides that the production did not suffice to satisfy the requirements each day brought forth in immense proportions. In fact, the constant increase of steam navigation and communication by railway, which, as it progresses, reaches districts in which coal was unknown, causes the demand to considerably exceed the supply, and all branches of industry, with their natural developments, necessarily tend still further to increase the consumption. Such a state of things has of course led to a great rise in the price of coal; and in the north as well as in the south of France, coal and coke became so scarce that some establishments had to close for want of fuel; the railways alone having been enabled to procure the coke they required. Some, thanks to their contracts, ensured a supply on moderate terms; but others, less fortunate, have been compelled to pay advanced prices.

The proprietors and shareholders of coal-mines generally have not, so far, profited by these high prices, from the contracts entered into with the State, for marine purposes, with the railway companies and the industrial establishments, which had been completed before the great demand for coal had commenced: but these contracts having now expired, or nearly so, the shareholders and proprietors will consequently begin to profit by the advanced prices. For example—the mines of the Loire, which paid in 1852 but 34 francs, and in 1853 but 42 francs, will in 1854 pay about 50 francs per share. The Grand 'Combe, which paid but 25 francs per share for 1853, can pay 50 francs for 1854, and the results, it is expected, will be similar for most of the colliery enterprises. A ton of coal costs 43 francs at Anzin, 56 francs at the mines of the Loire, 52 francs at Firminy, 56 francs at Blanzy, 63 francs at the Charbonnages Belges, 48 francs at the Grand 'Combe, 60 francs at Commentry, and 30 francs at Portes. Thus, the maximum cost for a ton of coal is that at the Charbonnages Belges, 63 francs per ton, and the minimum at the mines of Portes and Lénéchas, where it is only 30 francs per ton.—*Mining Journal.*

## ST. SIDWELL'S PAROCHIAL SCHOOLS, EXETER.



The Parochial Schools of St. Sidwell's were opened on the 2nd of November. They consist of a boys' and girls' school, each 78 ft. 6 in. by 18 feet, having open roofs of high pitch ceiled against the rafters. There is a girls' class-room 16 feet by 18 feet, and boys' 16 feet by 16 feet. The mistress's residence (built in conformity with the regulations of the Privy Council on Education) connects the two school-rooms. The style of the building is Old English, with square-headed five-light windows with transoms in all the gables, of Bath stone, the walls being of red brick, with tall chimneys of the same material. There are spacious play-grounds. The site was given by the Dean and Chapter of Exeter, and the buildings erected chiefly through the exertions of the incumbent, Rev. J. L. Galton, in raising a subscription, aided by a grant from the Committee of Council.

The contract for the schools was nearly 1500*l.* The cost of boundary fences, 250*l.* The works were carried out by Mr. Ware, of Exeter, from the designs of Mr. Ashworth, of the same city.

*References to Ground Plan.*

A. Girls' School, 78′ 6″ × 18′.
B. Girls' Class Room, 16′ × 18′.
C. Boys' School, 78′ 6″ × 18′.
D. Boys' Class Room, 16′ × 16′.
E. Mistress's Sitting Room, 12′ 6″ × 12′ 6″.
F. Kitchen, 12′ 6″ × 12′ 6″.
G. Scullery, 8′ 3″ × 7′ 0″
H. Pantry.
I. Watercloset.
The other Closets are against the east side of the Play-ground.
There are three Bedrooms over E and F.

K. Garden.

## ELECTROTYPE COPPERPLATES.

Among the specimens of miscellaneous philosophical processes of products exhibited at the New York Crystal Palace Exhibition, were some electrotype copperplates, produced at the United States Coast Survey Office. These plates are three in number, and consist of—1, the original engraved plate; 2, a reverse or matrix obtained therefrom by electro deposit; and 3, a "duplicate" or facsimile of the first or original plate, this last being also obtained by electro deposit upon the reverse or matrix No. 2; a printed proof or impression on paper from this latter completes the collection, and affords satisfactory evidence of the perfect manner of conducting the whole operation, all the most minute points and delicate lines being brought out beautifully sharp and distinct. As the several processes adopted in the production of these plates appear to be all of the most improved description, founded on sound philosophical principles, whilst some of them are claimed as the invention of Mr. Mathiot, of the Coast Survey Electrotype Laboratory, under whose able direction the whole work is conducted, a brief description of those processes may not be unacceptable.

The original plate as received from the engraver, is immediately electro-silvered, and then washed with an alcoholic solution of iodine, and exposed to sunshine or bright light. This is found effectually to prevent the adhesion of the electro deposit to the original plate (probably by the interposition of an infinitesimal film of the *vapour* of iodine), without in the slightest degree impairing the sharpness of the impression, the thickness of the coating of iodine vapour being estimated by Mr. Mathiot at *one forty-four millionth* part of an inch; or, upon the supposition that the iodine remains upon the plate in its elementary state, then the thickness of the deposit is estimated at the "*one eighteen thousand millionth* part of an inch."

The plate thus iodised is placed in the vat or decomposition trough in a *vertical* position (the necessary connections with the battery and other arrangements being effected, as usual), and as soon as a sufficient surface layer is produced (which usually takes about twelve hours), the plate with its surface layer is removed to another vat, in which it is placed horizontally with its face upwards, and the positive pole or plate of copper immediately over it, at a distance of about an inch,—the temperature of the copper solution in this horizontal bath being maintained uniformly day and night at about 180°. This is effected by means of a simple furnace with self-regulating damper and an internal coil or helix of pipe, with an upper and a lower tube leading to the corresponding parts of the vat or bath, in which the required temperature is thus maintained by the circulation of the fluid in the ordinary manner; it being found that a peck of charcoal will maintain 100 gallons of the copper solution at any required point between 100° and 200° for twelve hours; the result of such increase of temperature being that a plate of copper ⅛-inch thick, and containing 10 square feet of surface, can be produced in forty-eight hours, or at the rate of 3 lb. to the square foot in twenty-four hours. The quality of the metal produced under such increased temperature being moreover found to be of a very superior description, rivalling in hardness, ductility and elasticity the best rolled or hammered copperplate. This is satisfactorily exemplified in a couple of broad strips of copper, ⅛-inch thick, which are exhibited near these plates. One of the strips is flat, and found to be exceedingly hard and sonorous; the other is twisted up into a sort of open single knot, to prove the perfect ductility and tenacity of the metal.

It may also be mentioned that about 2000 impressions were printed from the first electrotype duplicate taken from the original plate in the Exhibition without its showing any appearance of deterioration, although the lines are many of them exceedingly light and delicate,—so much so, that it is said by competent judges that the original *engraved* plate would probably have failed in producing *one* thousand equally good impressions.

Mr. Mathiot manufactures or produces the negative silver plates of his batteries by electro deposition, and in order to remove from their platinized surfaces the impurities of the zinc plates, which are invariably found to attach themselves thereto, he immerses them *daily* in a solution of per-chloride of iron, which is found to immediately restore the action of the plate, and thus constantly maintain the "*tone*" of the battery.

## REVIEWS.

*Report of the United States Commissioner of Patents for the Year* 1853. Part I. *Arts and Manufactures.* Washington. 1854.

Some alteration has been made in the character of the Reports of the American Patent Office. The usual reports of the Examiners are omitted, on the ground that the Examiners' time might be more usefully employed, and that it was impossible to avoid invidious distinctions between patentees who supposed themselves equally meritorious.

We regret this decision of the Commissioner. The reports of the Examiners we have found most valuable; pointing out to inventors that which had been done before the experiments that had failed, and what remained unattempted, with descriptions of the more interesting of the patents. The only way to avoid all jealousy on the part of patentees, is to appoint as Examiners the most eminent scientific men of the country, and those who are universally considered to be far above all suspicion; and to induce such men to become Examiners, the salary must be increased to such an amount that more profitable employment cannot be sought elsewhere than in the Patent Office. The Commissioner says:—

"The Patent Office should command the highest order of talent. There is no person, whatever be his abilities or his attainments, who would not find, as an Examiner, full exercise for all his talents. A practical sound sense is nowhere more important. All learning connected with the arts and sciences finds here an ample field for exercise; and even questions of law, that tax to their utmost the abilities of the most learned jurists, frequently present themselves for the decision of the office, and should be rightfully decided by the Examiner.

The compensation of the lowest class of Examiners should be such as to command abilities that, with proper training, would grace the highest; and the compensation of all should be sufficient to induce each one in this employment to content himself with making it a business for life, as the information he is daily acquiring is constantly increasing his usefulness."

A material improvement has been made by every patent being fully described, and those which require it being accompanied by a woodcut showing the parts referred to. The Commissioner has gone into the question of the fees required of foreigners; he considers them enormous, and indefensible upon any principle of justice or sound policy, and is greatly in favour of reciprocity. He says:—

"Within the last two years Great Britain has greatly diminished her former high rates of patent fees. It is believed that in no country in Europe are our citizens taxed for these purposes as severely as we now tax theirs. It is well known that some European governments impose a lower rate of fees on an American citizen than he would be required to pay by this office; and yet we continue to charge a British subject $500, and any other alien $300, for that which we grant to our own citizens for $30.

But the granting of a patent is not a mere gratuity by the government: it is the recognition of an evident right in the inventor. No title to property can be more just or valid than his who has created that property. The rule of natural justice is the same in this respect whether the inventor be a citizen or an alien. It is right that the government should charge the patentee with the expense of securing him in his title to what was before rightfully his own; but it is questionable whether a revenue should be sought from this source, except in cases of great necessity. Is there any sufficient reason why the general rule should be departed from in the case of an alien?

It may seem reasonable that we should charge an alien the same fee that his government would charge one of our own citizens under like circumstances; but it should be recollected that European governments make no discrimination between natives and foreigners. The high or low rates are the same for all. Under such circumstances retaliatory measures are not resorted to by us in regard to any other subject.

The oppression to which an alien is subjected at home has never been held as a reason for oppressing him here, even prior to his taking steps to become a citizen. If he holds real estate, we do not levy extraordinary taxes thereon commensurate with what that same property would be taxed if owned in this country by one of our citizens. Why should a different rule be followed in regard to property in an invention?

But there is a reason, founded in sound policy, why greater liberality should be exercised towards a foreign inventor than towards the alien owner of tangible property. He pays a consideration, which the other does not: by taking out a patent, he makes the subject thereof public property at the end of fourteen years. The benefits of the invention are then secure, and can never be lost to the world. High charges deter inventors from parting with their secrets. Many an invention is thus strangled in its birth, which, under other circumstances, might have been developed into something of vast consequence to the world.

There are no lost arts under a liberal and well regulated Patent Office system; and this is one of its great advantages. If foreign nations choose to place these chief means of human progress in subordination to the requirements of their respective exchequers, we are forbidden to imitate them, both by the condition of our treasury and the well-established policy of our government.

Finally, while we extend the free and full benefits of all our institutions to the alien who come hither to seek them, should not a course equally liberal be pursued in regard to inventions,—the creations of his ingenuity? Why should these be subjected to incapacities and discriminating taxation? In regard to them should not the whole world be regarded as one republic, of which we should seek to render our Patent Office the capital, wherein every region should be permitted a free representation? We tolerate no onerous discriminations against the foreign exhibitors in our Crystal Palaces. At the cannon's mouth we extend the protection of our flag to the alien who has simply declared his purpose of becoming a citizen, in the same manner as though he were native born. Ought we to levy a discriminating tax upon the offspring of genius that seek our shores for the express purpose of being naturalised amongst us?

From the preceding considerations it seems evident that a great change should be made as to the fees required from foreign applicants. It is respectfully submitted, whether the most convenient, wise, and beneficial rule will not be to abolish all distinctions growing out of geographical considerations, and to charge every applicant a fair remuneration for the trouble given by him to the office, but no more.

Such a course would be just, generous, and noble; seeking to raise no revenue from those who are the special instruments of human advancement, showing a confidence in the capability of our inventors to cope on equal terms with those of all the world besides, and taking no inconsiderable step in bringing about that great brotherhood of nations for which a higher civilisation is gradually preparing the wolrd."

An augmentation of the fees paid by citizens of the United States is referred to; since the salaries and the number of persons in the office have been increasing, the fees have remained unchanged. A second annual appropriation by Congress is asked, that room may be provided in the Patent Office for the full arrangement and exhibition of all the models; if this be granted, specimens of fabrics and other manufactures and works of art would be classified and arranged in the manner which the law now requires, but which requirement absolute necessity has always compelled the office to disregard.

The whole number of patents issued during the year is 958, including twenty-four reissues, three additional improvements, twelve extensions, and seventy-five designs; the whole number which have expired is 375.

## THE NEWARK ZINC WORKS, JERSEY, U. S.*

Zinc is a metal more sparingly distributed on the surface of the globe than most of the other metals in ordinary use. In Europe our wants are chiefly supplied from the deposits of zinc ores in Belgium and in Russian Poland and Silesia, and the United States market is still largely supplied from the same sources, though recent researches have certified the existence of an enormous deposit in one of her Atlantic States. At the Exhibition of 1851, in the United States Department, a fine specimen of this ore was exhibited in the shape of a mass weighing upwards of 16,000 lb., and accompanied by some of its products. It excited considerable attention on the part of our own, as well as of foreign mineralogists, both on account of the remarkable fineness of the specimen, and of a peculiar mineral "franklinite" with which it was associated. The articles were sent over by the New Jersey Mining and Exploring Company, which, however, were not then very successful in their manufacturing operations. Since that period the company has been reorganised, and under the judicious management of Mr. C. E. Detmold, a gentleman whose scientific acquirements, combined with his well-known skill as an engineer, admirably qualify him for the post, the exploitation has been resumed, extensive works erected at Newark, and an industry firmly and successfully established that bids fair, in the course of a few years, not only to meet the requirements of the home market, but also to furnish a supply to other non-producing countries. Professor Wilson visited the mines at an early part of the summer, and at a later period Mr. Detmold accompanied him through the manufacturing establishment at Newark, which he describes as follows.

The ore, which is the *red oxide*, is worked in Sussex county, in the State of New Jersey; about fifty miles from New York, and is found in a regular vein of 9 feet thick, lying immediately upon a 12 feet thick vein of franklinite in small crystals imbedded in a paste of the red oxide, the proportions of each being nearly equal. The vein has a regular dip of 80°, and rests immediately on the gneiss, the surface being composed of a bed, more or less thick, of a highly crystalline metamorphic limestone. The mining operations are comparatively inexpensive; the ore, lying at a high level, is worked at about $2 per ton; the transport, partly by road and partly by water, to Newark, costs $4 50c. per ton—in all $6 50c., delivered at the works. There the manufacture commences, which at present is confined to one article, the white oxide, so extensively used as a substitute for white lead. Although large quantities of metallic zinc are imported by the States, no attempt has yet been made at the reduction of the ores for that purpose. The ore containing the small crystals of franklinite, when reduced to powder and mixed with oil, forms a deep brown coloured paint, for which a considerable demand has latterly sprung up, as it has been found to be an economical and excellent application to iron surfaces. This, quite recently, has been the means of bringing it into notice.

The manufacture of the white oxide from the red oxide* is very simple, and is effected in the following manner: The ore is first broken down by stampers, and then passing through two sets of iron rollers, is crushed to about the fineness of coarse sand. In this state it is mixed up with about one-third of its weight of fine coal† (screenings), and is then ready for the furnace. The furnaces are constructed after the shape of a long muffle, having a grate at one end, upon which an anthracite fire is sustained, and at the opposite end an aperture with an iron door, which is kept closed, save when the furnace is being charged or the charges being stirred by the workmen. About 800 lb. to 900 lb. constitute a charge, and it requires about eight hours to work off this quantity, so that each furnace works on an average three charges every twenty-four hours, and is kept going night and day, Sundays included. The fire-doors and ash-pit are kept closed, and a large volume of air is supplied by means of an ordinary fan-blast, blown into the ash-pit under the fire-bars. A small portion of the flame passes through the muffle, where the charge (ore and coal) lies, the remainder is carried through the flues, which occupy as much as possible of the exterior of the muffle—the whole being constructed in fire-brick. The furnace is kept at a bright red cherry heat. After having been charged about two hours, the charge begins to give off vapours of oxide of zinc, which increase gradually for four or five hours, during which time the workmen stir the mixture occasionally with long iron rakes. In about eight hours, or sooner if the ore has been crushed very fine, the zinc vapours cease, and the charge is then raked out, and the furnace recharged with the mixed ore, which has meanwhile been heated on the top of the furnace arch. The furnaces are arranged in "banks" of twelve in a row. The muffles communicate by means of vertical cast-iron pipes 18 inches in diameter, with a large horizontal pipe or main 3 feet in diameter. At the point of junction between these vertical pipes and the muffles, an aperture is left, through which a supply of heated air is passed for the purpose of more thoroughly oxidising the zinc vapour as it leaves the muffle.

At the extremity of the horizontal main, a powerful fan-blower is driven with high velocity; this has a double action, drawing the vapour from the furnaces and driving it along the pipe into another portion of the building, called the "catching-house," in which enormous bags made of cotton canvas are suspended horizontally in rows, having a large number of bags of smaller diameter attached to them in a vertical manner with open ends reaching to the floor. The large bags are about 5 feet in diameter and 150 feet in length; the smaller ones are from 18 to 24 inches in diameter. By passing along the pipe, which is made in thick boiler-plate, the oxide and accompanying gases are sufficiently cooled down to prevent their firing the cotton bags, through the meshes of which the gases speedily escape, the oxide remaining behind. The bags are shaken every two hours, when the oxide, which has been collected in them and adhered to their sides, falls down to the bottom, and is then removed into other bags, and carried to the storing-bins.

It is either sold in a dry state in barrels, holding 200 lb. each, or ground up with linseed oil as a paint, and sent to market in

* From the Special Report of Prof. Wilson, on the New York Industrial Exhibition.

* The red oxide is the common oxide of zinc ($Zn.O$), combined with small proportions of manganese and peroxide of iron, from which its red colour is derived. The "franklinite" is composed of the same metals, combined in larger and definite proportions: zinc, 17; iron, 66; manganese, 16 (Berthier).

† The Rhode Island coal was being used at these works.

kegs of various sizes. The oxide of zinc, though perfectly white in a dry state, possesses frequently a greenish tint when mixed with oil and exposed to the action of the light. This probably is due to the oxidation having been imperfect, a small proportion of sub-oxide (?) being sufficient to give it the objectionable tint. Mr. Detmold stated that he expected to remedy the effects by by submitting the oxide to a gentle red heat in ovens which he was erecting for the purpose, and then passing a current of air through, so as more thoroughly to oxidise it. By this process he has been able to produce it of the finest white colour. The present capacity of the works is equal to about 50 tons per week, with a ready market for it for home consumption.

The residuum, consisting chiefly of oxide of iron, manganese, and zinc, resulting from the partially-decomposed franklinite, has been experimented upon very successfully by Mr. Detmold. Iron of the finest quality has been produced from it, very much resembling in its character the "spiegel-eisen" of Germany. The fracture has large and brilliant lamellar facets, sometimes very beautifully crystallised, and so hard as to cut glass readily. Like the German iron, which is produced from the spathic ores of Siegen, Sayn-Altenkirchen, Mussen, &c., it contains fully 5 per cent. of carbon, and nearly the same proportion of manganese, and is easily converted into iron or steel of superior quality.

This method of utilising the residuum is also adapted for the reduction of the franklinite ores, hitherto in themselves of but little value, and will render the secondary products almost of equal value to the staple manufacture. The results of the experiments must be no less gratifying to Mr. Detmold than beneficial to the interest of the company of which he is the president.

## WAREHOUSE OF "LA PROVIDENCE IRONWORKS COMPANY," PARIS.

M. Leonide Marquet, of Paris, *Architect.*

*(With an Engraving and Details, Plate* XXXIX.)*

The "La Providence Ironworks Company" has a large depôt on the Quai Jemappes, on the banks of the Seine, at Paris, in which more than two thousand tons of their productions are stored up. For this establishment a great hall or station has been formed, under the direction of the architect of the Company, M. Leonide Marquet, whose object it was to arrange the above produce according to lengths and sorts in close compass, but so as to leave good wide passages for traffic and for examination of the goods, while he proposed to roof it over on an economical plan, so as to give an example of the cheap application of iron roofing in Paris. For an account of the structure and for drawings we are indebted to Professor C F. L. Förster, of the 'Allgemeine Bauzeitung,' of Vienna, in which valuable publication they have appeared.

As the object of Professor Förster, in giving the details, is to show the actual cost of the structure, we shall follow him in the quantities, measurement, and cost, and it will be necessary to preserve the French measures and currency. The length of the building is 53 metres, and the breadth 30 metres; these are outside measurements. The construction is very simple. Eleven principals, including the two gables, as seen in the Plan view, carry the structure of the roof. Each principal consists of two main beams of double T iron, which are connected together by a system of tie-bars, to prevent the spreading of the principals. These tie-bars are secured to the principals and the crown-plates by two cast-iron pillars, by support bands, and two diagonal bands or rods, by which the connection of all the parts is secured, and stability conferred on the whole structure.

The principals rest upon the inclosure walls, or more correctly speaking, on inner supporting pilasters of ashlar, as will be observed on the Plan view. On these pilasters they are carried by cast-iron shoes (Figs. 1, 5 and 7). The principals are otherwise completely independent of the masonry, so as to allow of the free expansion and contraction of the metal. Indeed, throughout the structure, it is provided as far as possible that the movement of the solids shall be independently exercised, but that they shall be so brought in contact that the elastic properties of the wrought-iron members shall not be disturbed.

The following is the cost of the members of the roof and of the covering:—

* See for the Plate our last number, p. 425.

Principals—(Figures 1, 4, and 7).

| | Kilog. | |
|---|---|---|
| 2 Principals of double T-iron of 0·22m., and together 30·29m. long ... | 794 | 00 |
| 5 Ties and diagonals of wrought-iron rods of 0·040m. diameter, being a total length of 40·20m. (fig. 1) ... | 400 | 00 |
| 2 Cast-iron pillars (fig. 4) ... | 140 | 00 |
| 2 Cast-iron shoes (figs. 5 and 7) ... | 130 | 00 |
| 16 Bolts of 0·040m., with heads and screw-nuts ... | 36 | 00 |
| 8 Flat wrought-iron stirrups of 0·075×0·015, and each 0·78m. long, and strengthened at each end ... | 56 | 00 |
| 2 Connection-plates of 0·45m. long by 0·2m. broad, and 0·014m. deep at the junction of the principals ... } 4 Connection-plates of 0·40×0·24×0·24 at the connection of tie-rods and pillars (fig. 4) ... } | 40 | 00 |
| 4 Plates at the connection of the pillars and principals 1m. long, 0·18m. wide, and 0·011m. thick (fig. 4) ... } For securing the same, 20 bolts of 0·15m. diameter, with heads and hexagonal nuts ... } | 80 | 00 |
| Total kilogrammes ... | 1676 | 00 |

Intermediate Connections.

| | | | | |
|---|---|---|---|---|
| 16 rafters and ridges and 1 crown ridge of double T-iron, the rafters in lengths of 15·60m., and the iron 0·05m., and with the necessary bolts ... | 2512 | 00 | | |
| Total weight of a compartment of the roof ... | 4188 | 00 | | |
| Total weight of two compartments ... | 8376 | 00 | | |
| *Detail of a Compartment with the Skylight.* | | | | |
| The principal as above ... | | | 1676 | 00 |
| 16 Rafters, 11·85m., 16 ridge-plates and roof-ridge, with 15 cast-iron pillars or supports of 10·02 kil. (fig. 3); 5 T-irons, to replace the rafters and carry the skylight-frames (109·50 kil.); 24 glass frames, each 4·16 m. long (378·50 kil.); top ridge-plate ... | | | 2982 | 50 |
| Total kilogrammes ... | | | 4658 | 50 |

| Total | | | | 3990·85 | 25·17 |

The total cost of the roof, including gutters and rain-pipes, was 40442·72 francs, or 1618*l.*; that is, per square metre of roof surface, 25·50 francs, and of horizontal surface, 26·93 francs.

Every part of the roof was tested before being put up, and it was carried out under the direction of M. Kaulek, so far as the constructive supervision was concerned.

## IMPROVED TWO-WHEEL CARRIAGES.

F. R. A. GLOVER, *Patentee*, April 7, 1854.

(*With Engravings, Plate* XLII.)

THIS invention for improvements in two-wheeled carriages consists—First, in constructing carriages with compound shafts in such manner that they shall also form or act as springs for supporting the load to be carried, by forming them of two parts attached together near to one end, and open or apart from each other at the other end, and by so interposing between them, near to the open end, one or more separating blocks or stops, that on one of the two pieces being secured at its end to the axle, and the load being placed upon, or suspended from, or attached to the end of the other part (or partly to the end and partly elsewhere), the load, in causing the extremities of the two parts at their open end to approach or come together, will cause the parts of the shaft intermediate between the separating blocks or stops and their point of contact to spring or open away from each other, and on the pressure being removed, to collapse and resume their original form.

Secondly. In shaping the two parts of the compound shafts, as above set forth, as to dispense with any separating blocks or stops, and yet produce the action above described.

Thirdly. In the use of either of the foregoing improvements in combination with the floor of the body of the carriage suspended beneath the axle.

Fourthly. In so constructing the body and arranging the seats that the hind-quarters of the animal may be brought close up to, or very nearly close up to the axle, by fixing the improved shafts above set forth to the axle, so as to enable the carriage to be turned in the narrowest limit, and the line of draught to be shortened to the length of the horse.

The manner in which the improvements may be respectively performed is as follows:—In fig. 1 (Plate XLII.) the side and plan view shows the improved double or compound spring-shafts, constructed of two separate pieces A and B, of any suitable description of wood, such as lance, ash, or red pine, and connected together by an iron protecting band or strap *a*. The upper piece A, is the entire length of the shaft, and the lower piece B, about 15 or 18 inches shorter. The general form and proportions of such shafts, and the manner of using them as springs, are the same as in the shafts made from a single piece of either lance, ash, red pine, or any other suitable wood, which is made of any convenient dimensions; as, for example, 7 ft. 6 in. in length, of a varying thickness from 5 inches at one end to 2½ inches at the other end, and of an uniform width of 2½ inches or 3 inches, or slightly tapering from about 4 inches at the thicker end to about 2 inches at the thinner end. The patentee cuts the wood in the direction of its length and along the middle, so as to divide it into two thicknesses, beginning the cut at the thick part, and continuing it till within about 15 or 18 inches of the thinner end, at which point the wood is protected from splitting or opening further by a band or strap of iron or leather, or otherwise.

Fig. 2 shows a side view of such a piece of wood with a cut run up the centre of it to within 18 inches of the small end; and fig. 3 is a similar view, representing the ends stretched open a little. In the latter figure *a*, is the protecting band or strap. The manner of applying a pair of these shafts and making them the springs of a carriage, is as follows. Supposing the axletree to be divided into three parts, the middle division of which is about 2 ft. 1 or 2 in. in length. The lower portion of each of the shafts is connected at its end *b*, to the axle, one at each extremity of such middle division; and the upper portion of each is fastened at its end *c*, by a hinge-joint to a transverse bar or transom above them. Fig. 4 shows the mode of separating the shafts by the fulcrum-block *d*, which is inserted into one of a series of pairs of morticed holes made for its reception in both portions of the shaft, and marked 1, 1, 2, 2, 3, 3, and 4, 4, so as to admit of adjustment according to the weight to be carried by altering the block from one pair of holes to another. Thus, if the weight were excessive, the blocks should be placed between in the holes 1, 1, and if very slight in the holes 4, 4. It is to be noted, that from the double end of the shafts for about 16 to 20 inches, more or less, each portion should be extremely rigid, and when this cannot be obtained by the wood only, the patentee fastens iron plates or shoes on the sides of these parts of the shafts.

The action of the improved double-spring shaft is represented by fig. 4, the full lines denoting the ordinary relative positions of the upper and lower portions respectively, and the dotted lines the relative positions they assume when any extra stress or weight is brought to bear upon them. The weight of the carriage resting upon or hanging from the end or point *c*, meets its resistance at the end or point *b*, which is connected to the axletree, the blocks being interposed. When extra stress is brought to bear against the point *b*, the tendency of the point *c*, is to approach it, and if the wood of either shaft broke at the fulcrum, the carriage would fall; but if the wood from *c* to *c**, and from *b* to *b**, is sufficiently strong to render that contingency impossible, and the wood from *b** to *a*, and from *c** to *a*, is sufficiently slender to allow the natural elasticity of the wood to play, then when the extra stress is applied at *e*, while the wood from *c* to *c**, and from *b* to *b**, retains its rigidity or inflexibility, the wood from *c** to *a*, and from *b** to *a*, is bowed out, and the result is a downward and upward motion at *e*, similar to that which takes place in an ordinary elliptic spring when extra stress is applied.

The figs. 5 to 7 represent a family car, and which serves as a good illustration of the mode of construction which is intended by them. Fig. 5, a side view of the car; fig. 6, a longitudinal section; fig. 7, a transverse section; fig. 8, a side view of the shafts and transom frame on a larger scale. The carriage consists of a body or case, and an under-carriage. The body consists of a bottom and two sides, which sides are joined together, and kept upright by a cross piece or transom *x*; this transom supports or carries the weight of the carriage or body, and its loading when the body is laid or hung upon the under-carriage. The bottom of the body or case is a rectangular oblong frame, having a similar oblong, but of about half the dimensions taken out of the middle of it from one end. The object of this opened space is to allow the horse's feet to go back so far as to pass under the axletree; by which means the horse is brought as close as is possible to the weight he has to move, and he is enabled to drag almost immediately from the very centre of gravity. The under-carriage consists of the axletree and wheels, and a pair of the improved double-spring shafts, together with a transom *x*, and transom frame *x**, the shafts being secured both to the axletree and to the transom in the manner described, and particularly illustrated by fig. 8. The transom is also secured to the body, and connects the two parts of the carriage together, the connection at the point *c*, being moveable, or more correctly speaking, a hinged joint, as it is important that it should not be a rigid connection.

In order to keep the upper carriage or body from swagging about against the wheels from side to side, he employs two cross-braces or stays of leather or chain, which are stretched or placed between the right end of the axle on one side, up to the left end of the transom on the opposite side, and *vice versâ*, from the left end of the axle up to the right end of the transom, and connects them with the axle and the transom respectively by suitable shackles or fastenings. He also employs two other straps *l*, *l*, fig. 8, which are essential to the easy action of the carriage when the horse trots. These pass completely round the double shafts, one underneath the lower portion of each shaft, and over a projecting arm or portion of the transom frame, which is prolonged for the purpose. These arms are not intended to be strapped down tightly, as this would hinder the proper elastic action of the spring shafts, but their use is simply to hold the floor of the carriage in parallelism to the ground, and to counteract the jogging motion of the horse in the trot. The entire carriage therefore consists of a body, an under carriage, two sets of straps, two for braces or stays, two for counterpoises, and two blocks. The seating of the carriage and the disposition of the weight to be carried has to be attended to as in every other two-wheeled vehicle in which it is necessary to balance the shifting load. The weight should never be thrown on the horse's back. The car is arranged to carry seven persons, including the driver, who sits at a standing seat *m*, fig. 6, on one side of the horse and in front of the car; another person sits in the corresponding place on the opposite side. Three persons sit with their backs to the horse, right over the transom on the seat marked *o*, and two others in the back corner seats of the carriage, which, for convenience, are made so as to let down and hang as flaps when not required to be used, and so as to afford more space to the occupants of the transverse seats. The carriage may be either closed up behind like a box, with a door in the middle, or the back may be altogether open.

It is to be noted, that instead of the lower portion of the shaft being rigidly connected with the axle, as shown in fig. 8, one or both shafts may be loosely connected therewith in any convenient manner, the draught being in either case direct from the axle which has hooks upon it for attaching the traces.

## INSTITUTION OF CIVIL ENGINEERS.

*Nov.* 14.—JAMES SIMPSON, Esq., President, in the Chair.

The business of the evening was commenced by the announcement of the dates of the ordinary meetings of the session; of the appointment of December 19th for the Annual General Meeting, for the election of the President, Council, and Officers; and of the 29th May 1855 for the President's Conversazione.

The paper read was *"On the Means of avoiding Smoke from Boiler Furnaces."* By W. WOODCOCK.

The author commenced by explaining the nature of smoke as existing in furnaces, the cause of its formation, its component gases, and the temperature at which they became inflammable, and then pointed out a method of preventing the evolution of opaque smoke by simple and apparently effective means. It was stated that ordinary pit coal, under the process of destructive distillation, gave off various volatile substances, some of which were gases, such as hydrogen, marsh gas, olefiant gas, carbonic oxide, &c.; these and others existed in the furnace only in a gaseous state, becoming liquid or solid when in the external air, and of such coal-tar was composed; and amidst them the carbon, in minute subdivision, was held in suspension, giving to the smoke its sable hue. All these gases were combustible at given temperatures, provided a certain amount of oxygen was present. It was then shown that the air containing this oxygen, if imparted to the gases after leaving the fuel on the bars, must be administered so as not to reduce the temperature of the gases below their "flame-points." The arguments on the chemical composition of smoke were enforced by extracts from a letter by Mr. Mansfield, published in the *Mechanic's Magazine*, in which the subject was fully investigated.

The formation of smoke or visible carbon held in suspension was stated to depend entirely upon the insufficiency of the supply of oxygen in the furnace, as the heat of the furnace would cause the various gases to be given off more rapidly than their combustion could be supported by the quantity of oxygen passing through the fire-bars in the same period of time; this evil being much aggravated by the heat of the air as usually supplied from the ordinary ash-pit, generally ranging from 200° to 300° Fah., and the air at that heat containing less oxygen by about one-third than that at the usual atmospheric temperature, and consequently that the combustion of the fuel to which it was supplied must be one-third less perfect.

The simplest means of preventing the formation of smoke were shown to be by providing for an ample supply of oxygen in a condensed state, in the form of cold air, to the fuel on the fire-bars, and by administering such further supply of oxygen to the heated gases as might be necessary for their complete combustion whilst in contact with the boiler; this latter supply being given at such a temperature as would insure the successive ignition of the gases as they were evolved. Thus, by establishing nearly perfect primary combustion, the quantity of smoke evolved was shown to be reduced to a minimum, of which no visible trace ever reached the summit of the chimney.

The apparatus by which this desirable end was attained was described to consist of two parts, each being the addition of a very simple apparatus to the ordinary boiler-furnace. The first of these was a double set of thin iron bars, lying horizontally in the direction of their length, parallel to each other, immediately beneath the grate in the ash-pit. Each set of bars resembled a Venetian blind in its arrangement; the bars being inclined at an angle of 45° to the horizon in the direction of their width. The bars of the two sets were thus inclined in opposite directions, and being so close together that a vertical straight line could not pass between any adjacent pair of them, yet far enough apart to allow all cinders to fall freely through, and the air to pass freely upwards to the fire. The bars were of the same length as the grate, so as to extend from front to back. It would be perceived that the effect of this arrangement must be to screen the ash-pit completely from the heat radiated directly downwards from the grate, and so that scarcely any would pass through by reflection. In fact, not a ray of heat could reach the ash-pit from the furnace without suffering four reflections from rough iron surfaces, which would leave a mere shadow of a ray for further progress.

Thus a large quantity of heat, which otherwise would be radiated out of the furnace into the ash-pit, thence reflected, and so lost, was saved for the boiler. The ash-pit also was only slightly heated by the cinders which fell through; and this source of heat might be reduced to any extent by frequently removing the rubbish from the pit. Another consequence was, that the air passing from below through the grate, not being heated in the ash-pit, entered the fire cold, and therefore not, as it did from ordinary ash-pits, in a rarefied condition. By its coolness, this air prevented to some extent the burning of the grate-bars; and by its unrarefied state it produced a more intense and rapid combustion of the fuel after it had passed the bars.

Another part of the contrivance was more especially the smoke-burning apparatus. It consisted of a set of tubes, open at both ends, passing through the furnace horizontally from front to back, and terminating within the wall of the front of the bridge, with valves to regulate the access of air into the tubes. The fire-bridge differed importantly from that of an ordinary furnace. It was hollow, and was divided into two parts, the larger of which stood up from below; the other, which was shallower, was in contact with the boiler. Between them all the products of combustion passed from the furnace. The two parts communicated with each other by channels at the sides, and thus formed together an annular chamber. The tubes before mentioned entered the front wall of this chamber, and thus established a communication between its interior and the outer air. The back wall or plate, both of the upper and of the lower part of this chamber or bridge, being perforated with numerous holes, opening from the interior of the bridge to the space beyond it, established a direct communication between the outer air and the throat of the flue. There was a second solid bridge beyond the first, descending from the upper side of the flue; this, by interrupting the direct channel through that part of the passage, retarded the flow of the smoke and gases, and caused their perfect mixture with each other within the space between the bridges.

The result of this arrangement was, that a current of highly-heated air, which passed through the tubes in the furnace, escaped at the bridge, through the perforations in the back wall, and mixing with the gases from the furnace which held the smoke in suspension, converted the smoke into flame.

It was contended, that by the adaptation of this apparatus to marine-boilers, the high temperature of the stoke-holes and boiler-rooms would be obviated, and that the steam-vessels would not be so evident from a distance as they now were, by the volumes of smoke they gave out; and by having a telescopic sliding funnel, and substituting, during the period of being in action, a horizontal tube with a small fan-blower, any injury to the main funnel would be effectually prevented.

It appeared that the results of this apparatus had been very satisfactory; that at Messrs. Meux's brewery there was not the slightest appearance of opaque smoke from the chimney, and that the money-saving, resulting not only from the more perfect combustion of the fuel, but from the use of an inferior quality of coal at a lower price, amounted to full 20 per cent. This success was so great as to warrant the introduction of the apparatus to the more general notice of the profession and the public, through the Institution of Civil Engineers.

*Nov.* 21.—The discussion being renewed on Mr. Woodcock's paper, it was shown, that although critically precise experiments for determining the amount of evaporation had not been previously made, there was no doubt of the fact of its being possible to use a lower-priced fuel, and to do the full amount of work with the boiler, without evolving any opaque smoke from the chimney; and thus, whilst complying with the requirements of the Legislature, a pecuniary saving could be effected. Recently, however, by experiments on a cylindrical boiler 17 feet long by 3 feet diameter, it had been shown, that $8\frac{6}{10}$ lb. of water injected at 42° Fah. was evaporated by 1lb. of Newcastle small coal, when Mr. Woodcock's apparatus was in use. It was found, that with small bituminous coal, a better evaporation was maintained than when Llangennoch coal was used, and without any appearance of smoke. The cast-iron bridges of the furnace did not appear to suffer from the effects of the fire; the passage of the air keeping the metal comparatively cool.

As soon as the valves of the apparatus at Messrs. Meux and Co's Brewery, were closed, there was a dense smoke; but on the instant of opening them, the heated gases combined with the oxygen of the air and flashed into bright flame. Llangennoch coals had been generally used at Messrs. Meux and Co's brewery, not from any economy they offered, as they were not so strong as the Newcastle coals, but for the sake of the neighbourhood, as they did not give out opaque smoke; however, with the apparatus described by Mr. Woodcock, small Newcastle slack could be used, and as it could be purchased at fourteen shillings per ton, whilst Llangennoch coal cost twenty-eight shillings, there must be a money-saving and the boilers worked quite as efficiently.

As to the general similitude between the principles advocated by Mr. C. Wye Williams, and those brought into notice by Mr. Woodcock, almost the only difference appeared to be, that the former insisted on the necessity for the coldness of the air admitted, whilst the latter contended for the advantage of heating the air, prior to its mingling with the gases. On this point many conflicting opinions were given, and examples quoted. It was, however, allowed, that the arrangement of the Venetian blind screens, below the grate bars, was novel, and was likely to be beneficial in preventing radiation into the ash-pits; and thence into the boiler rooms of steam vessels, and there would not be any inconvenience from not being able to introduce prickers from beneath the bars, as good stokers always cleared the bars from above, by the use of the T head tool, and none but idle, or bad stokers allowed the clinkers to accumulate, so as to run between the bars, and require the use of the pricker.

The use of heated air was practically contended for, because, when the air was admitted at a low temperature, there was a certain amount of loss from the chilling effect of the stream or film of air, before it mingled with the gases; whereas this effect was not perceived when the air was admitted at a certain temperature. Under Mr. Williams's system, this had been attempted to be provided against by multiplying the number and diminishing the individual area of the apertures for admitting air; but it was argued, that by extending the number of apertures still more, and previously raising the temperature of the entering air behind the bridge, the object would be more certainly attained. The system of supplying air at a very elevated temperature under gas retorts, had been very advantageously employed for many years, in conjunction with the hollow bridge, originally introduced by Mr. Farey, the father of the late Mr. John Farey (M. Inst. C.E.) In corroboration of these views, it was stated, that on board one of the "Citizen" steam-boats on the Thames, by a free admission of the air only through a series of parallel wire gauze screens in the fire-door, so as to distribute it in minute jets, the exhibition of opaque smoke had been prevented, whilst a saving of fuel was effected, without any loss of speed, or any extra labour to the stoker. A hollow bridge was also used, and a blast-pipe being extended from the base of the funnel, and opening into the bridge, further beneficial effect had been produced.

A model was exhibited of a hollow cast-iron bridge plate, with a series of vertical ribs, so arranged as to form tubes, leading up from the ashpit to the apex of the bridge, where the air mingled with the heated gases, and passed away in flame. The currents of air up these bridge tubes preserved the iron from destruction, by carrying off the caloric, and it became heated in its upward course.

The introduction of cold air was advocated, on the ground that a mass of air, once broken up into films or minute jets, would not again unite, but that each particle would pursue its independent course, until it combined with the heated gases. Therefore, the system of admission by the perforated fire door, so as to pass over the incandescent fuel, had been so strongly advocated.

It was urged that mechanical or other means should be adopted for regulating the proportion of oxygen, according to the state of incandescence of the fuel on the bars. This, it was contended, was virtually accomplished through the side tubes of Mr. Woodcock's apparatus; as it had been shown, that the velocity of the passage of air through the tubes, was exactly in proportion with the demand for oxygen by the fuel. That the air was really heated in its passage had been shown by inserting a thermometer, protected from radiated heat, into a flue in connection with the hollow bridge.

The question of the applicability of most of the systems of preventing the exhibition of opaque smoke, was shown to depend, to a great extent, on the area of the fire-grate and the size of the boiler, for, if both were restricted, so as to demand an excessively rapid draught, there could not be a sufficient mingling of the gases to insure perfect combustion.

## ROYAL SCOTTISH SOCIETY OF ARTS.

At the annual general meeting of this Society, on the 13th ult., the following Report of the Prize Committee awarding the prizes for Session 1853-54 was read, and the Prizes were delivered by the President to the successful candidates:—

1. To Thomas Stevenson, F.R.S.E., C.E., Edinburgh,—for his "Description and Drawings of Dipping and Apparent Lights for Sunk Reefs and Pier-heads of Harbours."—The Society's Gold Medal, valued Ten Sovereigns.

2. To James Elliot, Teacher of Mathematics, Edinburgh,—for his "Mechanical Illustrations of the Planetary Motions," including an Illustration of his Theory of the Stability of Equilibrium of Saturn's Ring.—The Society's Silver Medal, value Ten Sovereigns.

3. To Robert Henry Bow, C.E., Edinburgh,—for his "Description of New Designs for Iron Roofs of great clear span," &c.; with Drawings.—The Society's Silver Medal, value Ten Sovereigns.

4. To William Swan, F.R.S.E., Teacher of Mathematics, Edinburgh,—for Description of his "Simple Variation Compass."—The Society's Silver Medal, value Five Sovereigns.

5. To John Scott, Teacher of Mathematics, Edinburgh,—for his paper "On New properties and applications of Spiral Pumps, &c., with Models and Diagrams."—The Society's Silver Medal, value Five Sovereigns.

6. To George Mitchell, 101, High-street, Edinburgh,—for his Description of a "Safe Lock, incapable of being opened by any other means than by its own key."—The Society's Silver Medal, value Five Sovereigns.

7. To the Rev. James Brodie, Monimail, Fife,—for his "Enquiry into the principles on which the action of Sails and Rudders depends, with Diagrams."—The Society's Silver Medal.

8. To J. T. Thompson, F.R.G.S., C.E. and Government Surveyor at Singapore,—for his Description and Drawing of a "Semi-Revolving Light for Lighthouses."—The Society's Silver Medal.

9. To Thomas Rodger, jun., St. Andrews,—for his paper "On Collodion Calotype," with Illustrative Specimens.—The Society's Silver Medal.

10. To Alexander Melville Bell, Teacher of Elocution, Edinburgh,—for his Paper on a "New Principle of Stenography or Shorthand Writing."—The Society's Silver Medal.

11. To Thomas Steven, Builder, Bonnyrig, Lasswade,—for his Description of a "New Method of Shutting Doors," with a Model.—The Society's Silver Medal. The Committee have also recommended the Model to be purchased for the Museum.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated August 30.*

1899. L. P. Lehugeur, and M. Uttinger, St. Denis, near Paris—Improvements applicable to machinery for printing fabrics

*Dated September 4.*

1927. J. Parker, Birmingham—Improvement or improvements in the smoke-boxes of locomotive engines

1936. J. F. H. H. H. de Lavaur, Paris—Improvements in securing waterproof wrappers or coverings used in packing goods

*Dated September 8.*

1959. S. Frearson, Glascote, Warwick—Improvements in the construction and manufacture of buttons, a part or parts of which improvements may also be applied to other similar purposes. (A communication)

1960. T. Petitjean, Upper John-street, Fitzroy-square—An improved process for recutting or reforming the faces of files

*Dated September 12.*

1984. R. Laming, Carlton Villas, Maida Vale—Improvements in purifying gas from ammonia and other impurities, and preparing pure gas for burning, in obtaining ammonia and certain salts of ammonia and soda and in treating certain salts of ammonia

*Dated September 20.*

2024. A. Tylor, Warwick-lane, Newgate-street, and H. G. Frasi, Herbert-street, New North-road—Improvements in water-closets

*Dated September 26.*

2072. T. Griffiths, Madeley, Shropshire—An improved pump for raising and forcing water

*Dated September 30.*

2097. W. Wilkinson, Nottingham—Improvements in looped pile and cut pile fabrics, and in machinery for brushing or raising a cut pile or fleece upon the web on both sides the article, or on one side only, by which means he secures a looped web not liable to let down

2099. W. Tucker, Old Brompton—Preventing the escape of the fuliginous smoke from shafts and flues

2101. T. Collins, Gayton, Northampton—Improvements in manufacturing bricks and tiles

2103. M. Poole, Avenue-road, Middlesex—Improvements in condensers. (A communication)

*Dated October 2.*

2105. A. E. L. Bellford, Castle-street, Holborn—Improvements in suspended purchases (A communication)

2107. G. Wall, Manchester—Improvements in the manufacture of railway tickets and other similar articles from a substance or material capable of being re-used

2109. T. Sherriff, Glasgow—Improvements in moulding or shaping metals

2111. F. Durand, Paris—Improvements in looms for weaving

2113. N. Bennett, Furnival's-inn, Holborn—A substitute for the scaffolding at present employed in and for the erecting and repairing of buildings (A communication)

2115. C. Hill, Chippenham, Wilts—Improvements in the manufacture of pulp

*Dated October 3.*

2117. J. Hammond, Brunswick-street, Blackfriars-road—Holding a book in such a position that it may be read with ease and comfort in an erect, reclining, or completely recumbent position, to be called "Hammond's suspension reading-desk"

2118. W. Tatham, Rochdale—Improvements in machinery or apparatus for preparing, spinning, doubling, twisting, and winding cotton, wool, flax, silk, and other fibrous substances

2119. W. Blyth, Oswaldthwistle, and E. Kopp, Accrington, Lancaster—Improvements in the manufacture of soda-ash and sulphuric acid

2121. A. V. Newton, Chancery-lane—Improvements in motive-power engines applicable to the working of their valves and to the conversion of the reciprocating motion of such engines into rotary motion. (A communication)

2123. W. McNaught, Rochdale—Improvements in slide-valves for steam-engines

2126. W. Townend, Harden Bingley, York—An improvement in combing wool and other fibres.

*Dated October 4.*

2127. J. Kershaw, Stockport—Improvements in self-acting mules

2128. F. S. Thomas, Cornhill—Improvements in locomotives

2129. F. S. Thomas, Cornhill—An improved mode of obtaining motive power

2130. D. Chalmers, Manchester—Improvements in the mode or method of working railway breaks, and communicating signals

2131. W. P. Gaulton, Crag Works, near Macclesfield—Improvements in breaks applicable to railway carriages and other vehicles

2132. J. Disher, Edinburgh—Improvements in mashing-apparatus for brewing

2133. A. A. J. Legentil, Arras, France—Improvements in pumps or machinery for raising and forcing water and other fluids

2134. T. Crossley, Scott's-yard, Bush-lane—An improved mode of manufacturing printing-blocks. (A communication)

2135. T. Prosser, New York, U.S., now of Birkenhead—Improvements in the manufacture of certain hollow closed vessels, and in the machinery or apparatus employed therein, parts of which improvements are also applicable when preparing for and fastening tubes into steam boilers, or other vessels requiring tubes to be fixed therein

2136. W. H. Phillips, Camberwell New-road—Improvements in rotatory steam-engines

2137. T. W. Rammell, Trafalgar-square—Improvements in steam boiler and other furnaces

2138. J. Perry, Hunslet Old Mills, near Leeds—Improvements in preparing wool for combing

*Dated October 5.*

2139. T. E. Moore, Great Titchfield-street, Marylebone—Improvements in machinery or apparatus for curvilinear and annular cuttings in metals and other hard substances

2140. W. B. Adams, Adam-street, Adelphi—Improvements in rails for railways, and in the connections and fastenings for rails

2141. E. O. Tindall, Scarborough—Improvements in mangles and wringing-machines for smoothing and wringing clothes and woven fabrics

2142. T. Harris, Nantiglo, Aberystruth—Separating the steam from the condensed water and mud in its transit from the boiler to the cylinder of a steam-engine, stationary or locomotive

2143. G. Collier, Halifax—Improvements in the manufacture of carpets and other terry fabrics

2144. W. Frost, Wine-office-court, Fleet-street—Improvements in steam-engines

2145. T. Bennett, Woodbridge-street, Clerkenwell—Improvements in the apparatus employed in the manufacture of gold, silver, and metal leaf.

2146. J. A. Lander, Southwark-bridge-road—Improvements in machines employed in and for the manufacture of spikes and nails

2147. J. M. Dunlop, Manchester—Improvements in machinery or apparatus for preparing, spinning, and doubling cotton and other fibrous materials
2148. F. Durand, Paris—Improvements in circular looms

*Dated October 6.*

2150. J. Britten, Birmingham—A new or improved machine for sweeping or cleaning chimneys
2151. P. Kerr, Paisley—Improvements in the treatment and finishing of threads or yarns

*Dated October 7.*

2152. W. Chambers, Hampson Mill, near Bury—Improvements in machinery for beetling cotton and other fabrics
2154. R. W. Uren, Foggington, Devon—Improvements in machinery for the manufacture of bricks and tiles
2155. G. T. Selby, Smethwick—An improvement in furnaces
2156. J. B. S. Méritens, Paris—Improvements in the mode of dyeing cotton, flax, and other fibrous substances, and fabrics generally
2157. T. Roberts and J. Dale, Manchester—Improvements in obtaining and treating extracts from certain dye-woods, and in apparatus for obtaining such extracts
2158. W. Johnson, Lincoln's-inn-fields—Improvements in windlasses. (A communication)
2159. R. Maynard, Whittlesford, Cambridge—Improvements in machinery for threshing and dressing grain

*Dated October 9.*

2160. J. Aikman, Paisley—A roller for scouring and finishing textile fabrics
2161. J. Shanks, St. Helen's, Lancashire—An improved mode of manufacturing sulphuric acid. (A communication from R. Von Seckendorf, Gera, Reuss, Germany)

*Dated October 10.*

2162. W. Crosskill, Beverley, York—Improvements in the construction of portable railways
2163. N. Prothéry, Lyons—Improvements in machinery for making lace
2164. H. T. White, Queen's-terrace, Hammersmith, and G. Roberts, Great Peter-street, Westminster—An improved mode of rendering hats, caps, and other coverings for the head, self-ventilating
2165. V. W. Hammerich, Altona, Holstein, now at John-street, Minories—An improved construction of buoyant mattress
2167. J. B. Jackson, Etna Works, Sheffield—Improvements in furnaces or fireplaces, and in the prevention of smoke
2169. J. Kershaw, Brixton—Improvements in the manufacture of wrought-iron railway wheels
2170. H. Crosley, Camberwell-grove—Improvements in the manufacture of waddings for cannons and fire-arms
2171. W. Chubb, Clifton, Gloucester—Improvements in the construction of beams and parts of ships, ships' masts and spars, and other like structures
2172. M. A. C. Millier, Paris—Improvements in the manufacture of paper

*Dated October 11.*

2175. W. H. Tayler, South-row, St. Pancras—Improvements in cartouch-belts or cases for containing cartridges to be worn round the waist or otherwise, calculated for arms of every description, guns, pistols, and other fire-arms
2176. S. Rogerson and J. Rogerson, Manchester—Improvements in the production of ornamental patterns upon velvet and other woven fabrics, and in machinery or apparatus for effecting the same
2177. R. Cruise, Manchester—Improvements in machinery or apparatus for stopping railway carriages
2178. J. Jackson, Belfast—Improvements in treating or preparing tow, so as to render it fit for drawing or roving
2179. T. Shaw and R. Dixon, Preston, Lancashire—Improvements in slubbing, roving, and jack frames employed in the preparation of cotton and other fibrous substances

*Dated October 12.*

2180. E. J. Seville, Brixton—An improvement in the manufacture of hats. (A communication)
2181. W. White, York-villa, Kensington-park—Improvements in the manufacture of manures
2182. J. T. Chance, Birmingham—Improvements in manufacturing articles from the minerals or rocks of the descriptions commonly called basalt or trap, sometimes rowleyrag and whinstone
2183. A. A. Routledge, Neath, Glamorgan—Improvements in the manufacture of detonating railway signals
2184. J. Hood, Newmilns, Ayr—Improvements in ornamental weaving
2185. A. Parker, New Milns, Ayr—Improvements in ornamental weaving
2186. F. A. N. Delsarte, Rue Croix Boissière—A new mode of and apparatus for tuning pianos and other kind of stringed instruments

*Dated October 13.*

2188. J. L. Hancock, Milford Haven—An improved machine for ploughing or working land
2189. Sir J. C. Anderson, Fermoy, Cork—Improvements in locomotive engines
2190. A. Dobson, Belfast—Improvements in looms for weaving
2191. C. F. Stansbury, Cornhill—Improved apparatus for heating buildings. (A communication
2192. G. Weeks, Dorset-street, Portman-square, and G. Pinner, Globe-road, Mile-end—Improvements in the construction of furnaces
2193. W. J. Barsham, Stratford, Essex—Improvements in machinery or apparatus for crushing mineral and other substances

*Dated October 14.*

2195. J. Harrison, Brighouse, York—Improvements in the bosses applied to mill-stones
2197. J. C. Haddan, Chelsea—Improvements in the manufacture of cannon, and of projectiles for the same
2198. S. Hjorth, Copenhagen—An improved magneto-electric battery
2199. S. Hjorth, Copenhagen—Improved electro-magnetic machine
2200. C. Holt, New-road, St. Pancras—Improvements in fastenings for the laths of iron bedsteads, couches, and other similar articles of furniture
2201. R. Pinkney, Long-acre—Improvements in bottles, jars, and other like vessels, and in the method of stoppering them
2203. L. Monzani, Greyhound-place, Old Kent-road, administratix of W. T. Monzani, late of St. James's-terrace, Bermondsey, deceased—An improvement in brushes and brooms—This is the same invention as that for which letters patent were granted to her late husband, 20th June, 1854
2204. J. H. Young, College-street, Camden-town—Improvements in brooms or brushing apparatus
2205. J. H. Pape, Paris, Rue des Bons Enfants—Improvements in the manufacture of boots and shoes
2206. W. J. Biseker, Birmingham—A new and improved and durable method of labelling bottles, and such like vessels or articles as require or may require labelling

*Dated October 16.*

2207. T. E. Moore, Great Titchfield-street, Oxford-street—Improvements in apparatus for sharpening knives, scissors, and other similar edged tools
2208. J. Bonnall, Spittlegate, Grantham—Improvements in apparatus for holding oil for lubricating purposes
2209. J. Thompson, jun., New York—Improvements in life-pres
2210. E. Barnot, Paris—A new machine for cutting files, which I cutting machine."
2211. W. Rossiter, Goswell-road, and M. E. Bishop, Cannon-st ments in the manufacture of pulp suitable for paper, pastebo papier-maché, and other like purposes
2212. J. H. Johnson, Lincoln's-inn-fields—An improved apparatus leakage or escape of gas. (A communication from E. A. Macpam
2213. W. Wain, Brunswick-street, Southwark—Improvements in the screw-propellers
2214. L. J. Wetherell, Compton-street, Clerkenwell, and A. J. Hoffstaedt, Surrey—An improved construction of pump

*Dated October 17.*

2215. W. H. Child, Providence-row, Finsbury—Improvements in the manufactu construction of brushes
2217. J. Coghlan, Craven-street, Strand—Improved mode of signalling on railways electric telegraph
2218. L. Cornides, Trafalgar-square—An improved apparatus for amalgamating the gold and silver contained in pulverized ores
2219. J. L. Cole, Henry-street, Salmon's-lane, Limehouse—Improved construction of portable drill
2220. A. Veal, Oxford—Improvements in the manufacture of boots
2221. A. Illingworth and H. Illingworth, Bradford—Improvements in machinery or apparatus for combing wool and other fibrous substances
2223. J. Dockray, Leeds, and J. Dawson, Holbeck, Leeds—Improvements in machinery for raising woollen cloth
2224. R. Green, Sydney-street, Brompton—Improvements in propelling vessels

*Dated October 18.*

2226. A. E. L. Bellford, Castle-street, Holborn—Improvements in breech-loading fire-arms. (A communication)
2228. E. Gessner, Aue, near Schneeberg, Saxony—Improvements in gig-mills
2229. G. Hamilton, Great Tower-street—Improvements in obtaining soundings
2230. J. Mason and W. Robertson, Rochdale—Improvements in machinery or apparatus for preparing and spinning cotton and other fibrous substances, part of which improvements is also applicable for shifting straps, by which motion is communicated in other machines
2231. B. F. Cooke, Boston, U. S.—Improved mode of caulking ships; applicable also to the rendering of roofs waterproof
2232. M. Wheeler, Newton-street, Holborn—An improved mode of consuming smoke arising from the combustion of fuel in furnaces
2233. H. A. Holden, Birmingham—Improvements in roof-lamps for railway or other carriages, and for parts used in connection with the same

*Dated October 19.*

2234. R. W. Winfield, Birmingham—Improvements in tubes and rods used in the construction of articles of metallic furniture
2235. B. Nicoll, Regent-circus, Piccadilly—Improvements in shirt-fronts
2237. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in the construction of grates. (A communication)
2238. J. Platt, Oldham—Improvements in machinery or apparatus for making bricks
2239. T. Biggart and A. Loudon, Dalry, Ayr—Improvements in regulating motive-power engines
2240. T. Higgins, Liverpool—Improved apparatus applicable to the ventilation of ships and mines and other useful purposes

*Dated October 20.*

2241. W. Marsh, Bywater-street, King's-road, Chelsea—Improved rocking and lounging chair
2242. L. A. Chenu and F. Pillias, Fontainebleau, France—Improvements in preparing animal substances
2243. T. Allen, Adelphi-terrace, Westminster—Improvements in applying electricity

*Dated October 21.*

2245. J. Smith, Gainford-place, Barnsbury-road, and F. S. Thomas, South-terrace, Walworth—Improved apparatus for steering ships and other vessels
2246. W. J. Smith, Stretford, Lancaster—Improvement in buttons
2247. W. A. Edwardes, Brooke-street, Lambeth—Separating iron or steel from brass, gun-metal, and all other metallic filings
2248. J. Jamieson, Oldham—Improvements in steam-engines
2249. A. G. Brade, Salisbury-square—Improvements in the manufacture of gas-fittings (A communication)
2250. B. G. Heywood, Green Mount Cottage, Dalkey, near Dublin—Improved apparatus for affixing postage and other stamps to envelopes, letters, and other documents
2251. W. Green, Howard-buildings, St. Luke's, and J. Pickett, Duke-street—Improvements in treating or ornamenting textile materials or fabrics and paper, and in machinery or apparatus for effecting the same

*Dated October 23.*

2252. E. Abell, Lambeth—Improved instrument to assist the hand in writing
2253. H. Hales, Brighton—Improvements in the machinery for propelling vessels
2254. G. Savage, Adderbury, Oxford—New or improved singeing-lamp
2255. A. G. Brade, Salisbury-square—Improvements in the manufacture of plate and thread for gold and silver lace and bullion. (A communication)
2256. J. Maddox, Thomas-street, Brick-lane, E. Gardner, Buxton-street, and G. D. Green, Weaver-street—Improvements in weaving fringes
2257. G. Simmons, Liverpool-street—Improvements in the construction of railway bearers and sleepers
2258. J. Penn, Greenwich—Improvements in the manufacture of the pistons, slide-valves, and stuffing-boxes of steam-engines
2259. J. Scott, Argyle-square, Edinburgh—Improvements in apparatus for facilitating surgical operations and teaching anatomy
2260. E. H. Marié, Paris—Improvements in the machinery for preparing, spinning, and twisting cotton, silk, flax, wool, and other fibrous substances

*Dated October 24.*

2261. C. Cowper, Southampton-buildings—Improvements in preparing to be spun and in spinning silk waste. (A communication)
2262. F. J. Bouwens, Mechlin, Belgium—Improved rotary engine
2263. G. A. Somerby and C. W. Fogg, Massachusetts, U. S.—Improved break apparatus for railway carriages
2265. F. C. Warlick, Suffolk-street—Improvements in generating steam
2266. J. Hopkinson, jun., Huddersfield—Improvements in steam-engine boilers and safety-valves, and in apparatus for indicating the vacuum in steam-engine condensers, in relation to the existing atmospheric pressure
2267. J. Welsh, Greenock, Renfrew—Improvements in extracting liquids from saccharine and other matters

*Dated October 25.*

2268. J. Rickhuss, Worcester, and C. Toft, St. John, Bedwardine, Worcester—Improvements in the manufacture of parian, porcelain, china, and earthenware
2269. J. Spencer, Bilston, Stafford—New or improved fence for railway stations, docks, and such other places as the same is or may be applicable to
2270. W. Henderson, Cannon-street—Improvements in treating certain ores and alloys, and in obtaining products therefrom

A. Stocker, Poultry, Cheapside—Improvements in the manufacture of tubes applicable to gas and other purposes, also in the construction of certain engineering machinery and apparatus, and the application of the whole or part of the same to, and other means to be used or employed in, the manufacture of tubes, also in the mode of manufacturing and the application of certain articles connected with or necessary to the completion of such or other tubes
2272. R. Roberts, Manchester—Improvements in machinery for preparing and spinning cotton and other fibrous substances
2273. W. T. Smith, New Hampstead-road, Kentish-town, and G. Hill, City-road—Improvements in machinery or apparatus for winnowing, washing, sifting, or separating corn, gravel, minerals, and other materials
2274. R. H. Hughes, Hatton-garden—Improvements in transmitting motive power
2275. C. Mather, Salford Ironworks, Manchester—Improvements in machinery for boring in the earth, and for actuating a hammer for driving tubes into the earth, and for other uses
2276. F. Lambert, Rue d'Enfer, Paris—Improvements in compounds to be used as cosmetics
2277. E. Pechenard, Monthermé, France—Improvements in roofs or coverings for buildings
2278. L. V. Helin, Rue des Douze, Apotres, Brussels—Improvements in the manufacture of paper from straw
2279. J. H. Johnson, Lincoln's-inn-fields—Improvements in circular loooms. (A communication from M. Poivret)

*Dated* October 26.

2280. W. G. Craig, Gorton, near Manchester—Improvements in the mode or method of consuming smoke, and in the machinery or apparatus employed therein.
2281. R. A. Brooman, Fleet-street—Improved method of obtaining alcohol from organic substances, and particularly from wood. (A communication)
2282. J. Healey, J. Foster, and J. Lowe, Bolton-le-Moors—Improvements in machinery to be used for drawing, moulding, forming, and forging articles in metal
2283. J. Eccles, Blackburn, Lancaster—Improvements in machinery for the manufacture of bricks
2284. C. H. Olivier, Finsbury-square—Improved apparatus for drying. (A communication)
2285. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in bleaching, dyeing, and preparing hemp and flax to be spun. (A communication from Messrs. A. and H. Six, Wasemmes-les-lille
2286. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in transferring coloured pictures, portraits, and engravings. (A communication from L. Muller and A. Widl, Vienan)
2287. J. Griffiths, Wolverhampton, Stafford—Improvements in the mode or process of manufacturing certain kinds of iron, and in the machinery or apparatus used in such manufacture; parts of which improvements are also applicable to machinery used in the manufacture of other descriptions of iron
2288. J. Dudgeon, Fenchurch-street—Improvement in rendering ships and batteries shot proof

*Dated* October 27.

2289. A. E. L. Bellford, Castle-street, Holborn—Improved mode of operating trip-hammers. (A communication)
2290. J. Turner, B. Holdsworth, and R. Beamer, Burnley, Lancaster—Improvements in power-looms for weaving
2291. A. P. Price, Margate—Improvements in the calcination and oxidation of certain metallic, mineral, and metallurgical compounds, and in the apparatus and means for effecting the same
2292. W. Aston, Preston, Lancaster—Improvements in safety or escape valves
2293. W. B. Wilkinson, Newcastle-on-Tyne—Improvements in the construction of fire-proof dwellings, warehouses, and other buildings, or parts of the same

*Dated* October 28.

2294. H. Adcock, London—Improvements in strengthening castings of iron and other metals
2295. J. Morgan, Kidderminster, Worcester—Improvements in machinery or apparatus for cutting metals
2296. G. Mumby, Hunter-street, Brunswick-square—Improvements in reservoir pen-holders, and other writing apparatus
2297. E. Lindner, New York — Improvements in revolving-breech fire-arms and magazine.
2298. J. P. Savouré, Catherine-street, Strand—Improved gold coin detector; applicable also for weighing postal communications
2299. C. Blake, St. Leonard's, Sussex—Method of preventing or lessening the injurious effects arising from collisions at sea, and on other navigable waters
2300. C. F. Vauthier, Dijon, France—Improvements in blowing-machines
2301. R. A. Brooman, Fleet-street—Improvements in centrifugal machines, and in driving the same. (A communication)

*Dated* October 30.

2302. O. Maggs, Bourton, Dorset—Improvements in portable steam-engines
2304. J. Wainwright, Birkenhead, Chester—Improvements in fitting up shops, offices, and other like places, and shop-fronts
2305. J. C. Hadden, Chelsea—Improvements in projectiles, and in machinery for manufacturing the same
2306. P. B. Chapuis, Lyons, France—Improvement in the harness used for weaving. (Partly a communication)
2308. R. S. Newall, Gateshead—Improvements in electric telegraphs. (A communication)
2309. J. H. Johnson, Lincoln's-inn-fields—Improvements in axle-boxes. (A communication from B. Laurent, Houécourt, France)

*Dated* October 31.

2310. T. F. Tyerman, Weymouth-street, Portland-place—Improvements in preparing hoop iron and such like metal surfaces used for bondings in buildings and structures
2311. W. Reid, University-street—Improvements in the manufacture of galvanic batteries
2314. T. Prosser, New York, but now of Birkenhead—Improvements in condensers of steam-engines and parts connected therewith
2315. J. H. Johnson, Lincoln's-inn-fields—Improvements in lithographic printing-presses (A communication from P. D. Vaté, Paris)
2316. A. Craig, Paisley—Improvements in the manufacture of railway wheels
2317. B. Blackburn, Clapham-common—Improvements in the manufacture of pipes
2318. T. Osborne and W. Eldred, Liecester—Improvements in apparatus for retarding and stopping railway carriages

*Dated* November 1.

2320. J. and W. Bradshaw, Blackburn—Improvements in time-pieces
2321. J. Rae, Alpha-road, New-cross — Improvements in machinery or apparatus for assisting in propelling vessels
2322. J. B. Robb, Boston—Improvemements in breaks or retarding apparatus
2323. A. V. Newton, Chancery-lane—Improved method of forging or swaging railroad carriage and other wheels. (A communication)
2324. H. Brinton, jun., and R. S. Weaver, Kidderminster—Improvements in the manufacture of carpets, hearth-rugs and other like fabrics
2325. J. Francis, New York—The manufacture of wagons, caissons, and other vehicles, applicable to transport military and other stores on land and water.

*Dated November* 2.

2326. J. Godge, Wellington-street—Improvements in machinery or apparatus for grinding. (A communication from A. and A. St. Denis, Bastia, Corsica)
2328. L. D. Dewey, New York—Protection against fire in vessels or buildings by putting out the fire without personal aid, or with very little, and against incendiary or fraudulent fires and ravages of vermin—He is the true inventor of it in part, and proprietor of the whole

*Dated November* 3.

2332. N. Topp, J. Holt and J. Partington, Farnworth, Lancaster—Improvements in hand mules for spinning
2334. E. Alexandre, Paris—Improvements in organ pianos
2336. W C. T. Chaeffer, Stanhope-terrace, Hyde-park-gardens—Improvements in treating the waste washwaters of woollen and other mills

*Dated November* 4.

2338. J. Adcock, Marlborough-road, Dalston—The novel application of the stem or stalk of the tobacco-leaf for various useful purposes

*Dated November* 6.

2340. H. Bordier, Orleans, France—Making alcohol or spirit from different plants and vegetable productions of a farinaceous nature
2342. J. Shaw, Dukinfield, Chester—Improvements in guns and fire-arms
2344. F. R. Ensor, the Park, Nottingham—Improvements in bobbin net or twist lace machinery
2346. W. Childs the younger, Brighton—An improvement in the manufacture of pipes and tubes
2348. F. J. W. Packman, Puckeridge, Herts—A method of compressing air in air-guns and an improved air-gun

*Dated November* 7.

2352. E. Hogg, Charles-street, Gateshead—Improvements in shot and shell
2354. W. H. Woodhouse, Parliament-street, Westminster—An improved meter for water and other liquids
2356. E. Simmons, Birmingham—A new or improved candlestick
2358. J. Bird, Chance's fire-brick works, near Dudley—Improvements in reverberatory furnaces
2360. J. Blaikie, Glasgow—Improvements in the manufacture of driving belts, straps, and bands for machinery

*Dated November* 8

2362. L. Glukman, Saville-street, Dublin—Improvements in effecting electric communications in railway trains
2364. J. Whitehead, Patricroft, Lancaster—Improvements in self-acting mules
2366. C. W. Siemens, John-street, Adelphi—Improvements in electric telegraphs. (A communication)
2368. W. E. Newton, Chancery-lane—An improved mode of constructing saws. (A communication)
2372. C. D. Cranstoun, Elgin, Moray—Improvements in coupling and uncoupling railway carriages and rolling stock

---

PATENTS APPLIED FOR WITH COMPLETE SPECIFICATION.

2312. J. C. Hall, Monkwearmouth—Improved windlass.—October 31
2319. C. Taylor, Holbeck, near Leeds—Improvements in mills for grinding corn and other substances.—November 1

---

*Aberdare Local Board of Health.*—Mr. W. S. Rampling, of Liverpool, has been elected Surveyor to the Board. Seven candidates were invited to present themselves from a very large number of applications.

*Bury St. Edmund's Cemetery Competition.*—The Committee of the Burial Board have selected the designs of Messrs. Cooper and Beck, of London, from thirteen others sent in.

*New Midland Canal.*—Extraordinary as it may appear in the present railway times, a new canal is about to be cut in the heart of the manufacturing districts. The object is to unite Oldham with Manchester by canal; and the land for the purpose has been arranged for with the owners, and all the preliminaries agreed to. The design is to carry the canal from Oldham to near Middleton, where it will form a junction with the Manchester and Rochdale Navigation. The distance is four miles, and the ground so very unfavourable, that nine locks will have to be erected in that distance. It will run almost parallel with the Lancashire and Yorkshire Branch Railway line from Middleton to Oldham, and has been undertaken because of the alleged inadequacy of that railway to supply the wants of the manufacturers of those towns. It is clear from this enterprise that the war in which we are now engaged is not paralysing our trade and manufactures—is not diminishing employment.

*Discovery of Extensive Gypsum Beds.*—It is stated in some of the United States papers that Dr. Shumard, who is connected with the exploratory expedition under Capt. Marcy, in South Ameria, having reached the head waters of the River Brazos, had made the discovery of immense fields of sulphate of lime, one of which he had found means to measure at its outcrop, which he estimated at, at least, 700 feet thick. The waters of the river were excessively bitter, and the land unfit for agricultural purposes, producing scarcely anything, with the exception of the tree from which gum-arabic is obtained, of which the quantity was inexhaustible.
