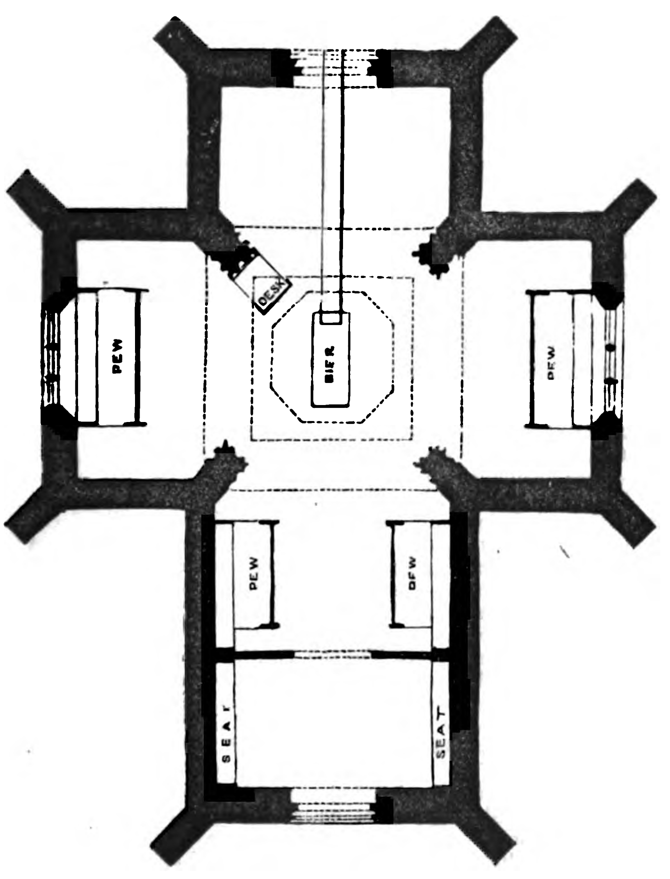
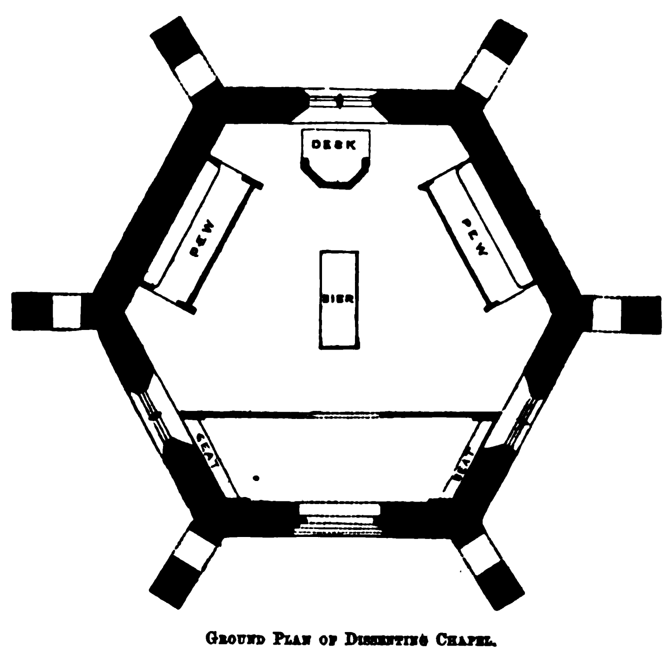
## ST. PANCRAS' NEW EXTRAMURAL CEMETERY, AT FINCHLEY

(*With an Engraving, Plate* I.)



Ground Plan of Episcopal Chapel.



Ground Plan of Dissenting Chapel.

The site of ground upon which the cemetery is in course of formation is situate upon the high road to Barnet, near the village of Finchley, and known as the "Horse-Shoe Farm." It was purchased by the Burial Board of the Parish of St. Pancras, at the commencement of the present year, for the express purpose of a parochial cemetery, under the General Interments Act, 1851, and this is the first cemetery which has been purchased under the new Act. The whole area of the ground is 87½ acres, and finely undulating throughout.

As it was considered that about fifty acres would meet the requirements of the parish, a proposition was made and agreed to by the Board, that a certain portion should be inclosed for the burial ground, and the remainder let upon building leases; a negotiation was, however, subsequently opened, and is still pending, with the sister parish of St. Mary, Islington, to purchase for themselves a part of the ground, and thus convert eighty acres into one large extramural cemetery for their joint use, subject to certain details of division, to be afterwards decided by the respective Boards.

Messrs. Barnett and Birch, of 3, Verulam-buildings, Gray's-inn, had been previously selected by the Board of St. Pancras as their architects and surveyors; and upon consideration, the members constituting the same body for St. Mary, Islington, arrived at the conclusion that it would be preferable to have the whole laid out under the same superintendence. Messrs. Barnett and Birch are therefore now engaged by both parishes to carry out the whole of the joint undertaking.

The foundation-stone of the Episcopal Chapel was laid on the 24th November 1853, by the Rev. Thomas Dale, Canon of St. Paul's, Vicar of St. Pancras, and Chairman of the Burial Board. The Rev. Vicar, having completed the ceremony of laying the foundation-stone, addressed the assembly. After adverting to the ancient origin of cemeteries, from the time of Abraham downwards, and to that very natural feeling which existed in the human mind to see the rights of sepulture decently observed, he set before them the necessity which demanded the provision of this great parochial cemetery. One hundred years ago, or little more, St. Pancras was a rural parish. Its entire population at that time did not exceed the average number of the present inmates of the parochial workhouse, about 1200; it now reaches at least 175,000 and is believed to be increasing at the rate of 5000 annually. The number of deaths registered within the parish during the last year amounted to 3826; the number of interments in the parochial burying-ground to 1230; or nearly one-third; and about the same number must have taken place in certain grounds pertaining to other parishes within the limits of St. Pancras, together with Kensal-green and Highgate Cemeteries, for which returns are periodically made to him as vicar. There are yet six or seven burial-grounds in the parish of St. Pancras, parochial or non-conforming, from which no such return is made; when, therefore, all these grounds shall be closed, for which, in almost every instance, an Order in Council has been already issued, it can hardly be reckoned that fewer than 2000 bodies will be annually deposited in the parochial cemetery; and should deaths or funerals subsequently increase in the same ratio with the population, the ground now preparing for parochial interment—about fifty acres—would become completely occupied by the dead of three generations, or less than 100 years. By that time, however, the great metropolis will have extended its mighty arms even to the walls of this now rural cemetery; but by that time also, under discreet administration, a surplus revenue would have accumulated sufficient for the provision of another and more distant place of sepulture. With regard to the arrangements, first, it is intended that the cost of interments, whether to individual parishioners for their kindred, or to the parish for its poor, shall not, under any circumstances, exceed the existing scale, but, if practicable, fall below it. Secondly, that whatever difference may exist in the condition of the departed or the cost of the grave, there shall be none whatever in the religious service; it shall not be mutilated for the pauper as it may not be expanded for the peer. Thirdly, that means of conveyance shall be provided for the mourners at a moderate cost, each party having, as far as possible, its own carriage or compartment, when going to or returning from the place of sepulture. Fourthly, that the ground shall be so planted and so arranged as to preserve the solemnity and impressiveness which befit a place of christian burial, with such facilities afforded for its visitation during the hours of daylight as will enable all members of the parochial family to repair to the graves of their kindred and friends.

We give in this month's Number perspective views of the Episcopal and Dissenting Chapels, with ground plans of the same. It will be seen that both buildings are in the Decorated or Middle Pointed style. The height of the spire of the Episcopal Chapel will be nearly 100 feet; the division on plan at the west end is to be a carved open screen. The bier will move upon its axis, and be placed in the centre, immediately beneath the spire. The doorway at the east end was rendered necessary to provide a tramway and exit for a low carriage or bier on wheels, to transmit bodies for interment with greater facility to certain distant portions of the ground. This exit is formed with a vault-like aperture, and above it is a large triangulated rose window. The reading-desk is to be placed at the base of the north-east pier of the tower.

The Dissenting Chapel is situated at a considerable distance from the high road, at the extremity of the main carriage drive, and upon the brow of a fine hill. The valley in its front will be spanned by an arched viaduct the whole width of the road, which will form an attractive contrast to the natural undulations of the ground around it. The form of the chapel referred to is hexagonal, with a buttress at either angle, to receive the thrust from the stone ribs of the roof for supporting the lantern, which will also be of stone throughout. We propose, in a future Number, giving illustrations of the entrance lodges and gates, and other details connected with the undertaking.

## THE ARCHITECTURAL SKETCHES AT LILLE, ATTRIBUTED TO MICHAEL ANGELO.

By T. L. Donaldson.

[*Read at the Royal Institute of British Architects, Nov. 14th*, 1853.]

The Public Museum at Lille contains a most precious collection of 1200 original drawings, of which 197 are attributed to Michael Angelo, 3 to Leonardo di Vinci, 68 to Raphael, 13 to Masaccio, 6 to Andrea del Sarto, 9 to Bandinelli, 1 to Paola Veronese, 1 to Perugino, 1 to Gian. Bellino, 8 to Annibale Caracci, 2 to Coreggio, 17 to Carlo Dolci, 10 to Fra Bartolomeo, 15 to Francia, 8 to Guercino, 5 to Ghirlandajo, 3 to Giulio Romano, 1 to Palma, 5 to Parmegiano, 6 to Poussin, 2 to Tintoretto, 8 to Titian, 2 to Albert Dürer, 3 to Lucas de Leyde, 1 to Rembrandt, and 1 to David.

Many of these are apparently first sketches of pictures, which have since acquired the highest reputation, and show the gradual steps by which the great masters progressively improved the rude embryos of their first thoughts; and in order to compare the original ideas with the finished works there are engavings of the pictures as completed. Some are in pencil, others in black or red chalk, and several in bistre.—A most lovely model in wax, attributed to Raphael, of a female head the size of life coloured to nature, the contour, pose, and expression of which recall the perfection of Greek art, rivets the attention of every visitor. It is fractured in the neck, and evidently is of so frail a nature, that however anxious has been the desire to take a cast, the success seems too hazardous to justify the attempt. The drapery covering the bust and the pedestal are of terra-cotta of a later period. I consider this the gem of the collection.

To architects the most precious portion of the drawings is a series of 185 sketches of architectural subjects attributed to the pencil of Michael Angelo. They are now mounted in glazed frames, so arranged as to show both sides of the sheets, as they originally were in a sketch-book, and with drawings on both sides, the size 8 inches by 5 inches. They are generally drawn in bistre, and the plans tinted with a light shade of that colour. To some there are dimensions; others have the words *a dischretione e no e misurato*: sometimes the word *anticho* is added. They consist of plans, sections, details, and some few elevations of various ancient and modern buildings. Among the former are the arches of Titus, Septimus Severus, Janus, and Constantine, at Rome; of Augustus at Pola, in Istria; a plan and details of the Coliseum. Some seem to be plans of ædicula or tombs, like those then abounding in the Campagna; and I find No. 439 to be identical with the plan of Plate 24 of Montano's 'Scelta di varii Tempietti Antichi.' There is a sketch in pencil of the drum under the cupola of S. Peter's at Rome, as designed and executed by Michael Angelo, with the abutment piers and coupled engaged columns, instead of the continuous colonnade of previous designs, whether by Bramante or S. Gallo; and above are some loose lines in pencil indicating the dome, though not very definitely, and more like the Pantheon than S. Peter's. There are several drawings of the parts of the Church of S. Pietro in Montorio, which was designed and built by Bramante, the cotemporary of Michal Angelo and uncle of Raphael; and many sketches of the Baptistery at Florence, of the Lantern of S. Lorenzo, a plan of the Chiesa degli Angeli by Brunellischi, and other buildings in that city, and particularly of the Medicean Library, designed and almost entirely executed by Michael Angelo, but completed by Vasari. There are sketches of vases, arabesques, pulpits, and groups of trophies of ancient Roman armour. The commission having the care of these drawings have intimated that it is their intention to publish them.

During the short period of time that I was enabled to devote to the careful examination of the drawings I sketched off some of the plans, which I have since drawn out to about twice the size of the originals, in order to give an idea of the interesting character of the series. One of these, enlarged more than the others on account of its importance, gives a restoration of the Ruin in the Campo Vaccino, known as the Temple of Peace, or as our friend, Mr. Burgess, and other antiquaries call it, the Basilica of Constantine. It gave rise to some discussion, when Mr. Burgess favoured us during the last session with his instructive paper on the ancient Basilica and early Christian Temple. The sketch contains these original remarkable words upon it in Italian: (*"Questa una pianta d'una chiesa moderna no so di chi sia mano,"*) "This is a plan of a modern church by I know not what hand." Now the restoration of this ruin, as you are aware, has puzzled antiquarians and architects from the time of Serlio to that of Palladio, and down to the present period. Its name, its destination, and its plan have been a constant enigma; but it appears stranger still, if Michael Angelo be the author of these sketches, that he should copy the idea of another, call it a modern church, and say he knew not by what hand, when, from his constant residence at Rome, he must have had a thorough knowledge of the pile, whose three arches rise with majestic grandeur among the ruins of the Campo Vaccino, and his eye, familiar with the building, must have recognised at once an adaptation and not a *"chiesa moderna."* A curious coincidence is, that he himself, whether before the date of this sketch or after, it is impossible to say, converted a similar hall in the Baths of Diocletian, to the purposes of religious worship. The church, a majestic one from its size and simplicity, is known as the Madonna degli Angeli, and is interesting also to artists as containing the tombs of Carlo Maratti and Salvator Rosa; the grand hall is 198 feet long by 84 feet wide, independently of the end chapels, which give an additional length of 65 feet each, making a total length of 328 feet. These measurements were taken by Mr. Hardwick and myself, when we were together in Rome in 1818.

This sketch suggests many remarkable considerations. It omits the large lateral niche; it fills in small columns between the large arches of the nave, and thus decidedly separates the central nave from the side aisles; it adds small columns to the niches, as though each had a tabernacle, as in the Pantheon, a very probable conclusion. But the most important circumstance is the addition, at one end, of a noble portico of large proportions; where, from the time of Serlio to the present period, comprehending Palladio and Canina, the space is supposed to be occupied by a paltry arcade. As such a feature is irreconcileable with the broad treatment of the rest of the edifice, and considering the arcade to be a construction of more recent times, it seems more consistent with the true spirit of the original design to give it a more dignified façade than that of Palladio or Canina, so as to be accordant with its size and disposition, maintaining its importance with the Temple of Venus and Juno immediately adjacent, and the other magnificent buildings of the Roman Forum, to which it is contiguous.

Our friend, Mons. Hittorf, to whom I sent a copy of this sketch, has called my attention to the similarity between the plan of this portico and that of a portico to S. Peter's attributed to Michael Angelo; they are placed side by side on one of the illustrations now exhibited, the only difference consisting in the number of the columns,—the one being for a tetrastyle, the other for a hexastyle portico, and the projection of the porticoes being respectively two and three intercolumniations. Our distinguished Honorary and Corresponding Fellow calls attention to another suggestion presented by the plan, which forcibly revives the early impression upon his mind, that the primitive plan of S. Peter's at Rome, as designed by Bramante, consisting of a simple Greek cross, and divested of its superfluous accessories, would seem to have been suggested by the plan of this ruin, with which in its main lines and features it palpably corresponds.

Such are some of the speculations which arise from the contemplation of this plan, and the startling words—*"chiesa moderna no so di chi sia mano."*

I shall not perplex you nor myself by any lengthened speculations upon the real character and destination of this edifice. Its plan is wholly at variance with the type presented in any known temple of the Greeks or Romans; hence the name of Temple of Peace seems inappropriate. Its plan is no less discordant from the precepts of Vitruvius, or any other basilica in ancient Rome, hence the term Basilica of Constantine would remove it from the usual basilican canon; and experience does not teach us that the Romans of later times departed very materially or radically from established previous types. But its vicinity to the Domus Aurea of Nero makes me inclined to consider it as a vestibule to that noble palace, partially saved from the conflagration, restored, added to by Maxentius, and possibly christened with a new name in periods much subsequent to its original erection—And now *requiescat in pace.*

The next sketch, to which I invite attention, is that of the plan of the vestibule to the Medicean Library at Florence. Those who have visited that building will remember the vestibule and its strangely-planned flight of steps leading up into the library; and they will recal the columns sunk in the walls, and other grotesque mixtures of heterogenous forms in the details, which fully bear out what Vasari says of Michael Angelo,[1] and who thinks to praise the master for having "composed a decoration of" what he calls "a richer and more varied character than had ever before been adopted, either by ancient or modern masters." The beautiful cornices," says he, "the capitals, the bases, the doors, the niches, were all very different from those in common use, and from what was considered *measure, rule, and order by Vitruvius* and the ancients; to whose rules *he would not restrict himself.* But this boldness on his part has encouraged other artists to an injudicious imitation, and new fancies are continually seen, many of which belong to *'grottesche,'* rather than to the wholesome rules of ornamentation. Artists," continues Vasari, "are nevertheless under great obligations to Michelagnolo, seeing that he has thus broken the barriers and chains whereby they were perpetually compelled to walk in a beaten path, while he still more effectually completed this liberation, and made known his own views in the Library of San Lorenzo, erected at the same place. The admirable distribution of the windows, the construction of the ceiling, and the fine entrance of the vestibule, can never sufficiently be extolled. Boldness and grace are in the work as a whole, and in every part: in the cornices, the corbels the niches for statues, the commodious staircase, and its fanciful divisions,—in all the building, at a word, which is so unlike the common fashion of treatment, that every one stands amazed at the sight thereof."

The Medicean family having collected a vast quantity of very fine manuscripts of the classic authors, from the Greeks who had been driven from Constantinople, and from other sources, were anxious to provide a receptacle worthy so rich a treasure.[2] Clement VII., one of the Medicean Popes, was desirous of establishing memorials to his fame in sculpture, painting, and architecture, as Leo and his other predecessors had done. This was about 1625, and Michael Angelo was summoned to Florence to design the library, to be called that of San Lorenzo, with a new sacristy to the church, wherein the Pope proposed to erect the marble tombs of his forefathers,[3] two to inclose the remains of the fathers of the two Popes, Lorenzo the elder, and Giuliano his brother, with those of Giuliano Duke of Nemours, the brother of Leo, and of Lorenzo Duke of Urbino, his nephew.

Eight years afterwards, in 1533, Pope Clement died[4], when the works then proceeding at the library and sacristy in Florence, which, notwithstanding all the efforts made, were not yet finished, were at once laid aside. Towards the middle of 1555, during the time of Paul III., "Duke Cosinio had sent Tribolo to Rome to try if he could persuade Michelagnolo to return to Florence there to finish the sacristy of San Lorenzo; but the master had excused himself, saying, that he was become old, might no longer endure the fatigue of labour, and could not leave Rome. Tribolo then inquired as to the steps for the library of San Lorenzo, for which Michelagnolo had caused many of the stones to be prepared, but for which no model nor any certain indication of the form in which they were to be constructed, could be found. It is true, that there were some few sketches of a pavement and other things in terra, yet the correct and final design of the work could not be ascertained. But not all the entreaties of Tribolo, although he brought in the name of the Duke, could move Michelagnolo to say more than that he did not remember. The Duke then commanded Vasari to write to the master, since it was hoped that for the love of him, Michelagnolo would perhaps say something, which might enable them to bring the work to conclusion. Vasari wrote to him accordingly as the Duke desired, adding, that of all which had to be done Vasari was to be the director, and would do everything with the utmost fidelity, taking care of every minutiæ, as of a work of his own. To this Michelagnolo replied by sending the plans for the work in a letter, written by his own hand, on the 28th Sept. 1555:

'Messer Giorgio, my dear friend—About the staircase, whereof there has been so much said, believe me, that if I could remember how I had arranged it, I should not

1 Vasari's Lives, translated by Mrs. Foster, vol. v. p. 272.
2 Page 271. 3 Page 274. 4 Page 282.

2*

require so many entreaties. There is a certain stair, that comes into my thoughts like a dream; but I do not think it is exactly the one which I had planned at that time, seeing that it appears to be but a clumsy affair; I will describe it for you nevertheless. I took a number of oval boxes, each about one palm deep, but not of equal length and breadth. The first and largest I placed on the pavement at such distance from the wall of the door, as seemed to be required by the greater or lesser degree of steepness you may wish to give to the stair. Over this was placed another, smaller in all directions, and leaving sufficient room on that beneath for the foot to rest on in ascending; thus diminishing each step as it gradually retires towards the door; the uppermost step being exactly of the width required for the door itself. This part of the oval steps must have two wings, one right, the other left. The steps of the wings to rise by similar degrees, but not to be oval in form. The ascent by the middle flight, from the centre to the upper part, shall be for the Signore; the turn of the wings must be towards the wall. But from the centre downwards to the pavement, they shall be kept at the distance of about three palms, in such sort that the basement of the vestibule shall not be infringed upon in any part. What I am writing is a thing to be laughed at, but I know well that you will find something suitable to your purpose."[5]

In a brief conversation on the subject, which I had with Monsieur Benvignat, the architect of Lille, he gave it as his opinion, that the sketch exhibited in the Wicar collection is the original idea of Michael Angelo; that he had lost the book, and forgotten this his first conception. But the sketch is equally at variance with the master's letter just quoted, and the staircase as executed. The sketch presents an oval series of steps, half without and half within the door of the library; but the number would not have accomplished half the height to which it was necessary to rise, and although oval like the boxes alluded to by Michael Angelo, there are no side steps.

So restricted is the vestibule, that the intrusion upon the space of the floor, by the capricious form given to the flight as executed, leaves very inadequate room for the landing at the bottom of the stairs; and if any method could have been devised of gaining space by making some of the steps rise within the doorway, much convenience would have been gained. I am inclined therefore to think that this sketch is a slight idea of Vasari's founded upon some vague rumour of Michael Angelo's arrangement, to try how it could be carried into execution, before he had received the master's formal instructions.

This brings us to the consideration of the important question, who was the real author of these sketches? My own impression is, that *the whole book* may be attributed to Vasari himself—that all the sketches of the Library, of the Cupolino of the Sepulchral Chapel, and of the other details of Michael Angelo's work, were taken for his own guidance, or for the purpose of sending off copies to the master, to enable him to give the proper instructions to direct Vasari's proceedings in the completion of the buildings confided to his care.

The sketches generally are executed with a certain ready freedom of hand and no great care; but some are drawn with much delicacy and with considerable precision and minuteness of form. Hardly more than two or three evince that bold and vigorous freedom of treatment, which we are accustomed to consider as characteristic of the Maestro, as Vasari repeatedly calls him. One circumstance particularly struck me, and that was the numerous sketches of the circular chapel built in the cloister court of S. Pietro a Montorio, by Bramante. This building excited vast admiration at the time, and Serlio himself gives the plans, elevations and sections of it in his work next to those of the cupola of S. Peter's, and among the numerous illustrations of ancient buildings, and Palladio also gives it among his ancient edifices. Other writers of the time mention it with unqualified praise. It would therefore be no wonder if Vasari, who was employed upon designs and models for tombs at S. Pietro a Montorio by order of Julius III., should have sketched parts and kept a record of such details. But that Michael Angelo, who despised the trammels of *ancient art*, should condescend to the task of minutely drawing the work of a cotemporary, and that cotemporary no friend of his, but the uncle and supporter of his rival Raphael, and one, who crossed him in his great work for the tomb of Julius, seems beyond probability, however noble were many impulses of Michael Angelo's generous nature. I am given to understand, that many French artists, who have visited the Wicar collection, concur in my opinion as to the propriety of not attributing this collection of sketches to Michael Angelo; and a distinguished member of the French Institute, a great amateur and connoisseur, assures my friend Hittorff, that he had traced the writing on some of these drawings, and that it did not at all accord with that of the great master. I am therefore confirmed in the conviction, that these architectural sketches are not the production of Michael Angelo.

I shall now notice a letter from Francis I. to Michael Angelo; but before I put you in possession of this most precious of the treasures of the Wicar collection, it is necessary for me to give a few particulars of one to whom it refers, and which I shall do by quoting another passage or two from Vasari. Francesco Primaticcio was sent by the Duke Frederigo of Mantua to France, at the request of Francis I., who, having heard of the decorations with which he was adorning the Palazzo del T, desired to have an able artist to execute like works for him at Fontainebleau, and elsewhere.[6] Primaticcio, according to Vasari, was the first to paint frescoes of any account for the French king, and we all know how admirably he succeeded in the great and superb ball-room at Fontainebleau:

"King Francis, being much pleased with the conduct and proceedings of Primaticcio, sent him in 1540 to Rome, he having put the wish, according to Benvenuto Cellini,[7] into that monarch's head to possess antiques. He purchased several antiques in marble, and served the king so diligently, that what with heads, trunks, and entire figures, he bought in no long time 125 pieces. At the same time Primaticcio caused Barozzi da Vignola and others to copy the bronze horse of the Capitol, the greater part of the relievi of the column, (probably Trajan's,) the statue of Commodus, the Venus, Laocoon, the Tiber, the Nile, and the statue of Cleopatra, which are in the Belvedere, and all which were to be cast in bronze".... "Being recalled to Paris he returned immediately. But, before attending to any other occupation, Primaticcio caused the greater parts of those antiques to be cast, when all succeeded so well, that they might be taken for veritable works of antiquity, as may still be seen" says Vasari "in the Queen's garden at Fontainbleau, where they were placed to the great satisfaction of King Francis, who may be said to have there made another Rome".... "The king, perceiving that he had been well served during the eight years, that Primaticcio had been with him, appointed the painter to be one of his Chamberlains. And shortly after (in 1544 that is to say) his Majesty made him Abbot of S. Martin (at Troyes.)"

The document, which rendered necessary these preliminary remarks, is as follows:—

Sr. Michaelangelo pourceque jay grant desir davoir quelques besognes de vre ouvrage jay donne charge a labbe de Sainct Martin de Troyes pnt porteur que jenvoye pardela den recouvrir vous priant si vous aves quelques choses excellentes faictes a son arrivee les luy voulloir bailler en les vous bien payant ainsique je luy ay donne charge Et davantaige voulloir estre contant pour lamour de moy quil molle le christ de la Minerve[8] et la nre dame de la febre[9] affinque jen puisse aorner lune de mes chappelles comme de chose que lon ma asseure estre des plus exquises et excellentes en vre art. Priant dieu Sr. Michelango [sic] quil vous ayt en sagarde. Escript a Sainct germain en Laye le VIII. jour de feurier mvxlv.

FRANCOYS.

No. 199. DELAUBESPINE.

This letter proves that Primaticcio must have made a second visit to Italy for the purpose of collecting more works of art, and its truly princely sentiments evince the taste, the liberality, and high-minded generosity of a real lover of the fine arts. How fortunate has France been for three centuries in having princes who felt that the fine arts can contribute essentially to the refinement, the happiness, and prosperity of a nation. This spirit has endowed Fontainebleau, Paris, and Versailles with the masterly productions of the greatest minds in Italy and France. The lower orders have their enjoyments in common with the princes, the nobles, and gentry of the land; and they grow up imbued with the love of that art, which is so mixed up with their holiday enjoyments, that it becomes a necessity, as it were, from their being used to it from their earliest years; and they are thus unconsciously educated by the contemplation of the finest works. How far are we in this respect behind our neighbours. The gardens of the Tuilleries have no parallel with our royal residence of Buckingham Palace; and Fontainebleau puts to shame the courts and terraces, gardens and walks of Windsor Castle, which contain hardly a single statue, group, or fountain, or other art accessories of any consequence, and appear cold and meagre, and poverty stricken from the want of such accompaniments. So niggardly and deficient in art feeling have those authorities been, who have hitherto had to provide for the palaces of our Sovereigns, and the places of public resort for the people. Often was Francis I. thwarted by his ministers in his munificent desire to promote the fine arts, but he was not to be turned away from an object which he knew would gratify his people and ennoble his country. And well has this noble spirit been rewarded for his early enlightened cultivation of the fine arts, for his example has been followed by the continued munificence of succeeding monarchs and ministers, which has produced that superiority in the art productions of their manufactures, which enables them to compete so

[5] Gaye in his Carteggio, makes it doubtful whether Vasari finished these steps or not; and a Florentine commentator says, "Although Michael Angelo had left the steps, the balustrade, and many other parts of this work in a state of preparation, it is manifest that Vasari did not succeed in comprehending the master's wish. He constructed a magnificent flight of steps, without doubt, but not that intended by Michael Angelo."—See *Ruggieri, Studio d'Architettura Civile*; also *Rossi, Libreria Medicea Laurenziana.*

[6] Vasari's Lives, translated by Mrs. Forster, vol. v. p. 371.

[7] Vita, vol. ii. p. 131, Ediz. di Milano, 1811, 8vo.

[8] This celebrated statue is still preserved in the Church of the Minerva, near the Pantheon, Rome.

[9] This statue was, according to Vasari, executed for the Cardinale di S. Dionigi to put in old S. Peter's, in the Chapel of the Virgin Mary of the Fever. I have made ineffectual inquiries to ascertain precisely where this statue is. Mons. Hittorff thinks it the Madonna della Pietà, the cast of which was in one of the chapels of Fontainebleau up to the time of the Revolution. Probably it may be the Pietà of S. Peter's, at Rome, re-named after the time of Vasari.

successfully with the mere mechanical skill and industry of other nations.

Michael Angelo has been the main topic to which I have been so bold as to claim your attention; and surely his position as an artist claims for him the respect and admiration of every painter, sculptor and architect. And although he was a great innovator in architecture, and introduced a license which was most pernicious to the art, yet we cannot but recollect that we owe to him the simplicity of design, to which he reduced the cupola and other decorations of S. Peter's, which had been sadly corrupted by the immediate successors of Bramante, whose original conception had been lost. Vasari mentions[10] that "while Antonio San Gallo lived, Pope Paul had permitted him to continue the building of the Farnese Palace. But the upper cornice on the outside was still wanting; and his Holiness now desired that this should be added by Michael Angelo, after his own design and under his direction. The master, therefore, not willing to disoblige the Pope, who esteemed and favoured him so much, made a model in wood, seven braccia long (13½ feet), and of the exact size which the cornice was to be. This he caused to be fixed on one of the angles of the palace, that the effect might be seen, when, as the Pontiff and all Rome with him were much pleased therewith, it was put in execution, proving to be the most beautiful and varied cornice ever erected, either by the ancients or moderns[11]. He continued the great court also, constructing two ranges of columns over those first erected, with the most beautiful windows, and a great variety of rich ornaments, ending with the great cornice; all of these works being so beautiful, that this court by the labour of Michael Angelo has now become the finest of all Europe."

You will doubtless remember the beautiful picture by Haghe in the New Water Colour Exhibition of the year 1848,[12] representing Michael Angelo, himself an old man, nursing by his midnight lamp his faithful servant Urbino, who was ill; his master sleeping at night in his clothes beside him, the better to watch for his comforts. Vasari gives the following touching letter written to him by Michael Angelo on this occasion:—

"My dear Messer Giorgio—I can but ill write at this time, yet to reply to your letter I will try to say something. You know that Urbino is dead, and herein have I received a great mercy from God, but to my heavy grief and infinite loss. The mercy is this, that whereas in his life he has kept me living, so in his death he hath taught me to die, not only without regret, but with the desire to depart. I have had him twenty-six years, have ever found him singularly faithful, and now, that I have made him rich, and hoped to have in him the staff and support of my old age, he has disappeared from my sight, nor have I now left any other hope, than that of rejoining him in paradise. But of this God has given me a foretaste, in the most blessed death that he has died: his own departure did not grieve him (so much) as did the leaving me in this treacherous world with so many troubles. Truly is the best part of my being now gone with him, nor is anything now left me, except an infinite sorrow. And herewith I bid you farewell."

I have been insensibly led, by the interest which attaches to the talents and character of this great man, to depart from the immediate subject of my paper, and to conclude my remarks by an allusion to his works at the Farnese, and by the contemplation for a moment of the affecting incident, which lays open the inmost soul of Michael Angelo, and shows him with the tenderest regard as a kind master, and the finest feelings of the most pious resignation in the contemplation of his own not far distant end, —as exemplary as a Christian as he had been eminent and admirable as an artist. But I will now conclude, and trust, that I may not be considered too presumptuous in so boldly offering my opinion as to the authorship of these architectural sketches. Whosesoever they may be, whether Michael Angelo's, or Vasari's, or any other artist's, they are extremely curious and interesting in the history of our art. I hope that none of my professional brethren, who have not yet seen these drawings, will now pass through Lille without visiting this fine collection. They will then, in addition to the delight they will experience in seeing the masterly thought-renderings of other great men, be enabled to judge for themselves and to decide, whether I am wrong or right in hesitating to attribute to the mighty Florentine these architectural sketches, which well deserve the minutest attention from every lover of architecture.

*Discussion.*—Mr. Tite stated, that it happened to him, in the summer of last year, to be detained in Lille for five hours on a wet afternoon, waiting for the train to Calais, when he was directed to the Musée, in order to pass a portion of that time. Proceeding to the rather magnificent Hotel de Ville, described by Mr. Donaldson, of which he had never heard before, he was astonished to find, not only the marvellous collection of drawings referred to, but an extensive and interesting museum, illustrative of art, antiquity, and ethnology. So easily might Lille be visited, and so well did the collection deserve further inquiry, that he strongly recommended his hearers to go there. In reference to the architectural portion of the drawings, he was sorry to find that Mr. Donaldson considered they were not, as he (Mr. Tite) had fondly hoped, the work of Michael Angelo. Mr. Donaldson had brought forward strong reasons in support of his opinion; and to his judgment and knowledge of the subject he must at once defer. He had himself copied from one of the drawings the name of Michael Angelo, which was clearly written upon it; and it would be very easy to compare that with his undoubted autograph, so as to settle the question. One of the largest of the drawings appeared to him to be the first sketch of the great architect for the dome of S. Peter's with the double cupola. He was informed at Lille that M. Wicar was employed by Napoleon Bonaparte in Italy to collect works of art, and that in doing so he helped himself to these drawings, which he bequeathed on his decease to his native city. In addition to the interesting letter of Francis I., which Mr. Donaldson had read, he begged to read the following from Bonaparte to M. Wicar, which was exhibited with the drawings; and which, notwithstanding certain peculiarities of diction, he had no doubt was dictated by Bonaparte himself, in 1796, from Milan:—

*Armee d'Italie.* *Republique Francaise.*
*Liberte Egalite.*
Au Quartier General.
Milan le 22 Prarial.
An 4 de la Republique—une et indivisible.
Bonaparte General en Chef de l'Armée d'Italie.

Au M. Wicart, peintre à Florence.

J'ai reçu votre lettre du 6 Prarial. Je 'ny ai point reçu les esquisses que vous m' vez annonciez.

Je vous engage a continuer d'occuper votre talent d'objets dignes de l'homme qui pense.

Je serai toujours fort aise de pouvoir de vous être bon a quelque chose.

Bonaparte.

The sketches generally were singularly curious and beautiful; and he had been so much struck with them that he had contemplated interesting the architects of France with a view to have them published in lithography, which might be easily and cheaply done; and he would suggest to the Council that they might be able to promote this object. Whoever was the author of the sketches, he thought they might prove very useful in restoring the magnificence of ancient Rome. With regard to the Basilica of Constantine, he should be very glad to believe that there had been such a portico as the drawing referred to by Mr. Donaldson indicated. He believed, however, that both Palladio and Canina (the latter especially) were quite inclined to include a portico in their restorations of that building; but that it would be found that there could not have been such a portico, unless, indeed, the Via Sacra could be supposed to have passed within it. The Institute were under the greatest obligation to Mr. Donaldson for the attention he had given to the illustration of these works, which were undoubtedly the production of some very clever man, if not of the great maestro himself.

Mr. Donaldson said, that he had intimated to M. Benvignat, who was a member of the Commission having the care of these drawings, that he was sure the Institute would be much pleased to have tracings of them; but that gentleman believed this would not be possible, inasmuch as the Commission had the intention of publishing them very shortly. It would, however, be desirable to express the interest which this Institute felt in the matter, with the view of promoting that result.

Mr. Bell, M.P., bore testimony to the extreme value and interest of the drawings, both in an architectural and artistic point of view. He had himself intended to revisit them, and prepared a paper on the subject; but he rejoiced, that in directing Mr. Donaldson's attention to them, he had insured its being much more ably done.

---

*Newcastle Docks.*—The plans and surveys for these docks have been made by Mr. W. A. Brooke, C.E., and Mr. John Dobson, architect, of Newcastle, and been deposited agreeably to standing orders. A dock of about twenty acres, with suitable basin, tidal basin, and locks, is projected, with a depth of 23 feet at the outer lock sills, and a width of 52 feet in the locks, for the admission of large steamers. A railway of about half-a-mile will effect a junction with the York, Newcastle, and Berwick Railway.

## GREAT EXHIBITION SURPLUS APPROPRIATION.*

The surplus funds of the Great Exhibition have, with a government grant, been applied to the purchase of an extensive site at Kensington, with the understanding that it is to be appropriated to buildings for the promotion of science and art. As yet no definite scheme for effecting these objects has met with acceptance. The formation of an industrial museum does not at present offer the means of occupying the area, nor does it present such attractions as to be likely to obtain a very large grant of public money. The erection of a palace of science, or a palace of the institutes, in which all the learned institutions should be united and provided with theatres, libraries, and museums, has met with little support from the members of the institutions, who prefer central situations to location in a remote part of the enormous metropolis. The removal of the National Gallery, likewise supported by residents at Kensington, and by persons keeping carriages, is too evidently suited to the convenience of the aristocratic classes, and so opposed to the convenience of the great body of the population, that it has been denounced instead of being allowed, as hoped by the promoters, to be carried into effect with little resistance. If the deportation of the scientific institutions to Kensington is opposed to the convenience of individuals in easy circumstances, and has met with determined resistance, the monstrous proposition of withdrawing an establishment especially devoted to popular uses, from the reach of the population, justly deserves severe reprobation. The National Gallery, while it is designed to assist in the education of artists, was certainly never meant for the delectation of the aristocracy, who have more valuable galleries of their own, from which the public are excluded. It was because the treasures of art in this metropolis, among the richest in the world, are—in a mean and narrow-minded spirit, and in opposition to the moral obligations incumbent on the owners—withheld from the public gaze, and because the English public, deprived of the opportunities of cultivation, are behind the standard of our continental rivals, that the National Gallery was established as a free public institution for the cultivation of the taste of the masses. If, from gross mismanagement the space provided for this collection is now found inadequate, that is no reason for its removal to Kensington, beyond the reach of the artizans of the east and south, and of their wives and children. Were it proposed to be moved nearer to the abodes of those classes, that would be a proposition more in conformity with the spirit of the institution than to move it to a remote part of those very districts from which the artizans are most removed. The same objection exists to the establishment there of a great industrial museum. The site is about as appropriate as Bethnal-green for the courts of law, or Battersea for the Bank of England.

In all schemes as to public buildings there is now this circumstance to be borne in mind—that the conditions of sites in the metropolis have been altogether altered by the abolition of the window duties. An adventitious and artificial regulation caused an enormous space to be covered over with small houses, in opposition to the natural habits of the population; but, now that the obstacles have been removed, large buildings have been erected in the heart of the metropolis, either as offices or as residences in chambers, suites of rooms, or flats; and this must go on to that extent, that suburban building will be checked, the population will be concentrated within the interior, or, by means of the suburban railways, enabled to choose their sleeping places and family establishments wholly in the country, instead of the mongrel villas and cottages of the suburbs, having all the inconvenience of a town residence, with the remoteness of a country site, and without either garden ground for the children or green fields. As the *Times* has well pointed out, a large space in the inner ring, as it were, of the metropolis, otherwise valuable for building ground, is covered with miserable courts and alleys, which can be obtained at a moderate price; and, in the end, these will be exterminated, and space will be given for large dwellings and for public establishments.

There is no occasion to remove either the learned societies, or the National Gallery from the neighbourhoods they now occupy, as a class of improvements similar to those in Paris, nay, similar to Victoria-street and Cannon-street, will give sites as cheap as Kensington, if not cheaper, and much more accessible. Any appropriation of Kensington must be with due attention to the course of events; and this is a most unpropitious period for the establishment there of any institution which is to be readily accessible; for, independently of what has been already stated, the admission of railways to the heart of the metropolis, and more particularly the recognition of suburban, have given greater advantages for the concentration of the population of the vast area within the old seat of business. It may, too, with truth be said, since the establishment of the railway system, that all England is a suburb of the metropolis, so far as the public collections are concerned, or any great celebration. The convenience of these visitants must, therefore, be consulted, by avoiding any out-of-the-way place for a public establishment, unless of an exceptional character.

The state of affairs as to the Kensington site is, that the site has been obtained, and there are no funds to do anything with it, nor, as we have said, any sufficient scheme for the appropriation of funds. Mr. Cole (Felix Summerley, C.B.), who was one of the persons connected with the Great Exhibition of 1851, as he still is with those who may be called its executors and legatees, has published a pamphlet, which he represents as being under the auspices of Prince Albert. The purport of this pamphlet is to recommend that the site shall be turned over to a joint-stock company, the operations of which Mr. Cole does not specify, though he states, in a dedication to Prince Albert, that he is prepared to do so whenever it may be considered necessary. Mr. Cole is the best judge of the propriety of this reserve and demand of confidence, which appears too close a copy of Sir Robert Peel in a memorable period of political emergency.

It is rather a strange testimony to Mr. Cole's impartiality as a witness, that he propounds strong statements against the efficiency of government management, though he has been long a government employee, having first held a clerkship in some office, and latterly, on the strength of his Felix Summerley productions, having the good luck to be put at the head of the department of practical art, with a very liberal salary. We have expressed very strong opinions as to the efficiency of government management and officials, but we are outdone by Mr. Cole, and we think he has drawn his case so strongly that we are not able to endorse all his statements.

Mr. Cole seems to think that a very large sum of money will be required, and that it will be advisable that the management, to insure responsibility and unity of action, should consist only of one person, or, at most, three persons. Mr. Cole seems to think the legislature or the government will never grant such powers, or repose such trust. Here we differ from him, for we think they will. With regard to one point he mentions, an Historical Gallery of Painting and Sculpture, we fully expect that the funds will be provided, and that a competent director will be entrusted with their disposal. If, however, Mr. Cole means that he, or some other of the Great Exhibition officials, is to be entrusted with an unlimited control over the very large expenditure of public funds for some undefined object, we think he is quite right in assuming that the Legislature or Executive will never countenance anything of the kind. It is, however, a misrepresentation that the Legislature will not liberally provide for our acknowledged institutions or grant extensive powers. The British Museum surely has no reason to complain of want of confidence. The Department of Education, although new, has already been largely endowed, and is allowed to dispose of its funds without parliamentary interference in details. The National Gallery and Schools of Design year by year receive further endowments. Kew Gardens, under Sir William Hooker, has become an establishment of which the nation may be proud; nor are we aware that Greenwich Observatory has any ground of complaint. Where there is a ground of complaint, it is not, as Mr. Cole alleges; for the legislature do liberally endow, and grant full confidence; but it is, that there being no proper minister of education or of the fine arts, there is too much power in individual departments, too little control over them; and the want of a systematic organisation, whereby neglected objects might be provided for, and the fullest results obtained from existing institutions. The expenditure of the government is lavish, and if Mr. Cole and his patrons can really make out a case for a useful institution, they will have no ground to complain of the measure of support.

A very strange position taken by Mr. Cole is that government bodies are much less prudent, and much less bold in the

* "Observations on the Expediency of Carrying out the Proposals of the Commissioners for the Exhibition of 1851, for the Promotion of Institutions of Science and Art at Kensington, rather by the Public themselves than by Government." (Submitted, by permission, to H.R.H. Prince Albert, President of the Royal Commission.) By Henry Cole, C.B. London: Chapman and Hall. 1853.

application and expenditure of money, because the money is the property of the public generally, and each individual at all interested considers he has a right to give his opinion on the mode in which they ought to be employed. This he does not consider to be the case with the directors of a public company. Our readers, who are more conversant with these matters, will differ in opinion with Mr. Felix Summerley. The British Museum and National Gallery managers have certainly not troubled themselves about individual suggestions or public criticism; and joint-stock companies, as railway directors well enough know, are particularly open to the interference of their shareholders. Had the writer instituted a comparison between individual management and that of boards, government or joint-stock, he would have been able to speak of the superior energy of one as compared with the other, but his preference for a joint-stock company is not supported by the arguments he adduces.

Another strange plea of Mr. Summerley is, that the administration of the government boards is constantly undergoing inquiry, and he enumerates several boards. This he adduces as a proof of the suspicion under which they lay. He quite forgets that railways, banks, assurance companies, and other joint-stock institutions, have been quite as often the subjects of inquiry and legislation; and if he had a Great Exhibition Company, or a Great Exhibition Commission, it would be just as liable to inquiry on public grounds by the legislature. He has also a notion that directors are more liable to penalties for malversation than government officials, but he does not refer to any evidence or experience of his own on the subject, and the state of the law gives no countenance for any such doctrine.

Other circumstances on which Mr. Cole relies are, that in the middle ages the churches were not built by the government but by the people, and that of late, canals, railways, &c. are the results of individual enterprise. This has nothing to do with museums and galleries of art, which are not remunerative undertakings, nor have any religious or superstitious recommendations. Of course Mr. Cole brings in that successive governments declined to undertake a national exhibition of industry, and, as he says, would probably do so again, and that at no time did the government give much countenance or help to the Exhibition. The Exhibition of 1851 was an exhibition of charlatanism and puerility, with the smallest amount of practical results and with a large amount of scandalous jobbery for the glorification of a contemptible clique. The manufacturers of this country have no particular reason to be satisfied with a performance in which they were treated with neglect and foreigners favoured; and the government had so much trouble and so little satisfaction with the exhibition and its concoctors, that they will not very readily subject themselves to a repetition of it.

Mr. Cole makes a comparison between private institutions for promoting science and art and those of the government, and says that the latter always suffer by it, instancing the Tower menagerie and the Zoological Gardens, and forgetting Kew and the Royal Botanic Gardens, Regent's-park. He therefore advocates "self-supporting" institutions, forgetting that for educational purposes we want not "self-supporting" but free institutions to put us on a level with our French rivals and American brethren. In confirmation of his dictum he says it is characteristic of the people of this country, that they do not value so much anything obtained gratuitously as that which they pay for, which is directly in the teeth of evidence; and we need go no further than the British Museum for that. He further says that there is an increasing dislike of the large provincial towns to the monopoly in London of great institutions to be paid for from the general taxation. This is a misrepresentation. The provincial populations do not complain of the British Museum, the National Gallery, or national institutions, which are used as much by them as by the Londoners: but they do complain, and justly, that they have not local museums, galleries, and libraries, which a better organisation gives to continental towns.

On these various assertions Mr. Cole contends that the plans for Kensington ought to be realised with the same success as the Great Exhibition, and the Crystal Palace at Sydenham, and that a joint-stock company should be formed for such purpose, to whom the area should be assigned, the government having a right of buying the whole or a part of the buildings, and of buying free admission for the public. Mr. Cole's joint-stock company is to erect spacious and attractive buildings for exhibiting collections, illustrative of the progress of science and art; the formation of the collections and "the execution of various extensive works conducive to popular improvement and recreation,"—in fact, so far as we can understand, to be an opposition Crystal Palace Company. Besides giving the area, the government are to be invited to lend or present to the company the National, Vernon, and other public galleries and collections, and to "agree to pay a fair rental for the space occupied by them."

We cannot say that Mr. Cole has made out any case for the support of the legislature or executive government, by grants or enactments in favour of his scheme, for we do not think they should be engaged in a kind of Crystal Palace, Vauxhall, or Hippodrome, which should properly be left to other speculators. If Mr. Cole, the Crystal Palace directors, Mr. Batty, or Mr. Charles Kean, while catering for the public amusement, choose to promote the cause of education by classical or artistic illustrations, we are thankful to them; but we see no reason to subsidise Mr. Cole or his company to enter into rivalry with the proprietors of theatres and exhibitions.

If it be true that the Kensington scheme has failed, it might be advantageous to sell the land to Mr. Cole and his joint-stock company to erect glyptothecas, colosseums, Mount Etnas, panopticons, glaciariums, pantheons, and hippodromes, as they may think most profitable. The funds from the sale of the area may be applied to the extension of the National Gallery, the building of a new one, or the formation of an industrial museum.

## PROPELLERS.

James Spotswood Wilson, *Patentee*, Nov. 8, 1853.

The inventor states, that the proper place for the application of the propelling force, to promote horizontal motion, is at the centre of gravity, and this, in other cases, is generally found true in practice—as, for instance, in the paddle-wheel of the steamship, and the driving-wheel of the locomotive steam-engine—and the proper position in which to apply the force in order to produce the largest amount of horizontal motion in proportion to the power employed. He learns from many examples, both in nature and art, that such position is at an angle of inclination 45° from the horizon. But his principal reasons for adopting that angle with regard to marine propellers is in consideration of the fact, that water increases in force in an equal ratio with the depth, from which arises its mean resistance at that inclination, and that the mean velocity of a falling body is obtained in that inclination also. By causing the power to act in the line of the former at that angle, upward gravity will be brought into action at a corresponding angle downward, but at right angles to the former, the resultant of which will be horizontal motion. The outer end of the propeller-blade, from its greater rapidity of motion, passes through a greater space than the portions nearest to the axle, and therefore does not require so much breadth of blade. In natural examples, we find that the fastest swimmers among fishes have their tails divided into long tapering lobes, instead of one broad sheet, and the swiftest among birds have long tapering wings. In imitation of these models afforded by nature the patentee forms his propeller, and therefore terms it the "Wing Propeller," not only on account of its situation and form, but likewise to distinguish it from the screw-propeller, as it does not retain any portion of the spiral character.

The vibration experienced in screw-propelled ships arises from the unequal density of the water in which the propeller acts; the force opposed increases in proportion to the depth, and the violence of the vibration is in proportion to the velocity. By the application of the wing propeller in the angular position (as represented in the engraving, fig. 1), the vibration would be completely removed—in consequence, first, of their acting in the line of mean resistance, by which means the difference arising from density would be one-half equalised; and secondly, their blades being made tapering toward their outward extremities, the forces and velocities would be more equally proportioned to the different sections of the diameter. It will be seen by the engraving that the propeller represents a pair of revolving wings. At figs. 3 and 4 it will be seen that the descending wings D, D, act like those of a bird, nearly horizontal, but descending in the line of mean resistance; while the ascending blades E, E, rise in a nearly vertical position, and press backward at the same time in a manner similar to the action of an oar in rowing.

The manner in which the patentee proposes to make the wing-propeller suitable as an auxiliary power is according to the following description. The propeller-shaft is traversed spirally by a broad screw-thread, on which the propeller (fig. 2) fits; while at work the action will keep it firmly down to the collar D;

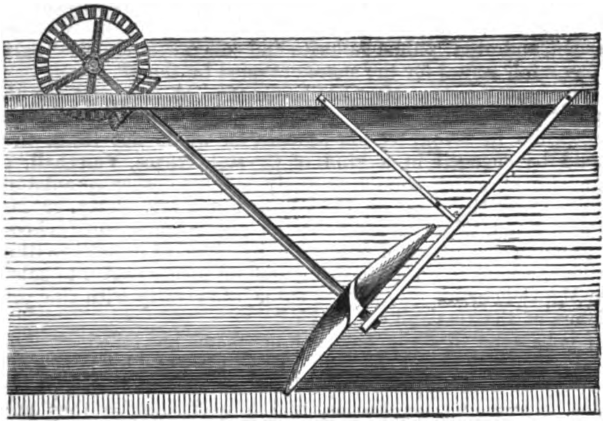

FIG. 1.

but when the engine is stopped and the ship continues in motion, the resistance of the water will cause the propeller to turn on the shaft, and in so doing it will travel up the screw, so that all that is necessary to be done in order to draw the propeller out of the water is to stop the engine or reverse the motion.

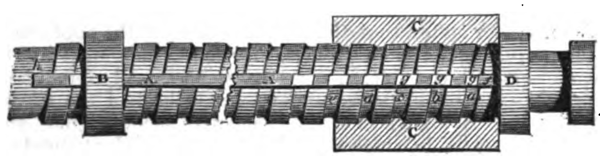

FIG. 2.

In ocean steamers the necessity for being able to back water is not great, and is likely to occur only when coming into or leaving port. The patentee would therefore prefer to avoid providing for that evolution rather than to encumber his apparatus with a complicated mechanical arrangement. Yet, that his auxiliary shaft and propeller may be as perfect as possible, he contrives to key the propeller to its place in so simple a manner that it may be secured or liberated in a moment. To effect this, he proposes making the screw-thread on the shaft considerably broader than the spaces *a, b, c, d, e*, between its spiral revolutions; then, by having a key-way running the full length of the screw on the shaft, and sunk about half-an-inch deeper than the spiral thread, and a corresponding way inside the propeller; also, the lower end of the key A, A, should be formed so as to make good the deficiency of the screw-thread when the propeller is at liberty to ascend, but having space *f*, at its lower end to allow of its being driven down so as to permit the portions of thread to pass across

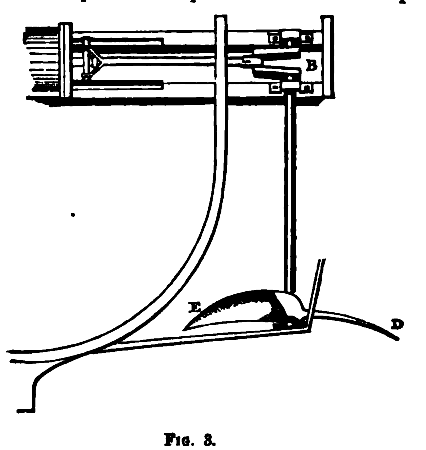

FIG. 3.

the spaces *a, b, c, d, e*, as shown at *g, g*, by which means the propeller would be prevented from turning on the shaft. The upper end of the key should be furnished with a nut B, fitted in such a manner, that when being run on it, it would drive the key A, A, down, and on being drawn off it would draw the key with it into the space *h*, and liberate the propeller. In applying the power, the patentee proposes using only one steam-engine for one pair of propellers by placing the cylinder thereof horizontally across the ship, level with and in a line with the centres of the two cranks B, B, figs. 3 and 4, and furnishing it with one piston and two piston-rods, or rather one piston-rod passing through the piston and out of each end of the cylinder, so as to act like a double engine by having each end connected with a crank-rod. Figs. 3 and 4 represent the mode of application, by comparing which with the modes in use may be observed the amount of machinery that would be dispensed with, and the smallness of the space that need be occupied by the engine. To increase the velocity of the ship under this arrangement, the propeller wings should be lengthened, the stroke of the engine

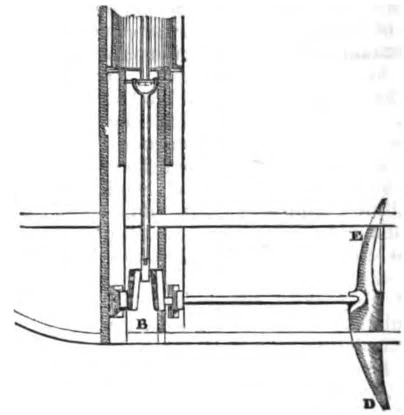

FIG. 4.

shortened, and the diameter of the cylinder increased to compensate for loss of leverage in the cranks. But as regards engines such as are constructed in the paddle-wheel steam-ships, they may be applied by using bevil gear to connect the propeller and engine shafts, and to multiply the velocity to the required amount.

*Claims.*—1. The peculiar form of the propeller-blades hereinbefore described and illustrated; 2. The exclusive right of fixing a shaft or rod on the sides of a ship or other marine vessel in an angular position, as hereinbefore described; 3. The connecting of these shafts or rods by cranks to the pistons of a steam-engine, the cylinders of which engine shall be laid horizontally athwart the ship, and have a piston-rod working through each end; 4. The mode of lifting the propeller by means of a spiral thread or screw encircling the shaft, as described.

## ESCAPE WATER-VALVE FOR MARINE STEAM-ENGINES.

By ROBERT WADDELL, of Liverpool.

[*Paper read at the Institution of Mechanical Engineers.*]

THE horizontal engine has of late years become a favourite engine in the British navy, for the screw steam ships have the advantage of being better protected from shot than the vertical engine, as the horizontal engine can be placed in the ship entirely under the water line; the boilers are also kept as much under the water line as possible, for the same purpose. All boilers are liable to prime, but when they are confined in the height of steam room, they are more apt to do so, as in this case, and carry a considerable portion of water from the boilers into the cylinders along with the steam. Water in the cylinders has, no doubt, been the cause of more accidents to engines than anything else; and many cases occur of the bottoms of cylinders being forced out, pistons broken, piston-rods bent, and side-levers broken—all from the effects of water in the cylinder. This can easily be accounted for, from the great power the one engine has over the other when water accumulates in the cylinder; the two engines being connected together in right angles, if a few inches of water has got into one cylinder, which will prevent the piston from getting to the end of its stroke, the opposite engine will be near half-stroke, at which point it gives out the greatest power, as the piston and crank are travelling near the same velocity, while the piston of the first engine, from the position of the crank, is nearly at a stand; then the power of the second engine, exerted to compress

# HASLINGDEN SCHOOLS.

Thos Holmes, Archt

Plan.

J R Jobbins

the water, will be in proportion to the difference of velocity of the two pistons, plus the momentum of the engine. The fly-wheel of the land-engine acts on it in the same way when the engine is turning its centre.

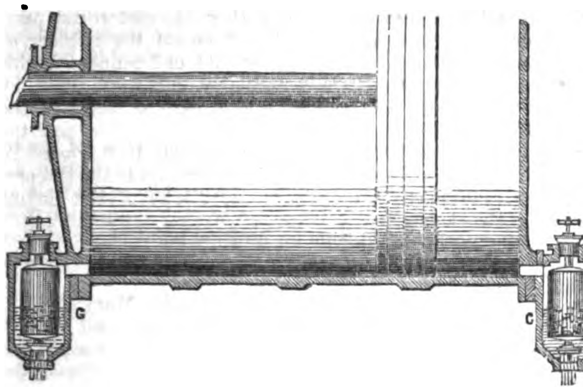

Fig. 1.

Escape water valves have been applied on cylinders to take off the water, to prevent accidents taking place from the accumulation of water in them, but with little success. The fault of the ordinary escape water-valve is its being loaded like a safety-valve, so that no water can leave the cylinder till the piston forces it out, and then the strain is very severe, from the small area that the water has to pass through, which causes the damage to the engine.

The object of the improved escape-valve, described in the present paper, is to draw the water off the cylinder throughout the stroke, and not allow it to accumulate, as with the ordinary escape-valves, till the piston strikes the water. The construction of the valve is shown in the accompanying engravings. Fig. 1 is a horizontal cylinder, with an escape water-valve attached to each end, to the flange G, shown separately in fig. 2. B, is a small cylinder attached at G; F, is a float inside the cylinder, a spindle passes through the float, and is attached to it. A, and C, are two conical valves nearly in equilibrium, attached to the spindle with nuts at top and bottom of the cylinder; the top valve A, is made like a piston on the under side, so that when it leaves its seat it will prevent a great rush of steam from passing. It is also made slightly larger than the lower valve C, so that the pressure of steam will assist in raising the valves, and a small accumulation of water about the float will open the valves; that is, suppose the float, valves, and spindle weigh 50 lb. for the largest size of engine, and the pressure of steam in the boilers not to exceed 15 lb. per square inch, and the top valve to be 3 inches more area than the bottom; then there will be three times 15 = 45 lb. excess of pressure on the upper valve, being within a few pounds of raising the valves, without any water about the float. The float should be made with sufficient buoyancy to raise the valves when there is no pressure of steam to assist.

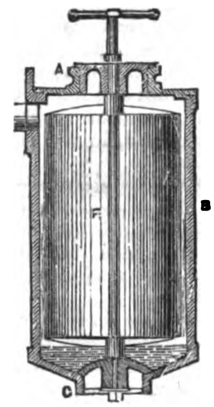

Fig. 2.

It will be seen from the construction that when water enters the small cylinder from the steam-cylinder, the float is buoyed up, opening the valves and allowing the water to escape through the bottom of the small cylinder. There is a hole in the spindle to carry off any water that might collect in the float.

The top valve is made larger than the bottom one to answer two purposes, namely, for the pressure of the steam to assist in raising them when a small quantity of water comes about the float; and, secondly, when a vacuum is formed in the cylinder the valves are kept shut by the atmospheric pressure being greater on the top valve than the bottom one; this will be the case if a great quantity of water enters the steam cylinder, the valves will then be kept open running it off, until the exhaust takes place.

The drawings show an escape-valve suited to a 400-horse power engine, with 93-inch steam cylinder; the escape-valves will then be about 6 inches diameter, and the float about 13 inches; this will give the float sufficient buoyancy to rise and open the valves before it is entirely covered with water, besides the assistance of the differential steam pressure on the valves.

## HASLINGDEN PARISH CHURCH SCHOOLS, LANCASHIRE.

(*With an Engraving, Plate* II.)

These schools are near the parish church, and have a most commanding prospect, looking over hill and dale, and bordering on an extensive churchyard, by which it is bounded on three sides. The style of building is of the early Decorated period. The plan consists of two schools, one for boys, the other for girls, each 56 feet long by 22 feet broad, with lavatories and conveniences attached. A spacious playground at the back of each is now in course of formation. There are north and south porches, the latter forming a lofty bell turret, as seen on the engraving. The walling of the schools is composed of thin flag pierrepoints, varying from 3 to 4 inches deep, of a rich, warm brown colour, with dressings of a light-coloured freestone. The walling is pitch-faced, the dressings tooled.

The western windows are large, deeply and richly foliated, and the chimneys, instead of being, as is often the case in buildings of this kind, an eyesore, are a set-off and finish to the different facades. The interior of the schools are open to the slating, with bold chamfered and dressed principals, and the heated air is removable by the aid of triangular-hinged and ornamented ventilators, worked by cord and pulleys on the school walls. The whole of the woodwork is stained and varnished. The doorways have large flowing and ornamental wrought-iron hinges and stancheons, with escutcheon locks, and handles of the same style. The chimney pieces are in keeping with the school, being exceedingly quaint in their design. It is intended to throw down a portion of the present wall of the churchyard and erect a low deeply-coped one, with buttresses every 12 or 14 feet apart, filled in between with a neat, plain railing of an ecclesiastical pattern, and which will add greatly to the beauty of the whole.

The approach to the schools is intended by an arched portal from the west leading to each porch.

The cost of the entire works will be about 1350*l.* The architect is Mr. Thomas Holmes, of Bury, Lancashire; the builders are natives of Haslingden. The parish church itself, which forms a back ground, is to be rebuilt.

## REVIEWS.

*Illustrations of the Spires and Towers of the Mediæval Churches of England, preceded by some Observations on the Architecture of the Middle Ages, and its Spire Growth.* By Charles Wickes, Architect. In Two Volumes. Vol. I., *Spires.* London: Weale. 1853-4.

The current topics of the day are, to a great degree, echoed in its general literature. And this is but natural, considering how intimately they are related. Questions which demand a more than ordinary range of thought, or that occupy a large share of public attention, can best be discussed in the arena of letters, and it is no bad criterion of the importance of a theme to find its salient points vigorously contested, or of the difficulty of its solution by the number and array of names enlisted in the investigation.

Undoubtedly, one of the most remarkable features of the present day (in the world of art at least), and a fruitful source of agitation, is the active sympathy which has been excited in all that pertains to the productions of mediæval times. Curious books and manuscripts have been hunted out—old relics stored—quaint carvings furbished up—the gorgeous pile and desolate ruin alike explored, in due devotion to that mysterious genius which presided over the craftsmen of the age, and stamped originality, beauty, and variety on their handiwork. Modern artificers are their humble imitators, and, creeping before they venture to walk, will furnish us with churches, houses, and furniture, "done after approved Gothic forms."

Whether all this be, as some will have it, a mere mania, shortly to disappear like other whims, or destined to survive, remains to be seen; but where the advocates of a movement claim for it the sanction of common-sense, adaptability, and experience, backed, moreover, by practical evidence (and one fact is worth a host of theories), their arguments are worthy of every consideration. Personal research is in all cases to be preferred; but failing this, the patient labours of others. In both these respects, the study of our ancient architecture is greatly facilitated: our railroads wing us through the length and breadth of the land, and our mine of information is continually receiving valuable accessions from the press.

Among the most notable of those which have lately seen the light is the one now before us, by Mr. C. Wickes, architect, of Leicester, who has produced a large and beautiful work on the 'Spires and Towers of the Mediæval Churches of England.' This book has been long in preparation; indeed, the author states in his preface that it "was commenced by him *imberbis adhuc.*" It is gratifying, on referring to the prospectus, to find that the promises therein made have been rigidly observed; that the lithographs are equal in fidelity and artistic effect to anything of the kind hitherto produced, and that the style of finish throughout is in excellent taste. The scale of the delineations is ample, showing the character of even the smaller parts with commendable accuracy. It is just the kind of work likely to be serviceable;—to the professional man in bringing before him some of the choicest realisations of his art, which he is thus enabled to analyse and compare; and to the community at large in propitiating them in favour of what is often rendered a needlessly dry and insipid study.

The letterpress is devoted chiefly to the history and progress of mediæval architecture, and the modifications it assumed in its various stages are cursorily defined. This part of the work is evidently prepared more for the benefit of the uninitiated than the experienced reader; but, inasmuch as it is not devoid of technical expressions, and is totally unaccompanied by diagrams (that invaluable assistance), it might have been rendered more generally useful. Then again, when the author, having traced the distinctive features in the different styles,—in the nomenclature of which, by-the-bye, we see he follows Rickman,—sums up the beauties of all in so eulogistic a manner, one might almost be disposed to infer, that, to use an Irishism, each is the most perfect of all the rest. Thus, after remarking on the *Early English*, and quoting Mr. E. A. Freeman's opinion, that its detail "possesses the most exquisite loveliness of any style of architecture whatever," he adds, "In conclusion, we would again draw attention to the peculiar interest that attaches to this style, and the claims that it has on our national regard." In dilating on the succeeding style (*Decorated*), he pictures a fabric in all its glories, and pronounces on it that "Art has exhausted her powers," &c. Of *Perpendicular*, "We would remark on its wonderful adaptability to all the requirements of church architecture, and its consequent claims to be recognised in this the 19th century as our national style."—(What will some of our ecclesiologists say to this?)

Doubtless Mr. Wickes is able to reconcile these opinions, and would have explained himself more fully, but for the fear of adding too much to an already bulky volume, and thereby rendered it inconvenient for reference, besides increasing the cost of its production. Nor is this latter consideration a minor one; it is notorious that architectural works (exclusively such) are seldom remunerative, and for this reason, that while the outlay necessarily incurred is often large, if they are of any pretensions, the proportion of readers of that class of book is but comparatively small. Hence we cannot be surprised if an author, only on the score of policy, endeavour to make his book attractive beyond its more immediate sphere; and hence the desultory and superficial tone it is apt to assume. But when, as in the present instance, a comprehensive subject is taken in hand, it ought to be fully, fairly, and systematically met. And, notwithstanding the high commendation to which the work is entitled, there are several points to which, in our critical capacity, we are compelled to take exception.

It appears to us an error of judgment that, in the letterpress, the illustrations, which are the main features of the book, are but here and there alluded to, and that incidentally. The author acknowledges this, but promises in another volume a detailed and critical examination of each. But, besides the implied presumption that every possessor of this volume will have the other also, this second is to consist solely of *Towers*, so that the separation is both inconvenient and unnatural. We could better have spared the Historical Essay than these explanatory notes.

Nor, turning to the plates, do we see any reason for their irregular order, although we have read the author's paragraph subjoined to the index. This would be scarcely worth notice, but that by the present arrangement they are deprived of all chronological interest. Ranged according to their approximate dates in the second index, they would have been far more consistent and useful than studied variety. It may be preferable, however, to reserve our remarks on this head till we have made our readers more familiar with the work by a sort of running comment on its contents.

First, then, we are presented with a glorious view of the triple-spired cathedral of Lichfield, lithographed to perfection, and forming an appropriate frontispiece. Two other cathedrals are included in the series, viz.: Salisbury, a worthy companion to the former, and Peterborough, from an unusual point of view, showing the fanciful design of the south-west tower and portions adjoining.

From Stamford two specimens are selected, St. Mary's and All Saints. The first is a well-known example, compound in style, yet harmonious in outline and detail. All Saints has some good points, but scarcely sufficiently important for special illustration. Of the north entrance, which is curious, but a glimpse is caught. Belfry windows of this type (double under a comprising arch) show a better example in Grantham (Pl. 5); and of the turretted parapet (a not very common design), Kettering, Exton, and Oundle, are given in other plates.

Kettering (Pl. 13), is one of the best Perpendicular steeples, and derives additional advantage from its favourable site.

Exton is also a successful design. The tower parapet, as we have just stated, has turrets at the angles, and from within springs an octagonal lantern crowned with a spire.

Plate 3 exhibits a careful drawing of Raunds tower and spire, one of the purest and loftiest in Northamptonshire, and early in date.

The next illustration is Keystone, Huntingdonshire, which has never, to our knowledge, been published before. It is a charmingly simple and good design. The panelling above the belfry story is unusual, but in keeping with the style, and so is the beautiful little square window set angularly in the first stage of the tower. The doorway below is exceedingly rich and effective. Though the double archway here introduced is not uncommon, the gabled and pinnacled exterior is a localism of which the same idea is traceable in Rushden (Pl. 25,) as also in Oundle (Pl. 15). Swineshead, in the same county is, if we recollect, another instance.

The magnificent steeple of Grantham next comes before us. The direct west view of this church is surpassingly grand. From that point it is not seen that the upper part of the aisle walls is a useless mask, and undoubtedly a great blemish in the design; as is also a similar instance, in the west front of Salisbury Cathedral.

Next we have views of Newark, and St. Mary's Redcliffe, Bristol—both well known.

Not so is Bloxham, a particularly interesting specimen, unique in design, whose beauties are at first scarcely appreciable in the outline plate. The diagonal buttresses to tower, and their mode of transition into other forms, are deserving of study, as are also the west doorway and the details generally, which are of unusual character.

Patrington is a curious design, also unique; this view includes the whole of the west end of the church, a valuable example. Oundle (Pl. 15) has all the characteristics of the Perpendicular style most severely carried out. We have before referred to its turrets. In striking contrast with this we have in the next plate a view of Louth steeple, an earlier offspring of the same style, and perhaps its most symmetrical specimen.

Next leaf but one we find its rival, St. Michael's, Coventry, a still more elaborate composition. This spire is loftier than that of any other parish church in England, being about 300 feet high; that of Louth is a trifle less. The beauty of the lantern between tower and spire, and the light double-flying buttresses have often been noted. The construction has been also evidently planned with mathematical study.

St. Nicholas, Newcastle-on-Tyne, is another triumph in construction, and well known.

Ketton is a beautiful example, and so is Market Harborough, but the latter is not here shown to advantage. The spire, too, is not quite perspectively correct at the eaves, which gives it a heavy appearance, inconsistent with the original.

Walcot, in the same plate, we suppose is to be accepted as a specimen of that class of steeple of which Ewerby stands the pre-eminent type. The author, alluding to the latter steeple and others, states that they would have found a place in his list had they not been so well illustrated in former publications; but the same might be said of others which he has admitted; yet the omission of Ewerby we think a great mistake, as, though it is simplicity itself as regards its parts, the exquisite proportions constitute it, probably, the most perfect steeple in existence.

Desborough is plain and good. (Where is its soaring neighbour, Stanion?)

Bythorne is a very poor affair, and yet within a stone's throw of Keystone. (See Pl. 4). It is the most indifferent in this collection.

The examples to which we have now arrived are drawn to a smaller scale than those in the earlier part of the volume—(it may be through press of matter)—but, generally speaking, they are clearly interpreted. We should have liked to have seen Rushden on a separate plate; it is a most superb design and cannot be too well studied.

Thaxted is another favourite. Steeples are rare in Essex, and we are glad to see this has not been overlooked. Lostwithiel is a curious little tower and spire. The sloping back from square to octagon is quite a Cornish peculiarity. There are several other specimens in this work, partaking very much of characteristics already enumerated. Indeed, this appears a fault in the series, that variety as to style and type has not been sufficiently exhibited. There is a progressive history which may be traced in the subject, and which the scope of this work might have instructively realised. Early examples, showing the successive transitions, might have been more freely introduced without diminishing the general interest.

Sutton St. Mary's is the only example given of a certain class (as Bibury and Almondbury); while the earlier shingle spires, such as abound in the once woody parts of England, are totally unrepresented. Horsham, or Lindfield (Sussex), would have been good instances.

Then we miss altogether a class of spires, of which Warmington, Hallaton, and Sleaford are such marked specimens. And again, St. Peter's, Aldwinkle, later in style. That of Warmington is one of the earliest stone spires known, and one of the most enriched. Perhaps it may be said, that it is already familiar; but still it deserves a place in illustrations of "spire growth." We have a right to expect at least one example of every development of a principle. Enrichment is not indispensable; some of the most valuable are indebted to their outline only.

The author appears to have confined himself too exclusively to the acceptedly beautiful proportion of nearly equal tower and spire, and other characteristics of those glorious groups which are to be met with in Lincolnshire and Northamptonshire. But there is a vast diversity in feeling created between the proportions of the needle-like Glinton and its diminutive neighbour Helpstone, without holding up to admiration either extreme.

There is effect also in materials as well as form, as the parti-banded masonry of Irchester will show, which we should like to have seen illustrated among the rest, as also a few diagonally buttressed towers, such as at St. Sepulchre's, Northampton.

In default of more palpable delineation, we shall look for a due recognition of all these features in the forthcoming history, as far as *description* will serve; but we strongly recommend a few marginal diagrams, if only in outline. The idea, which is but imperfectly conveyed by a multitude of words, may be often correctly expressed by this means in a tithe of the space. And we would moreover suggest,—and the thought may have possibly occurred to the author,—that from the mass of information which he must have accumulated, but which it will be impossible otherwise to make use of, an interesting and invaluable tabular list might be compiled and appended to his descriptions, indicating the several features of towers and spires (arranged chronologically, as far as possible), the leading features of their design, and other items, which would make the information on the subject generally as complete and useful as possible.

---

*The First Principles of Perspective Explained Theoretically and Practically, in a Course of Easy Studies.* By Felix Duffin. London: Spon, Bucklersbury. 1853.

In his introduction Mr. Duffin very justly observes:—

"To many, at first sight, the study of perspective has appeared so much enveloped in mystery that the idea of progress therein in the only manner likely to afford a feeling of satisfaction has been abandoned at the outset, owing to the dread of difficulty, while, in point of fact, the principles of the science are theoretically simple, their application practically, of great utility in the ordinary intercourse of life, and certainly most elegant adaptations of mathematical science."

This "mystery" that Mr. Duffin alludes to arises from the complex system (to most) in which writers on perspective seem to delight in shrouding themselves, as if for the express purpose of preventing ordinary students (who generally have not time to throw away in unnecessarily lengthened explanations) from grappling with the subject.

Another thing which occurs in this pamphlet, as in most others, is a number of unnecessary geometrical problems, of little use except to make the book look thicker, for we really cannot believe that it is required to show to the generality of students in perspective, how to draw two parallel lines, and some other of the propositions found in the first book of Euclid, as, for instance, "To let fall a perpendicular from a given point on a line," "To form an equilateral triangle upon a given line," &c. But should it be really necessary in teaching perspective to the young idea, we are only very sorry for it, and regret that geometry is so little understood as to require the insertion of such in works on perspective. However, we recommend the perusal of Mr. Duffin's very cheap and useful little book to those who may require information on the subject; and the different objects in the plates, the plane of picture, plans of subjects to be represented, &c., having a slight tint of colour on them makes them more easily understood.

---

*Practical Remarks on Railways and Permanent Way, as adapted to the various Requirements of Transit.* By William Bridges Adams, Engineer. London: Effingham Wilson. 1853.

Mr. Adams has been long known to the railway public for his practical economics in the mechanical operations of railways, adjusting means to ends with a view to the combined profit of the shareholders and the accommodation of the public, demonstrating in his former work on 'Road Progress,' and elsewhere, that for passenger-traffic light and frequent trains would best subserve the public wants, and at the same time diminish the wear of the moving and fixed plant, and which improvements were noticed some years back in this periodical. Mr. Adams is also known to the building world as the inventor of improvements in street paving and drainage, with the object of getting rid of dust, mud, and water, and avoiding annoyance to passengers and shopkeepers; and also for a mode of constructing flat floors or roofs of great span and duplicated strength without intermediate supports below. Apart from his improvements in locomotive engines and carriage machinery in all its branches—which may be found partially described in the 'Railway Machinery' of Mr. D. K. Clark,—Mr. Adams has been a large contributor to the press on mechanical as well as intellectual and moral subjects, and more especially as connected with general progress and the improvement of the working classes. Many of his contributions have been anonymous in the *Westminster Review* and other publications, and to some he has appended his name. His work on 'English Pleasure Carriages' is well known, as also 'Road Progress,' and other similar subjects; but many of his anonymous contributions are not generally known as from him. In the *Mechanics' Magazine* of 1831, there is to be found a paper of his, entitled 'Better Housing the Working Classes,' the original proposition for the model lodging-houses of the present day; and in another paper, in 1848, the same plans are advocated at greater length; but the buildings on Mr. Adams's system have yet to be produced. In a paper in the *Monthly Repository* on 'Housebuilding and Housekeeping,' the same plans are advocated for the middle classes. About the period of the first paper we find, amongst other minor things, a proposition of his for the identical steel-ribbed umbrellas of the present day. In the proceedings of the Institution of Civil Engineers it stands on record that Mr. Adams was the first originator, in the pages of the *Westminster Review*, of the glass and iron structure in Hyde-park, known as the Crystal Palace. We may add that in the pages of the *Journal of the Society of Arts* he has been a strenuous defender of the claims of originators under the protection of Patent Law, and in the columns of the *Spectator* are to be found many contributions of his on mechanical and other subjects, more especially on the important question of the "storage of grain," so as to produce "equalisation of price." The gold question has also been treated by him, showing the probability of the abundance of gold previous to the Californian discoveries.

Mr. Adams has been for a long period a worker for the public, and we have given this brief sketch of his labours because his writings have never been collected together, and few know where to refer to them.

The present publication deals, in the first place, with the economical question of railways, as to their uses to the public and the various classes of railways that are required; for it is a great mistake to suppose that all railways, whether trunk or main, or minor branches, should all be made on the same system, and this mistake has been the source of much mischief to the great lines.

In the opinion of Mr. Adams it is impracticable to run fast express trains on the same lines as heavy and frequent goods trains, with any safety to the public; and he thinks that there is wealth enough in many of our cities to pay for the construction and working of especial passenger lines at forty to fifty miles per hour, at a moderate rate of mileage. After demonstrating the principles that should govern the construction of permanent way, and of the engines to run on it, he thus proceeds:—

"Assuming the foregoing to be the principles that should govern the structure of rails and locomotives, the next consideration is, the social and commercial requirements. Let us first consider the question of

*High Speed Lines.*—Passenger trains actually travel at speeds of from 50 to 60 miles per hour on rails in inferior condition. This rate of speed involves considerable risk from bad joints, and from collisions with other trains travelling at various rates of speed. If light engines and light trains were used with corresponding rails in thorough order, and with no impeding traffic, these rates of speed might be maintained without any risk, and without any immoderate cost. But it would not do to permit any heavy destructive goods' traffic on such lines. If goods were permitted the engines and wagons should be equally well constructed with the passenger trains, and, if not travelling at the same speeds, the intervals of departure should be considerable.

"But would it pay to have distinct passenger lines of great speed?

"That must depend on the wealth or commercial importance of the district. If the expenditure in law, land, and compensation were light, lines of double way might be constructed for fast light trains at the rate of 15,000*l.* per mile, including locomotives and rolling stock. As such lines would be independent of communication with other lines, the gauge of 5 ft. 6 in. would be chosen as the now generally acknowledged eligible width. The convenience of man would be studied as the datum line for the construction of the carriages. They would be lofty enough to permit standing upright. They would be 10 feet in width, with a central passage-way for the guard to pass from one end of the train to the other, getting out of the great difficulty of communication between guard and driver. On either side the passage would be enclosed cabins or apartments for four persons each, for passengers wishing to be private; and open saloons would be provided for the gregariously disposed. The seats should be arranged to fold, so that each passenger might sit or stand at pleasure,—an important consideration to induce free circulation of the blood. Arrangements would exist to provide tea and coffee, and similar refreshments while travelling, and also for warming, ventilation, and lighting, and, by fitting construction, easy movement, and absence of oscillation, would enable the traveller to read or write at pleasure. In this mode a constant speed of 50 miles per hour could be maintained without the necessity of the traveller alighting, or injuring his health by swallowing food in too great a hurry, or at too distant intervals of time.

"If we assume a line 100 miles in length, and the cost of it to be 1,500,000*l.*, it would require 75,000*l.* per annum to pay interest at 5 per cent.; or say 206*l.* per diem. Assume maintenance at 10,000*l.* per annum, that would be, say 28*l.* per diem, total 234*l.* The expense of trains would be say 15*l.* each, going and returning a distance of 200 miles, with accommodation for say 150 passengers each train. Four trains each way, with 75 passengers in each, at 1*l.* for 200 miles, or about 1¼*d.* per mile, would maintain the line, and pay 5 per cent. A very small staff and outlay in maintenance of way and rolling stock would suffice for such lines.

"Thus, supposing land at its agricultural value, and law and government expenses *nil*, a high speed railway might be made between London and Liverpool for about 2,500,000*l.* Four high speed trains, with 75 passengers each, going and returning the whole distance, at 2*l.* per head, say 360 miles, would pay all expenses, and give 5 per cent. to the shareholders, and the passengers might go and return the same day within twelve hours, giving an interval of four hours to business. In other words, 2000 annual subscribers of 100*l.*, or 50 journeys per annum each, could maintain such a line for their own use.

"The distance from Calais to Toulon is 600 miles, and the probable cost of a railway promoted by the Government, and the rails and materials furnished from England, without duty, would not exceed 7½ millions. Four high-speed trains per diem each way, or eight trains total, with 95 passengers each, at 2*l.* 10*s.* each way, or 1*d.* per mile per head, would clear all expenses, and give 5 per cent. to the shareholders. And the journey from Calais to Toulon might be performed in less than 14 hours. Making a total of say 18 hours from London to Toulon, and this with no extraordinary fatigue to the passengers.

"On the same principle a high-speed railroad might be constructed from Paris to Irun in Spain for about 5,000,000*l.*, and thence continued to Madrid. Four trains each way, total eight, with 70 passengers in each, at 1*d.* each per mile, would pay all expenses, and give the shareholders 5 per cent., with the distance between Paris and Irun reduced to nine hours.

"Whether this is worth doing now, whether England and France have advanced sufficiently far in civilisation and wealth, and the value of time,—whether it is worth while to bring Madrid within 15 hours distance from Paris, and 23 hours from London, and Cadiz within 30 hours from London, and thus materially diminish the sea distance to Panama as the highway to Australia,—whether it is worth while to bring the orange groves and balmy atmosphere of Southern France within 18 hours of London, now, is simply a question as to the numbers of the wealthy who desire it, but that this will eventually come to pass is no mere problem. It is as sure a thing, sooner or later, as the transit between London and Windsor, or Paris and Versailles.

"At present the question is, are there wealthy capitalists enough in Europe to furnish 8¼ millions of money to shorten the distance between London and Toulon to a day's journey, and 7 millions more to bring Cadiz within 30 hours of London, and travellers enough to pay interest and expenses for speed travelling at from 40 to 50 miles per hour, at 1*d.* per mile. Are there, moreover, men with political power sufficient to overcome commercial hesitation, and willing to write their names on this new scroll of the world's civilisation, rendering distance no bar to the personal communication of the powerful and intelligent throughout Europe."

Of local lines, or communications between neighbouring towns and cities, he thus writes:—

"Such lines properly worked should preserve the equilibrium in the price of labour, and of the necessaries of life throughout the whole community, and would prevent the waste now frequently occurring by the injudicious location of individual operations. They would moreover facilitate the change of employments analagous to each other, and be an industrial school on a large scale. They would break down the distinction between agricultural and mechanical labourers and workmen, and be an insurance against fluctuations of employment.

"They must be rendered more available than at present for the stowage and transport of grain. By establishing air-tight reservoirs of metal, or huge canisters, beneath the surface, grain wagons might run on rails above them and discharge their contents into the openings, which being hermetically sealed, the grain might be preserved for any length of time. Stores could thus be established in desirable situations, ready for transport at a moment's notice, at the minimum of cost, or labour. And such reservoirs, wherein the supply of a nation might be stored if so desired, would require much less proportionate outlay of capital than the ordinary inefficient granaries at present used in which the grain is exposed to damp, vermin of many kinds, and pillage, with a constant cost in manipulation."

Mr. Adams has long advocated the practical conversion of common roads into railways without interfering with ordinary traffic:—

"But by the process of laying down rails of iron on such roads the difficulty is at once overcome, and all such roads may be made available for steam traction, subject only to the question of varying gradients of greater steepness than is common on ordinary railroads. But it would be quite practicable to run engines capable of drawing 30 tons net at ten miles per hour up gradients rising 1 in 25.

"Nor need there be any objection on the score of the rails interfering with the ordinary traffic, because it is quite practicable to sink the rails to the level of the road surface, so that any ordinary vehicles may pass over them in any direction as though the rails were a portion of the ordinary paving. Rails so laid exist in many places where railways cross public highways, and there is no difficulty whatever in constructing a whole line so."

The construction of street lines for omnibuses is also recommended, and the evils of the proposed underground tunnel lines are dwelt on. The City arcade lines are shown to be preferable. But Mr. Adams prefers, for streets of great traffic, the principle of keeping the whole of the street level for the purpose of railways, and covering them in from the highway with glazed lights, making the whole of the shops on the first floor:—

"But supposing it were in contemplation to lay out a new street in a new town, the true plan would be to consider the under surface as entirely belonging to sewers and drains, and quite unfitted for either dwellings or stores. The ground floors should serve for the purpose of stowage, and the street surface should be devoted to the purpose of railways. Above these, at a given height, should be the real street for the shops and dwellings, removed one story from the earth's surface; there would thus be an easy means of getting rid of rain and mud. In fact mud would not exist, because there would be no materials for mud-making above, and transit on rails below would prevent the disintegration of the roadway. The ancient city of Chester had the shops and dwellings raised above the roadway for the sake of security against sudden violence from stranger visitors, and if the inhabitants of our streets could be persuaded to move their shops to the first floor, a much pleasanter promenade would be provided for their customers, and an atmosphere much more conducive to health. Cleaner, lighter, and more elegant shops would thus be attained, and the street would be duplicated. There would be no difficulty in arranging such terraced streets for the transit of light carriages as well as foot passengers."

Agricultural lines are considered, and the very important question of moveable lines to carry manure in and crops off the the ground.

We have found that defects are not merely pointed out by Mr. Adams without providing a remedy. The defective joints of rails are thus spoken of by him:—

"As the inventor of the 'Fish joint,' now so commonly used on railways, the writer has found practically what may be definitely deduced from theory, viz., With the ordinary double-head rails, laid in chairs in the common mode, the strength at the joints is considerably less than at the intermediate portions of the rail, therefore to produce equal strength more metal is introduced at the joints in the form of the 'fishes.' And this amount of metal or more may be economised from the ordinary weight of the rail; thus a rail of 60 lb. per yard with 'fish joints,' will be far more efficient than a rail of 70 lb. per yard without fish joints, by the equalisation of the strength."

A new plan of fixing double T-rails to cross-sleepers is shown by the annexed woodcut, and is thus described:—

"Diagram fig. 1, shows a section and plan of a mode of laying the double-headed rail in common use, so that it is entirely bedded with timber side brackets on the timber sleeper, and it will thus be free from concussion and noise. In the ordinary mode of using this rail, a cast-iron chair or shoe is spiked down to a transverse sleeper of wood. In this chair of iron, the rail is fixed by a lateral wedge of wood, and when so fixed, the top of the rail is raised seven inches above the top of the sleeper. But in the mode of fixing the rail with timber brackets, the lower table of the rail is sunk an inch into the sleeper, and thus the total height of the rail above the sleeper is only four inches, instead of seven, as when used with iron chairs. It is obvious that the more the rail is elevated, the more difficult it is to keep it firm against the lateral blows of the engine and carriage wheels. The advantage, therefore, of the improved mode in lowering the rail nearly one half, must be clear.

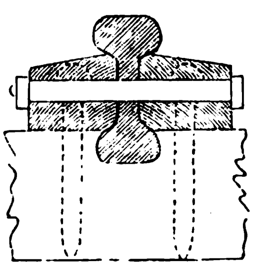

Fig. 1.

"In using cast chairs, which are spiked down to the sleepers, the spikes alone have to sustain all the lateral shocks. In the improved mode, the rail being grooved into the sleepers, takes the lateral resistance directly, and the only use of the spikes is to hold down vertically. This is a source of great safety.

"Again, the grooves for the two rails being cut by machinery, an accurate gauge is obtained and maintained, independently of skilled labour in laying down.

"Again:—The double-headed rail was originally designed for the purpose of reversing, so that, the upper side being too much worn, the lower side might be turned upwards. Practically, it has not served this purpose, because it is so battered and crushed in the cast-iron chairs, as mostly to be useless for any firm fixing in that mode.*

"But by using the rail only with timber fastenings, as shown in the diagram, the rail is in no way damaged, and may be effectually reversed.

"In the mode of using these rails with iron chairs and wood keys, the height and unsteadiness of the rail rapidly crushes and loosens the key, so that it is continually falling out. And this occurring at the joint, is a source of great danger, independently of the occasional fracture of the cast-iron chairs.

"It will be seen on reference to the diagram fig. 1, that two pieces of hard oak, or other timber, about 9 inches in length, and 3½ inches in width and thickness, are bolted by a single bolt through the rail, one in each channel, the lower rib of the rail resting on a cross channel of the transverse sleeper. Spikes are driven through the pieces of oak, into the sleeper, and the whole is secure. If the timber shrinks, the bolt is tightened in its dry condition, and will ever after remain tight At the joints, plates of iron are placed in the rail channels, between the timber brackets and the rail, the same bolts securing the whole. In some cases, in laying new rails in perfect condition, and with hard wood brackets, the joint plates may be dispensed with. If preferred the brackets instead of being in short lengths, may be continuous with the rails.

"In addition to the mechanical advantages, there is a considerable economical saving in maintenance to calculate on from the reduced height and better bedding of the rail. And by reason of the reduced height, a saving in ballast may be effected, and upon the general outlay, taking waste into consideration by breakage of chairs, the saving in laying down a line may be considered as equivalent to the whole value of the cast-iron chairs."

A plain and simple rail, admirably adapted for the United States, Canada, and Australia, and other countries where wood is plentiful, will be readily understood by the woodcut and the following description:—

"Diagram, fig. 2, is a girder rail arranged in the simplest form so as to employ the smallest number of parts, together with the maximum of vertical and lateral stiffness. It may be considered as a single-headed form with a pair of lateral supporting wings superadded at the position of the neutral axis. Two varieties are shown one larger then the other, the respective weights being 60 lb. and 70 lb. per yard, but may be increased to 70 lb. or 80 lb. The upper portion is 2½ inches in height above the sleeper, instead of 7 inches which is the height of the rail used with chairs. The portion below the side bearing wings is the same depth as above, consequently the rail has all the vertical stiffness of the double-headed rail before described, and it has moreover by means of the side bearing wings, a much greater amount of lateral stiffness, still without increasing the quantity of metal. The lower portion is firmly fixed in a vertical groove of the cross sleeper, with the wings bedded therein, and which grooves and bedding being cut by a machine ensure accuracy of gauge. The rail is fastened to the sleeper by one or more spikes or bolts and nuts clipping the edge of the bearing wings. The head or wearing table of this rail is only two inches in width. For transit of the wheels, unless under enormous and not very profitable weights, this is sufficient. The original rails were about 1¾ inch in width, and they were gradually widened to 2½ inches. But this required very much more metal, because as the rails wear down flat, the edges cut away when not supported by sufficient depth of metal. In the example shown, the head is sufficiently wide for the wheels, and of sufficient strength to prevent vertical cutting of the edges, and the two lateral wings give great strength against side shocks. This rail is steadier than fig. 1, and the economy of outlay is equivalent to all the chairs and keys, and one-half the spikes.

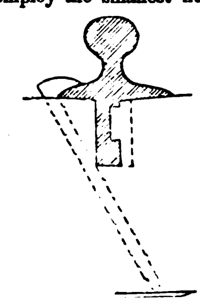

Fig. 2.

"The joints are formed by plates of iron 2½ inches to 3 inches in depth, bearing in a lateral groove of the lower part of the rail, and against the wing above, being secured by two bolts, one at each end, passing through rail and plate; the rail and joint plate being forced into the vertical groove of the sleeper, and, held down, the whole is firm.

The following explains a girder rail well adapted for countries where wood is scarce:—

"Diagram fig. 3, shows a girder rail, weighing from 115 to 120 lb. per yard, well suited to this purpose. With angle cheek plates bolted to the rails to connect the joints, and tie-bars to secure the gauge, this rail would serve very well for moderate rates of speed, and would keep in good condition in a hot climate. But when iron is at a high price it presents a difficulty in the construction of such lines. It must be remembered, however, that no other material is required. As the horizontal portion of this rail would not be damaged by occasional flaws in the edges or thin parts, it would not involve many 'wasters in the process' of manufacture."

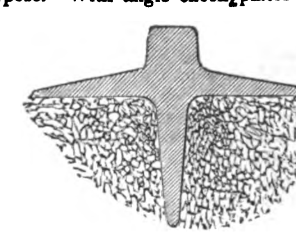

Fig. 3.

We recommend all those who are connected with railways carefully to study this publication, which contains the essential considerations how to make railways useful to the public in the widest sense, and most profitable to the shareholders.

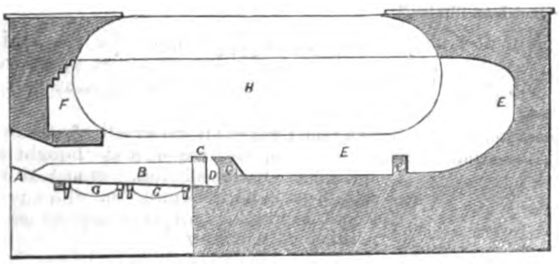
* "But in many cases, these damaged rails, unfitted for cast chairs, may be turned to account by securing them with the wood brackets. The side channels of the rails are generally unaltered in form, and to them the brackets can at any time be fastened, and the grooves in the sleepers may be cut to any form the table of the rail has taken. In this mode, several years' further work might be taken out of the rails, and the value of the old chairs might help to pay for the improvement."

## FURNACE FLUES.

BENJAMIN PRICE, *Patentee*, February 25, 1853.

IN describing his invention, the patentee says, in the first place, there is no complicated machinery, consequently no anxiety as to the probability of such being put out of order, the principle of the invention consisting in the construction of the flues, which are provided with large circulating chambers, where the various gases receive the current of air which passes through the tube B, and which is carried through the furnace; the effect

FIG. 1.



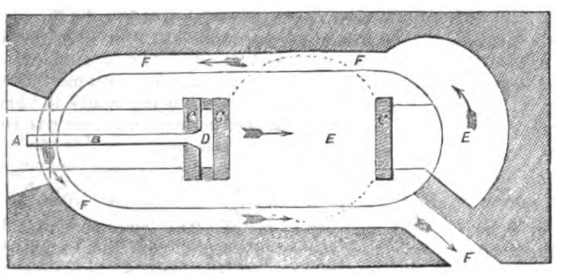


FIG. 2.

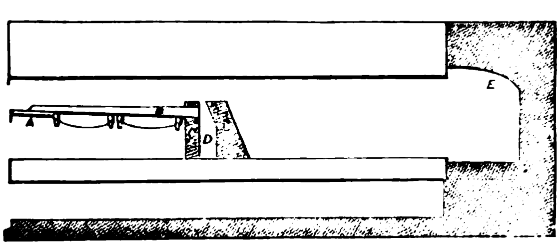
of which is, the air becomes rarefied, and the chambers supplied with the required quantity of oxygen to produce the most perfect combustion. The action of the heat is more regular than upon any other principle, and the boilers, &c., of whatever description, not so liable to destruction from caloric action. Another important feature is the saving of fuel: a furnace constructed upon any ordinary principle consumes, say, twelve tons of coals in a certain specified time; a more satisfactory result at a more uniform rate will be obtained by using nine tons, or even eight tons, upon this improved patented principle, thus showing a saving of from 25 to 30 per cent.

FIG. 3.



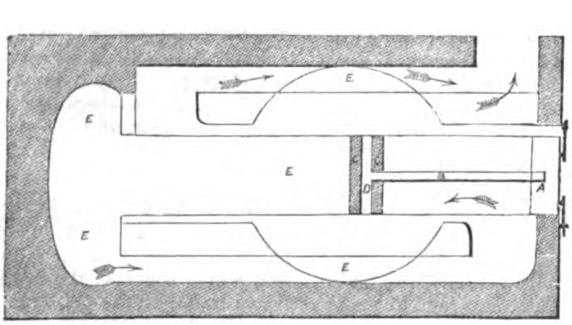


FIG. 4.

Fig. 1 of the annexed engravings represents a longitudinal section of a boiler and furnace built in accordance with this invention; fig. 2 a sectional plan of the same; fig. 3 (a longitudinal section) represents a modification of this furnace, with a different arrangement of the flues; and fig. 4 a sectional plan of the same. A, is the dead plate of the furnace; B, a tube, which passes from the mouth of the furnace through the first of the bridges C, C, C, and is connected with a hot-air chamber D. This chamber D, communicates with the circulating chambers E, E, and is constantly supplied by the pipe B, with a current of hot air, which being distributed through the chambers E, E, and mixing with the smoke and gases contained therein, insures their perfect combustion, and thereby effects considerable saving of fuel. F, F, F, are the flues; G, the furnace-bars; and H, the boiler.

## ON THE SEWAGE OF GLASGOW.

ON account of the great number and variety of chemical works in Glasgow which empty their refuse into the sewers, the contents of the sewers differ widely one from the other, and the sewage of some of them changes its character almost hourly; hence the treatment of sewage by precipitation in tanks near the mouths of the sewers becomes impossible, as no precipitant will answer for any two sewers, or for the same sewer at different times of the day. The sewage nuisance is become most intolerable and deadly in Glasgow; the river is in parts covered with a filthy yeasty foam, and in summer the " noisome reek" from the water, when stirred up by the paddles of the steam-vessels, often cause the passengers by these vessels to become exceedingly sick and ill.

In conformity with Lord Palmerston's recommendations, in his letter to the Synod of the Church of Scotland, the city authorities of Glasgow and the Clyde Trust Committee, with their excellent officers, Messrs. Carrick and Eure, have been anxiously endeavouring to remedy this crying evil, which threatens so seriously to interfere with the commercial prosperity of the city. We copy the following from the *North British Daily Mail* :—

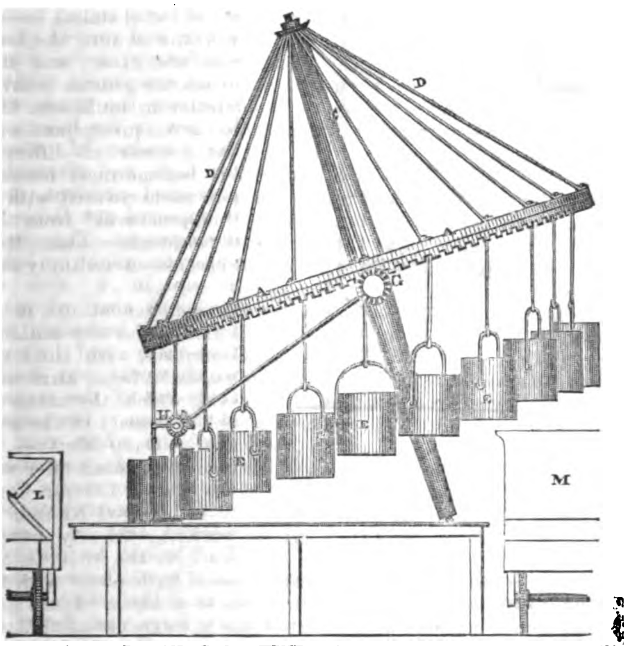
" It will be in the recollection of our readers that an offer was recently proposed for the acceptance of the Statute Labour Committee of Police, by Mr. Smith, whereby he pledged himself to enhance the amenities of the Clyde by purifying the city sewage, on the condition that the corporation gave him the title to the manure for the next 14 years. This proposal to do away with the pestiferous impurities which have so long been matter of just complaint by the citizens, without involving any expense to the corporation, was so fair and reasonable that a public test of the plan by which it was to be carried into effect was only wanted to secure its acquiescence. This desideratum was supplied lately on the river side, immediately opposite the foot of Dixon-street. Mr. Bardwell, of London, the patentee, attended personally to superintend the experiments. The process of purification as exhibited on this occasion, was exceedingly simple. The water operated upon was taken from St. Enoch's Burn by means of pipes, and being pumped up with a slight fall it ran down through a filter-bed, and thence was carried off by a common rhone. The filtering media consists of iron scoria, charcoal, and sand, which retain the filth, leaving the water as pure as that to be found in domestic use in many of the private dwelling-houses on the north side of the river. Although it was sufficiently clear for all practical purposes, the water could be made much purer by thickening the filter bed, which, however, would retard its exit, No offensive smell is raised by the process, a perforated bed on the top of the apparatus strewn with charcoal absorbing all the noxious effluvia thrown off by the residuum, which is very valuable for agricultural purposes, being a rich manure. As a matter of course the experiment was conducted on a small scale; but we understand that a filter of 60 feet square would be capable of purifying 5,000,000 gallons of water per diem. Were the plan adopted in this city the sewage of a particular district would be taken up first and purified in a grand centre filter communicating with all the drains in the locality. The gentlemen present all expressed their unqualified satisfaction at the result of the experiment, which was highly successful. Now that the authorities have witnessed the practicability of a scheme, whereby the great generator of disease in our city may be effectually abolished, we hope that they will enter into arrangements with promptitude and vigour for having it tried on some of the great sewers—at the Bridge of Sighs for example."

## IMPROVED COKING CRANE FOR SUPPLYING LOCOMOTIVE ENGINES.

By John Ramsbottom, of Manchester.

*[Paper read at the Institution of Mechanical Engineers.]*

This coking crane was designed by the writer about two years ago, in consequence of the great wear and tear of coke skips used for coking engines, at the Manchester station of the London and North-Western Railway, and the necessity that more particularly existed for coking the engines in the least possible time, owing to the limited space there was then for the traffic. The crane is shown in the annexed engraving, and consists essentially of a large wheel or circular rim 20 feet in diameter, made of iron segments A, A, having arms B, B, 20 in number, which may be considered to be the jibs of so many small cranes. These are



mounted upon one common post or pillar C, C, which revolves upon bearings at top and bottom, and each arm or jib is tied by a rod D, D, to a hollow cast-iron cone, which is fastened upon the top of the pillar, and is adjusted by means of a screw and nuts. In fact, the whole may be considered, so to speak, as twenty small cranes working from one common centre. Around the circumference of the rim are suspended, at equal distances, twenty wrought-iron cylindrical buckets E, E, 2 ft. 6 in. diameter, and 2 ft. 8 in. deep. Each bucket is fitted with a bow handle and swivels, so as to be readily turned over when its load is to be discharged. The segments A, A, are also provided with teeth upon the lower edge, which gear into a pinion G, and the movement is carried forward to the handle H, by means of the two pairs of bevil wheels, and in such proportion as to give 115 revolutions of the handle for one of the crane. The chief peculiarity, however, consists in the main post being fixed in an inclined position. This is done to such an extent as to throw one side of the rim 6 feet higher than the other, and it will be seen from the drawing that the buckets on one side are sufficiently low to be filled direct from the wagon L, and on the other sufficiently high to deliver their loads upon the tender M. The buckets hold in the aggregate 3 tons of coke, so that the crane will carry, ready for delivery at a moment's notice, sufficient coke to supply three passenger or two goods engines at least. Of course, when the crane is fully loaded, the whole is in equilibrium, and it can then be moved by a force sufficient to overcome the friction only; on the other hand, the greatest power is required when the buckets are empty on the descending side, and full on the other. The proportion given, however, will enable one man to work it under the worst circumstances.

In using this crane, the practice is to keep the buckets full as far as circumstances will allow, and any engine requiring coke has the tender backed under the higher edge of the crane; the coke-man then turns the crane round by the handle previously described, and continues to do so until the fireman or other person has turned over as many buckets of coke as are required. The time rarely exceeds two minutes for the delivery of 21 cwt. of coke, and is often less.

As respects the saving of labour, it may be mentioned that four men were formerly required to deliver coke at this station, and it is now delivered by two, and the skips are dispensed with.

The fact that this little machine has worked very satisfactorily during the last two years induced the writer to bring it before the meeting. It evidently possesses the advantage of carrying a considerable quantity of coke ready for immediate delivery, and of elevating, advancing, discharging, returning, and lowering the buckets by one simple movement.

There is one slight drawback, however, namely, that an engine cannot run past it, owing to the chimney; but where this is considered necessary, the crane may readily be fixed about 3 feet further from the rails, and the coke delivered by a moveable shoot.

*Discussion.*—Mr. Beyer (the Chairman) observed, that he had seen the coking crane described in the paper, and thought it a very simple and efficient plan; the one objection that had been named, of not leaving space for passing along the line by the side of the crane, might probably be remedied in several ways if required in another situation.

Mr. Ramsbottom said that object had not been thought of at all in the present case, as it was at the termination of the line, where it could not be extended beyond the crane, and that was the only one on the plan at present tried. The crane had been found very convenient for use, as it required very little power to work it, and held a large store of coke always ready for loading the tenders; it had been in constant work for more than two years, with scarcely any expense for repairs.

Mr. Cowper thought the crane was well contrived for the purpose, and suggested that it might readily be made applicable to a situation where a clear passage was required on the line past the crane by omitting a portion of the buckets on one side, perhaps one-third, which would always allow the passage of a train, when the blank side was turned towards the line; the same quantity of coke might be carried by increasing the size of the buckets or the diameter of the crane. He thought that a perfect coking crane should, if possible, be balanced in all positions, for the engineman to be able to pull it round by hand, and take in a supply of coke without requiring a second man to help; on the same principle as the present large 8-inch water cranes which supplied the water with great rapidity without help. This might be accomplished by working the crane round on a level instead of inclined, so as to be always balanced, and lifting the coke up previously to the level by other means.

Mr. Woodhouse thought there would be a difficulty in raising the coke by other means, and the oblique crane which he had frequently seen at work was a very convenient mode of gradually raising the coke by the same movement as changing the buckets. In some places the coke was raised up at once from the wagons to a high platform, and then loaded into the tenders by a shoot; but that plan was not so convenient for measuring the coke as the crane with buckets holding exactly 3 cwt. each.

Mr. Ramsbottom observed that the average height the coke had to be lifted in loading the tenders was only 3 feet, as the coke was already lifted an average of 3 feet, or half the total height 6 feet, in the process of filling the buckets all round.

Mr. Cowper suggested that each bucket when loaded on the platform might be slung up or raised by a small windlass, and then hooked on to the crane at the upper level.

Mr. Ramsbottom observed, it would certainly store up more power ready for coking the tenders, if all the coke were previously lifted up to the full height 6 feet, instead of an average of only half the height; but the simplicity of the machine would be somewhat interfered with.

Mr. Downing remarked that there might be room to pass the crane by fixing it a little farther from the line, and tipping the buckets over the side of the tender; there being no necessity he supposed to empty over the centre of the tender.

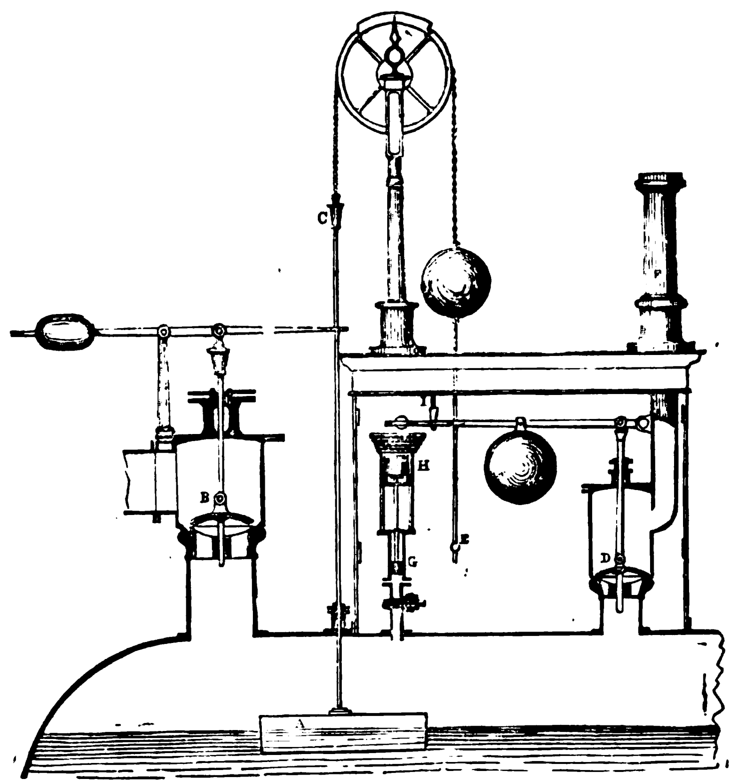
Mr. Lloyd suggested an octagon form for the purpose instead of a circle; he thought the same plan of crane would suit well for filling blast furnaces, where, as in Wales, there was not more than 6 feet to lift the materials in many cases.

## APPARATUS FOR PREVENTING EXPLOSIONS OF STEAM-BOILERS.

By John Rolinson, of Brierley-hill.

[*Paper read at the Institution of Mechanical Engineers.*]

The object of this apparatus is to provide a self-acting means of closing the stop-valve, and opening the safety-valve, when a boiler is getting short of water, thereby cutting off all communication with the other boilers until the boiler is again properly supplied with water, and causing an alarm to call the attention of the engineman, before the water has got so low as to risk any injury of the boiler, preventing at the same time any increase of the pressure in the boiler.



Our engraving is a longitudinal section of the apparatus. The float A, falls when the water gets low in the boiler, and closes the stop-valve B, by the tappet C, and opens the safety-valve D, by the tappet E, causing an alarm by the rush of steam through the escape-pipe F, as soon as the water gets down to the level to which the apparatus is adjusted, without the use of a whistle.

In a range of boilers working in connection, it sometimes occurs, from various accidental causes, that one of them becomes low in the water, causing danger of explosion, but with this apparatus such an accident is prevented; and by closing the stop-valve and opening the escape-valve, the boiler is cut off, and prevented from causing accident until properly filled with water again, when it resumes its former position, as the stop-valve then opens again and the escape-valve closes.

The pressure of steam is prevented from ever getting too high in the boiler by the small cylinder G, with a piston one square inch area, which is open to the boiler on the underside, and is loaded on the top of the piston-rod at H, with as many pounds weight as the number of pounds pressure per square inch intended for the limit of the steam pressure. The piston lifts these weights in succession as the pressure rises, and at last lifts the lever of the escape-valve D; a space is left between the different weights, so that the piston has to move nearly to the top of the cylinder before it comes to the full pressure, and by the continual movement of the piston in the cylinder from the variations of pressure in the boiler, the piston is prevented from sticking fast, and is kept always ready for action.

The escape-valve lever is held up by the spring catch I, if it continues to be lifted beyond a certain point, and then the escape of steam cannot be stopped, and the alarm will continue sounding until the engineman, returning to his duty, releases the valve lever from the catch, by pulling the handle K.

The whole apparatus is locked up in one cast-iron box, so that the engineman is unable to increase the steam pressure, or to prevent the sounding of the alarm and the escape of the steam whenever the water level is suffered to get too low from any cause, or the steam pressure gets too high. The apparatus is connected to the ordinary stop-valve fixed usually on boilers, and requiring only an alteration of the lever.

This apparatus has been at work for about two months at Mr. Benjamin Gibbons', Corbyn's Hall, New Furnaces, near Dudley, and has proved quite satisfactory. It has been tried fully by blowing off the water from the boiler down to the level to which the apparatus was adjusted, when it was always found to act completely, and also when the pressure of the steam was raised too high.

Mr. Gibbons said that the apparatus described in the paper was applied to a boiler 6 feet diameter and 30 feet long, one of a set of three boilers at his works, and proved quite satisfactory; it was found to act completely, either whenever the water was too low in the boiler, or the pressure of steam too high, and effectually prevented accident, and it appeared not liable to derangement. The whole apparatus might be locked up in a case of moderate size, about 3 feet high, including the float-chain and wheel, which would put it entirely out of the control of the men. He added, that the whole cost of the apparatus was about 15*l.* or 20*l.*

Mr. Ramsbottom remarked that a heavy float would be required to insure the action of the apparatus, and it would have to close the stop-valve against the pressure of steam in the boiler.

Mr. Rolinson said the float was made large and heavy to insure certainty of action; but the steam from the other boilers would be always pressing on the top side of the stop-valve, and the pressure in the boiler on the under side of the valve was lowered by the steam being let off directly the apparatus acted.

## MONKLAND SCHOOLS, NEAR LEOMINSTER.

(*With an Engraving, Plate* III.)

The schools are situated in a picturesque spot, on the river Arrow, near Leominster. They are erected from the designs of Mr. John Hicks, architect, Dorchester, on glebe land adjoining the churchyard, and will form with the church, when restored, of which great hopes are entertained, a very pleasing object, and be a great improvement to the parish. The land was given by the rector, by whose exertions the necessary funds were raised, including grants from the National Society and Committee of Privy Council. The cost of erection, including fittings, desks, &c., amounts to 400*l.*

The building is of sandstone rubble-work (new red), with Bath stone dressings, from Messrs. Randell and Saunders' quarries. The roof is open timbered of stained memel, and plastered between the rafters, and covered with plain tile of the neighbourhood, the colour of which, whilst new, is objectionable, but they were used for the sake of economy, Broseley tiles being specified. The schoolrooms are ventilated, and the class-room warmed, by means of a chamber in the back of the open fireplace or stove-grate in the schoolroom, and fresh warmed air by this arrangement is constantly supplied. Accommodation for fifty children is provided; the school is mixed.

## TRADE SCHOOLS.*

Not very long ago we made some remarks on the subject of industrial education, and now we have before us evidence of progress. The Rev. Henry Moseley, one of the Inspectors of Schools, is a canon of Bristol, and he has therefore been called upon by the Committee of the Bristol Diocesan School to consider the best means of giving efficiency to that establishment. So far as we understand, it was originally designed as an elementary school, but the progress of the national schools has to some extent superseded it; and Mr. Moseley proposes, therefore, as it was established for the benefit of education generally in Bristol, to make it supplementary to the elementary schools, and to establish it as the British Trade and Navigation School.

It is suggested, that as in the national schools there are some boys in advance of the rest, and capable of receiving instruction of a higher kind, that there should be offered to them a special course of instruction of *a practical kind*, having reference to the mechanical and manufacturing callings, and the trade of Bristol.

To determine the specific objects to which such a course should be directed, Mr. Moseley referred to the Bristol Directory, and counted up the number of manufacturers, tradesmen, and master workmen, the principles of whose manufacturing or mechanical pursuits or trades require, to be thoroughly understood, a knowledge of certain elementary principles of science. This list was divided into three groups.

The first group Mr. Moseley appropriates to the trades, eighteen in number, which are connected with building. This branch includes 750 tradesmen in the city, besides journeymen. Mr. Moseley observes that the department of school instruction adapted to youths intended for any of the trades composing it, will be understood by a reference to the 'Builder's Price Book.' He considers that youths might, at such a school, be thoroughly familiarised with measuring, and made to acquire facility, precision, and accuracy in all the various calculations referred to in that book, and might further be made to comprehend the principles on which those calculations are founded. Undoubtedly, this is a department of applied or special arithmetic, particularly useful for such a class, and which can be taught by any decent teacher of arithmetic.

The Inspector proposes, in addition, that the lads shall be instructed in levelling, geometrical drawing, in taking plans, and in those principles of experimental science which are connected with ventilation and sewerage, and with the lighting and heating of buildings. With regard to the levelling—although, if there were the opportunity, that might be taught—there are few classes of mechanics to whom it would be immediately useful. Geometrical drawing and taking plans are, however, of general utility; but the inspector has missed a branch of drawing which is particularly useful to every class of mechanics, and that is general drawing. For the building trades, modelling and the making of models may likewise be advantageously taught. Geometry on the French system should be an especial element in the course. The principles of experimental and applied science form another essential, and we presume that the lads will have access to the department of chemistry attached to Group C, though Mr. Moseley does not make mention of this circumstance.

Mr. Moseley considers, that with such a course the youths could not fail to enter on the building trades with great advantage to themselves and to the public, as compared with other persons who have received no such previous instruction. In this, we apprehend the profession will concur with him, for as the classes are to be opened to the sons of masters and journeymen, the result must be a better trained class of assistants in the building trades, competent to carry out the views and instructions of architects. It is to be noted, that as this is a preliminary or subsidiary course, the practical training in the workshop, which is so important, will not be interfered with.

Mr. Moseley's second Group B, contains seventy-two trades, giving occupation to 600 manufacturers and tradesmen, and these he ranges under the general description of mechanical pursuits; but he only briefly says that they require, in order that the principles on which they depend may be understood, an elementary knowledge of mechanism and of the science of practical mechanics. We should say that the instruction should further embrace drawing in the necessary branches, geometry, applied arithmetic, and chemistry.

His third Group includes sixty-two trades or manufactures, giving occupation to 358 manufacturers or tradesmen, dependent upon the experimental sciences, and more particularly upon chemistry, of which he says that each is, in fact, little more than an application. Nevertheless, in this department we recommend a general instruction in mathematics and in drawing.

A department specially requisite in a seaport like Bristol is a school of navigation, and we lament to say, that until the new Act the only schools of navigation in England were Christ's Hospital and Greenwich; but now the Marine Department have established schools in London and Liverpool, in the former of which are 300 pupils, and in the latter 200 pupils.

We consider it a defect in Mr. Moseley's scheme that there is no provision for the department of practical ornament or art. It may be that he considers this as belonging to the school of design; but when we look to the age of his pupils, and the desirability of constituting the schools of design as advanced and practical schools, it must be held desirable to prepare pupils for the superior instruction of the schools of design. What is called geometrical drawing—which is a great favourite with schoolmasters and theorists—is, when made the sole or chief branch of instruction in design, a most mischievous instrument of education. It substitutes certain conventional mathematical types for the grander geometry of nature. It injures the training of the eye, and restrains the artistic development, while it does not assist the mechanic.

Mr. Moseley takes a very moderate view of the benefit of the scheme proposed. He does not even allege that a knowledge of these various branches of science is necessary for carrying on the different trades which have been enumerated. He dwells, however, on the consideration, that if carried on in ignorance of such branches of science, they are carried on in ignorance of the principles on which they rest; and that whoever so carries them on misses that opportunity for the improvement of his mind, which is supplied by the daily habit of reasoning on and understanding what he is about; that he misses one of the highest pleasures of which the mind of man is capable—that of thus reasoning and understanding; and that he is wanting in that which is a legitimate source of moral dignity and self-respect. He relies upon it, that, taken collectively, these trades cannot but suffer, in a commercial point of view, from an ignorance on the part of those who carry them on, of the principles on which they depend, an assertion which every professional man will confirm. He says, further, that it is impossible but that new and improved processes of art and manufacture, and expedients of construction, should result from such knowledge; nor can any one doubt this who knows the many improvements which are constantly made by our manufacturers and mechanics.

Speaking of the value of a navigation school, the Inspector fails not to point out how the boys of the Royal Naval School at Greenwich having received previous instruction in the theory and practice of nautical science, are, when they go to sea, greatly benefitted by it; not only in this, that when they rise (as many of them do) to be mates and masters of merchant ships, they navigate those ships better than they otherwise would; but that whilst they are still sailors, they are better and more efficient sailors than they otherwise would be, and more contented and willing to undergo the hardships of a seafaring life. Mr. Moseley might have strengthened this by reference to the like department in Christ's Hospital. The experience of practical men in every department is in favour of these views. Without pointing to the many brilliant examples known to all of us, of men who have risen to the highest ranks from the working classes, there is not a workman who has not observed how his self-taught shopmate has benefitted by the proper application of his evening hours. It is to the recognition of this fact that the numerous mechanics' institutions and mutual instruction classes owe their foundation.

By the scheme as devised by Mr. Moseley, the requisite funds will be obtained from the existing endowments, from a grant through Dr. Lyon Playfair from the Practical Department of the Board of Trade, from the Marine Department, and from the Council of Education. The permanent masters will be two, at moderate salaries. These will be trained schoolmasters, one of whom is to have a general knowledge of experimental science and of practical mechanics, and the other to teach the navigation, mathematical, and mechanical drawing classes. A young architect or surveyor will be employed to give technological knowledge

* 'Trade Schools: A Letter to the Committee of the Bristol Diocesan School.' By the Rev. Henry Moseley, M.A., F.R.S., Canon of Bristol, one of Her Majesty's Inspectors of Schools. Bristol: Taylor. 1858.

to Class A; and occasional assistance of the like kind will be obtained from mechanics or other competent persons. A young engineer will be found very useful in Class C. There are very many young professional men, biding their time, who will be glad, for a very moderate fee, to give the required occasional instruction, looking to the office as one of honour and practice, and not of emolument. The charge to the boys is very properly fixed at a very moderate rate—sixpence per week for the sons of workmen and chamber masters, and one shilling per week for the sons of persons above that grade. Facilities will be given, under certain circumstances, to attend during only one-half of the day, and hereafter evening classes will be established. It is held out that pupil teachers will be appointed by government endowment, and encouragement be given to national school scholars by giving them exhibitions of 1*l.* a year in the trade school. We are glad to see the school establishment is put on a moderate scale, and we sincerely hope the experiment will be encouraged, and prove successful.

## APPLICATION OF PAINTED GLASS TO BUILDINGS IN VARIOUS STYLES OF ARCHITECTURE.

By Charles Winston.

[*Read at the Royal Institute of British Architects, Nov. 28th*, 1853.]

In composing this paper on Painted Glass with reference to its employment in buildings in various styles of architecture, I have endeavoured as much as possible to keep in mind the practical objects of this Society. Many matters, therefore, of interest to the antiquary will be passed unnoticed, or with a brief allusion to them—my object being, as far as I am able, to supply an answer to the question, What is the kind of painted glass best suited to a building of a given character?

On a question so wide and complicated, it is not only natural that very different opinions should exist, but extremely difficult to ascertain which is the most correct. The inadequacy of language to express ideas so subtle as those of which questions of taste are composed, must ever be an insuperable obstacle to bringing questions of taste to a certain determination by argument; a consideration which is condemnatory of the modern vice of dogmatising upon such subjects. And the nature of the only remaining tribunal—the concurrent opinion of men of taste—that is, of men who have given their attention to such matters, and whose views are respected by others engaged in the same pursuits—of itself sanctions a great latitude of sentiment. The feelings and habits, the education and temperament of individuals, even their natural appreciation of form or colour, all insensibly influencing their opinions on a subject respecting which there exists no definite standard. I am therefore very far from claiming any sort of infallibility for the views I am about to submit to your consideration—views which I shall attempt to support rather by calling your attention to objects with which you are already familiar, than by elaborate argument.

The variety of buildings which may require to be decorated with painted glass is great. Some are in the Greek or Palladian styles of architecture, others are in the Gothic styles; and each building may be more or less grave or solemn in its aspect than others of its class. Such differences in the buildings demand of course corresponding differences in their painted windows. But before entering upon this topic, it will be convenient to declare what I believe to be the best subjects for glass painting, and the best mode of executing them. With regard to the mode of executing glass paintings, I will recall your attention to a paper which I read here about a year ago, on the Methods of Painting upon Glass.[1] In which, after stating that there were three distinct modes of executing glass paintings—viz., by the *mosaic* method, in which the local colouring of the picture is produced by means of glass coloured in its manufacture, the shadows and outlines only being executed with an enamel colour; by the *enamel* method, in which the colouring of the design is effected by using enamel colours; and by the *mosaic enamel* method, by which the colouring of the picture is produced by a combination of the two former methods,—I concluded that the mosaic method was the best, because it was, from the nature of the thing, more favourable than either of the others to a display of the translucent quality of glass, and consequently of its brilliant and powerful colours; whilst, at the same time, it afforded the means of executing works as highly pictorial as the windows of the transepts and north chapel of Brussels Cathedral—works which maintain their superiority in point of effect when compared with a series of later examples, including some of the most beautiful specimens that modern continental art can boast. This conclusion—for the soundness of which I must refer you to the paper I have named, and to the works of art therein mentioned—will confine our inquiry to what are the subjects best adapted for representation in glass paintings, executed according to the mosaic method.

These subjects may be divided into the following classes:—Patterns, similar to those used throughout the mediæval period, and which usually consist of ornamental work in white glass, but sometimes of scrolls of foliage, either white or coloured, on a coloured ground. Pictures, where the objects are represented as seen in one plane, as in a bas-relief—such as we see in the painted windows of the 12th and 13th centuries; and pictures, where the objects are represented as occupying several planes, as in nature—such as we meet with in the painted windows of the first half of the 16th century; and, of course, compositions consisting entirely of such patterns or pictures, or partly of patterns and partly of pictures. To avoid any possible misconception, I should perhaps here state, that any reference to mediæval examples in this paper is made only for the purpose of illustration, and not with any intention of conveying any impression that they are fit objects of imitation. Most valuable hints are doubtless to be obtained from an enlightened examination of such examples; but before we think of copying them, we ought to be quite sure that they are worth copying; and I will undertake to say, that not one ancient example of painted glass, except, perhaps, those consisting of pattern work, can be considered as a perfect model for imitation. All, with the trifling exceptions I have named, of whatever date, are defective in one way or another, either in composition, drawing, or general effect. Even the finest cinque cento examples, which, taken collectively, are perhaps of all ancient examples the least open to criticism, were done at a time when the human figure was but imperfectly understood by the glass painters. And with regard to the often-expressed notion, that it is better to submit to copies of mediæval examples than trust to modern invention, permit me to say, that a more unjust imputation against the taste and skill of the 19th century never was made, or a more complete apology conceived for indolence and incapacity. Whose fault is it, I would ask, that low art, at least in regard to glass painting, should seem to be almost inseparably associated with what are called church principles of architecture? Are not the patrons of the art to blame for indolently acquiescing in and sanctioning a mere system of copying, because they have not sufficient energy to study glass painting thoroughly, and make themselves acquainted with its principles? We may depend on it, if glass painting, or I may say art in general, had a practical bearing on the affairs of life, instead of only furnishing a means of amusement, we should no more hear of currency being given to such doctrines respecting it, than we now hear engineers advocating our going back to the single-condensing steam-engine, or travellers by railway yearning for a return to the old horse-tracks.

The patterns to which I have alluded do obviously comply with the conditions of the mosaic method in the fullest and simplest manner; for the brilliancy of the glass is altogether unsubdued in these works, and the mechanical construction of the window is in harmony with their design—the leadwork connecting the pieces of glass either forming an integral part of the pattern, or else actually constituting the pattern itself. I may illustrate my meaning by a reference to familiar examples, such as the Five Sisters at York, and the geometrical pattern works, executed in white glass, so common in the 17th century, particularly on the continent.

Turning from these, the works which next appear the most completely and simply to comply with the conditions of the mosaic method are the pictures of the 12th and 13th centuries; for, of all pictures, these admit of the employment of glass of the most powerful hue, and the least diminish its brilliancy. Here, also the leadwork is made conducive to the effect of the design. It is true, that in the cinquecento style we meet with pictures in which, as in a bas-relief, all objects are represented as occupying one plane as effectively as in a picture of the earlier period; but in no glass paintings is the bas-relief principle of representation effectively carried out with so much *simplicity* as in

[1] See *Journal*, Vol. XVI. 1853, p. 190.

the pictures of the 12th and 13th centuries. This, I apprehend, is owing no less to the nature of the glass of which these works are formed, than to the composition of the picture. This glass, when compared with the glass used in later times, is remarkable for its apparent solidity—a quality which, without sensibly detracting from the brilliancy of the glass, imparts great depth and richness to its hues. Hence the artists of that early period were able to leave large breadths of glass in their pictures unincumbered with any enamel colour—with which, in the mosaic style, as I have already informed you, the painting of the picture is performed—without incurring the risk of producing a weak or flimsy effect. We all are aware of the fact, that the shields of arms and the panel grounds, which in later years were so profusely adorned with diaper patterns, executed with the enamel brown paint, are in the works of this period usually left quite plain—the artists appearing to rely for effect on the tone and richness of the material itself. So we perceive, on examining a figure in any one of these early pictures, that whilst the deepest shadows are represented in the simplest manner by opaque lines, and the shadows in half-tint by a slight wash of enamel brown, the proportion of the glass left quite clear for the high lights is much larger than in later glass paintings. That such a simple mode of execution, if applied to a more pellucid and watery material, must necessarily produce only a poor and flimsy effect, may be learnt from the modern copies of 13th century glass. But without dwelling on this point, I will call your attention to the composition of a 12th or 13th century picture, as of itself insuring distinctness without the aid of any great breadth of shadow. This is simple enough: it consists in arranging the figures in one line, usually on a bar crossing the picture; in keeping the action of the figures as much as possible in the direction of the plane of the picture, and in insulating and separating the figures by the ground of the picture—a treatment, as you perceive, corresponding with that of an antique bas-relief. And since this treatment is in general more intelligibly carried out in the earlier examples, I think we may venture to ascribe it to the fuller influence of classical art at an early period of glass painting. In addition to this, as a general rule, the colouring of the figures is kept lighter than that of the ground of the panel. Of course these remarks are derived from an examination of a great many examples. I mention this because I could easily contradict almost every one of them by a reference to particular works. It is from a majority of specimens only that a general principle is to be collected. The subjects to which I have just alluded are necessarily characterised by a certain archaic formality, arising from the stiffness of the colouring, and the simplicity of the design and execution.

I have now to direct your attention to subjects of another class, as remarkable for their pictorial effect. I mean the picture glass paintings of the first half, or more correctly, of the second quarter of the 16th century. These works are in many respects the very opposites to those just described. Their colouring is harmonious rather than deep, and they are highly finished—peculiarities which I could show to be connected with the nature of the glass employed in these works, which, without being as flimsy and pellucid as ordinary modern glass, is yet very inferior in depth and richness to that of the 12th and 13th centuries. Still these works will be found to comply with the conditions of the mosaic method, after making allowance for their different nature, equally with the works of the 12th and 13th centuries; and I hope I shall be able to prove that they are entitled to equal estimation. Their composition is various, consisting sometimes, as in the pictures of the 12th and 13th centuries, only of a line of figures occupying a single plane; but more commonly of a group—of *foreground* figures, it is true, but which in parts recede from the eye; the figures not unfrequently occupying in plan, the arc of a semicircle, as in some of Raphael's designs; and beyond the figures some distant object is usually represented, such as the sky, or a landscape. The picture, therefore, is designed on the principle of representing depth, and, in the best examples, is executed in such a manner as to produce the effect of depth. The means resorted to for this purpose are very simple. First may be noticed, the choice of such subjects as are capable, without a violation of probability, of being represented in a somewhat severe, if not harsh manner: thus a landscape, or a sea piece, a full idea of which cannot be conveyed without representing the graduated tints and soft outlines of nature, was never, at this period, selected as the *principal* subject of a glass painting. On the contrary, when a landscape background is adopted, it is used merely as an accessory, to set off and relieve a group of foreground figures, in which all the interest of the composition centres. And, secondly, we may remark, that all the objects in the picture are represented as if they were seen under the influence of broad sunshine—a mode of treatment the most favourable, not only to a display of bright lights and sharp decided shadows, but to the general transparency of the picture, it being possible by this means to separate the various objects from each other, without having recourse to extensive masses of shadow or concentration of light, the use of which, however effective in the works of Rembrandt and other oil painters, is wholly unsuited to the conditions of glass painting, on account of its very limited scale of transparent shade. The heaviness resulting from the adoption of the opposite principle, of concentrating the light in the middle of the picture and keeping the rest in comparative obscurity, is shown in the upper subject of the west window of New College Chapel, Oxford, and in the west window of Magdalen College Chapel, and in a variety of modern works; and the superiority of the sunshine principle becomes apparent on comparing these works with others in which it is adopted, as the windows of the North Chapel of Brussels Cathedral, those of St. Jacques Church, Liege, or the windows of Lichfield Cathedral.

A glance at the drawings on the wall, of portions of the glass at Brussels and Lichfield will explain my meaning better than any words I can employ. We there see, that the figures are cut out from the background, and the architecture from the sky or landscape, as much by the opposition of light and shade, as by the local colours: and thus the crispness and clearness of a sunshine effect is not only highly conducive to the brilliancy of the window, but is most favourable to the concealment of the leads, which form part of and are wholly lost in the sharply defined shadows with which the foreground objects are bounded, and even in the background are on a close view not unfrequently absorbed in the colouring, but at all events pass unobserved in the general crispness of the picture, when it is viewed from the proper distance. Of course I am not speaking of the broad modern lead, used in repairs of old glass, but of the ancient leads themselves, which never until almost the beginning of the 17th century exceeded $\frac{1}{16}$-inch in width. In cinquecento glass paintings therefore, the leadwork forms an integral part of the design, equally as in a 12th or 13th century picture. And these works also evince a thorough compliance with the mosaic system in preserving the translucent qualities of glass. A cinquecento glass picture, notwithstanding the power of its shadows and high finish, which entirely save it from the charge of weakness or poverty, is still a brilliant and diaphanous glass picture; owing, partly to the crisp treatment alluded to, partly to the care taken to leave considerable portions of the glass (though not such relatively large portions as may be seen in the works of the 12th and 13th centuries) unencumbered with enamel brown. But without going further into the minutiæ of the subject, I will ask any one accustomed to compare glass paintings of different dates, whether in any so high a pictorial effect has been produced with so little diminution of brilliancy, as in the works of the second quarter of the 16th century?

You will perceive that from this summary I have omitted all notice of glass paintings of the 14th and 15th centuries. I have done so from a conviction that the nearest approach to an artistically flat style of representation is to be found in the works of the 12th and 13th centuries; and that the nearest approach to an artistically rotund style of representation is to be found in the works of the second quarter of the 16th century: and that there is nothing to choose between a really flat and a really rotund style. At first sight there is, I admit, but little difference between a 13th century and a 14th century picture, in point of composition; but a closer examination generally brings to light various minute differences, tending to show, either that the artists of the 14th century were already contemplating a change from flatness to rotundity of representation, or that they did not strictly adhere to their predecessors' rules for ensuring distinctness in a flat style. The inconsistency, not unfrequently seen in works of the 13th century, of representing the figure in relief, but omitting to indicate the recess of the niche in which the figure is supposed to stand—a mistake which perhaps arose from imitating in glass too literally the designs of ancient goldsmiths' work, where, as every body knows, embossed figures are often stuck on a flat ground, having architectural forms drawn in outline upon it—is repeated and exaggerated in pictures of the 14th century. Indeed, most of the 14th century groups that, according to the usual fashion of the day, are surmounted with shrine work, look just like groups painted on flat panels, fringed by way of ornament with spires and crockets; so completely does the apparent flatness of the canopy—rendered no doubt more conspicuous by the increased elaboration of its details—correspond with the flatness of an ordinary panel. And the figures themselves, owing partly to the increased breadth of their draperies, inattention to the principle of insulating them by means of the ground colour of the panel, and a bad selection of the colours of the drapery, certainly do not in general appear at a distance so distinct as the figures in a 13th century picture. I therefore cannot but regard the 14th century style of glass painting as inferior to the 13th, and the 15th century style as inferior to that of the 14th. The 15th century was evidently passed in the effort to get out of a flat style of representation into a rotund one. It is true that all the pictures of this period appear to be flat, but they are flat in effect only, and not on principle; their flatness is the result of imbecility, not of design. They are designed as much on the principle of depth as a cinque cento glass painting, but they do not, like it, produce the effect of depth, because their designers were ignorant of the means of attaining the desired result. As in a cinquecento glass painting, so in one of the 15th century, the figures are not unfrequently arranged on the arc of a semicircle, and are not cut out or separated from each other by stiff colour. And that the intention was to represent depth is plain from the representation of distant objects, of sky and landscape, coloured with considerable regard to the hues of nature; but, contrary to the practice of the cinque cento artists, the shadows are sometimes misplaced, and are always too weak; and the gradations of colouring, though such gradations might have been as easily made as in cinquecento work—the nature of the material being the same in both cases—are not sufficiently attended to. Hence the glass pictures of the 15th century, beautiful as they sometimes are in detail, remind one in general of an assemblage of court cards. They frequently produce no other effect, even at a moderate distance, than that of a mosaic composed of strangely-shaped pieces of glass of various colours. I think, therefore, that we may leave the works of the 14th and 15th centuries as chiefly interesting to the antiquary.

Having thus indicated, as briefly as I could, the sort of subjects which appear to be most suited for glass paintings, I will endeavour to show what sort of glass paintings are best suited for particular buildings. And here the real difficulty of the subject may be said to commence; for since no example of contemporary glazing is to be found in any building earlier than the middle ages, it is only by analogy that we can arrive at the fitness of painted glass for classical buildings, if we rely on experience as a guide; and in a matter of this sort, I fear there is no guide so trustworthy as experience. It will be admitted, I apprehend, that the earlier Gothic styles are more severe in their architectural character than the later ones; and I think that you will likewise admit, on reflection, that the glass most in harmony with Gothic buildings in the Norman or early English styles, is that of the 12th and 13th centuries. I have tried for a long time past to discover the reason of this conformity, and have arrived at the conclusion that the harmony between the painted windows and the architecture depends far more on the colouring of the windows than on their design. I have often contemplated the general effect of 13th century, of 15th century, and even of 16th century painted glass, in the windows of a Norman or early English building, from a distance too great for admitting of my making out the design with any degree of distinctness, and have invariably observed that the colouring of the earlier glass most accorded with the character of the architecture, and that the harmony was the same, whether the windows were almost entirely formed of white glass, like the Five Sisters at York, or were richly coloured, as at Bourges or Canterbury. As might have been expected, I have not met with the same opportunities of contrasting the effect of 13th century painted glass with that of the 15th or 16th century, in reference to its harmony with the architecture of the 16th century, but such experiments as I have been able to make have tended to create an impression on my mind, that the glass paintings of the 15th and 16th centuries do harmonise more completely with the character of the architecture of the 15th century than the glass paintings of the 13th. However, without pressing the last point, I will venture to express a firm belief that the colouring of a 16th century glass painting does harmonise better with the character of a building in the Renaissance style, than that of a 13th century glass painting.

In these conclusions I would beg you to observe that I have been influenced by the general effect of the glass painting, rather than by its force, because I have remarked that good cinquecento glass paintings, which are hardly if at all inferior in power to early English ones, do not in general harmonise with 13th century buildings so completely as the windows of the 13th century. The inference I draw from these experiments is, that there is an analogy between the colouring of 12th and 13th century windows, and buildings remarkable for the gravity and solemnity of their appearance. And this, when the nature of the colouring of these windows is analysed, will I think be found to accord with Sir Joshua Reynolds' views. He says in his 4th discourse, "with respect to colouring, though it may appear at first a part of painting merely mechanical, yet it still has its rules, and those grounded on that presiding principle, which regulates both the great and the little in the study of the painter. By this the first effect of the picture is produced, and as this is performed, the spectator, as he walks the gallery, will stop or pass along. To give a general air of grandeur at first view, all trifling or artful play of little lights, or an attention to a variety of tints, is to be avoided. A quietness and simplicity must reign over the whole work, to which a breadth of uniform and simple colour will very much contribute. Grandeur of effect is produced by two different ways, which seem entirely opposed to each other. One is by reducing the colours to little more than chiaro-oscuro, which was the practice of the Bolognian schools, and the other by making the colours very distinct and forcible, such as we see in those of Rome and Florence. But still the presiding principle of both those manners is simplicity. Certainly nothing can be more simple than monotony: and the distinct blue, red, and yellow colours, which we see in the draperies of the Roman and Florentine schools, though they have not that kind of harmony which is produced by a variety of broken and transparent colours, have that effect of grandeur which was intended. Perhaps these distinct colours strike the mind more forcibly, from there not being any great union between them; as martial music, which is intended to rouse the nobler passions, has its effect from the sudden and strongly marked transitions from one note to another, which that style of music requires; whilst in that which is intended to move the softer passions, the notes imperceptibly melt into one another." Now if we compare the colouring of a 13th century glass painting with that of a cinquecento one, we perceive that the colouring of the former consists of an assemblage of powerful, distinct, positive tints, skilfully arranged, but more on the simple principle of a mosaic, than on the more blended principle of a painting; whilst the tints of the latter are less forcible, less decided, and more blended together. I have seen some cinquecento glass pictures in which there is no red, and but little positive blue, the colouring being almost entirely composed of secondary tints, and in which the transition from one tint to another is scarcely more marked or sudden than is the case in some of Titian's pictures. These considerations may perhaps be sufficient of themselves to justify the opinion that the colouring of an early English glass painting is more calculated to produce a grave and solemn effect than that of a cinquecento one; but in acceding to this opinion we ought not to overlook the fact, that the tone of colour of an early English glass painting is cool, and that the tone of colour of a cinquecento glass painting is warm, and that a cool tone of colour of itself has a tendency to produce a grave effect, and a warm tone to produce a gay effect. If these views are correct, it follows that we ought not only to continue to employ for the windows of 12th and 13th century buildings, glass paintings similar to those of the 12th and 13th centuries, as regards the tone and principle of the colouring, but that we ought to glaze in a similar manner, the windows of all other buildings which can be said to possess an air of gravity and solemnity equal to that of a 12th or 13th century building: using of course, weaker colours, warmer tones, and a more elaborate mode of execution for the windows of buildings in a less severe style. Some people are of opinion that in no style but the Gothic can so solemn an effect be produced, but it seems to me that the solemn character of a building depends rather on its plans and arrangement, than on the style of its details. A Norman cathedral is as solemn as a Gothic one, and parts of the Coliseum at Rome are, I am told, as gloomy and solemn as the aisles of a Norman building. The rule therefore might well apply to certain ecclesiastical buildings in the Roman style of architecture, and I see no reason why it should not equally apply to certain ecclesiastical buildings in the Greek style: certainly these buildings, owing to the simplicity of their plan, do not possess the gloomy effect of a Gothic cathedral, but the extreme severity of the architecture imparts to them an air of gravity and solemnity, which I apprehend is rarely equalled by a 12th or 13th century building of corresponding dimensions.

I am quite aware that the employment of rich and deep colouring in windows has a tendency to diminish the apparent size of a building, and I am ready to admit that it is to a fear of producing this result, that we may attribute the modern practice of decorating the windows of a Greek building, with glass too faint in its hues to rescue it from the imputation of washiness. But it is by no means necessary to go into the opposite extreme. A glass painting entirely composed of white glass, would harmonise with the character of Greek architecture equally as one principally composed of coloured glass; provided that the white glass was, like that of the 12th and 13th centuries, solid in appearance, and had a rich cool tone. And even when the employment of a larger proportion of coloured glass might be desirable, it would always be possible to make the window recede from the eye, by using in it a predominating quantity of blue and white. But whether the advocates for powerfully coloured, or for white windows, as being most in keeping with the character of a Greek building, are right, I trust that all will agree in preferring rich tints to poor ones. Had the ancient Greeks glazed their windows, we may be certain that they would have used glass of rich tint, whether it was white or whether it was coloured. For amongst all the ancient Greek glass vessels that I have examined, I have never met with any of a poor tint, or flimsy appearance in point of colour or texture of the glass. And indeed so closely does the glass composing these remains resemble in its appearance and chemical analysis, the window glass of the 12th century (from which that of the 13th differs but little), that were I desirous of forming an idea of what Greek window glass would have been like, I should endeavour to call to recollection the tints of Suger's glass at St. Denys, or that of the glass in the west triplet of Chartres. And besides, the remains of strong colour used in the decoration of ancient Greek buildings, leads to the inference that the ancients, had they used window glass at all, would have employed that possessing a rich tint, from choice as well as necessity. We are still less without authority to guide us in regard to the design for windows proper for ecclesiastical buildings in the Greek or Roman style of architecture. The views I have expressed with reference to the colouring of these windows, must confine me to an advocacy of a simple flat system of representation, because pictures composed on the principle of representing depth, cannot properly be executed in glass entirely consisting of strong rich tints. The only attempt I have hitherto seen at designing windows for a Greek building, is at the Church of St. Vincent de Paul at Paris. But however worthy of notice these windows may be as an embodiment of a new idea, they are neither sufficiently delicate in design, nor simple in execution, to serve as models for our imitation. It is very possible that this defectiveness may be in a great measure attributable to the thinness and watery character of the glass of which they are composed, and to the efforts of the artists to disguise the badness of the material by a more elaborate execution; but such expedients are no longer necessary, since as I have before informed you, the manufacture of 12th century glass has been revived; and which I have always considered the more fortunate, on account of the use that might be made of it, in the embellishment of classical architecture, consistently with which, unlike the Gothic, art may be fully developed. There can be no doubt that valuable hints might be derived from an examination of the designs of ancient sculpture, and even of tessellated pavements. Indeed classical designs, admirably adapted for glass paintings, are engraved from sculpture in Pistolesi's Vatican, the most remarkable one is given in the 2nd vol, plate 3.[2] These designs consist of figures and ornaments in one plane, and therefore if executed in glass, as I have recommended, would a good deal resemble some of the works of the 12th and 13th centuries. These mediæval works must appear to the most careless observer to be defective in many respects, particularly in relief. When viewed closely, the intention of the artist to bring out the various projections of the figure and drapery, by means of strong black lines, is often admirable, especially as seen in the heads of the figures; but, sometimes from want of boldness, sometimes from a want of knowledge where to place the shadow, early English figures in glass, when viewed from a little distance, are too apt to appear like flat surfaces; quite as flat, if not more so, as the men and horses appear to be in those copies of the inner frieze of the Parthenon, which, placed in situations distant from the eye, and exposed to the influence of full light, are used to decorate the outsides of some of our public buildings. I am far from agreeing with those who contend that no greater relief ought to be imparted to a simple flat glass painting, than is given to those flat relievi from the cella of the Parthenon. For those who urge such views seem to have entirely overlooked the original situation of these relievi, placed where no direct light could reach them. To use the words of one of our most accomplished artists: "it is a great mistake to suppose that the flat style of relief was intended to appear flat, and it is a great mistake to apply it in situations, as in the open air, where it must appear so, and be indistinct besides."[3] In accordance with this authority, I will venture to say, that quite as much relief ought to be given to the figures in the simplest and flattest glass painting, as is given to the alti relievi in the metopes of the Parthenon, which were intended to be seen in the open air, and from a distance. I throw out these observations however, rather with reference to those who may be about to design simple flat glass paintings for mediæval buildings. For since I am perfectly sure that none but first-rate artists can design windows fit for classical buildings, I may well be content to leave the matter entirely in their hands: and can only express my surprise that a field so favourable to a display of the highest art, should have been so long neglected. Flaxman's labours sufficiently show the possibility of employing the exquisite language of the ancients to express true christian sentiment; and some of his choicest designs might advantageously be reproduced in painted windows for classical buildings, were it only by way of proving to the public, what works of art painted windows might become in competent hands.

I shall trouble you with but few remarks on the selection of glass paintings for buildings in the Palladian style of architecture, in which I would include all Wren's churches, and even St. Paul's itself; for though that building has in parts a Roman severity, its interior in particular bears many marks of the taste of the 17th century, especially in the ornamental details. Such buildings taken on the whole, are less severe in character than true Roman or Grecian buildings, and therefore would seem to require a corresponding relaxation in the character of their painted windows. In my opinion, no greater mistake is committed than when a stiff Byzantine style of decoration is applied to the windows of a Palladian building. I have heard it defended on the ground that since such glass would harmonise with the character of a Roman building, it ought equally to harmonise with the character of a Palladian one—because both styles of architecture have a common origin—in the old Roman: an argument which is at once disposed of by the remark, that the Romanesque style betrays its more immediate origin, in the Greek character of its ornaments, and some of its mouldings, from which character the Palladian is free. I have also heard it defended on the supposed necessity of imparting a more religious air to a Palladian church. But surely there must be other and more legitimate ways of increasing the solemnity of a building, than by the introduction of incongruous ornaments and decorations, which oppress the architecture by their severity. Who would think of encrusting the walls of St. Paul's Cathedral with stiff Byzantine mosaics? I believe that it is amongst the works of the cinquecento period that the true models for painted windows suitable for Palladian churches are to be sought. Amongst these works, as has been remarked, many varieties of design and character may be seen. Some are more solemn and grave than others, but the blended and comparatively undecided colouring of even the most simple, renders them less solemn and severe than the ordinary works of the 12th and 13th centuries. In most matters of detail also, cinquecento glass paintings accord with Palladian architecture. So that on the whole, the cinquecento style of glass painting, as developed in its best specimens, seems more suited than any other known style for the windows of Palladian buildings.

In adopting this style, the glass painter, as before stated, is by no means confined to the use of pictures having receding backgrounds, but may use as flat a composition as a line of well relieved figures, placed in front of a sheet of tapestry; or even in small works, or in the accessory parts of greater works, would find authority for the employment of well-relieved figures on perfectly

[2] "Il Vaticano descritto ed illustrato da Erasmo Pistolesi."—Roma, 1829; see also vol. 6, plate 81, and vol. 2, plate 4.

[3] "Contributions to the Literature of the Fine Arts," by Sir Charles Eastlake, Pres. R.A., p. 104.

flat grounds. The use of receding pictures in painted glass in any buildings of any style has, however, been strenuously objected to; and the present seems a good opportunity of inquiring a little into the validity of the objection.

It proceeds, as far as I can understand, on two grounds. The first being the supposed unfitness of the material for any sort of representation more pictorial than the mosaics of the 12th and 13th centuries. The second, the supposed impropriety of representing a receding picture on the wall of any building. In support of the first ground of objection, we are told that a glass painting reverses the conditions of nature by making the lights transparent and the shadows opaque; that the violence of its colouring is wholly opposed to pictorial effect, and that to bound objects with black lines is reprehensible on every artistic consideration. The first of these arguments is at once disposed of by the observation, that we have nothing to do with anything but the *effect* of a glass painting; and that when the material is, like that of the cinquecento period, of a horn-like texture, the high lights do *not* appear to be less solid than the shadows.

With regard to the two other objections, I admit that they would be unanswerable if it was true that an artist was precluded from painting a picture under any other than the most favourable conditions. But to assert this would be to fly in the face of all authority, and, what is worse, to contradict all experience. According to such a rule, Raphael was blameable for making designs such as the Cartoons to be worked in tapestry; "a mode of representation," says Sir Charles Eastlake, "which, in the early part of the 16th century, was far from exhibiting the comparative force of colour, and light, and shade, which it afterwards attained." He should, according to the above rule, have condescended to no means of representation less complete than what oil painting affords. Nevertheless, his availing himself of such restricted means of representation, which doubtless was imposed on him by some necessary condition, so far from being made a matter of imputation, has but increased the reputation of the artist. To use again the words of Sir Charles Eastlake, whose admirable Essay on the Styles and Methods of Painting should be carefully read by those who interest themselves in glass painting: "With a view to such faint transcripts (the tapestries) the great artist worked. He knew that his drawings would be transferred to them, and that in the tapestries alone possibly his designs might live. Distinctness was nevertheless attained without any sacrifice of such of the proper attributes of painting as were compatible with the means employed, and without any violation of probability. When we consider the great qualities which were combined with these requisites—when we find such apparently unpromising conditions had the effect of raising even Raphael above himself, we can hardly refuse to admit that a due employment of limited means of representation may at least invite attention to the most important attributes of art."[4] Unless, therefore, the conditions of glass painting are so opposed to pictorial effect as to render the attempt to produce it nugatory, I can see no possible reason for an artist declining to fill the windows of a building with pictures in which the art of representation is carried further than in the glass paintings of the 12th and 13th centuries. In many cases it might be extremely desirable that he should do so, for there are subjects very proper to be represented in places of worship which are either wholly incapable of representation in a simple flat style, or when attempted to be so represented, only prove how easily the line which separates sublimity from absurdity may be overstepped. But when pictures in painted glass, representing receding objects, actually do exist, in the contemplation of which we forget the limited means the artist had at command, and in which excellencies are discovered such as are unattainable except in a painted window, the ground of objection to which I have addressed myself appears to fail altogether.

The remaining objection, that it is wrong to represent a receding picture on the wall of a building, and consequently in a window, the glazed surface of which is but a continuance of that wall, seems to rest less on a consideration of facts or the dictates of our external senses, than on a sort of mock philosophy, which seeks to escape laborious investigation by the enunciation of a "principle"—than which, by the way, nothing is more easy. It may be conceded, that to carry a receding picture all round a room produces an ill effect; but pictures, though representing the effect of depth and distance even almost to illusion, are admitted to be allowable, provided they occupy only a portion of the wall, either by being hung against it in a frame or by being actually painted upon it; the latter sort, indeed, can plead the testimony of ages in its favour. If, then, a glass painting should have the illusion of distance, it would be unobjectionable; because, necessarily, it could occupy only part of the side of the room or building containing it. And as we are accustomed to see out of a building by looking through its windows, those who mistook the painting for a real object might easily stretch the imagination a little further, and conclude that it was some object placed outside the building, until its unreality became apparent from the figures continuing to remain motionless. But, in truth, I suspect that no one ever mistook the representation of any object in a painted window, not even a landscape, for the reality, or, except while his attention was exclusively devoted to the painting, imagined that his view extended beyond the limits of the building; a feeling which, for the moment, might be equally excited by the contemplation of a picture hung in a frame against the wall. The instant the glass painting was regarded with reference to the building it would be perceived to be nothing else than a coloured superficies, whose plane lay in the same direction with that of the wall in which it was inserted. It might, indeed, sometimes happen, that for the sake of preserving distinctness at a very great distance, a glass painting, in which figures were represented on a flat ground, would be preferable to one having a receding background. But I think that the glass painter need be deterred by no other consideration from employing a receding design if he thought proper. Indeed, a glass painting having a sky or landscape background, such as we meet with in good cinquecento examples in general, would be peculiarly suitable for a window at the end of a building, on account of the retiring nature of most of its hues. I conclude, therefore, that in the preparation of painted windows for classical edifices, the artist has the choice of a more or less severe style of representation, to be used according to the character of the building he is required to decorate; and that the type of the one style is to be found in the remains of 12th and 13th century mosaics, and that the type of the other is to be found in the glass paintings of the second quarter of the 16th century. The artist might I apprehend, be guided by similar principles in preparing painted windows for buildings in the Gothic styles.

I have already stated my belief, that the glass paintings of the 12th and 13th centuries are most in harmony with the architecture of those respective periods, and therefore think that such of those works as most consistently carry out the simple flat style of representation ought to be regarded, with but few exceptions, not indeed as objects to be reproduced in copies, but as guides to assist the artist in forming new and original designs. The principle of an ancient composition might be more strictly adhered to now than at any former period, on account of the revived manufacture of the window glass of the 12th century; but this recommendation would by no means involve the necessity of copying the object itself. Indeed, nothing is more thoroughly opposed to sound sense and good taste than a mere servile copy of an ancient glass painting, or a copy with such trifling modifications as to be little else than a servile copy. If intended as a counterfeit, it must fail in its object—for none but the inexperienced are likely to be deceived by it; and once known to be a counterfeit, it would lose all interest from association with bygone ages. If intended to pass for nothing more than a copy, under the *bonâ fide* impression that nothing except a copy of ancient painted glass will harmonise with Gothic architecture, it serves but as a cover for indolence; it can advance nothing, because a copy is sure to fall short of the original in all real merit; and besides this, its production amounts to an unconscious satire on Gothic architecture, when we consider the imperfect state of the art of representation as displayed in ancient windows. The only true course is to treat every modern work in painted glass as an original work of the 19th century; and as such, to test it according to intelligible rules of taste. The inquiry ought no longer to be confined to the narrow issue of conformity with some ancient authority, but should extend to a consideration of its intrinsic merit as a work of art, and its extrinsic merit as being in harmony with the architecture with which it is associated. To prescribe so wide a field of inquiry might, indeed, prove inconvenient to certain critics, but would certainly tend to a more zealous investigation of the principles of ancient art than heretofore, and to the production of works more worthy of the 19th century: in short, it is by this means only that any progress can be made.

4 'Contributions to the Literature of the Fine Arts,' by Sir Charles Eastlake, p. 133.

A 19th century window, designed for a 12th or 13th century building, ought not only to harmonise with the architecture in the quality and treatment of its colouring, but, besides restraining conventionality within due bounds should likewise be free not merely from the bad drawing, but from the quaint and contorted attitudes of the figures of the 12th and 13th centuries; attitudes which, however fashionable they might have been at that period, are shocking to our present tastes and feelings. It should, in fact, reproduce nothing but the art of that period, the genuineness of which will only appear the plainer when the film of bad taste and deformity is stripped from it, through which we are now obliged to penetrate before we can fairly see it. I should add, that in designing a window for a 12th century building, the artist can never do wrong in going at once to the fountain-head, and correcting his taste by the remains of classical art, whose influence is so easily recognised in the glass paintings of the 12th and 13th centuries.

A consideration of the colouring best suited for the windows of a 14th century building presents an interesting subject of inquiry, but into which I cannot, for want of time, particularly enter. The glazing of the 14th century, until about the year 1380, in respect of the quality and disposition of its colouring, holds in general a sort of middle place between the rich mosaics of the 13th century and the paler picture-glass paintings of the 15th century. Its individual colours being as cool and almost, if not quite, as powerful as those of the 13th century—but being intermixed with a much larger proportion of white glass, and used in broader masses. But this difference in the character of the colouring seems attributable rather to the nature of the designs which became fashionable in the 14th century, than to any definite abstract principle. But however this may be, there is one lesson to be learnt from the works of the 14th century, if not from those of the latter part of the 13th, which is, that the glazing which chiefly consists of white glass is more favourable to the effect of window tracery than that which consists of a mass of intensely rich colours. For the latter tends to confuse the tracery, unless, indeed, the direction of the principal lines of the glass composition are strongly opposed to the lines of the stonework, in which case there is a sufficient contrast between the stone tracery and the deep coloured glass to render the former perfectly distinct. Thus the mullions and tracery come out strongly in some of the clerestory windows at Bourges, and in the windows of York Chapter House, where the glazing is principally white, but are not so easily made out in the windows of the Sainte Chapelle at Paris, which are filled with richly-coloured glass. On the other hand, the mullions of the southern rose at Chartres, which is likewise filled with richly-coloured mosaics, show themselves distinctly, as appears from the diagram I now exhibit. Here the principal lines of the stonework diverge, like rays, from the centre of the window, whilst the principal lines of the glass composition form concentric circles. The star-like effect of this and many other rose windows of the 13th century (the north rose of Notre Dame at Paris is another example) thus being produced by the opposition of two distinct designs; one of which, the stone design, appears as if it was laid upon the other. If this consideration should lead to the conclusion that glazing, principally consisting of white glass, is best suited for the windows of buildings in the Decorated style of architecture, there can be little doubt, I apprehend, that the best designs would be those consisting of pattern work painted on white glass, of which there are numerous and beautiful examples in the Cathedrals of York and Exeter, Merton Chapel, Oxford, and other places, with or without the enrichment of inserted panels containing groups or single figures on stiff coloured grounds, executed in the simple flat style before mentioned. I would on no account advocate the use of figures and canopies, because the stiff character of the colouring, which does not materially differ from that of the 13th century, is unfavourable to such a display of light and shade as is necessary to make the canopies seem as if they projected forward. I have heard the flatness of decorated figures and canopies defended on the score of their resemblance to some of the published outlines of the German engraver Retsch; but these outlines are only intended for near inspection, by which alone the varying thickness of the outline, which produces the effect of light and shade, can be appreciated. At a distance, these designs would of course be invisible; or if enlarged in painted glass, as I have also heard recommended, would appear flat and thin—just as would a copy of a 14th century monumental brass, if executed in painted glass.

The change in the nature of the material in 1380, or thereabouts, and the substitution of glass, such as we see used in the works of the 15th and 16th centuries, for the deep intense tints previously employed, is like many other points connected with the history of an art, one on which no light has hitherto been thrown. It is but a conjecture that the change was brought about by the glass-makers in Germany. But I think we may conclude, from the fact that glass painting was becoming more pictorial just before the change in the material, and that it became still more pictorial after it, that the lowering of the different tints in depth was intended to second the efforts of the artist to produce glass pictures in preference to glass mosaics. One is tempted to infer the existence of some harmony between the character of the architecture and the delicate tints and silvery tone of the glass of the 15th century, from their having been so long associated together. And in one respect, the glass is no doubt well suited to the architecture. For even the most elaborately painted window is, owing to the lightness of its hues, never confused with the stonework. And experience has abundantly shown that the effective pictures of the 16th century harmonise as well with the architecture of the 15th as the imperfect productions of that period. There is no apparent difference between the architecture of the windows of Fairford Church, Gloucestershire, and that of the windows of churches quite half a century earlier; and yet the 16th century glass, with which these windows are filled, is in perfect harmony with the character of the building. I therefore think that windows for 15th century buildings should be designed on the model of the glass paintings of the 16th century; in which case the artist might consistently employ canopies if he thought proper. The most splendid Gothic canopies in glass that I have ever seen are in two of the windows of Munich Cathedral; one is dated 1503. These canopies are so painted as to appear like what they profess to be—hollow niches. As a general rule, it appears more satisfactory that one scale of figures should be preserved throughout a window, than that the size of the figures should be regulated by the sizes of the lights they occupy, as in most Gothic examples. In the cinquecento period the uniformity of scale was preserved not unfrequently by the employment of angel boys instead of full-grown figures, to fill the smaller tracery lights. At Fairford and other places the expedient adopted is the use of demi-figures in the tracery lights.

In the 15th as well as in the 16th century it was a not uncommon practice to extend the design of a glass painting beyond the limits of a single light. In some instances, the entire window is filled with a single picture, which is spread over the whole opening, independently of the mullions. So great an outcry has, however, been raised against this practice that it seems worth while to say a few words in justification of it. In the first place, there is not, I conceive, a greater violation of principle committed in laying, as it were, the design of perpendicular tracery work over the design of a 15th century picture in glass than is committed in laying the design of a 13th century rose window over the design of its glazing. The stonework of the window sustains no injury of effect; on the contrary, it is rendered more distinct by the opposition of its design to that of the glass. Neither is the glass painting injured by being cut by the stonework, for, as remarked by a member of this society on a former occasion, the force of imagination is such, that the design may be preserved in all its unity through any number of lights; an observation which, I think, will be admitted to be true by those who have been in the habit of looking at such works with an unbiassed eye. But the practice may be defended on another and perhaps less questionable ground—on the score of necessity. Our ancestors were in the habit of representing in their windows vast numbers of legendary saints; but modern practice is in general so opposed to this as in effect to limit the choice of the artist to representations of our Saviour, the four Evangelists, the twelve Apostles, occasionally the Virgin Mary, and some of the Prophets and Patriarchs. I believe that I am speaking within compass when I say that his choice does not extend beyond three dozen single figures. Consequently monotony is inevitable, unless recourse is had to groups of figures. Here, indeed, the means of selection is almost unlimited. Flaxman declares (Works, p. 337), that it may be affirmed, "without danger of exaggeration, that many hundred subjects are to be found in the sacred writings, which, being ably designed, would be *new* to the beholder." But in order to insure a sufficient scale for the figures, the group must not unfrequently be extended beyond the limits of a single light. Upon the ground, of necessity, therefore, we may well justify the carrying a glass picture across a window, to a certain extent, irrespective of the mullions. And I should perhaps add, that when we consider that painted windows by their size might not unfrequently offer a field for the talents of the historic painter, it seems unadvisable to scare artists from it by imposing conditions, which were often broken through by the mediæval painters themselves.

In conclusion, I will repeat what I stated at the outset, that I claim no infallibility for any of the views I have advanced. I am conscious of having approached delicate ground more than once; especially in the course of my remarks on the sort of glass paintings best suited for buildings in the classical styles. On this point I consider that I have but raised questions which wiser heads than mine must solve. My object will have been accomplished if I have added but one grain of information to the common stock; or if have succeeded in proving that there is no mystery in glass painting—that it is a branch of the fine arts, distinguished from others only by certain conditions, and that the same sober rules of criticism equally apply to the productions of the glass painter. To take a familiar instance, we sometimes hear it disputed whether the flesh ought to be coloured or left white in a glass painting; the opponents of tinted flesh urging the impossibility of imitating nature exactly in this respect. The answer is obvious enough. The whole colouring of a glass painting is highly conventional, whether it be of the draperies, of the flesh, of the sky, or of any other object; still, so long as it does not exceed the limits of conventionality—a point to be ascertained only by observation and general opinion—the eye and imagination are satisfied. We should be startled and disgusted at seeing flesh painted green or blue, but the complacency with which pink or white flesh in a glass painting is regarded by the generality of mankind is a sufficient proof that neither of those tints contradicts nature too violently; and therefore that the artist does not exceed the limits of conventionality in using either white or tinted flesh at his discretion. The wide range of this paper, and the necessity of confining its length within reasonable limits, has of course compelled me to touch on several topics in a very cursory manner, and especially that relating to the actual mode of executing a glass painting, on which the argument in favour of the mosaic system almost entirely depends. However, as I went into this subject at great length in a little work I published in 1847,[5] and of which there is a copy in your library, I must refer those to it who are inclined to pursue the matter further. It may seem superfluous to those who have read this book to assure you that there is a perfect consistency between it and such views as I have just expressed; but as certain writers are in the habit of taunting me with inconsistency, I may as well state that the only foundation for the charge is this: that perceiving at the time when that book was written that modern copies of the 13th century windows, besides being very raw in colour, were, owing to the extreme pellucidness of the glass then in use, thin and poor in effect; the most favourable examples never having a more imposing air than a *veneer* of an old window might be expected to have, and that the process of antiquating the glass—that is, dulling it over with enamel brown in imitation of the effect of age, only produced dulness without imparting depth, I ventured to suggest the adoption of shadows, such as we see in cinquecento work, as well as a broader style of colouring than was used in the mosaics of the 13th century, as a means of correcting the flimsiness without destroying the brilliancy of the material, and, at all events, of giving *power* to the work. And that since the manufacture of the 12th century glass has been revived, I have advocated a nearer approach to ancient precedents, both in the execution of the painting and the method of its colouring. I trust this brief explanation will finally dispose of the charge to which I have alluded; a charge which never would have been made, any more than the absurd misrepresentation that I have at any time recommended the universal employment of the cinquecento style, details and all, had it not been for those writers' ignorance of the subject on which they professed to write, and their consequent inability to comprehend any argument in relation to it which is founded on general views. To you, gentlemen, I am indebted for the patience with which you have listened to so long and dry a discourse.

[5] 'An Inquiry into the Difference of Style observable in Ancient Glass Paintings,' by an Amateur, p. 236, *et seq.*

## MANCHESTER CORPORATION WATERWORKS.

Mr. J. F. Bateman has presented the following report, dated October 5, 1853, to the Waterworks Committee of the Council of the city of Manchester:—

The works are steadily advancing towards completion. The operations alluded to in my last report for preventing the leakage at the Woodhead Reservoir, which existed on the Derbyshire side, have been attended with great advantage. The leakage is only one-fifth of what it was when we commenced, and is now inconsiderable, notwitstanding that the water in the reservoir is kept several feet higher, and the pressure thereby increased. The water is maintained at a depth of about 50 feet, being about 30 feet below the waste weir.

The embankment of the Torside Reservoir is within about 18 inches of its full height, and all the work in connection with the reservoir may probably be completed by the end of the year.

At Rhodes Wood Reservoir the embankment has been stationary for some time, but the works for arresting the motion of the land-slip, and for rendering the reservoir watertight over the moved ground, are proceeding rapidly and satisfactorily.

At the Hollingworth and Arnfield Reservoirs the works are rapidly drawing to completion. The tendency to slip, which has occasioned a good deal of trouble in these embankments, has now, I hope, all but ceased. The water in the Arnfield Reservoir has for some time been within seven or eight feet of its full height.

Some repairs have been found necessary both on the Rhodes Wood Conduit and at Crowdon Weir, for the purpose of remedying leakages which occurred at both works after they had been supposed to have been satisfactorily completed.

## PAVING AND SEWERING OF STREETS.

Mr. John Francis, surveyor, has made the following report to the Paving, Sewering, and Highways Committee of the Council of the city of Manchester. He states that the seventh year's experience in tubular sewerage has served further to strengthen his conviction of the complete adaptation of glazed fire-brick tubes to the purposes of town drainage, under judicious regulations. The Manchester system of sending through the tubes not only house sewage, but the general surface drainage of the town, up to the measure of their capacity, is preferable to, and has met with a success unknown to the "separate system," because the tubes are flushed in every shower and storm, and deposit is thereby prevented or removed.

Table *showing the Cost of Paving and Sewering the Streets of Manchester, the years* 1843 *and* 1846 *being given to afford the means of Comparison with the Expenses of Subsequent Years.*

| Date. | Total Area. Square Yards. | Total Cost £ | s. | d. |
|---|---|---|---|---|
| From Oct. 1842 to Oct. 1843 | 32,572·4 | 12,684 | 1 | 9 |
| ,, 1845 to ,, 1846 | 58,890·7 | 20,799 | 5 | 3 |
| ,, 1848 to ,, 1849 | 22,915·7 | 7,807 | 9 | 7 |
| ,, 1849 to ,, 1850 | 56,844·0 | 17,687 | 7 | 3 |
| ,, 1850 to ,, 1851 | 27,097·8 | 7,311 | 18 | 9 |
| ,, 1851 to June 1852 | 20,826·5 | 5,120 | 6 | 4 |
| From June 1852 to ,, 1853 | 31,363·6 | 7,994 | 8 | 3 |

Various specimens of stone have been submitted for the inspection of the committee; but these, for the most part, have not been of a character sufficiently durable adequately to resist the heavy weights and continuous traffic to which the leading thoroughfares of the city are subjected; and in the few specimens where, from the appearance presented and the tests applied, durability might be presumed, the tendency to slipperiness has constituted an objection to their adoption.

The experience of the committee, so far as it enables them to determine, inclines them to think most favourably of the granite sets from Nevin, which, with almost equal durability, combine far less tendency to slipperiness than Welsh blue sets.

*Whitney's Inkstand.*—This invention consists of an ordinary glass inkstand, made entire, with the exception of two openings in its upper surface. One of these is covered with an elastic diaphragm, regulated by a screw; into the other fits air-tight a small glass funnel, the neck of which reaches nearly to the bottom. By compressing the air above the level of the ink by means of the screw, the ink rises up into the cone of the funnel. The whole fits into a neat frame supporting a rack for pens, &c.

## LIVERPOOL CORN EXCHANGE.

(*With an Engraving, Plate* IV.)

THE original corn market in Liverpool, like most other towns, was held in the open street, in front of the Exchange. In the year 1807, a scheme was set on foot for the erection of a covered market by the issue of 100*l.* shares. A building was accordingly constructed on the south side of Brunswick-street, which was opened for business in August 1808. The plan succeeded admirably as a pecuniary speculation, the original 100*l.* shares having advanced to the value of 350*l.* and 400*l.*

The increase of business, especially in the import of foreign grain, having led to the inconvenient crowding of the market, a new erection was determined on. The old structure was taken down, and premises adjacent purchased sufficient to enlarge the Exchange to nearly double its original extent. The present building was commenced in 1851, but owing to the difficulty of getting possession of part of the property, it had to be erected piecemeal. The façade was commenced in the spring of the past year, and is rapidly approaching to completion.

The ground plan is a little irregular, owing to the nature of the site. The situation being in the centre of the commerce of Liverpool, the front portion of the building is prepared for offices or commercial chambers, of which there are eight suites. The area of the Exchange itself is about 100 feet by 98 feet, which is divided into three aisles by two rows of iron columns. The centre avenue has a raised clerestory carried up, lighted from the sides. The two side avenues are lighted by continuous rows of plate-glass squares, forming the upper portions of the planes of the roofs. The roof itself is supported by cast-iron curved ribs, segmental in the side avenues and semicircular in the centre one. Two ranges of vaults for storage extend under the Exchange.

The number of stands for the accommodation of the dealers is 170, each of which is let for 15*l.* 15*s.* per annum.

The front façade is built with white Runcorn stone, which is of beautiful colour and excellent quality, but very limited in supply. The total cost of the building, exclusive of the land, will be about 11,000*l.* The architect is Mr. J. A. Picton, F.S.A.

## THE "PHŒNIX" IRON WORKS, RHENISH PRUSSIA.

IN 1844, a company was established at Eschweiler-aue, near Aix-la-Chapelle, under the arrangement called by the French "Société en commandite," for the purpose of working iron on a large scale, manufacturing rails, hoops for wheels, stakes, iron plates, and steam boilers. This establishment bears a high character, not only in the Zolverein, but also in the neighbouring states, and employs 2000 workmen. The company with a capital of about four million francs (160,000*l.*) have realised such large returns, that the balance sheet which was drawn up on the 30th of last June showed a yearly profit of *one million four hundred thousand francs* (56,000*l.*) This has been made in a manufacture, the cast-iron employed in which came from Belgium subject to heavy duties. The carriage of Belgian cast-iron from the nearest localities to Eschweiler costs six francs (4*s.* 9*d.*) per ton. The duty amounts to 18f. 75c. (14*s.* 10½*d.*), and in the event of existing treaties (which expire on the 1st of January) not being renewed, the customs dues will amount to twenty-five francs (1*l.*) Moreover, the cost of transporting the manufactured article from the present establishments to the Rhine, where it is almost invariably delivered, amounts to six francs (4*s.* 9*d.*) per ton.

To free itself from those enormous expenses the society decided on making its own cast-iron and starting a joint stock company, the Phœnix, with a capital of three million of thalers, divided into 15,000 shares of 200 thalers or 750 francs (30*l.*) each. The object to be attained was the production of a sufficient quantity of iron to supply the numerous orders which the development of industrial activity and great railway undertakings multiply every day. The customs returns for the year 1851 (at that period neither Hanover nor Oldenburg formed part of the Prussian Zolverein, and the commercial treaty concluded with Austria for twelve years had not yet been signed), yet showed that 127,000 tons of cast-iron were imported from England and Belgium, but principally from the latter country. The importation will rise to a much higher figure, for in 1851 the consumption in the Zolverein only represented in proportion to the population the third part of that of France.

There could be no hesitation as to the site of the present establishment. It was on the right bank of the Rhine on the Ruhr,—for there ore and coal were to be found in abundance, and of excellent quality. One of the new establishments is being erected at Ruhrort, on the Rhine, in the vicinity of three large coal mines which the Phœnix Company have taken for thirty years, on a plot of ground admirably situated at the mouth of the Ruhr, between the Rhine and the railroad from Cologne to Minden.

Other foundries are in progress of erection at Kupferdreh, on the Ruhr, not far from the Rhine, in immediate communication with the Steele-Vohwinkler railroad, and in the midst of ferruginous and coal beds formations. Twelve foundries are being constructed, and the first which are finished will be worked before the end of the present year 1853.

The annual production is temporarily fixed at 90,000 tons of cast-iron and 70,000 tons of wrought-iron. These quantities can easily be doubled in case of necessity. As to the advantage likely to accrue to the company (the Phœnix,) from these establishments, they are easy to appreciate—in fact, the outlay for coal, ore, and labour, as well as the preliminary expenses, will be much less than those of the Belgian manufacturer, and they will no longer have to support the heavy expenses of carriage from Belgium, &c.

These advantages constitute a clear gain of not less than 40 francs (1*l.* 11*s.* 8*d.*) per ton, or three million six hundred thousand francs (144,000*l.*). They will economise 371,250 francs (14,850*l.*) in the expense of transport, and the profit in manufacture of iron (and double profit with triple production is below the mark,) will be 2,700,000 francs or 108,000*l.*

There is the less exaggeration in the above result from the fact of the numerous orders which the company are at present executing, and must successively execute, presenting much more advantageous prices than those which produced the profit of one million four hundred thousand francs, cited above.

F. P. H.

## TYNEMOUTH BATHS AND WASH-HOUSES.

(*With an Engraving, Plate* IV.)

Messrs. ASHPITEL and WHICHCORD, *Architects & Engineers.*

IN our last Number we presented to our readers a plan of this useful establishment. We now give the elevation facing the principal street, which is the only part of the building of two stories in height; the other portion contains the baths and the washing compartments, which are lighted and ventilated from the roof.

The façade is simple and appropriate, and is executed entirely in Yorkshire stone, the column shafts and some of the more prominent lines being polished. The entrance on the left hand leads to the men's baths, while that on the right is for ladies, the centre window lighting the pay-office, which serves as a division between the sexes. The upper story is allotted as a residence for the superintendent of the establishment.

We have much pleasure in directing attention to a building for this valuable purpose, executed on a *moderate scale*, as it shows that there is no reason why they should not be added to every town in the kingdom. It is one matter to charge a public body with the erection and maintenance of a structure at an outlay of 6000*l.* or 7000*l.*; but when, as in this instance, the institution is produced at one-third of that sum, it comes within the range of towns of the most modest pretension.

## KIDDER'S GAS REGULATOR.

MR. KIDDER, of the United States, has designed a regulator to be attached between the service-pipe and meter in buildings, for the purpose of preventing the fluctuations in the light, due to the unavoidable variations of pressure in the street mains. It consists of a small telescopic gas-holder, sealed with mercury. The upper section carries a rod, to the lower portion of which is a conical valve, apex upwards, which fits into a corresponding socket in the lower opening, or that for the entrance of the gas, which, as it rises with the upper section of the gas-holder under an increase of pressure, controls the supply, and consequently the pressure. The apparatus resembles the governor used at the gas-works to control the supply of gas from the gas-holders to the street-mains; the latter, however, is sealed with water.

## RESISTANCE OF THE VERTICAL PLATES OF TUBULAR BRIDGES.

By H. Haupt, C.E.

The great desideratum in the construction of bridges is an arrangement of parts that, with a given weight of material, will possess the most efficient powers of resistance. An arch fulfils the condition of maximum resistance with a given weight of material when the distribution of the load is constant. With a permanent weight, whether uniformly distributed or not, there is a curve of equilibrium; and a given amount or weight of material arranged to conform to this curve, will give the maximum of resistance which the material is capable of opposing. But for ordinary bridges, especially for railroad purposes, there can be no curve of equilibrium; the load is not only variable, but very great in proportion to the weight of the structure, and were an equilibrium possible in one position, it could remain stable only for an instant, as the transit of the load to another position would at once disturb it.

It is evident, therefore, that the principle of equilibration is applicable only to aqueducts, or other structures upon which the loads are nearly constant, and that to render an arch capable of sustaining a variable load, it must either be made so deep that the variations of the curve of pressure will never pass outside the arch, or it must be combined with a resisting truss capable of effectually opposing any tendency to change of figure. Most of the bridges in general use are illustrations of this species of combination; but the main reliance is usually placed upon the truss, the arch being used merely as an auxiliary. When wood is used, this increase of material is not objectionable, except so far as it increases unnecessarily the weight of the structure; but where iron is employed, it becomes essentially important that the distribution of the forces should be understood, the strains upon all parts of the structure accurately determined, and the dimensions correctly proportioned to the required resistances.

The principles involved in these calculations have already been given to the public, in a work on the 'General Theory of Bridge Construction,' and no further reference to them is required, except to state that an application of these principles would lead to a radical change in the manner of constructing bridge trusses; and, instead of using an arch as an auxiliary to a truss, the arch would be made the chief dependence, and the truss employed to resist the action of variable loads, and prevent change of figure in the arch during their passage over the bridge. When disposed in this manner, a given quantity of material will oppose an efficient resistance either to vibration, flexure, or fracture.

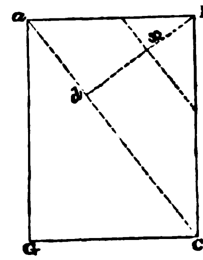
In tubular iron bridges, which have recently attracted much attention, no difficulty is found in determining the strains upon the horizontal tables, and in proportioning them correctly; but the dimensions of the vertical ribs, and the best manner of stiffening them, will depend not only upon the magnitude of the weight, but upon its mode of application. If the weight be supposed applied at the middle of a tubular bridge, its action would tend to shorten the diagonal extending from the middle of the top chord or table to the end of the bottom table, and at the same time to elongate the opposite diagonal from the middle of the bottom table to the end of the top table. As the strain upon the last diagonal would be tensile, its ability to resist would be nearly as the strength of the material; but the opposite diagonal, being subjected to compressive forces, would, if it formed a line of a thin plate of metal, be unable to oppose any efficient resistance, and the bridge would probably fail in the direction of this diagonal. It becomes necessary, therefore, to provide means for stiffening the ribs, and this is usually effected by riveting to them, vertically, pieces of T-iron at short intervals.

By these additions, the distribution of the strains is changed, and the action of the parts is similar to that of a truss on the Pratt plan—the vertical stiffness taking the place of the posts, and the lines of sheet iron connecting the opposite angle of any panels having a corresponding action to the ordinary diagonal rods. The resistance which such an arrangement is capable of opposing, it is proposed to determine from the following considerations.

In the general theory of bridge construction, it has been demonstrated, that where the load is uniformly distributed the vertical strain increases uniformly from the middle to the ends; the strain upon the diagonal of any panel will be as the length of the diagonal to the length of the vertical side, and also as its distance from the middle of the truss; the maximum vertical strain being of course equal to the whole weight of the bridge and its load, with the momentum due to motion and vibration, when the structure is not rigid.

It has also been shown, that the vertical and diagonal strains upon any panel which are always proportioned to each other in a fixed ratio, are also in proportion to the degree of annular motion or change of figure in any panel caused by flexure; and as the settlement of a bridge to the figure of an inverted arc would not change the rectangular shape of the middle panel, the vertical and diagonal strains upon this panel would be theoretically nothing; while, at the end of the truss, the variation from a rectangle, and the intensity of the vertical and diagonal strains would be greatest.

Knowing the whole weight of the structure, the strain upon any panel is readily determined, and it is now proposed to inquire what will be the resistance of a sheet of metal securely attached to all the sides of a rectangle, in comparison with an equal quantity of material arranged in the form of diagonal rods. It is evident that the consideration of this question will afford the means of comparing the relative efficiency of the distribution of the material in tubular bridges, as compared with diagonal panel rods.



Let $a$, $c$, in the annexed figure, represent the diagonal which is subjected to a tensile strain, and R, the resistance per unit of area which the material is capable of opposing; ($a$), its perpendicular distance B, $d$, from the fulcrum B. The strain upon a unit at the distance $x$, will be in proportion to this distance, and will be represented by $\frac{R}{a}x$. But as the efficiency of the resistance will be in proportion to the leverage, which is $x$, the whole effect of a unit of material at the distance $x$, will be expressed by $\frac{R}{a}x^2$, and the sum of the resistances along the line $d$ B, obtained by the usual method of integration, will be $\frac{1}{3}Ra^2$, or $\frac{1}{3}Ra + a$. As R, represents the resistance of the material per unit of area, and ($a$), the number of units in the distance B $d$, R $a$ would represent the resistance of a rod whose area is $a$, and $Ra + a$, its moment of resistance at the distance B $d$. As the resistance of the triangle $a$ G C, is necessarily equal to that of $a$ B C, the whole resistance of the rectangle $a\,b\,c\,g$, will be $\frac{2}{3}Ra^2$. The resistance expressed by $\frac{2}{3}Ra^2$, is obtained by the use of an area of material represented by $a\,c$ + B $d$. If this same amount of material should be placed in the form of a rod in the diagonal $a\,c$, its cross section must be equal to B $d$, or $a$, and its effective moment would be $Ra^2$.

It appears, therefore, that the power of a plate to resist an angular change of figure in a rectangular frame will be two-thirds as great as that of an equal quantity of material placed in the direction of the diagonal. Where a truss is designed to support a constant weight uniformly distributed, or, in other words, where counterbracing is unnecessary, the adoption of the tubular or plate arrangement involves an expenditure of 50 per cent. more material than would be required by diagonal rods; but where the load is variable, as is always the case in bridges, and where rods are consequently required in both diagonals, the relative economy of the two arrangements is more nearly equal, and may even be reversed. In a truss which is unsupported by an arch, a calculation of the quantities of material required in the two arrangements involves a consideration of the strains produced by the variable and constant loads in each panel. In the middle panels, the strain from the weight of the structure being theoretically nothing, the diagonals resist only the effects of the variable load, and must be equal. If the area of each rod be represented by $\frac{2}{3}a$, the two would be $\frac{4}{3}a$; but as the braces and counterbraces are never both in action at the same time, the plate arrangement requiring a quantity of material represented by ($a$), would be equivalent to the braces and counterbraces both, and would effect a saving of material equal to $\frac{1}{3}a$. The rods in this case would require 33 per cent. more material than the plate.

If $\frac{2}{3}b$ represent the material required in the rods of the end

* Read at the Meeting of the American Association for the Advancement of Science, July 1853.—Reported in the 'Journal of the Franklin Institute.'

panels to resist the weight of the structure, then $\frac{2}{3}b + \frac{2}{3}a$, would be required for the main diagonal rods, and $\frac{2}{3}a$ for the counter-brace, making $\frac{2}{3}b + \frac{4}{3}a$. The plate arrangement would require $b + a$. The difference is, $\frac{b-a}{3}$. Hence, if $a$ should be equal to $b$, the value of the expression becomes zero, or, in other words, if the variable and constant loads are equal at the end panels, the quantity of material in the rods and plates will be the same; but if the variable load is least, there will be a loss of material by the use of the plates which will be greater as the weight of the structure increases, and, consequently, the relative economy of plates would be less for very long spans than for shorter ones.

These considerations naturally lead to the substitution of sheet iron for the rods of wooden bridges, and its adoption will secure the essentially-important advantages of simplicity, economy, incombustibility, and durability, if practical difficulties do not arise from the expansion and contraction of the plates when attached to wooden frames. As the expansion of diagonal rods is not found to be productive of any injury or inconvenience, it is possible that the slight bending or buckling which must result from the expansion of the iron plates might not lead to any serious consequences; but whether the plan of constructing bridges by covering wooden frames with sheet iron be practicable or not, the result of the calculation that has been given proves, that with a sufficient number of posts or stiffeners, the vertical plates in tubular iron bridges may be very thin, and still possess sufficient powers of resistance—a conclusion, the truth of which is confirmed by the experiments on the Britannia Bridge.

A tubular iron bridge without arches, to be properly proportioned, should have the number or thickness of the top and bottom plates increased, and of the side of vertical plates decreased gradually from the ends to the middle. A tubular bridge, in which the plates are of the same dimensions in the middle and at the ends, must be very badly proportioned, and contain a large amount of useless material.

If $v$ represent the variable load upon a single panel or interval between two adjacent posts or stiffeners, $n$ = number of panels, $w$ the whole weight of the structure, then the proportion between the thickness of the vertical plates in the middle and at the ends, will be nearly as $\sqrt{\frac{n\,v + w}{2}}$; as this proportion may readily be as great as 1 : 5, it follows that a very great saving may be effected by proportioning the thickness of the sheets in each panel to the strains, an arrangement that appears to have been overlooked or neglected in the construction of tubular bridges.

## CONVERTING RECIPROCATING INTO ROTARY MOTION.

NATHAN ATHERTON, *Inventor.*

This invention consists in applying a cylinder with a right and left continuous groove (forming a double inclined plane or screw), the pitch and diameter of which is in proportion to the length of the stroke of the piston.

If for a steam-engine, for example, then, according to the length of the stroke of the reciprocating motion to which it shall be applied, the inventor constructs his cylinder, called the impulse cylinder, by having cast or cut in its surface a groove, starting at a point near one end of the cylinder, and continuing around the cylinder to a point on the opposite side from the starting point, and near the other end of the cylinder from the starting point; and from this second point he continues the groove around the cylinder, returning to the starting point; thus making a continuous groove, and forming a double inclined plane.

This cylinder is applied properly housed, so that it may revolve on its shaft. A friction-wheel is attached to the crosshead, and works in the groove of the impulse cylinder. The crosshead, upon being propelled forward, causes the cylinder to make a half-revolution, and upon the crosshead being returned down the groove of the other side of the cylinder to its first position, will complete the full revolution of the cylinder upon the shaft.

## ECHOL'S WATER GAUGE FOR STEAM BOILERS.

THIS invention, at present under consideration by the Committee of the Franklin Institute, consists of a metal cylinder, of about $2\frac{1}{2}$ inches diameter attached to the boiler by two smaller tubes, provided with stop-cocks, one entering above and the other below the water-line. Midway of the vertical height of the cylinder are two openings opposite each other, in which are screwed hollow nuts, the inner openings in which nuts are closed by hemispheres of glass, the convex portion inwards; between these rises and falls a graduated rod attached to a float, the numbers on the rod being visible as they come opposite the openings.

The stop-cock at the lower end of the gauge is a three-way cock, and may be thus made to cut off communication with the water in the boiler, and open a small vent-tube leading externally, by which means all the water in the gauge may be blown out in case of any obstruction. The height of the water in the gauge may also, if desired, be tested by thus blowing out the water, measuring its amount, and calculating its height for the known capacity of the cylinder.

## RAILWAY DRAWBRIDGE AND SWITCH SAFETY TELEGRAPH.

— MCRAE, *Inventor.*

The object of this apparatus is, to give to the conductor of a railroad train, when approaching a drawbridge or switch, a signal by which he may know that the bridge or switch is in the right position to pass the train with safety. To accomplish this, an electric current is established from a battery, including in it the drawbridge or switch, so that if these be in proper position, the circuit is complete at that point, but that if they be out of position, the circuit is there broken. The zinc which forms the conductor terminates at a safe distance from the bridge or switch, in a carefully insulated rail; and the next rail, also carefully insulated, is connected with a ground-plate, by which the circuit is completed. An ordinary electro-magnet is placed upon the locomotive, its armature so adjusted as to control the sounding works of an alarm, and the extremities of its coils terminating, the one on the front, the other on the hind axle of the locomotive. Then it is evident that the electric circuit is broken at the insulated rails, but that when the locomotive reaches that point, the front wheels being on one, while the hind wheels are on the other insulated rail, the circuit will be completed, and the bell sound, provided the drawbridge or switch be in a proper position; but that if they should not be so, then the bell cannot sound, for the armature will not be attracted, in consequence of the circuit being broken at the bridge or switch. It will be observed here, that the indication to the conductor that he may proceed is given by an actual audible signal, and that this signal cannot be given by any accident. The only effect of the apparatus getting out of order or not working, is to make the conductor proceed cautiously. It will also be seen, that if it be found necessary in practice, the insulated rails in which the parts of the circuit terminate may be separate from the track, and placed inside or outside of it; the connection with the engine being made by metallic springs at its front and back, projecting downwards so as to press upon them.

A modification of the above apparatus is proposed to prevent collisions on single tracks. In this case, a double circuit is established from the same battery to the turn-out, at the extremities of the part of the track on which the trains may meet. The lines here terminate by circuit-changers, by which all current is stopped while the apparatus is not in use. The conductor who first arrives at either end of this prepared track shifts the changer, by which means he establishes the circuit from the other end through his magnet, and if everything is right, gets the signal that he may go on, leaving the changer as he placed it. Then when the other train arrives at the opposite end, he cannot complete a circuit, because his circuit must come from the other end, and has been already broken by the first conductor; he therefore knows that the other train has passed the next turn-out, and must wait until it passes him. Each conductor, as he passes off the prepared track, places the circuit changer of that end in its first position, and the apparatus is ready for service again. It will be seen that these changes may be easily done, if desirable, mechanically by the engines themselves. And here, again, the derangement of the apparatus can only result in additional caution on the part of those in charge.

## McCONNELL'S EXPRESS LOCOMOTIVE.

SIR—In the *Practical Mechanic's Journal* for this month (December,) there is published some account of McConnell's Locomotive, with an illustrative plate, in continuation of previous articles on the same subject in that journal. As the writer has, in my opinion, misapprehended the merits of that engine in various respects, and as it is of importance that the public should not be misled by *ex parte* statements in questions of locomotive power, which materially involve the pecuniary interests of railway companies, I beg the favour of your columns for the insertion of the following observations, with a view to the proper discussion of the subject of Express Locomotives, and the establishment of correct principles in their design and construction.

In the article in question it appears to have been overlooked that McConnell's engine was investigated at the Institution of Civil Engineers, on the reading of my paper on "Locomotive Boilers," in March last, and subsequently in the joint Report of Mr. Edward Woods and Mr. William P. Marshall to the General Locomotive Committee of the London and North Western Railway Company. It was on both of these occasions proved that the new engine was radically wrong in all its boasted peculiarities, and that Mr. McConnell had disregarded the lessons of experience, whether in respect of the boiler, the engine, or the whole machine as a carriage.

And, first, of the boiler. Mr. McConnell, and, with him, the writer in the *Practical Mechanic's Journal*, started with two grand fallacies,—one was, that the fuel was imperfectly consumed in ordinary passenger-engines, and the other was that firebox surface is in itself superior to tube surface for the absorption of heat. I might very properly add a third fallacy, by which they were misled; namely, the assumption that the area of grate has no economical relation to the heating surface. Now, in respect of the combustion of coke in the locomotive firebox, I showed in my paper, from direct experiment, and by reference to the heat-properties of the gases of combustion, that the combustion was practically perfect, and that the immense, useless, and costly chambers of the patent firebox, and its perforated stays for the admission of air, were not only useless, but injurious; and these deductions were confirmed by most of those who took part in the discussion, while not even a show of reason for doubting their validity was sustained. But I am happily relieved from the necessity of insisting further on this point, by the evidence of two such authorities as MM. Ebelmen and Sauvage, who, shortly after the discussion on my paper, undertook a series of experiments on the engines of the Lyons Railway, the object of which was the analysis of the gaseous products of combustion discharged into the smoke-box. They found that in the passenger engines, there might be too much air admitted, but there *never was any carbonic oxide gas*; the whole of the carbon constituting the fuel was converted into carbonic acid, and this constitutes the complete combustion of coke. The two investigations, then, founded on the observed evaporative duty of this fuel, on the one hand, and the chemical analysis of the gases in the smoke-box, on the other hand, pleasingly confirm each other, and demonstrate the futility of the smoke-and-air mixing expedients devised by Mr. McConnell for his express engines. Again, as to the firebox surface, I do not know on what grounds Mr. McConnell asserts its superiority to tube surface; surely the tubes, ⅛-inch thick, may conduct the heat to the water at least as readily as the ½-inch walls of the firebox. It would perhaps, occupy your pages at too great length to go into the experimental evidence on this question; but the evidence of all genuinely-recorded experience shows that the distinction claimed by Mr. McConnell exists nowhere but in his own brain.

But Mr. McConnell has utterly forgotten, or, perhaps, has never understood, the essential relation that subsists between the grate-area and the heating surface. It is clear he had no suspicion that the larger he made the grate, beyond what was required for the complete and proper combustion of the fuel, the less efficient was the fuel for evaporation, on account of the inferior intensity of the heat of combustion, and the inferior rate of absorption of the heat. If he would only make his firebox large enough, he would find, bye-and-bye, he should get no steam at all; the production of steam would, in fact, be inversely as the bulk of his engine.

We are told, I know, and well told too, that his engine gets up the steam in a wonderfully short time; and he, with pardonable partiality, ascribes the prompt action of the boiler to the vastness of the firebox-surface. No such thing; it is connected simply with the very small water-room of the boiler, in which of course there is little water to be heated; and it is due also to the largeness of the grate, and to the shortness of the tubes, which thus offer little resistance to the draft. For these reasons it was, that the *Rocket*, in 1829, got up her steam in even less time than McConnell's engine. While on this point, I may allude to the injuriously narrow water-spaces, only 2 inches wide, round the "combustion chamber," and at the sides of the firebox. Mr. McConnell may rely upon it, that much of the inferiority of his engine is referable to the narrowness of the water-spaces, which baffle the ascent of the steam; it is certain that the throat of the "combustion chamber" will speedily burn out from this very cause, and entail costly repairs.

Referring, finally, to the actual evaporative power of this engine, it was distinguished for nothing but its mediocrity. With its contracted blast-pipe and wide air-space of grate, it did not boil off 190 feet of water per hour, and this at the rate of only 8 lb. of water per pound of coke, of which nobody knows how much was due to priming, with the cramped water-ways and steam-room; whereas the *Great Britain* broad-gauge boiler evaporates,—with smaller exterior dimensions than those of McConnell's engine,—half as much again, with the same ratio of water to fuel; and there are many boilers of half the size which will do as much work as this leviathan, with equal efficiency. It is true, a comparative trial was made with other engines, in which McConnell's engine is made out to have given the best result. But the trial was not properly one of locomotives as a whole, but of boilers; and it should have been stated, that, in these very trials, the *Heron* and *Prince of Wales*, of the Northern Division, evaporated 8·35 lb. of water per pound of coke, while the large engine raised only 7·99 lb. per pound of coke; and moreover, the fires were improperly lighted in the smaller boilers, as the steam, usually got up in one hour, occupied on the occasion of the experiment, about three hours in getting up, and even then the fuel was imperfectly kindled. These mishaps may readily arise from the admission of small rubbish into the firebox; and as the steam was got up under the charge of Mr. McConnell's assistants, at Wolverton, contrary to the laws of experimental justice, it is perhaps not very difficult to imagine a reason for the mishap.

Now, as to the engine. The leading dimensions are merely copied from those of the Great Western engines. An eight-feet wheel on the narrow gauge is sheer absurdity,—it is worse, for the larger the wheel, the larger must be the cylinder, or the higher the working steam pressure; and consequently the greater the strain on the working parts, and the probability of overheating the bearings, and breaking down the crank-axle. A six-feet wheel is quite large enough for a narrow-gauge express engine: it admits of a free exhaust, it sufficiently moderates the reciprocations, it moderates the direct strains on the machinery, it admits of a sufficiently wide blast-orifice, and it moderates the total weight of the machine, as the cylinder and other mechanism may be correspondingly moderate.

Lastly, as to the carriage, or the machine as a vehicle. It is difficult to conceive how Mr. McConnell could permit himself to fall into the error of making a 31-ton engine for express trains. The weight is enormous: to quote the language of the writer of the article in question, "as the road exists at present, it is simply impossible to run the London and Birmingham two hours' expresses with any reasonable degree of safety." And yet this 31-ton engine was deliberately designed for that very purpose, now declared impossible to accomplish. Nor could the blunder possibly have been committed in ignorance of such consequences, for, in 1849, the attention of the General Works Committee of the London and North-Western Railway was forcibly directed to the very question of heavy engines *versus* the capacity of the road to sustain the loads; and in the Report to that Committee, signed by Mr. McConnell in conjunction with other officials appointed to investigate the subject of Permanent Way, and published in 1849, it was admitted that the question of heavy engines and high speeds, was one of considerable embarrassment in its engineering aspects. "It is no longer a matter of argument," say they, and amongst them Mr. McConnell, "that the increased weight and speed of the engines and trains, has become very marked; and the *concurrent testimony of those who are engaged in the practical part of the repairs*, proves that the deterioration of the road has increased very rapidly since the period of the introduction of the heavy engines. There is no longer a doubt that *the immoderate damage to both the road and the stock from high speed,* outweighs, in positive loss to the Company, the additional fare received, if it does not far more than counterbalance any solid advantage *derived from it by the public*." (see Report p. 37). Since 1849, the causes of deterioration have been undiminished, indeed necessarily increased, for, in April 1853, the Permanent Way Committee not only admit that there has been an unanticipated increase in the cost of the maintenance of way, but they estimate that the probable "life" of the rails, notwithstanding the increased outlay in maintenance, is, on account of the probable increase of traffic, and of the weight of the engines, *reduced from* 20 *years to* 15 *years*; that is, the duration of the rails is diminished 5 years, and the road, though absolutely stronger than before, is now relatively weaker by 25 per cent. In the face of such accumulated evidence, then, is it surprising that McConnell's engine should have been found so destructive to the road as to have been prohibited from the running of express trains? The wonder is that the idea of such an express engine should ever have been seriously entertained by the Directors.

I have, I think, shown that in the chief patent points, McConnell's Express (?) engine is a failure, in so far as it is in any respect in advance of its predecessors on the rail. If, indeed, it was only equal to others—if it even attained the summit of mediocrity, it might have escaped censure, as it would have escaped notice. I do not deny that it is a remarkable engine, but it is remarkable only for its inferiority; and this is something to say, where thousands of pounds of expenditure are involved. I have shown that the inventor, Mr. McConnell,—if inventor he can justly be called, when not one of all the patent peculiarities originated with him,—I have shown that he has contemned the accumulated experience of others, whether in the boiler, the engine, or the carriage. But nature's laws may safely be left to themselves, as they are sure to find out and duly to correct the aberrations of ignorance and folly.

I had proposed to offer some remarks on what appeared to me the true course of improvement in respect of express engines and trains; but I am precluded by the length of this communication, from venturing to occupy your columns further at present.

D. K. Clark.

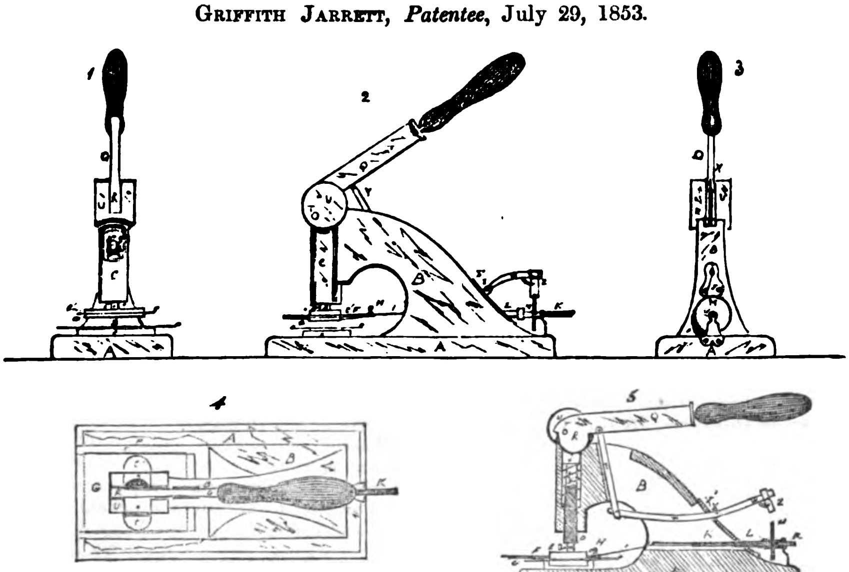
## PRESS FOR PRINTING IN COLOURS WITHOUT FLUID INKS.

Griffith Jarrett, *Patentee*, July 29, 1853.



The very general objection to endorsement stamps, &c., where fluid ink is used, from the inconvenience incident upon the drying or caking of the ink, which renders the production of a correct or satisfactory impression so uncertain, has induced the patentee of the above press to substitute carbonic or other chemically prepared paper or material for the ordinary printing inks. The apparatus is self-acting, adapted for the desk, counter, or writing-table; it is also very portable, and easily worked by the hand—the stamping action of the machine brings continually a fresh supply of colouring matter to the die or type, so that there is no interval of time wasted between the successive impressions; and the press is always ready for use.

Fig. 1 shows a vertical front view of the apparatus, fig. 2 a side elevation, fig. 3 an end elevation, fig. 4 a top or plan view, and fig. 5 a longitudinal elevation. (In each figure the same letters of reference denote similar corresponding parts).

A A, the pedestal or stand; B B, bracket arm or standard; C C, cylindrical head, for receiving and directing the movement of the die or type fount C; D D, slide or pressure bolt, working vertically within the cylindrical head upon which the die or fount is fixed or secured by means of the tightening screw E E; F F, traversing frame, upon which the chemically prepared paper or material for colouring is stretched or laid; G G, the chemically prepared paper or material; H H, tightening screw, for attaching or detaching the frame to insert or remove the said paper or material for colouring when required; I I, elastic bar or spring, by which the traversing frame and the chemically prepared paper or material are kept up horizontally against the die or fount and allowed to yield to its pressure in descending; K K, screw for traversing the frame working in hollow rectangular bearing L L, fitted to the stand or pedestal; M M, revolving nut and wheel, capable of moving in opposite directions, to give a backward or forward motion to the screw, and corresponding action to the frame; N N, leather pad or bed upon which the die or type is pressed; O O, metallic plate, for holding or retaining the same; P P, the paper or surface for receiving the coloured impression; Q Q, stamping or pressing lever, formed or fitted with eccentric or cam-head R R, for giving the required pressure to the die; S S, slide or bolt head, hollowed out so as to give a peculiar facility to the eccentric action of the cam R R; T T, pen or stud on which the stamping lever works; U U, lever boss; W, a spiral spring for retaining the die in a reacting position; W W, the curved motion lever working on the centre X, secured to the fixed plate X′; Y Y, the connecting link uniting the stamping lever and the curved motion lever; Z Z, small shifting tappet or paul, acting on the revolving nut wheel M, at intervals consequent upon the raising or lowering of the stamping lever; the tappet admits of being turned or adjusted so as to take into the teeth on either side, and actuate the nut and wheel in contrary directions, so as to give the screw K, and the frame F, a backward or forward motion. *The press is put in action* by simply pressing down the die or type through the medium of the stamping lever in connection with the slide or pressure bolt D; the die or type being thus caused to descend carries down the traversing frame and chemically prepared paper or material which is thus pressed against the paper or surface to be printed, producing a coloured impression thereon, at the same time that the short arm of the curved motion lever becomes elevated (as shown in fig. 5). The impression being made, the stamping arm of the eccentric lever is raised to its original position by the spiral spring V; the short arm of the curved motion lever W, is then depressed, and the shifting paul Z, pressing against the toothed wheel M, turns it partially round, thus carrying forwards or backwards the screw K, and the frame F, and exposing a fresh surface of the colouring paper or material to the action of the die or fount in readiness for the next operation. After the frame has traversed its whole distance, its motion is reversed by simply turning the tappet or paul Z. When the colouring matter on the chemically prepared paper or material is exhausted, a fresh piece is slipped on the frame.

## LIST OF PLANS DEPOSITED AT THE PRIVATE BILL OFFICE FOR SESSION 1854.

*Railways.*

Ambergate, Nottingham and Boston, and Eastern Junction Railway (Extension of line into Nottingham).
Ayr and Maybole Junction.
Bagnalstown, New Ross, and Wexford.
Ballymena, Ballymoney, Coleraine, and Portrush Junction (No. 1).
Ballymena, Ballymoney, Coleraine, and Portrush Junction (No. 2).
Barnard Castle and Bishop Auckland Junction and Branch.
Belfast and County Down.
Belfast and West of Ireland Junction (Armagh to Cavan).
Belfast and West of Ireland Junction (Armagh to Clones).
Blyth and Tyne (Extensions to Tynemouth, &c.)
Blyth Harbour Improvement Dock and Railway.
Border Counties (North Tyne Section).
Bradford, Wakefield and Leeds.
Caledonian (Lismahago Branches).
Caledonian (Alteration of Wishaw and Coltness Railway, &c.)
Cannock.
Carlisle and Silloth Bay Railway and Dock.
Carmarthen and Cardigan.
Caterham.
Clones and Cavan Junction.
Congleton and Biddulph Valley.
Conway and Llanrwst.
Cork and Bandon.
Cork, Blackrock, and Passage.
Cork and Waterford (with Branch to Fermoy).
Darenth Valley (Extension to Sevenoaks).
Darlington and Barnard Castle.
Dartmouth, Torquay, and South Devon Extension.
Derbyshire, Staffordshire, and Worcestershire.
Direct Southern Railway and Thames Terminus.
Dover and Canterbury and Dover and Deal (East Kent Extension).
Dowlais (Extension, &c.)
Downpatrick, Belfast, and Dublin.
Dublin and Wicklow (Extension to Woodenbridge).
Dundalk and Enniskillen (Branches to Cavan and Armagh).

## INDURATING STONE AND OTHER BODIES.

Barnabas Barrett, *Patentee*, April 30, 1853.

This invention relates to certain means of indurating stone, cement, plaster, and other like porous bodies, and thereby giving them the property to resist moisture, and also, in some cases, improving their appearance as well as increasing their durability.

It has hitherto been the practice in indurating stone, &c., to subject it to a very high degree of heat, in order to make the indurating substance penetrate and permeate through the material. This, however, has been found highly detrimental to the material under operation, and in many cases has failed to produce the desired effect. To remedy these evils it is proposed (in all cases where it is practicable), in applying these indurating mixtures, to enclose the stone or other materials to be operated upon in an air-tight chamber, and exhaust or partially exhaust the same; and then allow the indurating substance, whether hot or cold, to trickle down or flow into the chamber to fill the vacuum; the effect of which will be that the liquid indurating substance will readily find its way into the pores of the stone or other material, and become incorporated therewith.

Before subjecting the materials to this process of injection, they must be heated in a chamber or oven, to from 50° to 60°, for the purpose of driving out whatever moisture they may contain; and as the process greatly increases the natural tenacity of the materials submitted to such treatment, the articles should be worked or fashioned to their required form before being thus operated upon.

When the materials or works of art require to be coloured, they are stained with any suitable vegetable or mineral colour, by laying the same on with a brush, and allowing the colour to dry before commencing the indurating process.

*Mixture No.* 1.—the composition of this solution is as follows: —56 parts, by weight, of sulphur, dissolved by the aid of steam heat or dry heat, in 44 parts of dilute vinegar or acetic acid, containing 17 parts of acid to 8 of water.

In preparing indurating mixtures, to be applied to the exteriors and interiors of buildings, whether possessing a surface of brick, stone, cement, or plaster, the following ingredients are employed:—

*Mixture No.* 2, contains shellac, 14 parts, by weight; seed-lac, 14 parts; coarse turpentine, 1 part; pyroligneous spirits, 40 parts.

*Mixture No.* 3, is composed of gutta-percha, dissolved in coal-tar, naphtha, or other suitable solvent, in the proportion of 3 parts, by weight, of gutta-percha, to 8 parts of the solvent.

*Mixture No.* 4. The proportions and ingredients of this mixture are as follows:—To 1 bushel of limestone or chalk add 12 gallons of water and 12 lb. of alum, half a gallon of beer grounds and half a gallon of gall, and mix the same well together. If it is desired to colour the mixture, this may be done by adding thereto pitch, or vegetable or mineral colours. These solutions, when made lukewarm, may be laid on with a brush, until the surface treated will absorb no more. Works of art, blocks of stone, and other detached porous materials of the kind specified, may also, with advantage, be indurated by the use of these mixtures.

*Claim.*—Hardening and colouring natural and artificial stone, and articles composed of porous cements or plaster.—*Newton's London Journal.*

## THE TIME BALL, EDINBURGH.

By Professor C. Piazzi Smyth.

At the meeting of the Royal Scottish Society of Arts, on 12th Dec. 1853, Professor Smyth, at the request of the Council, gave an interesting exposition of the Time-ball recently erected on Nelson's Monument in connection with the Royal Observatory of Edinburgh. After alluding to the praiseworthy exertions of the late Astronomical Institution for the purpose of communicating the true time to the public, and the successive steps since taken by the Government in furtherance of those views, the Professor mentioned the time-ball as the last addition that had been made. The principle of this method of publishing the true time—viz., by the sudden dropping of some large and heavy body—was due to Captain (now Admiral) Wauchope, who, about 1829, frequently memorialised the Admiralty on the subject, and was at length rewarded for his trouble by seeing the erection of the signal, so useful to navigators, at the Greenwich Observatory. Within a few years after, such was the practical advantage found in consequence, that similar time signals were adopted at Portsmouth, Madras, St. Helena, and the Mauritius; and Captain Wauchope himself going out to the Cape station on duty in 1835, succeeded before long in having a time-ball established at the Observatory there. The Professor stated that he had had several years' personal experience (between 1837 and 1845) with this ball, or balls, for several were made, and literally used up, so difficult was it found with more simple workmanship to secure the perfect action which Mr. Field, of the firm of Maudslay and Field, had obtained by the adoption of a cylinder of compressed air, to break the force of the ball's descent. In 1841, when the Edinburgh Observatory was in full astronomical activity, and everything but the machinery of a time-ball possessed, the erection of one was agitated for by Admiral Milne, Captain Basil Hall, Captain Dall, and others, but unfortunately without success. In 1846, another attempt was made; for having had the honour of being appointed to the direction of the Edinburgh Observatory, and having received many representations from Sir T. Makdougall Brisbane, and others, of the urgent importance to Edinburgh and Leith of the establishment of a time-ball, he (Professor Smyth) reported the same to the Secretary of State for the Home Affairs. Soon after, Captain Washington, R.N., and Captain Veitch, R.E., Tidal Harbour Commissioners, were appointed to examine and report on the case; and they did make a minute examination of the locality and the interests of the inhabitants concerned, and strongly recommended the measure; but yet, strange to say, it was ignored by higher authorites. But the necessity for the erection of a time-ball by no means decreasing with these official difficulties, as the representations of the Edinburh and Leith Chamber of Commerce continued to show, he brought the matter forward again in 1848, in the printed report addressed to the then recently appointed Board of Visitors of the Royal Observatory. The Board seeing the importance of the subject, took it up warmly; the President, Professor J. D. Forbes, in the following spring in London waited on the then Lord Advocate (the Hon. Lord Rutherfurd), who, already much interested in the subject, immediately advocated it so powerfully in the Treasury, that it was forwith ordered to be undertaken, on the necessary estimates having been procured from Parliament. The procuring of the ball, with the money so obtained, was put into the hands of the Office of Woods and Forests; and they knowing well how admirably the Greenwich time-ball had performed, applied to Mr. Field to make a similar one tor Edinburgh, with all the additional improvements that had been suggested by the Astronomer-Royal, Mr. Airy, who took much personal interest in the execution of this new machine.

Professor Smyth then proceededto describe the apparatus—The ball is 5 feet in diameter, is painted black, and rises and falls through 10 feet. To annihilate the effect of the varying friction between the ball and the mast on which it slides as caused by the greater or less side pressure of wind, it is made very heavy, say 15 cwt. The celerity and certainty of the first part of its descent (all that is required for the observation) is thus ensured; while the latter part is effectually checked through the action of the air cylinder; a tube, which, closed below, receives a piston on the end of a long staff attached to the lower side of the ball, and being pretty nearly air-tight, affords at last so complete a resistance, that the ball in the piston is brought to a stand in the air, before it strikes any solid body. By opening and closing a small stop-cock below, the strength of this air-spring admits of very nice adjustment; for, when completely closed, the ball is thrown back half-way up the mast again; while, when fully open, it comes down with the report of a cannon. The ball is raised by crank-wheel-work acting on a pinion, which can be put in or out of gear with a rack edge on the ball-staff; and when the ball is raised up to the cross pieces on the top of the mast (its first descent from which is the instant of the fall to be observed), the piston, a mere iron disc, rendered close fitting by a plentiful lubrication of tallow, is lifted clean out of the cylinder about two feet, so as to offer no friction to oppose the rapidity of the first part of the descent. Again, to this end, the detents which hold the ball up when on high, and by whose movement it can be dropped, are made to catch into hooks on *either* side of the staff, and to work precisely together by a toothed-sector gearing, so that there may be no side pressure of the great weight then in suspension. Still although the detents and hooks are made of polished steel, there is more friction needed to loose them than a magnet could well overcome, especially as it would have to act through a considerable distance, from the touching surfaces of the supporters being made long enough, 0·5 inch, to guard against the vibration of the ball and staff in a high wind. But if, as is found, 1·200 or 8 lb. will pull the trigger of, and drop the big ball, then 1·200 of 8 lb. will be enough to drop a little ball of that weight, inside the apparatus; and it may be made to fall on the trigger of the other and drop that. This is the plan adopted, and as this smaller, or dropping ball, is not exposed to the wind, a very slight notch serves for its trigger, and a moderate magnet suffices to free it.

The electro-magnets are two in number, of the horse-shoe form, surrounded by close coils of fine wire covered with silk, and further saturated with wax, to guard against the damp of the top of the monument, and the communicating wires, covered with gutta-percha, pass down the side of Nelson's Monument in a wooden casing, and thence underground in iron pipes to the Observatory, where they rise through the floor, and are connected with the voltaic batteries and the contact maker on the case of the transit-clock. The contact maker is a very delicate sort of finger-note of brass, armed with a platinum-point, touching a platinum-plate on slight pressure; and this being within a few inches of the face of the transit-clock, beating its seconds audibly, enables a person to drop the ball on the top of the monument to a degree of accuracy of certainly less than the quarter of a second.

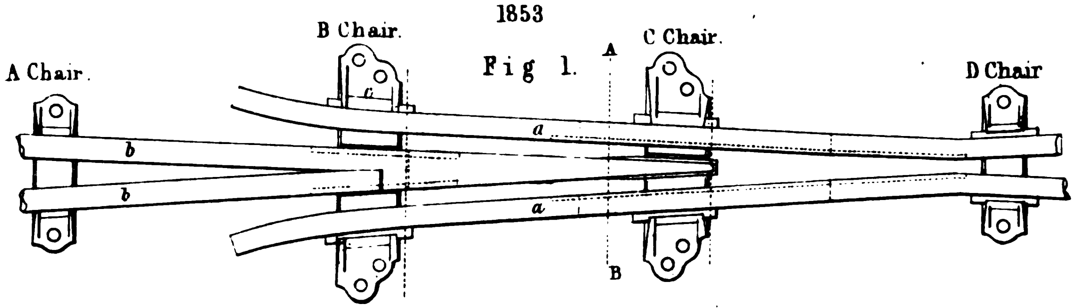
Such, then, is the signal-ball apparatus, as fitted up by Messrs Maudslay and Field, and very effective it is, as far as it goes; but the official use of it has not yet begun, though it is being experimentally dropped every day at one P.M. The reason is, partly, that the Observatory has not yet two disposable persons,—one to

# IMPROVEMENTS IN RAILWAY CROSSINGS AND CHAIRS.

Henry Carr, C.E. Patentee.

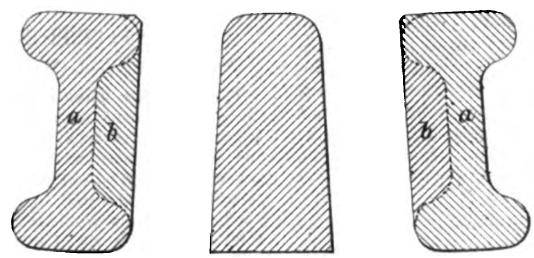
1853

Fig 1.



Plan of an Acute Crossing

Fig 2.



Section on the Line A.B. Fig 1.

Fig. 3. B Chair.

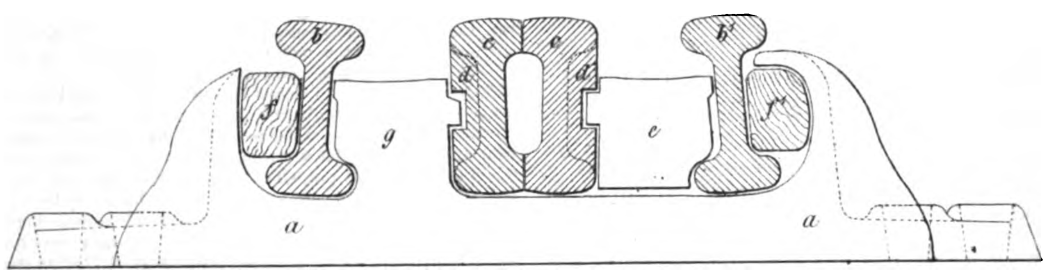


Fig. 4

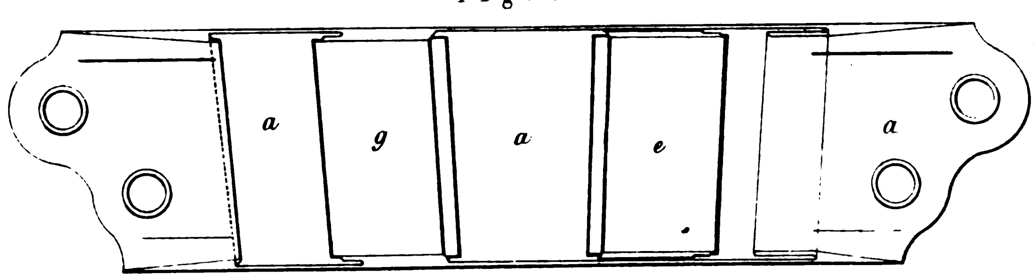
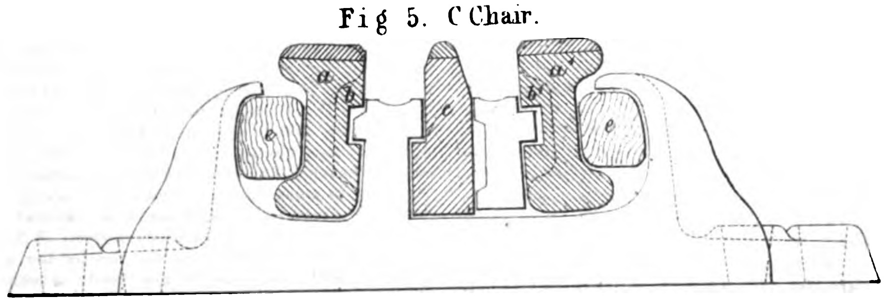


Plan of B Chair.

Fig 5. C Chair.



go to the top of the monument to wind up the ball, and another to drop it from the Observatory by the galvanic touch; part, also, because, although it is possible for a skilful person to drop the ball to a tenth of a second by the present means, still, after the time has passed, there is no record, no certain proof, that he did so,—nothing, in fact, to show whether he made the signal within even one minute of the time. Now, this should not be in a public establishment, especially one where all the previous parts of the operation are so recorded and certified; for the original observation of the stars for determining the error of the clock in the Edinburgh Observatory are published, together with all the steps of the calculations and ascertainment of the instrumental adjustments by which the clock error is at length obtained to the minute fraction required for astronomical purposes. A plan, however, to obtain this desirable end is in progress, and when in working order, a public notification of the commencement of official responsibility for the accuracy of the time-signal will be made.

The Professor concluded his account by exhibiting to the meeting the action of a model of the time-ball, 9 feet high, made in wood; and which, while keeping all the essential principles of the great time-ball, was altered in shape so as to suit a construction in wood. Inasmuch as in hazy weather our time-ball, even though mounted on the Calton Hill cannot be seen far, it becomes important to know if they can be multiplied cheaply, seeing that when local means are employed to raise them, they can all be dropped by one and the same galvanic touch. Accordingly, it had been found in the present instance, that by transplanting the metal form into the spirit of carpentry, replacing curved forms by straight, and generally adopting a triangular construction, a time-ball apparatus 9 feet high, with ball, windlass, air-cylinder, detents, and hooks, dropping-ball and electric trigger had been lately constructed almost entirely by one man, for 3*l.* to 4*l.*

## RAILWAY CROSSINGS.

HENRY CARR, *Patentee*, April 21, 1853.

(*With an Engraving, Plate* V.)

THE improvements in the construction of crossings of railways consist in—First, forming the inner part of wing-rails of railway crossings solid instead of with an overhanging flange, as in the ordinary crossing of I-formed rails. Fig. 1, Plate V., represents a general plan of an acute crossing, and fig. 2 is a section on the line *a b*, of fig. 1, showing two wing-rails formed in this manner; A, is the common I-rail, and *b*, a filling-piece between the upper and lower inner flanges. This filling-piece prevents the splitting or shearing of the upper flange of the rail where the edge of the wheel bears upon the overhanging part. It may be welded to the rail, or the rail may be rolled or otherwise constructed of the sectional form of the ordinary I-rail and filling-piece combined. The filling-piece is continued to the part of the rail where the wheel first takes its bearing, or as far as is found to be necessary.

Secondly, in strengthening the middle web and overhanging flanges of the point or point-rails by the introduction of the filling-piece above described.

Thirdly, in constructing the two middle chairs of a railway crossing (commonly called the B and C chairs) in such manner that the whole of the rails, when placed in each chair, shall be wedged up by driving in two wooden keys, for the purpose of giving solidity to the point or rails in the chair, and avoiding that motion which causes them to work loose. And for preventing the rails rising from the chairs, there is a fillet cast on the distance-piece, and also a fillet formed on the loose block, which fit into grooves or mortices made in the wing and point rails. Fig. 3 is an elevation of a B chair, with the point-rails, wing-rails, and keys in section; *a*, represents the chair; *b, b*, the wing-rails; *c, c*, the point-rails, strengthened with the filling-pieces *d, d*; *e*, is a loose block or distance-piece, in place of the usual block cast on the chair; *f*, is a wooden key or wedge for tightening the wing-rail *b*; and *f'*, the key for securing the wing-rail *b*, loose block *e*, and point-rails *c, c*, firmly against the fixed block *g*. Fig. 4 is a plan of a B chair, with the rails and wedges removed. Fig. 5 is a view of a C chair, with the wing-rails, point, and wedges in section; *a, a'*, are the wing-rails, with the filling-pieces *b, b'*; *c*, the point; *d*, the loose block or distance-piece, and *e, e'*, the tightening keys or wedges.

Fourthly, in supporting in a similar manner with filling-pieces the upper flanges of switches and stock-rails of the ordinary form, where the wheels bear partially upon the rails.

*Claims.*—1. The construction of the wing-rails of railway crossings with filling-in pieces; 2. The construction of the point of the point-rails of railway crossings with filling-in pieces; 3. The construction of point-rails with filling-pieces; 4. The formation of wing-rails, points, and point-rails of railway crossings by rolling them in one entire piece, of the sectional form of the ordinary I-rail, and filling-piece combined; 5. The formation of wing-rails, points, and point-rails of railway crossings, by forging them in an entire piece, of the sectional form of the ordinary I-rail and filling-piece combined; 6. The formation of wing-rails, points, and point-rails of railway crossings, by casting them of malleable iron of the form of the ordinary I-rail and filling-piece combined; 7. The construction and arrangement of railway chairs with loose blocks and wedges, in the manner above described.

## INSTITUTION OF CIVIL ENGINEERS.

*Nov.* 29, 1853.—J. MEADOWS RENDEL, President, in the Chair.

The discussion being resumed on *"Ocean Steamers,"* it was contended that the statement of a supposed wave pressure of 85,000 tons of water, or even of 40,000 tons, to which it had since been reduced, by a modified estimate, was inadmissible; it would be manifestly impossible for any vessel to withstand such impact from a body of water; and if the position was admitted, it must be evident that any of the ordinary coasting steamers would constantly be liable to a pressure of 1000 to 1500 tons, which would suffice to utterly destroy them.

The comparison of the qualities for safe riding, when lying-to, between a line-of-battle ship and a privateer, was not to the point, as the former was incumbered by the enormous weight of her armament, and by her top-hamper; in short, the whole misconception had arisen from confounding the wave of oscillation with that of translation; this was exemplified by the case of a disabled vessel,—as long as she remained afloat she was comparatively safe, but as soon as she touched the ground, and the wave of oscillation became one of translation, she was immediately knocked to pieces by the impact of the waves.

Next, as to the proportions of 6 to 1, which had been derived from as ancient a type as Noah's Ark,—now, as far as was known, as that construction had not been designed either for sailing or steaming, but only to float with a very large cargo, it afforded no analogy for vessels built for speed, however propelled; and, in fact, modern fast-sailing vessels had abandoned those proportions, which had only been perpetuated by the old tonnage laws, under which merchant vessels were enabled to be constructed to carry enormous cargoes, but they were unable to attain any considerable speed. It was further argued, that as steam propulsion was employed, the analogy became still less apparent; and, as an instance of the advantage of lengthening ships, the case of the vessels belonging to the North of Europe Steam Navigation Company was mentioned. The *City of Norwich*, 183 feet long, 26 feet beam, 471 tons burthen, and 200-horse power, could carry as cargo 220 head of cattle, at a speed of 10 knots per hour, but she rolled considerably with a beam sea; whilst the *Tonning*, 222 feet long, 27 feet beam, 734 tons burthen, and 200-horse power, carried 360 head of cattle, at a speed of 12 knots per hour; she was a remarkably easy vessel, and had proved her seaworthy qualities by coming safely round the coast of Scotland, during the late gale in September. Thus, with the same engine-power, by merely altering the proportions from 7 to 1 to 8 to 1, nearly 60 per cent. more cargo space was obtained, and 2 knots per hour were gained in speed, with improved sea-going qualities. It must be remarked, also, that the relative proportions of the *Tonning* were almost identical with those of the proposed iron vessel for the Eastern Steam Navigation Company.

Taking the *Wave Queen* as an extreme case—her length being 213 feet, with 15 feet beam, and proportions of 13 to 1, with a draught of water of only 5 feet, and comparing her performances with those of the *Christiania*, a good vessel, about 170 feet long, and with about the proportion of 6 to 1—it was found that whilst the latter in a moderate head-sea continually shipped the waves, the former in a similar sea was perfectly dry. This evidence was given from the personal experience of the speaker. The *Wave Queen* had since been running between Newhaven and Dieppe, and it was to be expected, indeed it had been predicted, that from local circumstances connected with the entrance of the harbour at Newhaven, she would meet with some casualty. She was not stranded in consequence of any inefficiency in the power of the rudder, but after a very bad passage across the channel in the trough of the sea, which was running very high, she arrived off Newhaven when there was scarcely depth of water over the bar for her to cross, she touched the ground heavily, and hung by her 'heel;' a beam sea catching her at the same moment, swung her round and threw her broadside on the beach, where all the passengers were safely landed. It was a good proof of the strength that could be given to iron ships, that though she was thrown broadside on the shore by the waves of translation, she was safely got off and brought round to the Thames without material damage.

As to the elaborate calculations entered into with respect to the three great navigation projects; before admitting the correctness of those results, it must be clearly understood that the *Rattler*, which had been used as the type, was built during the most depressed period (scientifically) of construction in H. M. Dockyard. Her dimensions were 176 feet long by 32 ft. 6 in. beam,—a proportion of about 5½ to 1, and from what had been published it must be evident that she had just performed what might have been anticipated from such proportions. At the time of the construction of the engines of the *Rattler*, marine engineers had scarcely adopted, and rarely practised, the use of the steam at a certain amount of pressure, and expanding in the cylinder, whereby such a vast economy in the consumption of fuel was now realised. Now, if the calculations of fuel required for long voyages were based upon the old scale of consumption, instead of the present rate, which in good ships did not exceed 3½ lb. per real horse-power, the deductions from the calculations must be still more unacceptable.

It was then contended, that all arguments based upon calculations of the speed and other qualities of such a type must be utterly fallacious. It had been shown what increase of speed and of carrying qualities had been produced by lengthening the *Tonning*, without increasing her power, and by analogy it was only reasonable to presume, that if the proportions of the *Rattler* had been altered from 5½ to 1, to nearly 8 to 1, there would have been a still more striking amelioration, and she would have been a more trustworthy type for the calculations and arguments as to the practicability of constructing and of commercially working large ships. It was argued, that with all these, and many other examples to the contrary, it was evidently incorrect to attempt to assume that 6 to 1 was the best proportion for vessels of any kind.

It was assumed, that when it was stated a large steamer was intended to run to India or Australia and back, without re-coaling, it was only meant that she would carry coal enough to avoid detention at the intermediate ports, as (unless it was ascertained that she could not procure a more profitable cargo) it would evidently be more economical to send coals to the ultimate and distant port by sailing vessels, who would convey them cheaper than she could do.

It must not be supposed that the meeting received for granted the results of calculations based on such a type as the *Rattler*, nor that the Institution could pretend to do more than offer a field for the investigation of the scientific portion of the magnificent commercial experiments about to be tried, and for the success of which all must unite in offering their best wishes. Engineers, unless especially called upon to give opinions on the prospects of commercial success offered by undertakings, were only expected to consider the best means of executing given works at the cheapest rates, compatible with security and durability, but the ultimate remuneration for the outlay must be mainly a subject for the consideration of the speculators.

The advantages of employing a smaller number of large ships rather than a greater number of small ships, for a given trade, especially for long voyages, was beginning to be generally admitted by shipowners. A return was published in the *Times* of Nov. 22nd, 1853, copied from the *Liverpool Albion* of Nov. 21st, which presented the results of that experience in a remarkable form:—

"The following Table shows the average number of days occupied on the passage by the vessels of different tonnage, ranging from 200 tons upwards, dispatched from Liverpool to Australia in the years 1852 and 1853:—

| | Average number of days in 1852. | Average number of days in 1853. |
|---|---|---|
| Under 200 tons | 137 | 133 |
| From 200 to 300 tons | 122 | 122 |
| „ 300 to 400 „ | 123 | 113 |
| „ 400 to 500 „ | 118 | 112 |
| „ 500 to 600 „ | 113 | 112 |
| „ 600 to 700 „ | 107 | 103 |
| „ 700 to 800 „ | 108 | 101 |
| „ 800 to 900 „ | 103 | 100 |
| „ 900 to 1000 „ | 102 | 95 |
| „ 1000 to 1200 „ | 96 | 91 |
| „ 1200 and upwards | 91 | 90 |

From the above table it will be seen, that in almost every instance the average is in favour of the largest ships, the 600-ton ships having an advantage of 24 days, on the average in 1852, over the 200-ton ships, and the 1200-ton ships having an advantage of 22 days over the 600-ton ships. In 1853, also, it will be seen that the results are much the same."

But even with this evidence, it would not be wise to rush to the conconclusion, that vessels of enormous size would be applicable in all circumstances; in fact, that which determined the expediency of using a large ship was the coincidence of a great amount of traffic and great length of voyage. For example, it might be questioned, except for some special branches of commerce, which appeared now about to be greatly developed, whether a very large ship would be likely to be commercially beneficial, between any two ports of Great Britain. It must be evident, that for each length of voyage and description of trade there was a particular size of vessel that would be most suitable; and, indeed, as in most other engineering works, the circumstances of the traffic would of themselves mainly determine the proportions of the structure; take, for example, the trade between England and America, as originally opened by the *Great Western*; that vessel, as first designed, although much the largest ship of her day, was of the smallest size by which such a trade could be conducted; and her length was actually increased, during her construction, to a point then generally considered dangerous.

Since that period, all vessels on that station had been successively augmented in dimensions as the trade increased; but even those vessels were too small for the Australian voyage of 25,000 miles, and the necessity of increasing the length was shown, by calculating how much coal would require to be carried, beyond that needed for an American voyage, in order to do the Australian or the Indian voyage equally well. Such calculation demonstrated that a vessel similar to the *Great Western* would require to be lengthened to 520 feet to accomplish that voyage. This argument showed that the conditions of the case compelled the adoption of vessels of extraordinary length for steam voyages of extraordinary distance.

Then, as to the commercial question: the merchants engaged in the Indian and Australian trade had calculated, from the data afforded by their own business, what amount of freight and passengers would require accommodation, and it was found that the quantity was greater than could be received by the ship just calculated. The dimensions, therefore required to be enlarged to meet the demand of the existing trade. Thus the traffic itself did actually fix the dimensions of the proposed large class of vessels.

As to the mechanical strength of such vessels, there was no difference of opinion on that point among engineers, provided the structure was of iron. Ships of wood, on the contrary, were limited in size by the nature of the material, which was *grown*, and not *manufactured*, and therefore the produce was of limited size; whereas plates of iron could, on the other hand, be rolled of any required dimensions. It must be observed, also, that the strength of wood across the fibre was so small that two planks could not be so united as to be equally strong in all directions, whilst two plates of iron riveted together were of nearly uniform strength.

Further,, as to the resistance of large vessels to waves: it was evident that the waves of the Atlantic, being of the same size, whether the vessel was small or large, their proportional magnitude would be decreased as the size of the vessel was increased, so that the large ship in a gale would merely encounter waves of the same proportional size as a ship of half the dimensions in half a gale; and it should be remarked that the largest ships which had been proposed were only double the lineal dimensions of existing vessels.

As to the impact of waves upon ships, it should be remembered that a vessel riding on a wave became, virtually, a part of that wave, and moved along with it, as the mass of water displaced by its bulk had previously moved. The large Atlantic waves, observed by Dr. Scoresby, did not strike the ship, but made her rise and fall in a gentle oscillation, each of which lasted sixteen seconds, a period of too long duration to admit of any approximation to violent collisions between bodies. It was only the small wind waves or crests which moved at a different velocity from that of the ship, and the proposed vessels were so much higher out of the water than the observed altitude of these waves, that the decks would probably never be more than wetted by the spray.

It was explained that H. M. S. *Rattler* had been assumed as a type of locomotive efficiency, because the formula $\left(\frac{V\ \sqrt{}^{3}\ D^{\frac{2}{3}}}{\text{Indicated H. P.}}\right)$ gave the highest result of any steamer examined by that rule. It would be seen that the formula merely embraced the relations of velocity, displacement, and working power.

It was stated, that a vessel which from any fault of construction, or from imperfect steering power, was liable to fall off into the trough of the sea, would in that position be liable to fearful accidents; and instances were cited of two vessels, of 800 tons and 1200 tons respectively, being struck by waves which had carried away all the upper works and swept the decks clear. These practical facts were given to show that the gentle oscillation of heavy waves must be received with some qualification. In answer to this, it was explained that in a storm there were generally two sets of waves, the long low oscillating wave, and the smaller waves, which were much shorter, rising under the action of the wind. It was those short waves which struck the smaller vessel with so much force when they got on the crest of a large one, but the deck of a very large ship would be too high for such wind waves to break upon it except as spray.

Returns were presented of the performances of a number of paddle-wheel ocean steamers, for a period of twenty-two years, tending to prove how greatly the velocity has been increased. This was shown to have arisen from the augmented size and better build of the vessels, with greater power of engines and other engineering improvements. These tables showed the necessity of a careful selection of the period, from which a mean average of velocity was deduced; for example, the *Hugh Lindsay*, H. E. I. Co.'s steamer, gave in 1830 a mean average of 5¼ knots per hour; whereas the best of the Cunard and of the Collins' lines of steamers gave a mean average of 12¼ knots per hour for the last three years.

It was explained, that the average of 7$\frac{6}{10}$ knots per hour had been derived from Admiralty returns, extending from 1848 to 1851,—which were the only reliable documents of the kind hitherto published. Members were urged to supply the present evident want of information on this subject.

As to the question of measurement for tonnage, after discussing the present method, describing that proposed by the Parliamentary Committee and those by the practical men who had been consulted, the system indicated by the author of the paper was examined with care, and was admitted to possess novel features worthy of consideration in fixing a legal standard of measurement. It was, however contended, that for scientific purposes, the displacement to the load-line was required, and for fiscal purposes it was submitted, that the light and other dues would be more equitably imposed by an *ad valorem* duty on the cargo, rather than on the bulk or form of the vessel.

In winding up the discussion, the dimensions were given of a great raft ship called the *Baron of Renfrew*, which was built in Quebec in the year 1825, by the late Mr. Charles Wood, of Port Glasgow. Her extreme length was 304 feet; extreme breadth, 61 feet; clear depth, 34 feet; registered tonnage, 5294½ tons; and cargo of timber 8500 tons. The draught of water at the end of the voyage, when waterlogged, was 31 feet. She had four masts and the sails of a 36-gun frigate. Her greatest inclination under press of sail was about 20 degrees. Her greatest speed before she became waterlogged, but with 19 feet of water in the hold, was 8½ knots, which was reduced to 6 knots when she was quite full of water. She made the passage from Quebec to the Isle of Wight in forty-eight days. It was due to Mr. Charles Wood to mention this daring innovation at so early a period.

It appeared, that if the dimensions of vessels had been increased, it was evident that there had not been any increase of danger, nor was any to be anticipated. The hesitation in receiving new propositions of startling projects was very natural, and therefore their discussion was valuable and really useful in eliciting opinions which might otherwise probably not have been given. The feasibility of the Britannia Bridge had been quite as much doubted as that of very large iron ships, and yet it had been executed, and the result was before the world. It appeared evident, that in future engineers must look even further forward than they had done, and in their maritime constructions must adopt dimensions for their docks and harbours to accommodate the increased sizes of the vessels they were destined to receive, but which some years since would have been deemed visionary.

*December* 6.—The paper read was, "*On the Drainage of the District, South of the Thames.*" By J. T. Harrison, M. Inst. C.E.

The district south of the Thames, comprised in the "Surrey and Kent division of the sewerage of the Metropolis," was briefly described as extending between Battersea and Greenwich, over an area of upwards of 9 miles in length, with widths varying from ¼ mile to 2¼ miles, bounded by the river Thames on the north, east, and west sides, and by the rising ground on the south. Its chief peculiarities were that the surface was almost entirely below the level of high water mark,—that it was, to a considerable extent formed of alluvial deposit, permeable to and surcharged with water, and it was moreover subject to frequent flooding from the adjoining high land. For such a district the points demanding attention were shown to be;—thorough drainage of the land,—means of preventing the inflow of water from the neighboring high land,—the rapid discharge of the rain-water falling on the area,—and the regular conveyance away of the sewage matter, not only from the houses but from the main sewers.

The present system of drainage was shown to be very defective, but the author expressed his conviction of the possibility of remedying the existing defects, and of taking advantage of the assistance of the rise and fall of the tide, and of other local circumstances, for thoroughly effecting both the cleansing of the sewers and the drainage of the district, by means inexpensive in themselves and independent of the casualties of steam pumping machinery or of the caprice of ratepayers.

It was shown, that the existing sewers acted partly as drains for the land water, but they only extended over a portion of the area, whilst from their being so frequently full, and even being under pressure, the sewage matter escaped from them and saturated the ground;—it was therefore contended, that a system similar to ordinary agricultural drainage should be carried out. The question was incidentally raised for discussion, whether advantage might not be taken of the known rapid filtration of the chalk formation, to facilitate this operation, by sinking several wells into which the land drains might converge. The interception of the upland water by catch-water drains was insisted on, and the necessity for it pointed out. The rain-water was proposed to be conveyed away by the existing sewers, which would require some addition.

The conveyance of the sewage matter from the houses of the district was next discussed. This was divided into two stages,—the first; from the houses to the public streets, and the second, from the streets to its destination. The means of obtaining the first point were simple, and the stoneware pipes were recommended as sufficiently good, if of large diameter, and laid properly on a system of separate rather than of combined drainage. For the second point, Greenwich marshes being fixed upon for the temporary reservoirs or recipients of the sewage matter, and the Thames as the ultimate distributor of it, it was proposed to take advantage of the fall of the Thames between Battersea and the Greenwich marshes, which was stated to be 3 feet at the lowest neaps, 5 ft. 6 in. as a mean, and 7 ft. 6 in. at the highest spring tides, and by a copious use of Thames water to flush out the main sewer daily. This could be accomplished by forming a main sewer 8 feet in diameter, from Battersea to Greenwich marsh, having the same fall as the Thames at low-water neap tides; its invert being one foot below low water, and having a communication with the Thames at each end, so that water from the river might flow through at low water; forming, also, reservoirs for arresting and collecting the sewage, and a canal for receiving the liquid after the filtration or precipitation of the solid matter. This canal, excavated 6 feet below low-water spring tides, extending across the marsh and being connected with the Thames at each end with proper gates, &c., so that water from the river might flow through it towards and at low-water, leaving it full of pure water when the gates were shut on the rising of the tide. The overflow from the reservoir into the canal might be 2 feet above the highest low-water mark, so as under the most unfavourable circumstances to give that depth for the filtered sewage water and that used for flushing, to accumulate during high-water. It was contended, that by having the mouths of all the cross sewers communicating with this main duct fitted with flaps, the head of water derived from the Thames, which would be 15 feet at springs, and 10 ft. 8 in. at neap tides, would give a velocity through the main sewer of about 2 ft. 6 in. and 2 feet per second respectively, which would be sufficient to clear away any deposit. This canal might also be used for loading barges to carry away the sewage, either for agricultural purposes or for discharging lower down the river or out at sea.

It was further proposed to form cross drains at convenient distances apart, from the Thames to the main sewer, which should be flushed by a head of water from the river at high water, all the collateral drains into these being fitted with flaps. These, it was contended, might be kept nearly level, the head of water being abundant for thoroughly flushing them. The collateral drains being constructed with a good fall and communicating at each end with the cross drains, could be thoroughly flushed at stated periods.

The question of the applicability of the existing sewers was then examined, and from data afforded by Captain Vetch's sections, it was considered that they might be made available; the large proportion of 41 miles of open ditches (in 1848) to 30 miles of closed sewers, was urged as a strong argument for the introduction of an entirely new system. It was urged, that the chief point to aim at was the adoption, if possible, of a system that would work well without any mechanical pumping, as steam power could be added if found necessary for discharging the sewage matter into the Thames at high-water.

Comparisons were drawn between Captain Vetch's plan, and that now proposed to be carried out by the Commissioners of Sewers. It was urged, that Captain Vetch's "long covered tank, reaching far into the district to be drained," retained some of the most objectionable features of the present system, and that the Comissioners' plan of flushing from the Thames, being dependant for its success on the steam-engine pumping out the water as fast as it was let in from the Thames, was undesirable, and liable to be entirely frustrated by accident.

An appendix contained some communications made by the author, in August 1849, to the Metropolitan Commissioners of Sewers, in answer to their appeal to the public for suggestions on the subject of the sewerage of London. In those documents, a system of drainage was proposed the chief point of which was the making use of the head of water afforded by the rise of the tide in the Thames, for a general system of flushing the whole of the sewers of the low-lying districts, and in many respects similar to the system described in the paper.

*December* 13.—The discussion was resumed on Mr. Harrison's paper, and was continued throughout the evening. The complete system of sewerage introduced at Hamburgh, since the great fire, by Mr. Lindley, C.E., was alluded to as a good instance of the efficiency of the plan of flushing sewers, even in very flat districts, and with syphon dips, when there existed a head of water like that from the Alster lake, which was 13 feet above the high-water mark of the Elbe.

The culvert through which the Frome passes beneath the float, and flows into the Bristol river, was also described, and from these and other examples of the advantages of flushing sewers, that system was urged to be preferable to the labour and expense of pumping up from depths below low-water mark, the ordinary sewage contents, without dealing with the rain-water falling during thunderstorms, which it was contended could not be raised by any amount of steam-power which could be practically adopted. In fact the employment of steam-power for pumping out the sewage was opposed on the grounds of the constant expense, and the liability to stoppage from accidental causes. It was also argued that the drainage of fen lands by steam-power was not analogous, as the fen water-courses were so large as to form reservoirs, whence the pumps lifted the water in a given, but lengthened period of time; and even then not so as to avoid such back flooding as could not be admitted for town drainage.

The best systems proposed were stated to be the interception of the highland waters, the carrying away by gravitation all the contents of the sewers which could be discharged into a low point of the Thames by natural means, and resorting to pumping only for such portions of the metropolis as were too low for any other system. Such, it was contended, was the plan which had been proposed by Mr. J. R. M'Lean, to the Commissioners of Sewers, in 1849; and in a review of the systems proposed by Captain Vetch, the late Mr. Forster, and Mr. Bazalgette, the accordance with and the deviations from the original plan were pointed out and commented on.

The necessity for providing against any chance of flooding the basements of the houses, by allowing the main sewers to become filled and be under pressure, was insisted on. Doubts were expressed as to the possibility of obtaining sufficient velocity to scour out such main sewers as those proposed to be flushed from the Thames, and having their outlet at Greenwich.

The question of pipe drains and brick sewers was again entered upon, and it appeared that experience confirmed the previous impressions of the applicability of the pipes to house drainage only when they had rapid fall and were of sufficient area, but that nothing could be relied upon for sewers except brick constructions, sufficiently large to permit access within them; they should also be permeable, so as to act as drains in conveying away the land water from the district which they traversed. It was stated, that in Lambeth there were spots which about 25 years since were full of water, but which at present during the summer were found to have been thoroughly dried by the action of the sewers passing through or near them.

It was urged, that the question of the proper outlet for the sewerage could only be fixed by careful investigation of the period during which the matter remained suspended, and the distances it travelled up and down the river with the ebbing and flowing tides; the experiments made on this point did not appear to be received as authority.

In treating the questions of detail, it was shown that the brick sewers never practically became elongated cesspools, as had been asserted; that there was really greater scouring power in an egg-shaped sewer than in a pipe drain; that the alleged smooth interior of the pipes was illusory, as their joints were more liable to occasion stoppages than the joints of the brickwork; that the interior of the latter did, practically, soon become covered with a slimy matter, which aided the flow; and that deposits rarely occurred, except where the sewers were too flat and too small.

As to the question of cost, it was shown that the statements of the comparative expense of the metropolitan and of the country drainage works, as published "by authority," must be received with caution; the cases were not analogous from the impossibility of comparing the ducts made to convey sewage one quarter of a mile, with those intended to convey the cumulative proceeds of many miles of dwellings. The mere difference of the cost of labour beeween London and the country would preclude comparison as to the expense of works; and the local difficulties of cutting underground in large cities must be taken into consideration.

*Dec.* 20.—Annual General Meeting.—The evening was devoted to receiving the Annual Report of the retiring Council, to the election of the President, Vice-President, and other Members of the Council for the ensuing year, and to the presentation of the Medals and Premiums which had been awarded.

The Report succinctly reviewed the progress of engineering works at home and abroad, and the general prospects of the profession, which appeared to be most satisfactory. It touched upon the successful results of the Industrial Exhibition at Dublin, due to the liberality of Mr. William Dargan, whose name was so intimately connected with engineering works.

The sanitary improvements and other branches of engineering, having for object the social advancement of the community, were commented on, and the great works, both of public utility and architectural embellishment, in progress in France, under the present energetic ruler of that kingdom, were pointed out as worthy of exciting our national emulation.

With so extensive a choice of subjects, the paucity of papers transmitted for the meetings was pointed out; and rather startling statements were given, showing how few of the members of all classes had fulfilled the obligations entered into on joining the Institution.

The principal papers read during the past session were enumerated, with a short notice of each, and the tenor of the discussions, which were shown to be the distinguishing features of the meetings of the Society. It was apparent that those were the most valuable papers which were the most readily furnished by engineers, as being observations of the effects of natural causes in constant operation, in the vicinity of work constructing under their direction, and the attention of members was urged to that point. It was gratifying also to observe, that premiums were awarded for four papers, contributed by gentlemen who were not connected with the Institution.

The following medals and premiums were presented:—Telford Medals to Messrs. Coode, Clark, Brooks, Huntington, Burt, Duncan, Siemens, Cheverton, and Barrett; and Council Premiums of Books to Messrs. Richardson, Armstrong, Rawlinson, and Sewell.

Attention was directed to the engraving of Mr. Andrews' portrait of the Past-President, Sir John Rennie; to the portrait of Brindley, presented by Mr. Hawkshaw, and to a marble bust of the first President (Telford), by Hollins, which had been lost sight of for many years, and only accidentally recovered by the Secretary within the last few months. It was now restored to the Institution, for which it had been originally destined, and Mr. Rendel, as a last act of Presidentship, presented for it a pedestal appropriately carved from a block of Peterhead granite—a material which had been so extensively employed in the works of the first President of the Institution.

The deceases noticed were few: they were Major-General W. G. MacNeill (U. S. Army); John Green and Tomaso Cini; Members:—Col. J. N. Colquhoun, R.A.; and Messrs. E. J. Dent and G. Bradshaw, Associates. The memoirs detailed the services of these two distinguished officers, who to their military tactics united great aptitude for engineering pursuits; the numerous works of an old member of the profession; the labours of a foreign coadjutor, too early removed from a sphere of usefulness; the ingenuity and excellence of workmanship of the well-known chronometer maker; and the kindly disposition, the watchfulness for opportunities of doing good, and the energy in pursuing his useful course, of him who was the pioneer in all guides for travelling the complicated network of railways in this country and on the continent.

The financial statement showed that though there was a heavy debt for printing, yet the annual income now, for the first time, exceeded the ordinary expenditure; it was deemed expedient to expunge from the accounts a large amount of arrears of subscriptions, and to erase the names of the defaulters from the register of the Institution.

It was shown that the cost of rebuilding the house of the Institution had been entirely defrayed from the Building Fund, by which also all repairs were now provided for; and that the past and present Members of Council had made voluntary contributions, in aid of the funds of the Society, to an amount far exceeding anything imagined by the general body of the members.

The vital importance of printing the arrears of the Minutes of Proceedings, and of giving rapid publicity to the papers and the abstracts of the discussions, was generally admitted; the question had occupied the serious attention of the Council, and nothing but the fear of involving the Institution in hopeless financial difficulties, had caused the present arrears of publication. After giving an account of the progress of the printing of the volumes of the Transactions and of the Minutes of the Proceedings, showing the gradual extension and the cost, it was demonstrated, that there existed no other bar to the rapidity of publication, than the extent to which the members of all classes were willing to assess themselves, by voluntary or compulsory contributions, to defray the inevitable amount of expenditure for printing.

This statement produced a lengthened discussion, which resulted in the determination that contributions should be collected from members of all classes, on the following scale:—President, thirty guineas,—Past Presidents, Vice-Presidents and Members and Associates of the Council, twenty guineas each,—Members, five guineas each, and Associates, one guinea each.—This assessment was cheerfully agreed to, and several Members and Associates present, doubled the amounts of their contribution, to aid in the very desirable object of immediate publication of the Minutes of Proceedings.

The thanks of the Institution were unanimously voted to the President, Vice-Presidents, and other Members and Associates of Council; also to the Auditors, the Scrutineers of the Ballot and to the Secretary for their services.

The following gentlemen were elected to fill the several offices in the Council for the ensuing year:—James Simpson, *President:* G. P. Bidder, J. K. Brunel, J. Locke, M.P., R. Stephenson, M.P., *Vice-Presidents:*—J. Cubitt, J. E. Errington, J. Fowler, C. H. Gregory, J. Hawkshaw, T. Hawksley, J. R. M'Clean, C. May, J. Penn, and J. S. Russell, *Members*; and H. A. Hunt and C. Geach, M.P., *Associates of Council.*

Mr. Rendel, President, on quitting the chair, which he had occupied for two years, with such advantage to the Institution, addressed the meeting; he alluded to the general professional employment in all parts of the world, and noticed with pride the preference exhibited for British engineers, whose scientific and practical skill was no less acknowledged than their known probity and honour. The importance attached to the title of Member of the Institution, was referred to, for the purpose of pointing out the necessity entailed by it for fostering and sustaining the reputation of the Society, and for making its archives the depository of the records of all the best engineering works. He pointed out also that all periods of agitation for change were dangerous epochs for societies, and more especially for the Institution of Civil Engineers, whose peculiar bond had hitherto been the merit of having closely united those members of the profession who formerly could rarely be brought together. All changes, then, should, he urged, be gradual, and above all result only from careful consideration by the older members, who on all occasions had demonstrated their anxiety to bring forward their juniors. He then thanked his coadjutors and the Secretary for their assistance; commended his successor to the same kind consideration as he had experienced, and with regret retired into the class of Past-Presidents, after being an active member of the Institution for thirty years, during thirteen of which he had been successively elected on the Council, and had now completed his second year of tenure of the office of President.

The meeting was then adjourned until Tuesday, January 10th, when the discussion will be resumed on J. T. Harrison's paper, "On the Drainage of the District South of the Thames," and if time will permit, the paper "On Incline Planes for Canals," by J. Leslie, M. Inst. C.E., will be read.

## RECENT AMERICAN PATENTS.

[Reported in the Journal of the Franklin Institute.]

*Oven Doors for Cooking Stoves and Ranges.* G. North.

*Claim.*—The application of an adhesive coat of enamel, or other substance answering the same purpose, to the inside of the oven doors of ranges or cooking stoves.

*Scythes.* W. P. Greenleaf.

*Claim.*—Widening and curving the blade of the scythe at the shank, for the purpose of strengthening the same, and adapting it to cutting bushes as well as grass.

*Facing Buildings.* M. B. Dyott.

The nature of the invention consists in an improved mode of uniting, fastening, and supporting cast-iron or other plates to the external walls of buildings, whereby the said plates form an ornamental facing thereto, are protected against external injury, and secured from the injurious and disfiguring effects of moisture from the interior.

*Boring Cannon.* L. A. B. Wallach.

The invention consists in producing a cylindrical hole in any solid substance suitable for making cannon or small arms, by boring out an annulus of the diameter of the required hole, leaving a central core two-thirds, more or less, of the diameter of the bore, which can be broken off when the annulus is completed, to the required depth, and removed in a solid mass, instead of being cut into fine chips or shavings, as in the ordinary way of boring, whereby much labour and time are saved, and the expense of boring is greatly reduced. The core likewise furnishes a sample or test of the nature or quality of the material in the interior of the substance being bored, and this method of sampling the material, which is highly important in the boring of cannon, constitutes another branch of the invention. The means of removing the core after the annulus is bored, also constitutes another branch of the invention. This mode of boring cannon differs from all others now practised or known—first, in leaving a solid core formed by the cutting of an annular space around it while the boring progresses, and which core is usually of greater bulk than half of the material to be removed; and secondly, in afterwards detaching this core as a solid, instead of reducing it to particles in the form of chips and dust; as in the usual mode of boring. The dead centre of the ordinary boring-tools, which is a great impediment to the progress of the work, is entirely avoided by this method of circumaxial boring, wherein no such centre exists. The centre of every common boring-bit forms its pivot or axis of revolution, and having little or no circumferential motion, cannot possibly cut out a chip. It can therefore only progress through the substance by the force of pressure or crushing alone. In this method the cutting edge is reduced in extent to at least one-third of that of any other boring tool, by which both time and expense are saved, in proportion to the diminished amount of material to be removed; and being placed at and near the periphery of a hollow cylinder, it works there with greater effect in the ratio of its greater distance from the axis, and by avoiding the dead centre of other modes of boring, effects a still further saving of time, in proportion to the greater facility of cutting over that of forcing or crushing a tool into the mass to be perforated.

*Claim.*—The method of boring cannon, or the barrels of other ordnance or fire-arms, by perforating the same with an annular hole, which leaves a central core, in combination with a second operation for detaching and removing the core, whereby the amount of material to be reduced to chips, the time and labour of boring, and the wear of tools are greatly diminished, and the accuracy of the work increased. Also the transverse cutter for grooving or cutting off the base of the core; and the method of ascertaining the quality of the gun by taking out a core of sufficient diameter and length from the axis or centre of the bore, to be tested mechanically.

*Turbines.* U. A. Boyden.

*Claims.*—1. The leaning or inclining of the leading curves or guides to the plane of the wheel. 2. The making of the inside of the garniture, or the part of the gate next the disc, or both, of such a curvature or form, that the water at the upper part of the stream or streams, where it leaves the garniture or gate, will have a downward motion, or a direction inclining to the plane of the water-wheel, and making the upper sides of the passages for the water through the wheel descending or inclining to the plane of the wheel, from the commencement of the passages next the gate to about half-way from the inner to the outer edge of the upper rim of the wheel, where they are nearly or quite horizontal, or nearly or quite parallel with the plane of the wheel; the inclination of that part of the lower surface of the upper rim of the wheel which is next the gate, being the same or nearly the same as that of the lower surface of the gate next said upper rim, and the change from inclining to horizontal being gradual, as by a curve; or making the upper surface of the disc, next the lower rim of the wheel, to incline up toward this rim, and making the lower sides of the parts of the passages through the wheel, which are next the disc, ascending or inclining to the plane of the wheel, so that the stream or streams will gradually diminish in height at the entrance or entrances into the wheel, so that the water which passes in the upper parts of the stream or streams will converge toward that which passes in the lower parts of the stream or streams, before striking the floats, and continuing this converging into the wheel to about one-half the distance from the inner to the outer edges of the rims of the wheels. 3. The forming of the lower part of the tube which sustains the disc, and the forming of the top of the disc on that part of it next the tube, and fastening these parts together. The inventor in his claims has written of the turbine as having its common position, in which case the water descends to pass between the leading curves, without alluding to its ever having any other position; but extends the claim to the cases in which the wheel is vertical or inclined to the horizon, and to the case when the water ascends to pass between the leading curves.

*Turbines.* U. A. Boyden.

*Claims.*—1. The arrangement of a gate at the entrance of the water into the wheel, with a part or all of the garniture or lining, and other parts of the turbine within, over, and about the gate, such that the gate and a part of the garniture, if any be attached to it, may move freely, while the part of the garniture not attached to the gate, and other parts over and about the gate, remain stationary, and so closely fitted that little or none of the water in the flume can run to the upper part of the gate, excepting by passing under the stationary garniture, and afterward upward, so as to diminish the liability of sediment, dirt, or other substances being carried by the water to the upper part of the gate, or moveable part of the garniture, if any be attached to the gate, so as to obstruct the motion of the gate, or moveable part of the garniture. 2. The leaning or inclining of the floats or buckets of turbines to the rims of the wheels, so that when the wheel of a turbine is working, with the gate next the wheel partially open, the parts of the floats opposite the aperture formed by such partial opening of the gate, will be forward of those parts next the other rim of the wheel, so that the leaning of the floats will diminish the spreading or deflecting of the streams into the part of the wheel opposite the gate. The claim extends to all degrees of inclinations, which will substantially answer the same purpose, as this effect of inclining the floats depends on the streams only partially filling the wheels. It does not extend to inclining the floats to any such turbine or hydraulic motor as has no gate at or near the water wheel, or other means of varying the width, thickness, or number of streams which enter the wheel. 3. The arrangement of the diaphragms or partitions in reacting wheels, and in the wheels of turbines, at different distances from the rims of the wheels, in the several spaces between the floats, to facilitate regulating the motions of the wheels, as the effect of these diaphragms depends on the streams only partially filling the wheels. The inventor does not extend the claim to this arrangement of the diaphragms to such motors as have no gate next or near the water wheels, or other means of varying the width, thickness, or number of streams which enter the wheels. 4. The combination of the device of making the gate at the entrance for the water into the wheel, to move separately from the garniture, with the leaning guides or leading curves, which direct the water into the wheel, so that when the gate is partially open, the part of the water which passes by or near the surface of the gate, in flowing toward this passage into the wheel, made by such partial opening of the gate, has its motion directed the way the wheel turns, in consequence of the leaning of the said guides. The claims extend to such turbines or hydraulic motors as discharge the water at their peripheries, and to such as have the water enter their wheels at their peripheries.

---

*Hydraulic Motors.* U. A. Boyden.

*Claim.*—1. The arrangement of the gates around and next outside of the peripheries of the water wheels, between the wheels and the guides, or other things which cause the water to move obliquely toward the wheels in the way the wheels turn, when the water first strikes the floats or buckets. 2. The device to cause the height of the wheel, or the position of the parts which partially confine the water which presses the wheel upward, to vary as the height of the water or fall varies, so that the width of the aperture which lets the water escape from the place where it presses the wheel upward, varies proportionally to the quantities of water pressed into it; so that the force with which the water pressed the wheel upward will be nearly or quite constant, though the height of the fall varies greatly. 3. The combination of a gate around and near the periphery of a water wheel, between the wheels and the guides, or other things which direct the water the way the wheel turns into the wheel, with the parts of the floats near the gate curved, so that the water will strike their concave sides. The inventor does not limit his claim to an annular gate, between the wheel and the things which cause the water to move the way the wheel turns, before it enters the wheel, but extends it to all things which will substantially answer the purpose of a gate, in varying the height, thickness, width, or number of streams that enter the wheel. 4. The shape of the spaces between the rims of water wheels, which the floats are fastened to, in which they flare toward the axes of the wheels. The first, third, and fourth branches of the claim apply only to such hydraulic motors as have guides, or other things which cause the water to move obliquely toward the wheels, in the way in which the wheels turn, and pass into the wheels at their circumferential parts, and after acting on the floats, discharge from the floats inward. The inventor does not extend these divisions of his claim to the class of tub wheels and undershot wheels, in which the water generally flows into the wheels in streams, with spaces between the streams, at which spaces the water does not flow into the wheels. He does not limit either branch of his claim to cases in which the wheels are horizontal, or to cases in which the gates are opened by raising.

---

*Gear of Variable Cut-off Valves for Steam-engines.* M. W. Baldwin.

The principle of varying the cut-off by means of a vibrating arm and sliding pivot block has long been known, but the contrivances for changing the position of the block upon the arm have been very defective. The radius of motion of the link by which the sliding block is changed on the arm, the radius of motion of that part of the vibrating arm on which the block is placed, have in this kind of valve gear, as heretofore constructed, been different, which produced a continual rubbing of the sliding block upon the arm while the arm is vibrating, and as the block for the greater part of the time occupies one position on the arm, and only has to be moved towards either extreme occasionally, that part of the arm on which the block is most used soon becomes so worn that the block is loose, and jars. This can only be remedied by dressing up the arm throughout its entire length; for if the brasses of the block were set up so as to make the block fit on the narrow portion of the arm, it could not be moved towards the extremes. To remedy these defects in the link motion, has long been a desideratum. The plan, however, of most engines now built, does not admit of the position of the parts of the old motion being so disposed as to avoid the difficulties specified, while this improvement can with the greatest facility be applied to any of them. This contrivance the inventor has essayed, and he states that it works well in practice, overcoming all the difficulties incident to the use of the numerous other gearing for variable cut-off valves.

---

*Safety Valves.* Z. H. Mann.

The invention has for its object an increase of sensibility of the safety-valve, so as to ensure its opening at the desired maximum of pressure, and also so as to increase the size of opening in proportion to the force of steam, and thus ensure promptness of action and an adequate vent for the steam under all circumstances, thereby removing all danger or possibility of explosion with a suitable boiler. A flutter wheel, governor, and supplementary lever, or equivalent devices, is constructed, and applied to a safety-valve.

---

*Working the Valves of Steam-engines.* R. H. Townsend.

*Claims.*—1. The combination of a cam and eccentric by means of the sector, or its equivalent, to operate on the valve or parts that move the same, and cut off or work with the full pressure by the eccentric, according to the position of said sector. 2. Adjusting the position of the sector by means of the governor, through the screw or other suitable means, whereby the governor regulates the position of the sector, to communicate the desired motion to the valve of the engine from the eccentric or cam, or both, according to the power required from the engine, as specified. 3. The rod and points to take motion from the block at its extremes of motion, and communicate the same by means of the right angle lever to the throttle or stop-valves as specified.

The invention consists in a peculiar combination of the eccentric and cam, the eccentric working as usual when operating on the valve to give the engine steam nearly the entire stroke; the cam so shaped that when it is brought into operation, the valve is moved in such a way as to cut off at the smallest part of the stroke at which the engine is required to work. These motions are combined by means of a sector operated on by the governor, that when the governor balls fall in consequence of the increased power required from the engine diminishing the speed, the eccentric is brought into operation on the valve; and when the engine is doing little work, the operation of the governor by sliding the sector brings the cam into operation, to cut off, and allow the engine but little steam; the regulation of the position of the sector by the governor thus at any intermediate point or at the extremes, supplying steam and causing the valve to cut off, in proportion to the work to be performed; and by a peculiar apparatus, in case the valve does not supply the required steam to keep up the momentum, the throttle valve is opened farther, or the reverse operation is performed if the work be thrown off the engine so as to need little steam.

---

*Fences for situations exposed to Floods.* H. S. Ross.

*Claim.*—Zigzag and interlocked arrangement of panels, supported by a swivel joint to posts at suitable intervals, and having the joint between the two middle panels furnished with inclined hook and eye, each of said middle panels being provided with boards sloping in opposite directions, so that by the action of a flood, each half of the intervening line of panels may separate midway, and giving in the direction of the current.

---

*Oskrigg Church, York.*—This church having become in a dangerous state, and unfit for the performance of divine service, it has been determined to partially rebuild it, and effect several other restorations. A committee has been formed to carry out the intended works, which will consist of the rebuilding of the nave and north aisle walls, new-north windows and east window of five lights. The nave roof of massive oak, a good specimen of the molded flat roof of the 15th century, will be replaced if decay, which has set in, be not too far spread. The whole of the present seating and galleries will be removed, and the church reseated with low open seats of an appropriate character, of memel wood stained. The stalls at the east-end, pulpit, reading desk, and communion table will be of English oak. This church not having a clearly-defined chancel, the eastern portion of the nave will be divided from the aisles by open screen-work of oak, and which, from portions of screen-work being found in the church, gives authority to this having been the original arrangement, the space behind being used as chapels. The general character fo the new work will be of the Perpendicular style. The present contract has been let to Mr. John Holmes, of Bramham; the architect is Mr. Thomas Dickons, of Durham.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated Aug.* 9, 1853.—1853. H. des Moutis, Paris—An improved system of publicity.

*Dated Oct.* 5, 1853.—2272. A. Turiff, Paisley, Renfrew, engineer—Improvements in retarding apparatus for the prevention of accidents on railways.

2278. H. Stevens, Trafalgar-square, gentleman—Improvements in the preparation of vegetable substances for the purpose of preserving the same. (A communication.)

*Dated Oct* 11, 1853.—2328. J. C. Sharp, Paisley, Renfrew, engineer—Improvements in retarding apparatus for the prevention of accidents on railways.

*Dated Oct.* 12, 1853.—2344.—Robert William Waithman, Bentham House, York, gentleman—Improvements in apparatus for applying paint, varnish, and other liquid substances, and also for cleaning carriages, ships, roadways, houses, and other buildings.

*Dated Oct.* 14, 1853.—2364. William Jones, Porchester-street, Hyde-park-square, gentleman—A certain chemical compound or compounds applicable as a remedy for cuts, scalds, burns, wounds, and accidents of a similar nature to which the same can or may be applied.

*Dated Oct.* 19, 1853.—2407. P. A. L. de Fontainemoreau, South-street, Finsbury,—An improved composition to be applied in substitution of bone and horn. (A communication.)

*Oct* 20, 1853.—2428. J. Woofenden, Belfast, engineer—Improvements in power-looms for weaving.

*Dated Oct.* 21, 1853.—2432. J. G. Marshall, flax spinner, and P. Fairbairn, machinist, Leeds—Improvements in machinery for combing flax, tow, wool, and other fibrous substances.

*Dated Oct.* 24, 1853.—2454. C. F. Blunt, Montague-place, Russell-square,—An improved artificial fossil coal-fuel, which he desires to denominate "Blunt's diamond coal-fuel."

*Dated Oct.* 27, 1853.—2490. W. McNaughten, Manchester—Improvements in printing yarns or worsteds for weaving carpets, also in printing carpets, woollen, silk, cotton, and other textile and felted fabrics and fibrous substances.

*Dated Oct.* 28, 1853.—2499. W. Thompson, Clayton-street, Lambeth, gentleman—Instantaneously extinguishing conflagrations in ships' holds, warehouses, and other buildings.

*Dated Nov.* 1, 1853.—2520. J. Bottomley, Bradford, manufacturer—Improvements in ornamenting textile fabrics.

*Nov.* 1, 1853.—2532. T. S. Bale, Cauldon-place, Stafford, china manufacturer, and D. Lucas, Stoke-upon-Trent, artist—Improvements in ornamenting the materials of and articles manufactured in pottery, as bricks, tiles, slabs, &c., and also in glass, slate, stone, and other plastic substances.

*Nov* 2, 1853.—2542. B. Butterworth, Calder Cottage, Caldershaw, grocer—Improvements in combining oil with other liquids, for the obtainment of a new lubricating compound. (Partly a communication.)

*Nov.* 3, 1853.—2554. P. Hindle, Ramsbottom, manufacturer—Improvements in power-looms for weaving.

*Nov.* 4, 1853.—2556. James Scott, Shrewsbury—Improved apparatus for shifting carriages, wagons, engines, and other vehicles on railways and tramways.

*Dated Nov.* 5, 1853.—2570. J. B. Nicklin, Bartholomew-lane and Richmond, merchant—Improved gelatinous or glutinous compounds for lubricating railway and other machinery.

*Dated Nov.* 10, 1853.—2601. J. Atkins, Birmingham, writing-clerk—An improvement or improvement in ash-pits for grates.

*Dated Nov.* 10, 1853.—2602. W. Pidding, Tachbrook-street, Pimlico, gentlemen—Improvements in the manufacture of fabrics made of silk, cotton, wool, flax, hemp, straw, grasses, fibres, mohair, and other hair, spun glass, and enamelled, glazed, or plain wire, and in the application of some of those materials, and also in the machinery or apparatus connected with such manufacture.

2603. W. Rodger, Lieutenant in the Royal Navy, Shawfield-street, King's-road, Chelsea—Improvements in anchors.

2604. J. Stevens, Darlington Works, Southwark-bridge-road—Improvements in the steps or bearings of the axles or shafts of gasmeters.

2605. S. M. Folsom, Massachusetts, United States of America—A new and improved instrument for ironing clothes or various other articles. (A communication from J. W. Brown, United States of America.)

2606. P. A. Lecomte de Fontainemoreau, South-street, Finsbury, London, and Rue de l'Echiquier, Paris—Improvements in preventing accidents on railways, also in shifting and lifting railway carriages. (A communication.)

*Dated Nov.* 11, 1853.—2607. W. Parker, Birmingham, wire-worker—An improvement or improvements in bearings for machinery.

2608. S. Sturm, Carpenter's-buildings, London, and Vienna, optician—Machinery for the manufacture of optical lenses.

2609. A. A. V. S. de Montferrier, Paris, and South-street, Finsbury, gentleman—A new rotatory steam engine.

2610. E. G. Banner, Cranham-hall, Essex, gentleman—Improvements in saddlery and harness.

2611. H. Walker, Gresham-street West, London, manufacture—Improvement in means of communication from one part of a railway train to another.

2612. J. Willis, Wallingford, harness maker—Improvement in buckles.

2613. R. Dryburgh, Leith, cooper—Improvements in the means of holding staves while being cut.

2614. W. Steel, Glasgow, brewer—Improvements in machinery or apparatus for mashing malt.

2615. J. Platt, Oldham, machinist—Certain improvements in apparatus or machines for forging drawing, moulding, or forming spindles, rollers, bolts, and various other articles in metal.

2616. H. Kilshaw, Birch, near Middleton, manager, and Richard Hacking, Bury, machinist—Certain improvements in machinery or apparatus for spinning cotton and other fibrous substances.

*Dated Nov* 11, 1853.—2617. A. Easton, Barnard's-inn, gentleman—An improved lamp.

2618. A. Easton, Barnard's-inn, gentleman—A liquid chemical compound for the production of artificial light.

2619. J. H. Dickson, Evelyn-street, Lower-road, Deptford, flax manufacturer and flax machinist—Improvements in the process of preparing flax or similar fibrous materials, and rendering it fit for spinning and weaving.

2621. J. M. Levien, Davies-street, Grosvenor-square, upholsterer—An improved construction of expanding table. (A communication.)

*Nov.* 12, 1853.—2622. S. Barker, Birmingham, manufacturer—Improvement or improvements in shaping metals.

*Dated Nov.* 12, 1853.—2623. F. A. Delande, Paris, and of South-street, Finsbury, gentleman—A new metallic composition.

2624. H. Kilshaw, Birch, near Middleton, manager and R. Hacking, Bury, machinist—Improvements in machinery or apparatus to be employed in the preparation of cotton and other fibrous substances for spinning.

2625. J. Gedge, Wellington-street, Strand—Improvements in the means of consuming or otherwise preventing the escape of smoke from flues or other smoke-vents. (A communication.)

2626. J. Gedge, Wellington-street, Strand—Improvements in the manufacture of metallic compounds. (A communication.)

2627. W. Austin, Holywell-street, Westminster—Improvements in the manufacture of casks.

2628. T. De la Rue, Bunhill-row—An improvement in the manufacture of paper.

2629. W. Austin, Holywell-street, Westminster—Improvements in apparatus in trapping passages into sewers or drains.

2630. C. Busson, manufacturer, Paris—Improvements in finger-key musical instruments. (A communication.)

*Dated Nov.* 14, 1853.—2631. J. S. C. Hill, gentleman and E. Cottrill, Birmingham, manufacturer—Improvement or improvements in stamps and presses, a part or parts of which improvements may be applied to other purposes.

*Nov.* 14, 1853.—2632. W. Hadfield, Manchester, spinner and manufacturer—Improvements in looms for weaving.

2633. S. F. Cottam, Manchester, engineer—Improvements in machinery for spinning, doubling, and reeling cotton and other fibrous substances.

2634. H. Willis, Manchester-street, organ-builder—Improvements in the construction of organs and free-reed instruments.

2635. A. Cunninghame, Glasgow, iron-master—Improvements in the manufacture or production of sulphuric acid.

2636. M. Gray, Glasgow, engineer—Improvements in weft forks for power looms.

2737. A. P. Coubrough, Blanefield, calico printer—Improvements in bleaching apparatus.

2639. W. Smith, Mauchline, gentleman—Improvements in ruling ornamental figures.

2640. M. Fitzgerald, Sorrel Island, Clare, Esq.—An improved means or method of communicating between different parts of a railway train.

2641. Charles De Bergue, Dowgate-hill, engineer—An improvement or improvements in machinery or apparatus for removing patterns from moulds for castings.

*Dated Nov.* 15, 1853.—2642. J. J. Catterson, Islington, civil engineer—Improvements in carriage springs.

2643. C. E. Blank, Trump-street, merchant—Improvements in winding yarn into hanks. (A communication.)

2644. J. Liddell, Glasgow, merchant—Improvement or improvements in power-loom weaving.

2645. J. Cameron and J. Napier, Loughor, practical chemists—Improvements in obtaining gold and silver from ores, alloys, or compounds containing such metals.

2646. J. H. B. Thwaites, dentist, and W. B. Herapath, Bristol, M.D.—Improvements in the manufacture of quinine and other alkaloids.

2647. A. Delcambre, Paris—Improvements in machinery for distributing type.

*Nov.* 15, 1853.—2648. J. Fry, Cannon-street West, merchant—Improvements in preparing solvents for india-rubber and gutta-percha, and in rendering waterproof fabrics free from odour.

*Dated Nov.* 16, 1853.—2649. P. A. Halkett, the Albany, Lieut. R. N.—Improvements in apparatus for lifting and lowering ships and other heavy bodies, either submerged or otherwise.

*Nov.* 16, 1853.—2650. J. Ellerthorpe, Kingston-on-Hull, master mariner—Retarding and stopping railway trains and railway carriages.

2651. J. W. Wayte, Gate-street, Lincoln's-inn-fields, engineer—Improvements in self-feeding furnaces.

2652. J. R. Musgrave, R. Musgrave, and J. Musgrave, Belfast—Improvements in hot-air stoves.

2653. P. Hill, Gravel House, Coggleshall—Improvements in weaving plush and other piled fabrics. (Partly a communication.)

2654. J. Ronald, Paisley, manufacturer—Improvements in fixing colours on yarns and cloths.

2655. J. H. Johnson, Lincoln's-inn-fields, gentleman—Improvements in thrashing-machines, and in apparatus connected therewith. (A communication from Mons. Lotz, Nantes, machine maker.)

2656. D. Pratt, Birmingham—Certain mechanical arrangements for raising thimbles, the same to be worked by steam, water, or other power, thereby superseding hand labour.

2657. J. Ferguson, Heathfield, brick and pottery manufacturer—Improvements in furnaces and fireplaces, and in the prevention of smoke.

2658. W. F. Greenfield, Ipswich, clerk, master of arts—Improvements in communicating from one part of a railway train to another.

2659. T. Jackson, Commercial-road, Pimlico, contractor—Improvements in the manufacture of hats.

2660. J. Bristow, Bouverie-street, miller, and H. Attwood, Holland-street, Blackfriars-road, engineer—An improved mode of constructing marine boilers.

*Dated Nov.* 17, 1853.—2661. G. Carter, Mottingham, gentleman—Improvements in the construction of steam-engine boiler, and other furnaces.

*Nov.* 17, 1853.—2662. J. Clare, jun. Exchange-buildings, Liverpool, produce-broker—Improvements in the manufacture of bar and sheet metals, in machinery connected therewith, and in the application of such metals to various useful purposes.

2663. G. Dugmore and G. H. Millward, Birmingham, manufacturers—A new or improved method of signalling or communicating between trains on railways.

2664. S. Abraham, and S. V. Abraham, Lisle-street—Communicating information or directions to persons in charge of railway trains.

2665. W. Ashton, Manchester, machinist—Improvements in machinery or apparatus for manufacturing braid.

2666. J. Banfield, Birmingham,—Double-acting railway signal for preventing collisions or accidents on railways.

*Dated Nov.* 17, 1853.—2668. C. Burton, New Oxford-street, carriage manufacturer—Certain improvements in hand and draught carriages for common roads.

2669. T. Bourne, West Smithfield, saddler—Improvements in the construction of buckles.

2670. A. J. Hoffstaedt, Albion-place, agent—An improved mode of preparing the colour known as artificial ultramarine.

2671. R. Griffiths, Strand—Improvements in propelling vessels.

*Dated Nov.* 18, 1853.—2672. P. F. Keogh and W. A. Wilson, Liverpool, engineers—Improvement in steam-engines.

2673. P. M. Parsons, Duke-street, Adelphi, civil engineer—Improvements in railway and other carriages and vehicles.

2674.—A. Guy, Upper Rosomon-street, Clerkenwell, iron worker—A portable water-closet, with water supply without the action of pump.

2675. C. Fernihough and J. Fernihough, of the firm of J. Fernihough and Sons, Victoria Iron Works, Dukinfield, boiler makers—Improvements in machinery or apparatus for wringing or twisting, glossing, stretching, and drying silk, cotton, wool, flax, and other fibrous materials.

2676. T. Holmes, Pendleton, bleacher—Improvements in ventilating drying stoves.

2677. J. Gall, jun., Edinburgh, sculptor—Improvements in electro-magnetic engines.

2678. Amedee François Remond, Birmingham, gentleman—Improvement or improvements in the construction of steam-boilers or generators.

2679. W. Taylor, Park-street, Regent's-park—Improvements in anchors.

2680. J. Melville, Roebank Works, Lochwinnoch, calico printer—Improvements in printing textile fabrics and other surfaces.

2681. Jean Baptiste Clavières, Paris, engineer—Improved mode of giving publicity.

2682. M. Poole, Avenue-road, Regent's-park—Improvements in surface-condensors, and in evaporators and heaters for steam-engines. (A communication.)

2683. P. B. O'Neill, Paris—Improvement in the manufacture of perforated buttons. (A communication.)

2684. J. H. Brown, Arthur's-seat, Aberdeen—Improvements in the manufacture of artificial skins.

2685. H. R. Cottam, Sussex-terrace, Hyde-park-gardens—Improvements in the construction of portable houses.
2686. J. Rice, Foley-place, surgeon, and W. Matthews, Portugal-street, surgical instrument maker—Improvements in instruments for taking and applying vaccine matter.
2687. R. S. Norris, Warrington, railway engineer, and E. Talbott, Crewe, manager of ironworks—Improvement or improvements in the manufacture of iron.
*Dated Nov* 19, 1853.—2688. J. Harris, Hanwell, engineer—Improvements in apparatus for heating water and other fluids.
2690. M. Poole, Avenue-road, Regent's-park—Improvements in breech-loading fire-arms, and in cartridges for use with such fire-arms. (A communication from W. W. Marston, New York.)
2691. W. Austin, Holywell-street, Westminster—Improvements in the manufacture of tiles and tubes.
2692. E. Rowland, Mossley, near Belfast—Improvements in apparatus to be applied to a railway truck or carriage, to enable a guard or person to sound a whistle, and when necessary to put such truck or carriage in motion, independent of the locomotive engine.
2693. T. I. Dimsdale, Dublin, gentleman—The use and preparation of certain solid and liquid substances for the defecation, purification, and decolorisation of saccharine juices, and syrups or solutions, and for neutralising, decomposing, and absorbing noxious and fetid gases.
2694. J. G. Potter, carpet manufacturer, and R. Mills, designer, Darwen, Lancaster—Improvements in the manufacture of carpets.
2695. E. Wharton, Birmingham, engineer—Improvements in the manufacture of railway wheels.
2696. H. Daniell, St. Austell, Cornwall—Improvements in apparatus for drying clay.
2697. R. F. Brand, South-terrace, Bermondsey — Improvements in fire-arms and ordnance.
*Dated Nov.* 21, 1853.—2698. W. H. Tucker and W. R. Reeves, Tiverton—Improvements in locks.
2699. J. Scott, jun., Greenock, Renfrew, engineer—Improvements in steering vessels.
2700. H. Wiglesworth, Newbury, bachelor of medicine—Improvements in istons.
2702. Sir J. S. Lillie, South-street, Finsbury—Improvements in apparatus for the production of carburetted hydrogen gas. (A communication.)
2703. R. J. Sibbald, Paddington, Lancaster, surgeon—Improved mode of communicating from vessels to the shore, or from one vessel to another.
2704. A. Radcliffe, Chichester-place, King's-cross, glaziers' diamond manufacturer—Improved construction of glaziers' diamond.
2705. J. Cashmore, Bevis-marks, City, watchmaker—Improved mode of communicating signals on railways.
*Dated Nov.* 22, 1853.—2708. W. Greaves, Leeds, chemist—An indicator alarum, applicable to railways and railway trains.
2709. A. Bain, Paddington, engineer—Improvements in cases for holding cards.
2711. A. Bird, Birmingham, chemist—Improvements in apparatus to be employed for the purpose of communicating signals on railway trains and railways, which improvements are also applicable to other similar purposes.
2713. F. Meyer, Paradise-street, Lambeth—Improvements in treating fatty and oily matters to render them applicable for the manufacture of candles and night-lights.
2714. F. Levick, iron master, and J. Fieldhouse, Cwm Celyn and Blaina Iron Works, engineer—Improvements in machinery for raising coal and minerals from collieries and mines.
2715. F. Meyer, Paradise-street, Lambeth—Improvements in bleaching oils and fats.
2716. C. Ramsay, North Shields, brassfounder—Improvements in ships' and other pumps.
2717. W. Pegg, Leicester—Improvements in instruments for cutting out parts of garments and other articles, and in grinding and sharpening cutters for the same.
2718. F. Arding, Albert Iron Works, Uxbridge, agricultural implement manufacturer—Improvements in machinery for cutting, splitting, and bruising vegetable substances.
2719. B. Burleigh, Great Northern Railway, King's-cross—Improved railway crossings, as adapted to the double-headed rail, and the ordinary rail and chair.
*Dated Nov.* 23, 1853.—2720. H. R. Abraham, Howard-street, Strand,—Improvements in coffins and in hearses, and improvements in receptacles for coffins for their transmission.
2721. C. F. Stansbury, of the firm of Nourse and Co., Cornhill—An apparatus to be attached to a drill for sowing grain or other seeds for the purpose of mingling guano or other pulverised manure with the grain or seed to be sown, and depositing it in the ground at the same time with the seed, thereby greatly diminishing the quantity of guano or other manure required to produce the best fertilising effects. (A communication from T. F. Nelson, Clarke County, Virginia.)
2722. J. F. Empson, Birmingham, manufacturer—Improvements in the manufacture of wire.
2723. J. Hill, sen., and J. Hill, jun., Manchester, machine-makers—Improvements in machinery for winding, doubling, and spinning silk.
2724. J. Amos, Bristol—Improvements in preparing wood to be employed in the manufacture of casks and other vessels for containing liquids.
2725. J. Timewell, Duke-street, St. James, tailor—Improvements in cutting or shaping materials to be employed in the manufacture of articles of dress.
2726. J. Dilks, Parliament-street, Nottingham, lithographer and embosser—Improvements in bands for binding more effectually than heretofore packets or parcels of lace and other articles.
2727. E. Wilkins, Queen's-row, Walworth, gentleman—An improvement or improvements in draining land.
2728. W. B. Johnson, Manchester, manager for Messrs. Ormerod and Son, engineers and ironfounders—Improvements in steam-engines.
2729. J. D. Brady, Cambridge-terrace, Esq.—An improved mode of or a new arrangement of straps for slinging knapsacks.
2730. T. W. Kinder, Dublin, engineer—Improvements in the construction of the permanent way of railways.
*Nov.* 24, 1853.—2731. J. Lovell, Glasgow, gentleman—Improvements in the application of heat to various useful purposes.
2732. D. Chalmers, Manchester, manufacturer—Improvements in railway breaks and signals.
2733. H. Mason, Ashton-under-Lyne, manufacturer and J. Jones, Manchester, machine-maker—Improvements in machinery or apparatus for doubling, twisting, and spooling woollen, cotton, and other yarns.
2734. S. Holman, Colney-hatch, engineer—An improved construction of double-action pump.
2735. A. V. Newton, Chancery-lane, mechanical draughtsman—A novel construction of apparatus to be used as a chest-expander and as a uterine or abdominal supporter. (A communication.)
2736. E. M. Richards, Swansea, merchant—Improvements in feed-plates to be used for oxidising lead and refining silver and lead.
2737. S. C. Lister, Manningham, manufacturer—Improvements in combing wool, cotton, and other fibrous material.
2738. E. Townsend, Massachusetts—New and useful improvements in machinery for sewing cloth and other material. (A communication from W. Butterfield, Massachusetts.)
2739. W. Jones, Kilney Cottage, Swansea—Improvements in rotatory engines.
2740. D. L. Banks, St. James-place, Liverpool—Improvements in rotatory engines.
*Nov.* 25, 1853.—2742. D. Nichol, Edinburgh, stationer—Improvements in the manufacture of envelopes.
2743. J. Berry, Manchester, warehouseman—Improvements in the machinery or apparatus for manufacturing wire fencing.
2744. W. Calder, Glasgow, manager—Improvements in the treatment and finishing of threads or yarns.
2745. W. L. Brook, Meltham Mills, near Huddersfield, cotton-spinner, and C. Brook, jun., of the same place, cotton-spinner—Improvements in preparing, dressing, finishing, and winding cotton and linen yarns or threads, and in the machinery or apparatus connected therewith.
2746. A. Drew, Glasgow, calico printer—Improvements in ornamenting woven fabrics and other surfaces.
2747. J. H. Johnson, Lincoln's-inn-fields, gentleman—Improvements in carding engines for carding cotton and other fibrous materials. (A communication from G. Wellman, Lowell, U. S.)
2748. J. H. Johnson, Lincoln's-inn-fields, gentleman—Improvements in the production of printing surfaces. (A communication from A. Feldetrappe, Paris, engraver.)
2750. A. E. L. Bellford, Castle-street, Holborn—Improvements applicable to pens and pencils for writing or drawing. (A communication.)
2751. A. E. L. Bellford, Castle-street, Holborn—Improvements in rotary engines. (A communication.)
2752. C. C. A. Grenier, Paris, merchant—Improvements in the preparation of paints for buildings and other uses.
2753. E. Wilkinson, and W. Rye, Oldham—Improvements in power-looms.
2754. E. Barthelemy and T. Petitjean, Upper John-street, Fitzroy-square, mechanists, and J. P. Bourquin, Newman-street, Oxford-street, merchant—Improved means of ornamenting glass.
*Nov.* 26, 1853.—2755. J. Wormald, Vauxhall, and George Pollard, York-road, Lambeth—Improved pipe-wrench.
*Nov.* 26, 1853.—2756. W. C. Moat, Strand—Improved truss.
2757. J. Stenson, Northampton, iron manufacturer—Improvements in the manufacture of iron.
2758. G. E. Gazagnaire, Marseilles—Improvements in the manufacture of nets for fishing and other purposes.
2759. H. Coutte and J. M. Hammerbacher, Paris—Improved machine for washing linen and other textile articles.
2760. J. Roth and H. Danner, Mulhouse, France—Improvement in cards for carding.
2761. A. E. L. Bellford, Castle-street—Improvements in straining mill-saws. (A communication.)
2762. L. Cornides, Trafalgar-square, Charing-cross—Combining gelatine with certain other substances, and colouring the same, so as to produce various objects capable of resisting atmospheric influences.
2763. T. Chambers and J. Chambers, Thorncliffe Iron Works near Sheffield—Improvements in kitchen sinks.
2764. J. S. Rousselot, Nismes, electrician—Improved application of magneto-electricity for driving machinery and for neutralising the impulsive force of machinery in motion.
2765. J. M. H. Perodeaud, Rue Godot de Mauroy, Paris—Improved mode of treating peat for the conversion of the same into an artificial coal, which may be used in that state, or afterwards reduced to coke.
*Nov.* 28, 1853.—2766. W. Pritchard, Clerkenwell, cabinet maker—Improvement in buffers for diminishing the shock in the collision of railway trains.
*Nov.* 28, 1853.—2767. J. Walmsley, Accrington, manufacturer, and J. Ingham, Blackburn, mechanic—Improvements in looms.
2768. P. C. J. B. Sochet, Paris—Improvements in obtaining motive power by means of heated gases.
2769. R. H. Nicholls, Bedford, gentleman—Improvements in hoeing and otherwise cultivating land.
2772. A. Macomie, Percy-street, Rathbone-place—An ornamental piece of furniture, shaped like a vase, constructed to contain or form a writing and drawing desk.
2774. S. Hurrell, New North-street, smith—Improved machinery for measuring and winding or rolling fabrics.
*Nov.* 29, 1853. 2775. P. Kelly, West-street, Drogheda, printer—Improved apparatus for cultivating, preparing, and treating land, and for sowing seeds.
*Nov.* 29, 1853.—2778. A. E. L. Bellford, Castle-street, Holborn — Improvements in fire-arms. (A communication.)
2779. J. Moore, Lincoln, gentleman—Improvement in or addition to ploughs.
2780. J. A. Manning, Inner Temple, Esq.—Improvements in the treatment of sewage and other polluted liquids, and the products thereof.
*Nov.* 30, 1853.—2781. J. Jackson, Wolverhampton, manufacturer—A new or improved signalling apparatus.
2782. J. Elce, Manchester, machine maker—Improvements in machinery for spinning.
2783. P. A. Lecomte de Fontainemoreau, Rue de l'Exchiquier, Paris—Improvements in the construction of the Jacquard machine. (A communication from Mr. R. Rouse, Lyons.)
2784. E. K. Davis, Howley-street, Lambeth, metal pipe manufacturer—Improvements in machinery for making pipes, sheets, still-worms, and other articles from that class of metals called soft metals, as lead, tin, zinc, bismuth, or alloys of soft metals, that are capable of being forced out of metal receivers or chambers, through dies, cores, &c.
2785. J. Hewitt, Salford, machine maker—Improvements in machinery or apparatus for spinning cotton and other fibrous substances.
2786. J. Redford, Pilkington, weaver—Improvements in power-looms.
2787. R. Balderstone, Blackburn, overlooker—Improvements applicable to spinning-machines known as mules, and to machines of similar character for clearing or cleaning certain parts of such machines.
2788. J. Patterson, Beverley, engineer—Improvements in land-rollers or clod-crushers.
2789. A. Loubat, Paris, gentleman—Improvements in the construction of tramways.
2790. L. Jennings, Fludyer-street, Westminster, mechanical engineer—Improved mode of producing plain and ornamental sewing, and in machinery applicable thereto.
2791. N. de Lantsheer, Ghent—Improvements in machinery for combing flax or other fibrous material.
2792. F. S. Cole, Childown, Surrey—A smoke-consuming apparatus for enabling every fire to consume its own smoke.

## PATENTS APPLIED FOR WITH COMPLETE SPECIFICATIONS.

2777. L. A. Michel, Paris, and Castle-street, Holborn, merchant—A system of apparatus for sawing and breaking sugar.—Nov. 29, 1853.
2819. C. W. Hockaday, Port Hall, Brighton, gentleman—Certain mechanical compound or compounds applicable as a remedy or remedies for scorbutic and other affections of the human body.—Dec. 5, 1853.
2830. J. Mold, Portland-terrace, Walworth—Improvement or addition to augment convenience by transformation and facility the different lines required in the erection or manufacturing edifices or structures by apparatus, tools, or instruments suitable for the different capacities of operatives and general surveying.—Dec. 6, 1853.

## CHURCH OF ENGLAND TRAINING COLLEGE, CHELTENHAM.

*(With Engravings, Plates VI. and VII.)*

The foundation stone of this building was laid by the Earl of Shaftesbury (then Lord Ashley) on April 19th, 1849. The site selected for its erection is on the north side of the town, on an ample space of ground adjoining Lady Ricketts' property (the Elms), and with a frontage to the Swindon-road, having been presented to the committee for that purpose by Miss Jane Cooke, a lady whose liberal grants to many of the public charities and benevolent institutions of that town, will cause her name to be long remembered by its inhabitants.

The style adopted is that of the Domestic Middle Pointed of the 14th century, and the whole of the design modelled after the fine old examples of the collegiate buildings of the middle ages. On reference to the engravings, it will be seen that the plan is in the form of a quadrangle; and as the arrangements are expressly adapted for the requirements of the Institution, without the least regard to uniformity, the exterior presents an irregularity of outline, which combines a pleasing and picturesque effect with a truthfulness of the adaptation of every part. The plan is divided into six distinct divisions, appropriated as follows:—

1st. A residence for the Principal, at the south-west angle of the building.

2nd. A complete residence for the Vice-Principal, at the south-east angle.

3rd. A residence for the Training Master, in the east front.

4th. The domestic offices of the College and servants' apartments, situated between the residences of the Vice-Principal and Training Master, and with immediate communication with the dining-hall.

5th. The Scholastic department, consisting of a large hall, and entrance under the tower from the north; class rooms; a spacious day-room, and lecture-room or theatre, with graduated seats; dining-hall, with great staircase to a range of dormitories over, having eighty detached sleeping apartments, and room for the assistant master. The dormitories consist of four large rooms, all communicating, in which are placed the separate bed-rooms for the students enclosed by partitions about 7 ft. 6 in. high (each compartment having its own separate window and door), and open above this to the collar of the roof, in which are placed large dormers to light and ventilate the dormitories; thus ensuring complete light and ventilation to the whole, and giving to the masters the means of quickly hearing any disturbance that may take place. The whole is also under the immediate supervision of the Training-Master and Principal, whose residences have each a door on the same floor opening into the dormitories.

6th. On the south side of the quadrangle is the entrance gateway, forming an approach to the board-room, secretary's room, and porter's residence, &c. on one side, with the waiting-room and large library on the other. The whole of these rooms have open timber roofs of stained deal.

All these various divisions, though entirely distinct, are readily approached by a light and spacious corridor of communication, extending round the quadrangle, in the centre of which is a large open area, surrounded by a cloister and battlemented walls, screening the necessary yards and offices required by each department.

The great staircase tower, forming a striking feature in the north front, is carried up an additional story for the purpose of forming an infirmary, with nurses'-rooms, bath-rooms, convalescent rooms, and dormitories, approached by a separate staircase, and having no other communication with the rest of the building.

The external walls are constructed with rubble-work, of stone from a neighbouring quarry; the dressings are executed with a fine oolite from the Cotswold Hills. The internal fittings are all of the simplest character, of stained deal and varnished.

The architect is S. W. Daukes, Esq., of Whitehall-place; and the builder, Mr. Thomas Haines. The contract for its completion amounted to 11,982*l.*

## THE LOUVRE AND THE TUILERIES.*

The advanced date of the grand design of the union of the Louvre and the Tuileries, has induced the Imperial government to reproduce the work of M. de Clarac on the two buildings, with some modifications by M. Victor Texier. Of these volumes the first alone is now before us, and we are therefore limited to considerations rather antiquarian than architectural.

The united edifice of the Louvre and Tuileries constitutes one of the grand architectural monuments of the world, and represents what the vast edifices of Luxor, of Thebes, and of Nineveh once were. We have nothing of the like class, though the ambition of Barry may, before many years, furnish us with an architectural group, colossal in character, but acquiring greater dignity from the antiquity of some of its members, and from the rich historical associations attaching to it. When the Palace of Westminster is provided with an approach of correspondent character by the new bridge over the Thames, and when it is associated or perhaps united with the Abbey and its appendages, we shall be endowed with a monument unique as that of Paris is.

The antiquity of the Louvre, as an occupied site, does not go beyond the beginning of the 13th century, or the reign of Philip Augustus; but of the mediæval structure nothing remains, and its oldest relics are of the Renaissance. These buildings have, however, been the abode of some of the most powerful monarchs of Europe—of Henry the Fourth, of Louis the Fourteenth, and of Napoleon the Great, and the scene of many important and historical events. As the abode of the arts they are, however, still more distinguished than as the abode of princes; they contain one of the finest galleries of antiquities, and invaluable collections of the gems of modern art. Here, too, the yearly exhibitions are held of the works of living French artists. Thus the name of the Louvre is that of a temple of art, and this is united with the sumptuous halls of magnificent kings to constitute one edifice, as in Egypt the palace and the temple were similarly brought into combination.

At Westminster there is neither the same mass of structure nor the same treasure of arts, but on a site consecrated for twelve centuries remain the relics of ages enshrined and preserved in a framework of corresponding style, and illustrated by the mighty men and mighty deeds of olden and of newer days. Commencing with legends losing themselves in the mist of antiquity, with such fables as those of which St. Peter is made to play the hero, the history of Westminster swells in importance even as it embraces in its sphere the events of the passing hour. As distinct in its character from the Louvre as the Memnonium was from both, we here see united the palace, the temple, the shrine, the tomb—close together, the senate-house, the judgment-hall, the scene of execution. There saints have lived and been worshipped, there kings have dwelt, and there, too, kings been brought to judgment and to death; there the rulers of kingdoms and of provinces have come to judgment—the senate of a free people and a vast empire have deliberated on the destiny of the world; there the laws and jurisprudence by which two hundred millions of men are governed, have been matured during ages. In those halls the greatest orators of modern days have declaimed—and within reach of their voices repose in death the poets, the statesmen, the warriors, the kings, of twelve centuries. The artist looks on the Louvre with veneration, as a wondrous triumph of the resources of art; but the halls of Westminster are reverenced as a temple sacred to freedom by the most powerful race in the world, wherever its sons may be found—in Europe, in America, or in the still newer world of the Southern Seas. Its traditions govern the senates and courts of the many sovereign commonwealths of the United States, with the same power as they do at home, and its inspiration is sought by embryo communities scarcely emerged into civilisation. From Liberia, Mosquitia, Hawaii, Sarawak, or even from the household community of Pitcairn's Island or Bonin, the principles of organised government will be communicated to new regions and be a blessing to new generations. The Walhalla, which Lewis of Bavaria thought to found on the shores of the Danube, the Hall of Glory, has stood for centuries on the banks of the Thames.

It is in these reflections we seek for comfort when we consider how, by the consolidation of architectural and artistic resources,

* 'Description Historique et Graphique du Louvre et des Tuileries.' Par M. le Comte de Clarac. Paris: à l'Imprimerie Impériale. 1853.—['Historical and Graphical Description of the Louvre and the Tuileries. By the Count de Clarac. Paris: Printed at the Imperial Printing Office. 1853.]

the kings of France have at length succeeded in bestowing on Paris one grand, crowning monument. The completion of this vast enterprise, vainly projected by Louis the Fourteenth and his successors, and but begun by the Emperor, will be a distinction to the reign of Louis Napoleon, whatever else may befall. This single undertaking would have been enough to entitle Paris to the palm in the career of architecture; but it is connected with such a gigantic scheme of street construction, as will renew the claim of Paris to the honour of being the most magnificent capital of Europe. The example of Paris had caused great improvements in London, Berlin, Munich, and Brussels, and many inferior cities of Europe and America were greatly enriched; and it may be after all that this new Paris may cause fresh exertions. There are the elements for this in London already. The Crystal Palace at Sydenham has stimulated a new class of enterprise, and the consequences of the abolition of the window duties are now beginning to produce fruits. What is done in Cannon-street is only an earnest, in comparison with Paris; it is only an infantile beginning, but it will be followed by worthier results. A larger class of street-house can be constructed, and not only are various edifices designed for purposes heretofore unthought of or impracticable, but plans are in progress for new thoroughfares and avenues of a more distinguished character.

The isolated public buildings in progress or contemplation, although important, would not alone be sufficient to redeem the character of our street-architecture, but they will be accompanied in many cases by suitable approaches. Whereas, formerly, the ambition of architects was limited to isolated monuments, often inconsiderable, we have to notice as a characteristic of the present day long-continued or connected façades and avenues. Many causes have contributed to this; among others, greater attention to street-architecture; but the crowning influence has been the political necessity which has dictated to Louis Napoleon the widening of the streets of Paris as a military resource against popular insurrection. In London, the necessities of an unexampled population and a vastly increasing traffic are equally imperious, and the formation of a few junction lines and the completion of the projected routes will give a new character to the great thoroughfares. New Cannon-street will be connected with Blackfriars-bridge; Carey-street will in time unite Cheapside and the Long-acre line. Victoria-street, Clerkenwell, and Victoria-street, Pimlico, will be avenues to other improvements. Although Cannon-street has entailed a cost of 200,000*l*., yet, in other cases, first-class thoroughfares will be cut through inferior property of a low class for ground-sites, and affording, in the upper stories of the large houses or hotels, accommodation for the working-men and others at low rentals.

Whatever may be done in our streets, nothing will give us a rival to the Louvre and Tuileries, to the formation of which the labour and genius of three centuries have contributed. Originally the Louvre and the Tuileries were separated by a small river and the wall of the City of Paris, and both had at one time been beyond the town bounds; one palace taking its name from a wolf-hunting station in the woods, and the other from some tile-kilns and fields. Saint Louis seems to have been the first king who inhabited the Louvre, and in the reign of Charles V. it was brought within the fortifications of Paris. Francis the First began the reconstruction of the Louvre under the direction of Pierre Lescot, which was continued by his successors. In 1564, Catherine de Medicis built a chateau in the tile-fields beyond the fortifications: Philibert Delorme was the architect.

Henry the Fourth, notwithstanding the intervention of the city wall, united the grounds of the Louvre and the Tuileries, and even connected the buildings by a gallery. In 1624, under Louis XIII., the reconstruction and extension of the Louvre was put under the charge of Lemercier.

Louis XIV. employed the architect Levau to raise a new façade for the Louvre on the river side, and likewise an eastern wing. In 1664, the plan of Claude Perrault for the decoration of this wing by the colonnade was adopted. Wren, in his tour of continental study, availed himself of the opportunity of examining the designs of Perrault. Throughout the 18th century the works of the Louvre were prosecuted, but it was under Napoleon that the completion of the Louvre was chiefly effected, though the decorations were in progress much later.

For the great plan of the union of the Louvre and Tuileries, a competition was opened from 1806 to 1810, and the designs of Messrs. Percier and Fontaine were adopted. They were put in charge of the works, and the second northern gallery of junction was commenced. These works, however, have been interrupted from time to time, until the desire of employing the population of Paris has led to their active resumption and approaching completion under new auspices.

The volumes which describe these works, and which issue from the Imperial press, are the productions of the late Count de Clarac, a distinguished French archæologist. This gentleman was forced to emigrate at an early age, but managed to pursue his studies in Switzerland and Germany. Although compelled by the circumstances of his position to join the army of Condé, he neglected no opportunity of showing kindness to his political adversaries, and particularly to the wounded of the French armies. He afterwards served for a time in Poland. These military studies did not, however, cause him to neglect the cultivation of drawing, nor that of the ancient and modern languages; of the latter, he was acquainted with English, German, Italian, Spanish, Portuguese, and Polish, besides his mother tongue. He likewise gave some attention to chemistry, mineralogy, and zoology; studies which, nevertheless, proved to him of considerable value afterwards in his archæological pursuits, more particularly when he wished to ascertain the technical processes of the ancients, or to discriminate between the materials which they employed.

On an amnesty being granted to the emigrés, Clarac returned to France, and continued his studies at Paris, devoting himself to Greek. His patrimony having been lost, he was obliged to have recourse to literary occupations. While attending the gratuitous public courses of ancient history and literature, at the Institute, he became acquainted with some of the more distinguished students and professors, which had an influence on his advancement, as he was recommended to Queen Caroline Murat to superintend the education of her children. To the student of limited means, no facilities for acquiring information are to be found here correspondent to those of Paris. The favourite, but false idea, that educational institutions are not valued unless they are paid for, stands completely in the way of the poor but zealous student. The pursuit of knowledge under difficulties may be well illustrated from the experience of England,—the indomitable application of genius, or the chapter of accidents alone opening a career to the aspirant. The man of inferior or mediocre powers, the man of the rank-and-file of science, is left to scramble on as he can. In Paris, Faraday would not have been abandoned to the chances of life for the opportunities of continuing his studies. There are schools where the greatest professors teach, and the poorest mechanic can enter. In London, the only gratuitous courses we have are those of Gresham College, which are a farce, and those of the Royal Academy, which are not accessible to the public. The schoolmasters' classes of University College are hedged-in with restrictions; and as to the Swiney course on Geology, that is under the regulations of an eccentric founder. The Hunterian, and some other medical lectures, we do not dwell upon, as they are limited to a special class. The superior wealth of the population in some degree remedies the defects, but the state of affairs is by no means creditable to the country.

The establishment of cheap classes and schools amounts to little more than a confession and palliation of the evil, and it amounts chiefly to the schools of design, the school of practical geology, and the schools of navigation, few in number. The Royal Academy still bears away the palm, and its experience is sufficient to show that education may be zealously pursued without the degradation of a money payment. High art alone can be studied without expending a small capital on instruction fees; and assuredly the Royal Academy, the National and Vernon Galleries, the British Museum, the British Institution, and the other galleries, are not in want of students. With regard to mechanics' institutions and young men's classes, laudable as the motives of the founders are, they are inefficient substitutes for what is really required. We want evening colleges for gratuitous general and applied instruction. These we may wait long to obtain; but it is scandalous that, with the means we have, the higher branches of study are not better cared for in the metropolis of the world. The British Museum admits students to its Elgin and Townleian collections, and professes so to do to its other galleries; but why should it not, as has been often advocated, charge its officers with the task of giving occasional gratuitous lectures on the collections under their charge? There is one objection we are aware of to gratuitous lectures, and that is the inconvenient congregation of the public that would follow. With regard to the objection of the inroad that lecturing would make on the time of the keepers, we think little of that, for if facilities were given to the public to lecture as well as to attend lectures, there never would be a reserved day without its lecture. Those architects and others, who at the Royal Institute of British Architects have delivered learned discourses on the Parthenon, to the great advantage of the members of the profession who heard them, would willingly give the same explanation of their views before a miscellaneous audience, having the benefit of referring to the relics of the Parthenon distributed around them. How much, too, would archæology gain by the illustration the treasures of the Museum would receive from Layard, Fergusson, Fellowes, Rawlinson, Wilkinson, or Hinckes. There the theorist could expound his system, there new illustrations of archæology would be rapidly spread among men none the less zealous because they cannot afford the limited subscription of the Society of Antiquaries. Geology and natural history would benefit by such freedom. The public spirit which prompted Saull and Bowerbank to throw open their collections, and to give explanations of them, would not be wanting; and many who want means or time to form museums, would gladly give their assistance in illustrating the museums belonging to the public.

The public require not only gratuitous lectures, but access for men of science to the public collections for the purpose of lecturing. Thus, not only the strictly public institutions of the British Museum, National Gallery, Vernon Gallery, Museum of Practical Geology, Hampton Court, Kew Gardens, and Greenwich Observatory, would be made useful, but other proprietary institutions might become available. Through the chicanery and quibbling of the judges and lawyers, the act for exempting scientific institutions from taxation has been converted into an utter abortion, and it is said that some institutions will be closed in consequence of the withdrawal of the exemption enjoyed under the act. It is exceedingly desirable that the measure should be re-enacted, and it might be accompanied by stipulations enabling the Board of Education or Board of Trade, to obtain correspondent advantages for the public. Thus, the Royal Botanic Society already admit as a favour students of the schools of design and of the Pharmaceutical Society to their gardens in the Regent's Park; but for relief from their rates, they might be induced to give facilities for public lectures on botany, of which too their fellows would have the advantage. The Zoological Society might make correspondent terms, and there are many institutions which have collections most valuable for the illustration of the lecturer. By such measures we should be enabled in some degree to rival Paris, and should become possessed of what we much want—schools of astronomy, natural history, archæology, the oriental languages, and history. The only school of archæology in England is that munificently founded at Cambridge by Mr. Disney, and who proposes to supply another public want by establishing in London a school of navigation, nautical astronomy, naval architecture, and hydrography, in connection with the Cosmos Institute in the Great Globe in Leicester-square. It is lamentable we should be without such schools, for we want neither money nor buildings, neither lecture-rooms nor illustrations, any more than we want lecturers. What cost the French authorities many thousands a-year, may here be obtained by a simple effort of the administration. Indeed, the want of means for supplementary and superior instruction leads to those great and public-spirited exertions of individuals in gratuitous lecturing, in the reading of papers and memoirs, and in the support of literary and scientific institutions.

A very serious consequence of the want of public instruction is, that the appointments of curators in our public institutions often become jobs, or the inferior institutions are obliged to put up with a monkey-stuffer to take care of their collections.

We have taken advantage of an incident in the life of M. de Clarac, as of others connected with this history of the Louvre, to show how they do things better in France; for we have so long co-operated in many successful public movements, that we are not afraid of agitating when an opportunity presents itself. France spurred us up to the establishment of schools of design and industrial schools; perhaps she may shame us to more magnificent streets, and to structures more truly approaching the character of palaces than those we so call. M. de Clarac obtained a great advantage from his appointment under the Murats, as it led him to Naples, where a fruitful field of archæological study was opened to him. He was there for six years, and had under his charge the exploration of Pompeii, in which he distinguished himself.

On the return of the Bourbons to France he obtained the opportunity of accompanying the embassy of the Duke of Luxembourg to the Brazils. There he occupied himself with natural history, the representation of nature and ethnology. Among his drawings, one of a virgin forest on the banks of the Rio Bonito, since engraved, has been quoted by Baron Humboldt as the most faithful representation he ever saw of the vegetation of the new world. In his exploration of the Oyapoc river, M. de Clarac made himself acquainted with the language of the aboriginals, and not only made a large collection of arms and other objects, but constructed many models, in which he was very expert. He was indeed so fond of mechanical modelling, that he pursued it as a relaxation from his constant studies, and worked as hard at his lathe as if he had earned his living by it, though his chief zeal was to supply toys to the children of his friends.

On his return to Paris he was appointed to succeed Visconti as conservator of the Museum of Antiquities. In this capacity his chief and admired work is his 'Museum of the Ancient and Modern Sculptures,' on which he was employed for twenty-five years, and which he left incomplete. As accessories to this are the 'Description of the Royal Museum of Antiquities in the Louvre,' and the 'Manual of the History of Art among the Ancients.' In his works he received the assistance of the government,—another peculiarity we may observe of France. In 1833, M. de Clarac visited England, and he was so deeply interested by its numerous collections, that he projected other visits, but his home occupations prevented him. He died suddenly in 1847, having corrected proofs in the morning.

The 'Historical Description of the Louvre' now before us, is a service rendered to all architects, and particularly to those of France, as it is likewise a contribution to the history of the art in France.

## APPLICATION OF PAINTED GLASS TO BUILDINGS IN VARIOUS STYLES OF ARCHITECTURE.

The discussion upon the above paper, read at the Royal Institute of British Architects, by Mr. C. Winston (see *Journal, ante* p. 18) was commenced by the Chairman (Mr. T. H. Wyatt) inviting Mr. Trotman to give some explanation of several drawings exhibited by him.

Mr. Trotman proceeded to describe the subjects in chronological order. The first was one of a series of four subjects relating to the history of Christ, from the Church of Rivenhall, Essex, which had been procured from Tours some years ago by the present vicar, for the decoration of the church. These specimens dated from about the beginning of the 12th century. The whole of the ground colour was a rich bright blue; a quantity of green was intermixed with this in the figures, and great relief and brilliancy was given to the design by the introduction of characteristic lines of white. Mr. Trotman next referred to similar specimens from Canterbury Cathedral, and to four subjects from York Cathedral, the most perfect, out of seven, representing the corporeal Acts of Mercy—Giving shelter to the Houseless, Visiting the Sick, &c. Two large drawings of windows in the Church of West Wickham, Kent, representing the Virgin and Infant Saviour, and the Virgin and St. Anne, were next noticed; these being of the latter half of the 15th century. A Nativity from Great Malvern Church; one of the heraldic badges from the East end of Henry the Seventh's Chapel; the Visit of the Queen of Sheba to King Solomon, from Fairford Church, Gloucestershire; and an interesting specimen from the Hammermen's Chapel in the Cowgate, Edinburgh, representing the National Arms of Scotland ("the Scottish Lion"), were then referred to and described; and Mr. Trotman further directed attention to a series of small drawings of painted glass from the Continent, including specimens from Paris, Rouen, Brussels, Cologne, &c. Mr. Trotman expressed his concurrence in the views of Mr. Winston generally, and regretted that some false principles should have been promulgated on the subject of glass painting by Mr. Redgrave, in the Catalogue of the Contents of the Museum of Ornamental Art, that gentleman having objected to the introduction of shadows, and observed that "glass painting should consist of flat tints without shadow." On the contrary, he (Mr. Trotman) considered that if shadow were to be omitted, there must be an end of glass painting; and certainly the folds of drapery, &c., could not be better represented by outline than by shadow, especially as painted windows must be seen from a great distance. The real question was, to what extent the principle of shadow and rotundity should be carried. Some of the medallions in Canterbury Cathedral were in simple outline, whilst the east window of St. Bride's Church (the Descent from the Cross, by Muss, after Rubens) was remarkable for depth of shadow; and each of these alike failed to realise the resources of glass painting. The object to be attained was the highest degree of brilliancy consistent with a high degree of art; and he therefore could not sufficiently admire the sentiments of Mr. Winston, who had given a severe blow to the merely antiquarian view of the subject, and to the fallacy of direct imitation of mediæval glass painting. Ward and Nixon, in their work at Westminster Abbey, were to be commended for not adhering too rigidly to the old models, although they had not succeeded in developing all the resources of the art. As a general principle, in order to insure that brilliancy which glass offered, it was necessary to treat every subject with considerable subdivision, and great attention to detail. In some modern glass painting much of the interest was lost by a neglect of accessories and details, and the modern glass at Cologne Cathedral was objectionable in this respect, as it consisted of single figures with large masses of drapery. By subdivision he meant a more complicated style of composition than was necessary in any other kind of painting. Thus, the Church of St. Vincent de Paul, at Paris, possessed some of the finest specimens of modern glass; but from the figures being too colossal, and occupying each one window, the subjects were less interesting, and less brilliancy was obtained, than a different treatment would have insured. The effect of colossal figures in glass painting tended to diminish the apparent magnitude of the building, and was exemplified at the east end of the Chapel of Eton College, where the windows of Mr. Willement had an injurious effect. Upon the whole, he considered it would be very wrong to study the specimens exhibited with a servile regard to precedent, but rather as offering so many steps towards the attainment of a good and effective style. The human figure must be considered essential, either singly or in groups, as windows representing only foliage, &c., could not be interesting, and should rather be classed as ornamentation than art. The subjects should be on as small a scale as was consistent with distinctness, and, so long as the necessary brilliancy was not detracted from, there was no limit to the application of shadow. Useful hints might be taken from sculpture in relievo, and from such works as the Bronze Gates by Ghiberti, at Florence, care being taken to render the figures important and the accessories subordinate.

The Rev. J. L. Petit concurred with Mr. Winston, whose object, it appeared, was to combine the merits of the glass of the 12th and 13th centuries, with a degree of art and beauty not then obtained; and in so doing he would not violate the principles of that era, when the artists got the best models and drew as well as they could. Servile imitation should be scrupulously avoided, and if works of art of a high character were unsuited to Gothic buildings, then the Gothic was not the style for the age. The architect should make himself independent of the painter and sculptor; but when their aid was offered in the finest art, he should be able to exalt that art, and so to place the specimens of it that they should appear exalted even in their subordination to the architecture. Thus the Grecian, the Roman, and Italian styles, admitted of the application of art in its highest character; and so the mediæval architecture admitted the best specimens of art that could then be obtained. If, on the contrary, at the present time Gothic and the highest art were incompatible, that style ought not to be pursued. Architects should endeavour to revive, to modify, and improve it; but if they could not make it a noble style, let it be abandoned.

Mr. E. T. Parris drew attention to the cartoons of Raffaele as being, in his opinion, composed upon principles similar to those which should regulate glass painting. In those works every relief was gained by an opposition of colour, rather than by shadow; and, as in the best stained glass, the horizon was very high, its line being always broken by colour or form of some sort —in one instance by a house on fire, the object of introducing which could only proceed from some artistic principle. He fully agreed with the remarks of Mr. Winston. Many painted glass windows had been erected from his (Mr. Parris') designs, but he was generally trammelled by the person who had the order. He had declined the work at Westminster Abbey, executed by Mr. Nixon, for this reason.

Mr. Papworth observed that the discussion had been directed rather to the best styles of glass painting for mediæval architecture, than to "the proper application of painted glass to buildings in various styles of architecture." The question to be laid before them by Mr. Winston, was whether they ought to have any stained glass at all. Stained glass either was or was not a necessity to the architect, and it would be well to settle this as a principle. In the majority of the works of modern architects the question was a difficult one. They could not all build churches and fill the windows with stained glass, or decorate old churches in the same way, their business being rather with a great variety of public and domestic buildings; and the difficulty was whether painted glass was applicable to domestic uses, and if so, what style should be adopted. The reply to this question would answer the previous inquiry—whether they were to have painted glass at all. He considered there was a great deal of merit in that kind of glass which had been largely introduced since 1800, consisting chiefly of ground glass, with arabesques and other ornaments painted upon it. Probably Mr. Winston would state whether he thought that kind of painting applicable to the wants and purposes of the present day.

Mr. Alfred Bailey observed, that there was one variety of mediæval painted glass which had not been referred to. This was to be found in the minor towns of Central Italy, and appeared to have been executed late in the 15th century, and designed on totally different principles to any other kind. They resembled in general design the English glass of the 13th century, but instead of the colours being arranged in small lines, they were introduced in masses, giving a broad effect of colour. Figures were introduced but sparingly, and generally small; which was remarkable, considering the perfection attained in the fine arts at that period. Mr. Bailey referred to specimens at Arezzo, Perugia, and Assisi. With regard to the question of the style of art suitable to painted glass, he believed that a finished pictorial composition was not suited to that material. In S. Petronio, at Bologna, two of the grandest figures designed by Michael Angelo were introduced in stained glass, with a great deal of light and shade, and produced a most unpleasant effect. Mr. Winston did not object to shadows, perspective, and even landscape backgrounds, but it required great study to know what effect a picture would have, and whether it was a fit subject to permit the passage of light. None of our best artists would like a good picture to be placed in the situation of a painted blind. Architects often neglected to consider where they should place painted windows, and a very bad effect was sometimes produced by having them at the level of the eye. A grand and broad effect of colour should be sought for rather than a result resembling patchwork; and the architect should especially remember the importance of painted windows, as striking the immediate attention of the spectator on entering the building; and, consequently, if these were too much elaborated, they must detract from the effect of the building itself.

Mr. Twining was of opinion that stained glass should not be made to compete with oil-paintings, but should be rather of an ornamental character. Painted windows being generally placed at a considerable height, were not adapted by position to receive representations of landscapes,—especially of flat scenery; and moreover architectural subjects seen in an elevated position must be represented by false perspective. The representation of groups on different panes was objectionable, because the metallic slips which formed their outlines were necessarily of the same thickness throughout.

Mr. Hesketh called attention to some books containing a series of original illuminations from MSS. on vellum, collected by Major Macdonald in Arabia, Syria, and Italy. The beauty of these illuminations, and the principles upon which they were designed and coloured, admirably adapted them for imitation in glass painting. In reference to paucity of subjects for stained glass, he might suggest the metaphorical subjects abounding in the Scriptures,—such, for instance, as the meeting of Righteousness and Peace; and many others, which Flaxman had mentioned as never having been treated by artists.

Mr. Talbot Bury regretted that a sufficient amount of talent had not hitherto been brought to bear upon glass painting. He agreed with Mr. Winston that those designs in which the light was centralised were failures, because the objects represented must be transparent or semi-transparent. One obstacle to enlisting talented artists as glass painters arose from the mania for collecting specimens of old glass of any kind, and putting them together as "ruins,"—or copying and imitating them. A first-rate painter would not be fettered by a glass-cutter, or by any rules or dogmas as to the style of drawing he should adopt. The advice of the artist was too often neglected, and people would not give sufficient remuneration for his work—that was the true cause of the inferiority of the art. It had become a matter of competition, and the person who gave the most glass and the most colour for the money, was employed, without regard to merit. Individuals, committees, and the clergy, were alike ignorant of the principles of the art, and were too often influenced by a mere prejudice in favour of antiquity. He wished, therefore, that Mr. Winston's paper could be extensively circulated, for the dissemination of good taste. So long as nine-tenths of the world preferred the barbarisms of antiquity to the finest works, he did not know what could be done to improve the art of glass painting. Mr. Bury referred to a drawing of the east window from Lincoln's Inn Chapel, &c., as an illustration of bad taste in modern work. He agreed with Mr. Winston that by an artist the mullions dividing a window might be overlooked; but that was not the case with others, and when, as in some instances, a canopy or other object on the glass was completely divided by a mullion, as in a German specimen among the drawings, the effect was bad.

Mr. Winston expressed the great pleasure and instruction he had derived from the discussion on the subject of his paper. Not being a professed artist, he had been obliged to study the subject in a desultory way, and rather by actual observation and comparison than by deep reflection. Hence, he had not given his attention to the subject of painted glass for domestic purposes. He agreed with Mr. Trotman as to the principle of subdivision, and in his objection to colossal figures. Some of the figures in ancient windows did not appear so large as they actually were, in consequence of their skilful treatment by the artist. A figure of St. Christopher, at Strasburg Cathedral, of the 12th or 13th century, was nearly 14 feet high; but the drapery was broken in every direction by lines of different colours, and there was little or no shadow; so that the general effect to the eye was similar to that of a mass of colours, or a regular pattern. The remarks of Mr. Parris, as to the Cartoons of Raffaele, were new to him, and he quite agreed with them. Sir C. Eastlake had also pointed out the manner in which Raffaele had adapted his compositions to their execution in a material incapable of any great effect of depth. He agreed with Mr. Papworth that ornamented ground glass had much merit. It looked somewhat flimsy; but it was very pretty, and certainly better than plain glass. It might be a question how far painted glass was suited to modern domestic habits. Mr. Winston mentioned the round patterns seen in German glass, and Mr. Powell's patent for stamping glass. The weight of this latter material, however, rendered it objectionable for a window to be raised and lowered, but it was suited to staircase windows, &c. What he had stated respecting the flat and rotund style of glass painting should be borne in mind; and the material should not be forced beyond its capabilities. The early MSS. certainly contained valuable hints in their illuminations. Mr. Bury's remarks on the question of the cost of good windows were perfectly true; and it was impossible to deny the superiority of foreign stained glass. The specimens in the Great Exhibition of 1851 amply proved this. These were works produced under the fostering patronage of powerful individuals. It should be remembered that not only was there an objection to pay adequately for good works, but that a vast deal of money was wasted on bad works. It would be better to have one good one than fifty bad ones. The erection of one fine window in a church was sufficient for a generation, and doing more than that in an imperfect way, was only impeding what might be better done hereafter. It was the province of architects to elevate this art by impressing its importance upon their employers; and he felt sure that there would be no want of skilful designers, if proper encouragement were offered to them.

The Chairman, in proposing a vote of thanks to Mr. Winston, concurred in the necessity of architects forcing their employers in every possible case to encourage a higher style of art. He would never himself be a party to the erection of a stained glass window, unless he had a choice both of the cartoon and the artist. Their difficulties had arisen from a combination of circumstances, —of which not the least was the fact, that the whole world professed to be critics, especially in mediæval art, and acknowledged no judgment but their own. He took occasion to refer to the new window in Mr. Hope's church, in Margaret-street, which he described as most unsatisfactory, though he had met several persons who considered it the finest of modern specimens.

## SAVINGS BANK, PROVIDENCE, RHODE ISLAND.*

The annexed engraving represents an edifice which was commenced early last year, and was designed by the Messrs. Hall, architects, of Providence and Boston, under the sanction of the building committee, Messrs. R. H. Ives, Isaac Brown, and Seth Adams, jun. We thus particularise the committee for their good taste and judgment in the selection of the design. The building, on the exterior, is wholly of granite, executed in the best manner, agreeably to the plans and drawings of the architects, and under their directions. The location is on South Main Street, between the Providence Bank Building on the north, and the mansion of Isaac Brown, on the south. The building is, of itself, 37 ft. 6 in. frontage, and 55 feet deep, raised on a basement of about 6 ft. 6 in. in height. The basement is in courses of split granite grooved ashlar; and the superstructure is wholly of hewn granite, hammered in the best manner, finishing around the building with a full, elaborative and dental cornice. The end of the building facing on the street, finishes with a pediment.

## THE STATE CAPITOL OF TENNESSEE, U. S.†

The site for this building is, perhaps, the most beautiful in the world. Imagine a hill within the centre of the city, rising in every direction to the height of 197 feet above the level of the Cumberland river at Nashville, 4 feet of its crest being removed, and leaving a plateau of solid limestone for the construction of a building. You look down upon the city beneath your feet, and the prospect beyond is bounded on all sides by a far distant amphitheatre of mountain ranges. Neither Rome, from her seven hills, the Athenian Acropolis, nor the cape at Colonna, affords so splendid a site for an Odeum.

In plan and elevation, the design and whole character of the architecture is essentially Grecian, consisting of a Doric basement, supporting, on its four fronts, porticoes of the Ionic order, taken from the example of the Erectheum at Athens. In the centre of the building rises a tower above the roof, to the height of 80 feet, the superstructure of which is after the order of the Choragic monument of Lysicrates at Athens. The whole structure is composed of fossillated limestone, hewn and chiselled from quarries in the neighbourhood of Nashville, the blocks of stone weighing from 6 to 10 tons.

The various chambers, halls, and porticoes, are arched throughout. The rafters of the roof are of wrought-iron, having a span of the whole width of the building, being supported by the interior walls at the north end, and by the columns of the southern division of the building, the whole covered by thick sheets of copper. In plan, the basement story is intersected by longitudinal and transverse halls, of wide dimensions, to the right and left of which large and commodious rooms are to be appropriated to the uses of the Governor, Supreme Court, Secretary of State,

* Extracted from 'Gleason's Pictorial Drawing-Room Companion.'

† From the 'Nashville Banner,' U.S.

Federal Court, &c. The crypt, or cellar story, in part, is to be used as a depository of arms.

From the great central hall you approach the principal story by a double flight of stairs, which leads to the chambers of the Senate and the House of Representatives, to the library, and to the other rooms in connection therewith. The committee-rooms of the House are disposed on the same floor to the right and left, communicating immediately with it and the lobbies. Over these rooms the galleries are placed. Flanking the public hall private stairways are constructed, leading from the crypt to the various stories, and to the roof.

A geometrical stairway leads from the level of the road to the top of the tower, where you land upon an arched platform, which is intended for an observatory. The tower is built up from the foundation of solid stone, containing four niches in the basement and eight in the principal story, with spacious halls leading to the right and left. The principal stairway, which is 30 feet in width, leads from the centre of the building to the Hall of Representatives, Senate chamber, and Library.

The Hall of Representatives contains sixteen fluted columns of the Roman Ionic order, 2 ft. 8 in. in diameter, and 21 ft. 10 in. in height, from the level of the galleries over the committee-rooms. The shafts of these columns are all in one piece.

A chief beauty and convenience in the design of the principal story, so much superior to the plan of the Capitol at Washington, is, that the committee-rooms are on the same plane with and surrounding the Hall of Representatives; the dimensions of this room are 100 feet by 70 feet; height of ceiling from floor, 42 feet.

The forum of the House of Representatives consists of a semicircular platform 3 feet in height, forming three steps, upon which there is a screen of East Tennessee variegated marble, 13 feet in height, 12 feet wide, and 1 foot in thickness; on the top of which is a cornice and blocking-course, surmounted by an eagle resting upon a shield of cast-iron, bronzed and gilt. One foot from each end of the screen, on a die of black marble, the Roman fasces are placed, which are of beautiful variegated East Tennessee marble, 1 ft. 2 in. in diameter, and 10 feet in height.

The Senate chamber is of an oblong form, 35 by 70 feet, having pilasters of the Ionic order, with a full entablature; the ceiling of this room is formed into radiating panels or lacunaria, and is 43 feet in height; there is a gallery of 12 feet in width on three sides of the room, supported by twelve columns of variegated East Tennessee marble, with white capitals and black bases, from the Erectheum. The forum in this room consists of a platform of two steps; the speaker and clerks' desks are of fine East Tennessee marble.

The Library is immediately opposite the Senate, and is 35 by 35 feet; on each side there are committee-rooms, communicating. Over the arches of these rooms are alcoves for books, papers, and archives of the State; the doors and windows, which are of a large size, are all of solid white oak, moulded, pannelled, and ornamented with devices; the windows are all double, divided by stone pilasters, enriched with consoles, ovolo, and spears.

All the floors are groin-arched, and flagged with rubbed stone; hanging stone steps throughout the building. The building stands upon a rusticated basement, 18 feet in height, which is tooled on all fronts, and the superstructure is of rubbed stone inside and out. All the walls of the foundations are 7 feet in thickness, and those of the superstructure 4 ft. 6 in.

The building is in the form of a parallelogram, 140 feet by 270, surrounded by a terrace 17 feet in width and 6 feet in height, flagged with stone, with flights of steps in the centre of each front, opposite the doors of entrance.

There are twenty-eight fluted columns, 4 ft. 8 in. diameter, ornamenting the four porticoes, with elaborately wrought capitals. The north and south porticoes are finished with pediments containing ceilings of stone, and the east and west porticoes are surmounted by parapets. Those of the north and south are octastyle, and those of the east and west hexastyle. The columns of the principal story rest upon bases 6 feet square.

The water is conveyed from the gutters of the roof by means of cast-iron pipes, 8 inches in diameter, buried in the walls. The glass, which is of double thickness, is of a superior quality, and was made at the works near Knoxville, East Tennessee. Indeed, all the materials are furnished by the State of Tennessee. The whole building will be heated with furnaces communicating with hot-air flues within the walls.

## M. LECLERE.*

Monsieur Leclere, it appears, carried off the *Grand Prix* in 1808, at twenty-two years of age—a very unusual circumstance in the life of an architect. The programme of the competition was a large establishment of public and private baths for the capital; and the manner in which he had carried out his conception was most remarkable. During his residence at Rome the studies of the young *pensionnaire* were always well chosen, and conscientiously and well executed. His restoration of the Pantheon was the crowning point of his many researches amongst antique monuments, and placed him among the most distinguished architects who had given their attention to the restoration of that magnificent building of the Augustan age. M. Leclère also made an interesting collection of studies on the modern edifices of Italy. A student in the celebrated school of Percier, whose taste and learned maxims extended throughout Europe, the pupil, after his return to Paris, was attached by his worthy master to the administrative department of the Conseil des Bâtimens, in whose works he took part for thirty years; and when the celebrated Professor was unable to continue his labours in the school, he entrusted them to the direction of M. Leclère. These circumstances were the chief cause which prevented M. Leclère from being engaged in the erection of more public buildings; however, he executed in France many large country houses, and in Paris some of the finest houses of modern times. One of the most remarkable monuments in the Eastern Cemetery of Paris, that of Casimir Pèrier, was designed and executed under his direction. His brilliant début as pupil, and his subsequent works as *pensionnaire* of the Academy, were followed by M. Leclère's early entrance into the Institute, where he was called upon to take part in the works of the Professors in the School of Fine Arts, who appointed him "*Archiviste.*" Of a kind and conciliating disposition, full of love for his art, persevering in those principles which he believed to be the best, encouraging those pupils who were studious and distinguished, M. Leclère well deserves all the encomiums which accompany his memory to the tomb. M. Leclère presented to this Institute some very important tracings of the constructions of the Pantheon at Rome, next the portico, with a view to explain whether the portico formed a portion of the original design, or was a subsequent addition of a later period; they are preserved in our collection of original designs and drawings, which are now forming a very valuable series.

On the 26th of December last his remains were accompanied to the Cimetière du Nord, amid the regrets of his colleagues, his friends and his pupils; and eulogiums were pronounced by Messrs. Raoul Rochette, Vinet, Visconti, and Isabelle.

## M. VISCONTI.*

In the funeral cortège of M. Leclère, just noticed, the name of Visconti will be remarked, as one of those who addressed the assembly at the grave of his friend; within one short week Visconti was himself cut off suddenly by an apoplectic fit, and borne to the cemetery of Père la Chaise amidst the grief of all France—and may it not be added of all Europe. M. Visconti was present on the 29th of December at the first meeting of the Commission for the Exhibition of 1855, at the Palais Royal, under the Prince Napoleon, and remained there from 1 to half-past 3 o'clock; he then left, and went to his office at the Louvre with a friend, M. Semard; with him he had an animated conversation, and having to dine out, he asked for his carriage, but it being then only half-past 4, and earlier than the time he usually quitted the works, it had not arrived, and he sent for a hackney carriage. M. Semard saw him into the carriage, and it drove off, and soon reached his residence; the coachman got down and opened the door, when he found M. Visconti quite dead.

He had just reached the culminating point of glory for an artist by having had confided to him the completion of the Louvre, whica, had occupied the genius of French architects for two centurihe He had reaped the fruits of laborious and profound studies in the very highest departments of our art, by solving the problem which seemed to present difficulties apparently irreconcileable and almost insurmountable; and he had commenced, and to a great extent carried into effect (to the height of 30 feet in some parts) with in-

* Communicated to the Royal Institute of British Architects by the Honorary Secretary of Foreign Correspondence, January 1854.

conceivable rapidity, the outlines of his grand design, which united all suffrages, and promises to render the Palaces of the Louvre and Tuilleries the finest sovereign-residences in the world. At the same time it must be confessed that the conception of other architects, as Percier and Fontaine, and more recently, of M. Dusillon, had considerably assisted him in the solution.

I had from his own lips the following account of his appointment to this important work. He received very unexpectedly, about three years since, a notice from the officer of the household of the President of the Republic, to the effect that he would be received next day at the Elysée Bourbon at a certain hour; he duly attended, and was soon ushered into the Cabinet of the Chief of the State, by whom he was received most courteously. "It appears to me," said Louis Napoleon, "that the Palace of the Louvre should no longer remain in a condition which reflects disgrace on the government, and it is desirable that employment should be provided for the working classes; I have therefore conceived the design for the completion of this palace, which I wish you to undertake." "Sir," replied Visconti, "I am gratified by so honourable a mark of your confidence, but I venture to remind you that M. Duban is architect of the Louvre, and it is impossible for me to interfere with a position which he fills with so much credit and ability." True," replied the President, "but M. Duban is architect of the works of the Old Louvre; I wish you to undertake this appointment as architect of the works of the New Louvre, which are to be quite distinct, and to be a charge entirely separate, and not interfering with or superseding the other." "In that case," said M. Visconti, "I am quite at your command." The Prince then explained a scheme that he had himself conceived and roughly sketched, which he wished Visconti to draw out architecturally, and asked how much time would be required. When informed a month, he said, "Well, in a month I shall expect you to come, and you shall be admitted at once."

At the end of that time, Mons. Visconti took the plans, and submitted them to the President, who highly approved of the manner in which his views had been carried out. Mons. Visconti than ventured to suggest, that in the course of study to which the plans had given rise, it had occurred to him that a much nobler and more desirable arrangement could be adopted, which he should wish to submit to his Highness's approval. The Prince immediately encouraged the architect to develope his views, and this he did in his succinct, clear, and convincing manner, so as to carry the conviction of the President, who then asked him how much time he would require to prepare the necessary drawings. Six weeks. "Enough," said L. Napoleon, "and in six weeks bring me your project thoroughly considered." Accordingly, in six weeks Visconti again attended at the Elysée Bourbon; but during the interval the Republic had become an Empire, and the President Emperor. It was sufficient for Louis Napoleon to see the design which his architect had prepared; his ready aptitude seized all the superiority of the arrangements proposed, and he expressed himself perfectly satisfied. Taking out a paper from his breast-pocket, he presented it to Visconti, saying, "Take this document, it constitutes you architect of the new works of the Louvre." In fact it proved to be a formal document, signed by the proper authorities. The Emperor desired him to be ready to attend a council in a few days, and explain the plan, and to be prepared with general estimates as to the cost. Our architect, of course, was punctual to the appointment, and while awaiting the meeting of the council engaged in conversation with several of the members. Being anxious to ascertain their sentiments, he asked their opinion: one thought it a very fine design; another, that it must cost a great deal of money; but none would venture to pronounce that it was a desirable and executable project. At length the council met, and the most vehement objections were taken to the idea; the principal one being, to its vast cost. At length the chief minister said, "It is the wish of the Emperor." These words at once calmed the storm, like oil poured upon the waves; not a dissentient was heard; many raised their voices in praise of the noble conception of the Emperor, and the immense talent of the architect; and the requisite millions no longer forming any obstacle, the design was approved, and ordered for execution, with the necessary funds.

I do not at the moment call to mind any very large public building that Mons. Visconti has erected at Paris; but the monument of Molière in the Rue Richelieu; the fountain on the site of the old Opera Place Louvois; the noble fountain of the Place S. Sulpice with the sedent statues of the four great Doctors of the Gallican church; a fine façade at the angle of two streets in the Rue Neuve des Petits Champs; and lastly, the tomb of the Emperor Napoleon under the Dome of the Invalides, attest the fertile imagination, originality, knowledge, and taste of Visconti, and doubtless contributed to indicate to Louis Napoleon one capable of realising the noblest projects in his art.

In October last I experienced many marked attentions from our colleague, due doubtless to the position I hold among you as your Foreign Secretary. He received me at his house, and I must own that his reception-rooms displayed refinement and elegance superior to any other private residence in Paris. The furniture was of a superb description, and full-sized cheffonnieres of black ebony with glazed fronts contained most exquisite enamels of various sizes, dishes and vases of Raphael and Lucca della Robbia ware, or china of the revival; there were fine bronzes and choice pictures: in fact, one seemed to breathe an atmosphere of art, evidencing the host a man of refined taste, and one who possessed a perfect discriminating relish for all the arts.

He was heir to a great European name, one of a family distinguished for archæological learning, and has nobly maintained the reputation of his ancestors. His personal presence did not seem to indicate the noble qualities within him; but his exalted genius, his simple, unaffected manners, his cordial address, his loyal and generous sentiments, were the confidence, the esteem, and admiration of all who were admitted to his friendship. I need hardly say how highly he valued the gratifying compliment paid him by this Institute in electing him an honorary member. He entrusted me for presentation with a copy of the work showing his design for the completion of the Louvre, inscribed with his own hand, and, at my request, has sent you full-sized drawings of certain iron girders for the floors, one of 70 feet span, which he purposed employing. At some future time I may perhaps give a history of the Louvre and Tuilleries, note the various projects for their union, describe that of our lamented colleague, and explain some points of ingenious construction in the floors.

On the 4th ult. his remains were deposited in Père la Chaise, followed by one of the carriages of the Emperor, and attended by many ministers of State and noble functionaries, the leading men in science, literature, and the fine arts; his pall borne by the most distinguished men in France, and accompanied by the tears and regrets of several hundred workmen, who felt that they had lost indeed a noble leader. The long line of streets which led to the cemetery abounded with testimonies of respect to the memory of this great man. And a minister of State, the perpetual Secretary of the Academy of Fine Arts, our colleague, Mons. Caristie, Mons. Rohault de Fleury, and Mons. le Baron Paul de Richemont successively addressed the thousands assembled, as did also our Honorary and Corresponding Member, M. Hittorff, from whose touching discourse I borrow a few sentences, which seem penetrated with a due appreciation of the character of his colleague and friend.

"The loss," said M. Hittorff, "of an artist, who united the highest faculties of the mind to the no less noble qualities of the heart, is afflicting to those who were privileged to possess the opportunities of appreciating in him those high natural gifts. But when, as now, this artist is carried off in the midst of the most important works, at the moment when he might naturally look forward—as we all might—to their happy completion and glorious success, this loss is no longer a mere family bereavement, it is a public calamity. Certainly, in the immense and grandiose work which fell to the lot of Visconti, it required, in addition to the conception of the architect, a rare combination of circumstances to carry up, in less than two years, that which had occupied nearly half a century under the greatest of our kings; it required still more to know how, as did our friend, by incessant activity—by a rapid *coup d'œil*—by a discernment as prompt as just, to render available all those precious elements, and to organise an army, as it were, of able and intelligent assistants and artificers to carry out the work.

"The head of the State was doubtless glad to connect his name with the completion of the finest palace in the world, and still more to recall by such a work, minds which had too long been led astray; nor did the architect peril his fair fame in this surprising rapidity of execution, which astonished all Paris, and excited the wonder of those foreigners who flocked hither. M. Visconti bestowed the utmost care upon the soundness of the construction, as upon the exquisite beauty of the design. These incessant occupations and flattering combination of circumstances did not at all alter the natural character of our friend. Although naturally aware of his own capacity, surrounded by numerous gifts of fortune, raised to the enviable position of architect to his Emperor, Member of the Institute of France, President of the Central Society of Architects, nothing altered the constant amenity of his character; he was still the same unaffected, modest man, always ready to oblige, and ever disposed to recognise the merit of others."

To such an eulogium it is unnecessary for me to add one word; but, in conclusion, I beg to notice an inadvertant expression which escaped M. Rohault de Fleury in his address; it is contained in these words: *"It has been said with just reason that the loss of Mons. Visconti is irreparable."* To his family and friends such a bereavement is irreparable; but you and I, gentlemen, must feel, that however great this loss may be to architecture, it cannot be irreparable to France, when she possesses so many men of such distinguished tastes to uphold the high rank which she has attained in the commonwealth of the arts.

## SYSTEM OF RAILWAY TRACTION DURING SNOW.

During the late severe weather the apparition of sledges in the streets must have suggested how easily iron glides over a smooth surface; and the exercise of skating, during which a man with little muscular exertion glides over a very considerable space, is another proof of the same fact. According to the present system, steam-engines could not draw a train along rails coated with ice, or covered with snow, were not gravel continually dropped between the two surfaces of the wheel and the rail. Such an expedient as this cannot evidently be adopted as the definitive mode of remedying the evil alluded to.

But the absence of the natural friction between the wheels and the rails is not the only obstacle presented by the snow. The greatest difficulty arises from the accumulation of the snow on the railway, which obstruction the engine cannot overcome, paralysed as it is from the above-mentioned absence of friction. To meet the difficulty it would scarcely be sufficient to provide the engine with irons acting like ploughshares, for the purpose of clearing the way as a plough opens a furrow; for this exceptional service the present engine will only have its usual power, and from this must be subtracted the loss of friction occasioned by the snow or ice, and this friction, be it remembered, results from the weight of the engine alone.

M. Léguier has proposed a system which he thinks will have the desired result, with the additional advantage of relieving the ordinary rails of the excess of weight which a steam-engine presents over other vehicles.

His project consists in a third rail placed between the other two, and especially destined for traction. The motive-wheels would be replaced by smaller ones, working opposite each other in the same horizontal plane, and having between them the middle rail, on which they would act by turning like the rollers of a flatting-machine (*laminoir*).

It is possible, in fact, to construct a special machine, with large pistons, long moving bars (*manivelles*) and very small rollers. The power of such an engine, provided with suitable means for piercing the snow and throwing it on the sides of the railway, would only be limited by the surface of the pistons, and the solidity of the rail on which the rollers would work. However, for the purpose of clearing the line, speed might be sacrificed, and it is probable that a machine of ordinary dimensions, provided with rollers of small diameter, would possess sufficient power to struggle against an accumulation of snow.

M. Léguier, in submitting his plans to the French Academy of Sciences, stated the principal advantages inherent to the system of traction proposed, which would admit of the engine being divided into two distinct parts, thus relieving the ordinary rails, and facilitating the action of the machinery and generator, isolated one from the other.

[The novelty and advantages of M. Léguier's system of traction might be more apparent, were the description more intelligible. His method of dividing the engine into two parts is at present inexplicable. The idea, however, may give rise to some more valuable suggestions, when it is understood. Ed.]

## PERPETUAL VENTILATION OF THE GREAT PYRAMID OF EGYPT.

By G. W. Smith.*

This method of solar ventilation, which has so recently been applied in the United States, is nevertheless the most ancient in existence; having been applied at least 4000 years ago in that most venerable monument of Egypt, the great pyramid of Cheops (Khoufou or Suphis). In the first volume of Vyse on the pyramids of Gizeh, a description is given by Colonel Vyse, of the operations for removing the obstructions from two narrow apertures or tunnels, which ascend from the great chamber near the centre of the pyramid to the surface in an inclined direction. These had long been conjectured to be ventilators, and when the rubbish had been removed from them, the previous conjectures proved to be correct. The suffocating mephitic air of this, the King's chamber, was immediately changed by a rush of pure air from without.

The manner by which these air channels acted when the present entrance passages were closed, has not hitherto been explained, Mr. Smith stated, by any writer on these monuments. As the mode of action is extremely simple and efficient, and the very durable apparatus entirely self-acting, requiring no attention whatever, being moreover in as perfect a condition as on the remote day when it was finished, 120 generations ago, it deserves our attention. An inspection of the accompanying diagram will

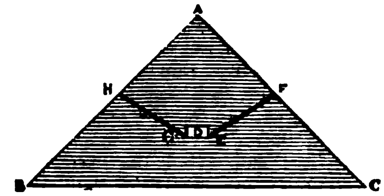

exhibit the plan at a glance. A, B, C, shows the pyramid in section (the closed passages are not represented); D, the King's chamber; E, F, the north air channel; G, H, the south air channel, which being more heated from the sun's rays striking on the south side of the mass A, B, the air will be heated, and thus rarified will rise in it by the pressure of the dense column in the northern or cooler side of the pyramid, day and night for ever.

During the process of building the chamber, and until the external casing of the pyramid was added, it cannot be doubted that the action would be perfect; but even when cased, the joints would not be perfectly air-tight, and therefore would permit some circulation of air.

Recently, in Philadelphia, advantage had been taken of certain brick walls containing flues; the walls being heated by the sun to which they were exposed, rarified the air in the flues which communicated at their lower portions with the apartments to be ventilated, and the plan has been found, even with thin walls, quite effectual, and was strongly recommended for adoption in many places where it might be applicable.

## BUILDING IN BIRMINGHAM.

The returns which have been published, under the Birmingham Improvement Act, exhibit, in a remarkable manner, the expansion of the town—the consequence of its great manufacturing and commercial activity. During the last 40 years of the century the average increase was 608 houses; for the last three years ending 1851, the increase of houses was about 800 per year. The last two years, however, exhibit a far more extraordinary and gratifying character. For the 15 months ending March last year the increase in houses was 3020. The last year, taken altogether, from the 1st of January to the 31st of December 1853, shows an increase of 2784 houses, exclusive of warehouses, manufactories, and multitudes of other buildings springing up on every side, and invading the agricultural precincts of Warwickshire, Worcestershire, and Staffordshire. If these were to be comprised, 1000 more might be added to the number already given.

* Paper read before the Franklin Institute, U. S.

## ORDNANCE SURVEY OF SCOTLAND.

As the subject of correct surveys in connection with sanitary and other improvements, and more especially the long-promised survey of Scotland, has been very prominently under the consideration of government for the last few years, and as every information on the subject must be highly interesting to the profession generally, we have in a former number reviewed and made extensive extracts from 'Letters upon the Survey of Scotland, by a Practical Surveyor.' We considered that the subject was treated fairly and practically in these Letters, and that they contained many practical hints which might be turned to good account in a national as well as in a professional point of view.

We have understood, however, that some of the Ordnance Survey authorities have complained that they were treated rather harshly in these Letters; but as public men, conducting a purely civil operation, and at a very great expense to the country, they ought not, in this age of progress and inquiry, place themselves beyond the reach of fair, legitimate criticism; and as we find it extremely difficult to obtain reliable information upon the manner in which these great and important national works are conducted, or to arrive at the cost of any specific operation, we are therefore happy to lay hold of the materials within our reach.

Our columns are however open to the military as well as to the civil surveyor; and as we are thoroughly convinced that publicity and a searching but fair criticism are the main safeguards of all our public departments, we see no reason why the military surveyors should be so fastidious as to consider everything which is said about the important public duties in which they are engaged, as so much personal insult offered to themselves.

This sensitive feeling must be the result of their military education, of the high-caste system which they assume and endeavour to perpetuate by the impassable barrier which they place between themselves and the operatives, or rather machines (*a la* Yolland), which they employ, and upon which the execution of the whole of their operations must necessarily depend. If civil engineers were as much annoyed at the fair criticism of their various works as military engineers appear to be, they would be deprived of many valuable hints which at present they frequently turn to very good account in the improvement of their subsequent operations; which is much better than to stand still in an age of gigantic and rapid improvement.

Those who are acquainted with the progress of science in England must be aware, that when the survey of Ireland was commenced in 1824, the details of extensive surveys were but very imperfectly understood, and it would have been no disparagement to the conductors of that extensive operation if they had commenced by experimenting upon the best mode of conducting so complex an operation, and not to have proceeded further than mere experiment until the Commissioner of Valuation had ascertained correctly and stated explicitly what documents he required to be supplied with, and the degree of accuracy, which was indispensable; but instead of this, Col. Colby, who could have had no previous knowledge of extensive detailed surveys, states, in his letter of the 6th May, 1840, that he "commenced the task by drawing up a code of instructions."

What would be thought of George Stephenson if, before he had constructed the first railway in England, he had "commenced the task by drawing up a code of instructions," which should be binding upon the profession for all time to come? Had this been the case, the very important improvements in bridges, viaducts, and other important works connected with railways and railway machinery, could not have been effected. This subordinate action produces a paralysing influence upon the mind, the very essence of which is freedom of action, and without which its varied powers can never be developed. Progress is unquestionably the supreme law of the soul; but without the freedom of thought and action, this progress cannot take place.

As the papers which are being prepared by the Treasury, and which will no doubt contain the final decision of the government upon the long-contested question of the scales at which the national surveys shall for the future be constructed, are not yet before the public, we will at present simply advert to a few of the most prominent and most important points contained in the Report of the Select Committee on the Ordnance Survey of Scotland, and the correspondence between the Treasury and the Ordnance in reference to the recommendations contained in the above report, ordered by the House of Commons to be printed, 22nd June, 1852.

The above report, like all other "Blue-Books," contains much valuable information, with an immense mass of mere twaddle. Select committees, particularly on scientific subjects, appear to be at a very great loss in not being able properly to shape their questions so as to elicit the truth from a reluctant witness, or a witness who is determined to support certain preconceived views and opinions. Another hindrance to the production of a clear consecutive train of evidence, and a cause of much embarrassment to a witness, is the mode of examination pursued by the committee. One member, probably the chairman, may take a witness consecutively through the greater part of the subject under investigation with tolerable success, but upon the slightest pause being made in the proceedings, another member chimes in, and asks a question probably unconnected with the subject altogether, or a question that had been previously answered over and over again, and quite out of the former line of examination.

Honourable members are frequently placed upon a committee in consequence of entertaining antagonistic opinions upon the subject about to be investigated. This circumstance, not unfrequently and not unnaturally, results in the highly objectionable practice of leading questions being very much indulged in. In some cases, one would suppose that the committee were composed of two batches of hostile lawyers, endeavouring to make the *most* and the *least* of each witness who came before them, and acting without the control of a presiding judge.

Much has been said by several witnesses respecting the applicability of the 6-inch map of Ireland for parliamentary deposit in the case of railway bills. The advocates of the Ordnance 6-inch maps have very much exaggerated their utility for railway purposes, and probably they have been somewhat depreciated by other witnesses.

It is well known to railway engineers and surveyors, that the most imperfect, rubbishy plans and sections of proposed railways will, if *unopposed*, pass a Committee on Standing Orders without any objections being made to them; and we do not recollect a single instance in which there has been a well-contested opposition to an Irish railway bill on Standing Orders. By an opposition on Standing Orders, plans, and more particularly sections, are rigorously tested; but as respects plans, the allegations that can be sustained on Standing Orders are more technical than real. For example, the Standing Orders require that every field or inclosure shall appear on the map, and be described by a reference number, but a field containing twenty acres in area may be delineated on the map of the same size as a field containing half that area, and no allegation upon the subject could be sustained; so that even to pass Standing Orders against a strong opposition would be no proof of the accuracy of the map for valuation and other important purposes.

It must also be observed, that 6 inches to a mile is not a sufficiently large scale to obviate the necessity of supplemental plans on a larger scale, as the Standing Orders require that "an enlarged plan shall be added of any building-yard, courtyard, or land within the curtilage of any building, or of any ground cultivated as a garden, either in the line of the proposed work or included within the limits of the said deviation, upon a scale of not less than a ¼-inch to every 100 feet."

In a densely-populated country, where the tenements are small and the houses and cottages numerous, these supplemental maps would embrace a very considerable extent of the whole line of railway, and as they must be engraved or lithographed, the time and expense saved by the use of the 6-inch Ordnance maps would be very inconsiderable.

The 6-inch Ordnance sheets, with section and enlarged plans detached, make a very inconvenient mass of documents to refer to; and in carrying an opposed bill through parliament, forty or fifty copies would be required for engineers, land valuers, solicitors, counsel, &c., it is therefore found to be more convenient, if not less expensive, to have the whole plan lithographed, upon a scale which would not require additional enlarged plans.

The great stress which has been laid upon the applicability of the Ordnance 6-inch map of Ireland to railway purposes affords another strong proof of the great length to which puffing can be carried in the present speculative age.

The question has frequently been asked by the committee, whether the survey could not be "drawn in the books of the Ordnance on the 6-inch scale" for future reference, and only published on the 1-inch scale? These questions were put and answered in such a manner as to convey a very confused impression of what was really meant by the committee or their witnesses. The committee appear to confound the survey made in the field—that is, the results of the various measurements made on the ground and entered in a book—with the operation of transferring those measurements to paper, so as to construct a map or plan, which map or plan may be constructed on any required scale; but the field-notes, abstractedly considered, can have no reference to scale. It is true, that in taking field-notes for a map to be constructed on a scale of 1 inch to a mile, those objects only would be surveyed and entered in the field-notes which could be drawn upon a map of the required scale; and the larger the scale at which the map is to be drawn, the more accurately should the measurements be made on the ground, and the greater the number of objects would be inserted in the field-notes.

If the committee had an idea that the field-notes could embrace all the detail which is generally shown upon a 6-*inch* map, and only those portions of the notes laid down upon paper which it would be desirable to exhibit upon a 1-*inch* map, reserving the great mass of detail to be laid down on the 6-inch at some future period: nothing can be more fallacious. It is quite bad enough at present, when one man is measuring lines in Glentilt or Glenmore, or some of the mountain districts of Scotland, and another man, who has probably never stretched a chain in his life, laying down the work in Southampton.

The confused notions which the committee appear to have had on this subject is not in itself of much importance, but it allowed them to be led astray when the subject of the Admiralty Coast Surveys came to be discussed, and it afforded the advocates of the 6-inch scale an unfair advantage in the investigation.

Can any unprejudiced person, at all acquainted with the subject, carefully read over paragraphs 1429 to 1451, and 1458 of Captain Yolland's evidence upon the subject of Admiralty charts, without arriving at the conclusion that these paragraphs exhibit an admirable specimen of what lawyers call "fencing?"

Such is generally the result, even with the most honourable men, when determined to advocate, at all hazards, any preconceived opinions. Take for example:

1429. "The *one-inch* map of the western coast of Scotland would not be sufficient to enable the Admiralty surveyors to put in their coast line from it."

1437. "With regard to the coast, what is the scale the Admiralty are going on?"—"I think *under half-an-inch* to a mile."

1438. "Would not the scale of two inches to a mile be sufficient for all the purposes of an Admiralty chart; and might they not survey the harbours on the large scale in the same way as you survey the towns upon the large scale?"—"*Practically, not.*"

1444. "Do you know the scale to which they make their maps as to the soundings in the inland navigations?"—"They are stated to vary from *three* to *twelve inches a mile.*"

1445. "Would your six-inch survey do away with the necessity of the Admiralty making a further survey?"—"An accurate six-inch survey, if enlarged to a scale of twelve inches to a mile, would be more accurate than any nautical surveyor can survey it, with the means at his disposal."

1446. "If an accurate map, drawn to a *six-inch* scale could be enlarged to *twelve inches*, would there be any difficulty in enlarging a *two-inch* map to a *four-inch*?"—"The nature of the survey for a two-inch scale and a six-inch scale are essentially different."

This answer is a mere evasion of a very plain and pointed question. If an acute lawyer had the handling of a witness of this description, he would soon impale him upon the horns of a dilemma, from which he would not very easily nor very honourably extricate himself.

1470. *Answer.*—"If a one-inch map of Scotland alone were required, I think it might be made with the accuracy that that scale admits of—probably at one-third of the other; *but that will involve the throwing overboard of the surveys of all large towns;* because the triangulation that suffices for a survey of two inches to a mile will be entirely insufficient for a survey of a scale of sixty inches to a mile, or even the *supplying of points* if they were asked for by the Admiralty surveyor."

This is not simply fencing in favour of the six-inch map, but it is absolutely contrary to the facts of the case, and calculated to mislead the committee, whether intentionally or not we do not pretend to say; we would be sorry to suppose it was, but most assuredly the government have a right to better treatment from their own witnesses. As Capt. Yolland states to the committee that he is the "executive officer at the head-quarter office at Southampton," we must charitably suppose that he is well acquainted with the whole *modus operandi* of the survey, and well qualified to direct the committee in their important investigation. He might therefore have said, and with great truth, that to give up the *six-inch* scale and to adopt the *one-inch* scale for the survey of Scotland, will *not* involve the throwing overboard of the surveys of all *or of any* large towns, nor will it throw any impediment in our way in supplying any number of points to the Admiralty surveyors. To come from the six-inch, or from the one-inch to the five or the ten feet to the mile, is only a matter of degree, and involves no more difficulty in the one case than in the other; for in surveying the rural districts on the six-inch or any other scale we adapt the number of fixed trigonometrical points to the amount of detail to be surveyed. In an open mountainous district, the fixed points may be two or three miles apart, but in a closely-cultivated district they will only be about one mile from each other. And with respect to towns, we simply increase the number of points in the same way, and with very little additional trouble, from this circumstance: that in a town there are a great number of natural objects, as church-spires, towers, turrets, flag-staffs, factory chimneys, &c.; and an observer perched upon the top of a mountain in the neighbourhood of a town can never prevail upon himself, when sweeping his telescope round the horizon, to pass over a well-defined, permanent object without recording its bearing. We doubtless require the points to be more numerous in a town than in the open country, but this would be the case if the survey of the town was to be laid down on the same scale as the surrounding country.

And in reference to the Admiralty, we can very easily, without much additional trouble or expense to the Ordnance, give the Admiralty surveyors much more assistance than we have ever given them before. We can request the Hydrographer to the Admiralty to furnish the Ordnance with a statement of the scales at which he will require the coast-line to be constructed, and also the several inland navigations in connection with the whole kingdom: we will then increase the number of points in those portions where a large scale is required, and also give directions to the field surveyor to make more minute measurements of those portions; and this will enable us to supply the Admiralty with plotted plans for the basis of their important operations, which will be superior to reductions or enlargements.

We are aware that at present the Admiralty surveyors labour under very great disadvantages in consequence of being in advance of the Ordnance; indeed, they are thrown almost as much upon their own resources with respect to the Coast Survey of Scotland as if they were surveying the coast of New Zealand or the Feejee Islands, and that no efficient body of Ordnance surveyors existed.

This we can very easily remedy, irrespective of the pending question of scale, as we have our primary triangulation completed for the whole kingdom. We can produce a survey of the whole of the coast line at probably one-tenth of the expense at which the Admiralty surveyor can execute the same work much more imperfectly; and as we *really* belong to the same government, and that both departments are paid out of the same taxes, perhaps this might be a good practical view to take of the subject.

We will say no more about the Report on the Scotch survey at present, as we will have to advert to it again in connection with contouring, and probably the valuation of land. But *apropos*, can any of our numerous scientific readers inform us what has become of Captain Yolland?—he appeared to be the great gun at the time of the sitting of the Committee. Is it possible that he was stepping in front of his chief; or has he committed the unpardonable sin of knowing more about the matter than those above him in the graduated scale of rank, which also regulates the graduated scale of knowledge? It appears, at all events, that he is *non est*, as far as the recent investigations are concerned.

The result of the deliberations of the Committee has long been before the public:

1. " That the six-inch scale be abandoned.
2. " That the system of contouring be abandoned.
3. " That the survey and plotting on the two-inch scale be proceeded with as rapidly as is consistent with accuracy, with a view to the publication within ten years of a one-inch map, shaded and engraved in a manner similar to the Ordnance one-inch map of England, with as many elevations as possible given in figures.
4. " That the survey be proceeded with steadily from south to north, as was the original intention."

The communication of the above decision of the Select Committee to the Ordnance threw the survey authorities into consternation, well knowing that as the present generation of Ordnance surveyors have been mechanically instructed in the several distinct operations into which the execution of the six-inch survey is divided, a more intellectual class of individuals must of necessity be sought for to execute with rapidity and accuracy an artistically finished one-inch map of Scotland.

This crisis of the affair produced a letter from Colonel Hall, in which the most remarkable feature is an allusion to Lord Langdale's letter of the 30th November 1848, in which his lordship enumerates various uses to which accurate maps on a large scale can be applied; such for example, as the purposes of "the *poor-law tithe commutation, parochial assessments, sanitary purposes*, the *registration of deeds*, or assurances of land, show only some of the many great and important purposes for which good and accurate public maps are required."

Colonel Hall must have been aware that the six-inch map is altogether inapplicable to the various purposes which Lord Langdale enumerates, and that they can only be carried out by an accurate map constructed on a scale of twenty-five or twenty-six inches to a mile. Colonel Hall may, no doubt, have been led astray by the Commissioner of Valuation in Ireland, attempting the gross absurdity of making a tenement valuation upon the imperfect data supplied by a six-inch map.

The opinions of civil engineers upon the decision of the Select Committee were also solicited by the survey authorities, but as the letters requesting those opinions are not given in the correspondence we have no means of ascertaining how the proposition was put. The answers would appear to imply that the question was as between the six-inch and the one-inch, and not between the six-inch and a larger and a more efficient scale.

We are, however, very much surprised to find Mr. Vignoles so uncompromising an advocate for contouring, as we are aware that in the selection of a line of railway (in which operation we consider him second to no engineer of the day) he employs a very efficient system of surface levels, which, in his own practice at least, he evidently prefers. It is very true this gentleman was writing in "great haste," as he was taking his "departure for Russia to meet the *Emperor* and the *Minister of Public Works*." He had also some business to transact with "the great eclipse of the sun on the central line of shadow at Ooman." These and many other important matters contained in the letter, and not bearing very directly upon the *one-inch* or the *six-inch* scales, must, to any reasonable critic, be a sufficient apology for any apparent discrepancy between practice and theory.

## ON RAILWAY TURNTABLES.

By SAMUEL LLOYD, Jun., of Wednesbury.

[*Paper read at the Institution of Mechanical Engineers.*]

IN the construction of turntables, three leading principles have been followed; either the bearing has been on the centre only, with no bearings at the circumference, or with bearings at the circumference and none at the centre; or a combination of these two modes has been adopted by allowing the weight to rest in part upon the centre, and in part upon the bearings or rollers at the circumference; this last construction has been most frequently adopted. Most of the turntables first laid down on railways were made to rest on fixed rollers, for the sake of economy; but although fixed-roller turntables are the cheapest kind in first cost, and were much used on the first railways made, live-roller tables have been generally adopted latterly, from the greater ease with which they turn;—as in the fixed-roller turntable the weight bears on the axle of the roller, producing rubbing friction, but in the live-roller table it bears upon the circumference of the roller, producing only a rolling action without any rubbing friction except in the guiding ring. Some fixed-roller turntables have however of late been constructed with much larger rollers than those formerly used, which has the effect of perceptibly lessening the friction; but these tables seldom continue long in good working order, in consequence of the rollers *indenting* the top table. This is an objection to which all roller turntables are subject, but those with fixed rollers most especially, from the top table always resting upon the rollers in these, in the same position, thus receiving the pressure always on the same points; and as the amount of surface in contact between them is very small (the whole amount of surface in contact between the surface of the rollers and the top table being not more than three square inches, if so much), the rollers soon wound the under surface of the top table, so that the latter becomes indented over every roller. As soon as this takes place, considerably more power has to be exerted to turn carriages upon them, as the resistance to be overcome is greatly increased by the whole weight having to be lifted out of each of the hollows formed from the above cause.

But in addition to the increase of friction occasioned by these indentations, they cause also great unsteadiness, making the table rock, and thus clatter and hammer against the rollers as each pair of wheels passes on and off its two opposite sides. This deteriorating action goes on to a greater or less extent in almost all roller tables, often occasioning the top to break, if it is not very strongly made; this rocking is often greatly increased, and occasionally entirely originates from the centre being too tightly screwed down, so as to take the weight entirely off the rollers on one side of the table.

This defect has led to the construction of turntables with a centre pin that acts merely as a centre guide, without taking any weight. Turntables of this class, if made with radiating rollers, have the advantage of remaining very solid for a time after they are put in, but frequently this is not of long continuance, for all roller turntables are unsteady, if the rollers are not *all* correctly turned to the same diameter, and cottered or screwed up exactly to the same distance from the centre; each roller being a portion of a cone, its outside diameter is greater than its inside, and if either of the rollers is screwed up too tightly, the table rides on it. This is sometimes occasioned after a few months' wear, by the pressure of the table top continually exerting a force tending to drive the rollers upon which it rests outwards, which is sure to be the effect if either of the nuts that screw them becomes slack. This pressure tending to force the rollers off the roller-path, causes considerable friction against the guide-ring at the boss of every roller, and is one cause of the heaviness with which even live-roller turntables work, causing railway labourers in goods stations, whenever they have the chance, to wrench them round by horse-power.

In an improved construction of roller turntables extensively adopted, the weight of the table top is nearly counterbalanced by a weighted lever which constantly tends to lift the centre pin without actually doing so, making the table much easier to turn, by diminishing proportionately the pressure on the rollers; the rollers also are not fixed as in common turntables, but in an inclined position, with their upper surfaces level, for the purpose of preventing the level of the table top from being disturbed by the surge of carriages passing over. In some turntables the rollers have been made with rounded edges and level roller-paths, with the view of lessening the friction of turning, and increasing the steadiness of the table by resting it on a plane instead of a cone; but these rollers have not been found to be durable, and the roller-path becomes worn hollow by them. A more successful plan for diminishing the friction has been the use of spherical balls instead of rollers, travelling round in a live ring, to prevent the balls from rolling off, but allowing them room to shift their position on the roller-path as they move round, which prevents them from wearing the roller-path into grooves; and as the balls travel in a circle, sometimes in one direction and sometimes in the contrary direction, they continually present a fresh portion of their surface for the bearing, which preserves them from being worn unequally.

There is one objection to these tables, but which applies still more strongly to roller turntables—namely, the extreme difficulty of turning them in frosty weather, when the dirt on the rollers and roller-paths becomes frozen; horse-power is then often required to stir them, or a fire has to be lighted to thaw the congealed mud collected on them.

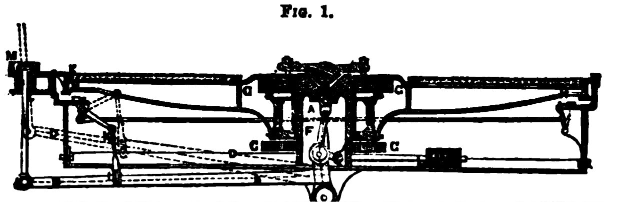
*Centre-bearing turntables* are practically free from this objection, and also from the one before referred to—namely, the bearing surface becoming indented, from the small extent of surface in contact with the rollers.

They also, as usually constructed, have most of them two defects—namely, great extra cost of foundations, and unsteadiness and liability to deflect; the last being the most serious defect, which renders them objectionable for any situation where much traffic is likely to pass over them. Their deflection upon trains passing over them being caused by the whole of the weight of each carriage acting at a great leverage to strain the working parts of the table while running on and off.

The *unsteadiness* of the centre-bearing turntables described above may be considered as the principal cause of their disuse, notwithstanding their superiority over roller-tables in ease of turning; another cause being the expense and depth of the foundations requisite.

Figs. 1 and 2 show an improved mode of constructing turntables, by which the result is obtained of supporting the table top by its circumference when out of use, and upon its centre when in use. The action of the lever B, B, in this table is to raise the table sufficiently to disengage the blocks H, H. When the table is not in use the lever is in the position shown at B, B, but as soon as it is necessary to turn a carriage, the table top is eased off the four blocks H, H, at the circumference, under the main-line rails, by being raised from $\frac{1}{4}$-inch to $\frac{3}{8}$-inch by the action of the knuckle-joint lever F; by this time the stud I, which is fixed upon the long lever B, B, having traversed to the end of the slot in which it works, carries the rod K, with it; thus withdrawing the four blocks HH, from under the outer ring E, E.

Fig. 1.



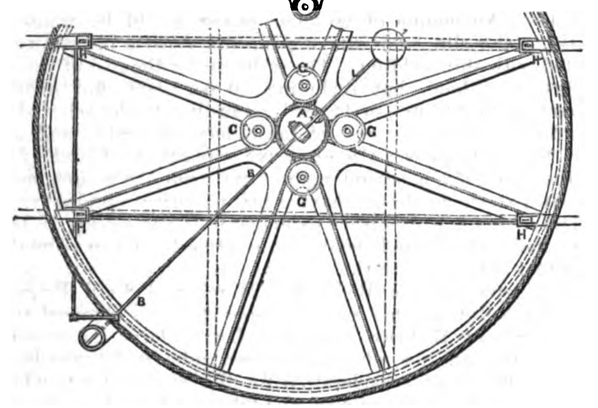


Fig. 2.

The long lever is now at the position shown in the drawing, or at the bottom of its stroke; the centre joint of the knuckle-joint lever F, has now passed from one side of the centre line of the table to the other. The table top is exactly at the same level when the long lever is at the bottom of its throw as when it is at its top; the difference being that when the long lever is up as shown by the dotted lines D, D, the table top is supported entirely at its circumference on the four blocks, which may be made of any convenient size; and while it is down the weight is on the centre pin C, when carriages may be turned with ease and rapidity. By means of the stud I, traversing the slot in the rod K, during the first part of the motion, the table top is eased off the bearing on the blocks H, H, before the rod K, is set in motion to withdraw the blocks; and by the same means, in lowering the table, time is allowed for the blocks to be pushed home before the table top is lowered upon them, so that the blocks are relieved from the weight whilst they are being moved. Fig. 2 is a plan of this turntable, showing the position of the long lever B, B, and the horizontal rollers G, G, that work round the centre pillar A. At the end of the lever L, a weight is fixed to balance the weight of the table top to within a few cwts.; the balance weight not being made heavy enough to raise the table top without the exertion of a slight pressure on the handle M. Other modifications of this improved table might be described, but as the principle in them all is the same, viz., to carry the weight on the centre pin when the table is being used, and upon the circumference when not in use, it is not necessary in the present paper to do so.

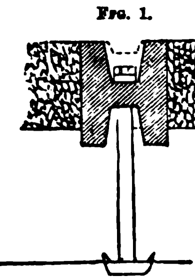
This mode of construction insures a *solid turntable*, one very *easy to turn*, and a very *durable* one; the working parts do not get deteriorated by the passing of trains, and are so placed that dirt cannot collect upon them; the extent of bearing surface at the circumference is greatly increased, and prevented from becoming indented as in roller tables; a smooth and easy motion is obtained by turning entirely upon the centre, as no inequality of bearing surface has to be overcome; also less oil is consumed for the centre bearing than for rollers, and the working parts are more easily oiled. In roller tables an increased load increases greatly the resistance to turning, and after some years wear they work more heavily; but in centre bearing tables much less difference is experienced. Also, the cost of foundation, instead of being more, is rather less than that required for roller turntables with a live ring and rollers, as a continuous ring of masonry is not required round the circumference, but only six or eight blocks of stone, one under each arm of the centre pillar, in addition to the centre stone, which is required in both descriptions of turntables.

## STREET OR HIGHWAY RAILWAYS.

William Bridges Adams, C.E., *Inventor*.

Our engraving fig. 1 shows a "channel" rail especially adapted for street or highway lines where other vehicles are intended to run. It is shown as intended to reverse. The form is that of the letter H. The horizontal web which connects the two vertical sides together is formed with holes, through which pass bolts or screws to fasten it to the transverse, or horizontal sleeper, into which it is slightly grooved to secure the gauge. For street and road work it is required that the paving should come close up to the rail to secure it, and preserve the level. Consequently, the flange of the wheel must run between, and it can be either a central or side flange, according as the wheel may be required to sustain a heavier or lighter load. This rail may be made with a single channel if preferred, but with a double channel it is capable of four reversals if used with light loads. Made with a single channel it would be about 70 lb. per yard. Double, it would be about 95 lb. per yard. It must be borne in mind that rails exposed to be run over by heavy road-carts and wagons would require to be more firmly fixed than such as are protected from lateral blows. The joints are made by an iron casting, or a piece of the same rail, bolted beneath or laterally. Instead of timber sleepers stone may be used, and the sleepers may be either transverse or longitudinal. If stone sleepers be used elastic material should be placed beneath the rails.

Fig. 1. Fig. 2.



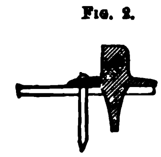


Fig. 2 explains a system of moveable rails of the form best adapted to give strength with the lightest weight of metal laterally and vertically. The rails might be made of angle-iron, with the corner upwards; but more metal would be needed, as a weight would spread it out. The rails are each about 18 lb. per yard, and they are connected at the joints by a flat cross bar, to which they are notched, while a forked staple holds them end to end, holes being pierced in the horizontal web at the rail ends at different distances, so that by using one set of holes a straight line is formed, and by the other set a curved line.

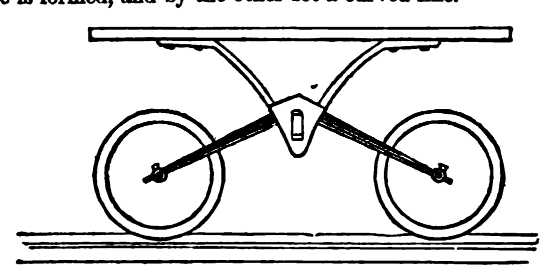

Fig. 3.

Fig. 3 shows a light spring wagon, such as should be used on these rails. The importance of flexible springs cannot be too highly estimated; not merely for lightness of draught, but for the saving the rails and wagon from destruction, and for enabling the wheels to press equally over rails out of level by reason of rough ground. This wagon is composed of the fewest possible parts. Four cast-iron wheels, with revolving axles, each wheel revolving separately, the axles being connected by a single spring on each side, in the centre of which is an iron casting, with two wrought-iron arms supporting a flat platform, which may be fitted with a basket or any kind of body required. The wagon only consists of five parts, exclusive of wheels and axles. With a load of from 20 to 30 cwt. it may be pushed along by a labourer.

## FOYLE NAVIGATION.

The great increase within the last thirteen years in the shipping trade to the Port of Derry has rendered the present accommodation of the port insufficient to meet the requirements of its gradually expanding trade. Many disabled vessels applying for repairs at the patent slip at present in existence, are compelled, in consequence of its limited capacity, to proceed to Troon, to the great detriment of the Derry trade. In the year 1840, the tonnage of vessels trading to the Foyle, including foreign and coasting steamers and sailing vessels, was 84,178 tons; whereas, in 1852, it amounted to 215,499 tons. To meet this great increase, the Ballast Board of the Port of Londonderry commissioned Messrs D. and T. Stevenson of Edinburgh, in 1847, to examine the harbour and estuary of the Foyle, with the view of reporting as to the establishment of a graving dock or patent slip, suitable for vessels of large tonnage requiring repairs, &c. Accordingly, a marine survey was made, and sections and borings taken; and from the data thus obtained, it appeared that the situation possessing the greatest facilities for the formation of a wet or graving dock or patent slip was that portion of the slob-land below the town, on the north side of the river, which extends from opposite the Asylum towards Pennyburn, called the New Land. This site affords an excellent foundation for marine works, the beach being composed of rock, covered towards low-water mark with a slight deposit of silt, and having a rise of tide of from 8 feet to 9 feet at springs; the depths also shoal rapidly from low-water mark to the navigable channel, so that the entrance to either a dock or slip would not be much removed from the current of the tides. The Messrs. Stevenson were also instructed to report on the relative merits of graving docks and patent slips, and the best means of withdrawing vessels from the water for the purpose of repair. Many applications have been resorted to for effecting this, both in our own and foreign countries, embracing the "Graving Dock," "Patent Slip," and "Gridiron," which have been generally adopted in the British dominions, and the "Hydraulic" and "Screw" docks, which are much employed in America. But the Messrs. Stevenson decided that the choice in the case of Londonderry must rest between the graving dock and the patent slip, and state the advantages which the latter possesses over the former to be as follows:—First, the cost of construction is less; secondly, where the fall of tide is languid, a vessel can be more quickly laid dry; thirdly, when so laid dry, it can be more easily examined; and from the greater duration of the daylight in such a situation, compared with that of a deep graving dock, the hours of work are extended, not less during winter months than forty minutes per day; and fourthly, although the upper part of the slip be occupied by a vessel undergoing repairs, an additional vessel may be taken up for a shorter time than its predecessor, without disturbing the progress of the works.

The advantages afforded by a graving dock, on the other hand, are—First, that although its construction is more costly, it is, if properly built, unquestionably a more durable structure, the rails, rollers, carriages, and chains connected with the slip being liable to derangement, and requiring occasional repair; secondly, the management of a graving dock is much more simple, and involves comparatively little superintendence; whereas that of a patent slip is intricate, requiring more than mere nautical skill; thirdly, the graving dock is equally simple, whether the docking of small or large vessels be considered, whilst the raising of a large vessel on a slip is a delicate operation, and can be attempted only under the direction of persons thoroughly versed in the matter, and having ample mechanical resources at command; fourthly, the graving dock possesses the advantage—which is sometimes of importance—of affording the means of partially filling a vessel with water, so as to detect leaks which may not be discoverable in any other manner; fifthly, the back water contained in the dock affords the power of scouring the entrance to it, a facility which the slip does not possess; sixthly, in any current or tide way it is a much easier process to dock a vessel than to land her safely on the cradle of the slip, an operation which, when not cautiously conducted, has been attended with accident even in sheltered situations.

The proposed graving dock for Londonderry was calculated to accommodate vessels of 1000 tons burden, and also to have room, at one time, for two square-sailed vessels of ordinary dimensions. For this purpose, the chamber of the dock would require to be 200 feet in length of floor, and 40 feet broad across the bottom; width of entrance, 45 feet. The depth of water on the sill would be 11 feet at high water of spring tides, which, as vessels always enter in light ballast, would be capable of floating vessels of very large draught. The rise of tide not being sufficiently great to admit of the efficient use of the dock without employing artificial means for emptying it, a pumping engine of 16-horse power would be required, fitted with saws and other gearing for cutting wedges, trenails, planks, &c. The slip, also calculated to receive vessels of 1000 tons, would require to be extended 220 feet landward of high-water mark at spring tides, and 378 feet seaward, so as to be 21 feet below the high-water level at its seaward extremity. The slope of the slip for vessels of 1000 tons to be not less than 1 in 18. An engine of 20-horse power would be wanted for working the slip, and carrying on the various operations connected with shipbuilding. The estimate for the cost of the dock, exclusive of land, but including 10 per cent. for incidents, amounted to 13,540*l*., or 15,626*l*., according to site selected; and for the slip, including cost of machinery, apparatus, and 10 per cent. for incidents, &c., also exclusive of purchase of land, 12,361*l*. In the year 1852, a second report was made, in consequence of the sites above mentioned having become private property.

The second marine survey extended from the Bridge of Derry to Culmore Point; and the only site available for graving docks or patent slips between those points was found to be the portion of slob land between Rock Mill March and Sir R. Ferguson's property. But as this site is proposed to be occupied by the Lough Swilly Railway and the Londonderry Improvement Scheme, the bills for which have been submitted to parliament, it is an important consideration for the city of Derry, whether these proposals should prevent the future extension of the docks and quays. The Lough Swilly Railway is intended to start from the "New Land," to pass outside of the Rock Mill, and thence extending downwards to pass the turnpike halfway between the roads leading to Pennyburn and Buncrana; thus cutting off from connection with the harbour of the only remaining available space for the extension of the Port of Londonderry, as has already been done by the Coleraine Railway on the eastern bank of the river, and by the Enniskillen Railway above the Bridge of Derry. The Londonderry Improvement Scheme proposes to occupy the slob land by a new town; so that the land which should be devoted to warehouses, docks, storing-yards, and ship-building stances will be devoted to the erection of dwellinghouses. The execution of either of these plans, as at present proposed, would, in the end, prove a serious drawback to the prosperity of the shipping trade of Derry, upon which it is so considerably dependent.

The Foyle presents great facilities for navigation, as regards depth of water. The dredging required in connection with the graving and basin or tide docks proposed by Messrs. Stevenson would be principally confined to Rosse's Bay, Culmore Point, and the inclosure opposite to Thornhill. The quays recently constructed by the Coleraine Railway Company would require to be removed to preserve the lines of conservation laid down by the Lords Commissioners of the Admiralty.

The estimate for this extended scheme, including 10 per cent. for incidents, &c., would amount to—

## THE FRENCH METHOD OF CONSTRUCTING IRON FLOORS.

By H. H. Burnell.

[*Paper Read at the Royal Institute of British Architects, Jan. 9th.*]

In describing the system of the "Planchers en fer," or Wrought-iron floors, it is not my attention to enter into a detailed account of the various experiments made before the systems now so generally used in Paris were brought to their present state of perfection,—to occupy your time with calculations of the resisting powers of rolled iron, or discuss the suitability of the forms adopted; but avoiding all that might tend to embarrass the question, I propose to confine myself to a succinct and simple description of the systems now most frequently executed, and to furnish such practical information as I have obtained by visiting the works where they are employed, and hearing the opinions of the architects conducting them.

It would seem that, for some years past, floors composed of rolled iron joists have been occasionally executed in Paris; in most cases, the joists were flat and without flanges: such constructions were known as the Système Vaux. The systems to which I am about to draw attention are little more than an improvement in the form of the joists, and may be said to have come into general use at the commencement of the extensive alterations in the Rue de Rivoli, in the spring of the year 1852.

In the various works treating on the subject, several systems are described, but upon visiting the Parisian buildings now in progress, we perceive but two: one purporting to be the system of M. Thuasne, and the other appearing to be that of any one who may get an order to execute it. From the observations made by parties conversant with the matter, I am induced to believe that the different systems are no longer recognised in general practice, and that the architect or builder combines at pleasure the advantages of all.

The "Système Thuasne" may be described as being composed of joists of iron, rolled in the form of the double T, and slightly arched in the proportion of 0·005 mètre in the mètre or of 1 in 200. They are placed at the distance of 1·00 mètre (or 3 ft. 3¼ in.) from centre to centre, and are united by interties, formed of flat iron bars, fixed at the same distance of one mètre apart. These interties rest on the lower flanges of the joists, and are let into wrought-iron bands fixed round them; a small pin is then driven through the hole at the extremity of the intertie, between the joist and the band, and the transverse tie is formed.

The fantons are light iron rods, from ⅜ to ½-inch square, of the same length as the joists, and parallel with them; they are laid on the interties, and bound to them with copper wire, and may be said to take the place of the ceiling laths. Some of the joists and interties next the walls have their ends so formed as to make them act as ties; thus the ends of the system being firmly built into the walls, the sides of the house are effectually united. The iron-work is usually painted, and allowed to dry thoroughly, before it is brought to the place of construction.

The above-described net-work of iron being completed, the next process is the plastering or grouting. This process differs so materially from the English mode of forming a ceiling, and is so important a part of the scheme, that it requires to be understood before the success of the whole can be comprehended. It is done thus: a board or flat centering is placed under the part intended to be filled in; a grouting composed of the coarsest quality of plaster is then poured in upon it, and running in between the lower portions of the iron-work, it stops against the board beneath, and forms the ceiling of the room below, which one coat of fine plaster serves to finish. The plastering thus applied is from 2½ to 3 inches thick, and sets in about half an hour; it shortly becomes as hard as stone, and assists much to stiffen the floor.

The second system referred to differs in some degree from the first, the joists being placed nearer together, perhaps 2 ft. 4 in. to 3 feet apart. The interties are formed of iron bars, from ⅜ to ½-inch square, bent at the ends so as to clip the upper flange of the joist, and again crooked downwards to rest on the lower one; the elbow so made pressing against the side of the joist, a strut and tie is at once formed between the joists. Interties upon this principle are of course made as nearly as possible of the same size, and when placed between the joists, a blow with the hammer is sufficient to fix them in their position, and make them touch at the required points. They are placed about 3 feet apart, and as nearly as may be in a direct line, so that one may resist the action of the other. The fantons or light iron rods lying parallel with the joists are laid on the interties, and the grouting performed as in the former method. The floors of the new Louvre are made upon this principle, and filled in with pottery.

It need scarcely be remarked of these rolled iron joists, that they may be made of any intermediate thickness between the stoutest and lightest of the patterns given, the depth of course remaining the same. This offers some advantages, particularly in France, where iron is dear, and the apartments divided into rooms of very different dimensions; as, in many cases, it may be desirable that the floor of the smaller room should be of the same depth as that of the larger one; but the span being less, the lighter description of joist would suffice, the internal walls being assumed to have the necessary strength to take the bearing.

As I have elsewhere observed, the grouting is always more or less of plaster, but in many cases the space between the joists is filled with pottery, that is to say, small cylinders of baked earth, about 7½ inches high and 4 inches in diameter, having the ends closed, and somewhat resembling flower pots; these are bedded in a layer of plaster, poured in between the lower portions of the iron-work, and then receive a grouting to fill in the insterstices. Perforated bricks, and pipes like those used to form land drains, are manufactured for the purpose, but are rarely used. Where a wooden floor is required (which is frequently the case) it is nailed to small joists notched in between the iron joists; sometimes, however, where economy of space is less an object, the wood joists are laid across the top of the iron work.

With regard to the relative merits of the two systems, little need be said: that of M. Thuasne binds the joists more effectually at the bottom, where they are best calculated to resist the expansion of the plaster, and it may also be accompanied with some trifling economy of iron; but notwithstanding this it has the character of being on the whole the dearer, and on this account the other method is more generally adopted. Both offer advantages on the score of being easily fixed, and when executed with common intelligence, answer well, producing a light fire-proof floor in two-thirds of the space of the ordinary wooden construction. It will be seen that floors made upon either of these principles are as incombustible and sound-proof as most others professing to offer the same advantages. It is clear that violent heat, if long continued, would calcine the plaster and ultimately bend the joists; but even in this case, were pottery of any kind judiciously employed, it would offer a serious opposition to the flames, and would be infinitely less dangerous to those in or near the building than cast-iron girders or joists with heavy masses depending upon them.

It is with some misgiving that I speak concerning the cost, feeling that it is unlikely that a common calculation made from the French tarifs should be found a correct guide to the expense in England, as so much depends on the skill and enterprise of the parties undertaking the manufacture, the effect of competition, and the demand for the material. Perhaps for present purposes it may suffice to consider the probable prices in England to be the same as those of Paris, for it should be remembered that though we have iron in greater abundance, the wages of English exceed those of French workmen. The want of a material like the French plaster will next be felt. I am not aware that we have anything that effectually takes its place at a moderate expense. The price of French plaster in London is 32*s.* or 33*s.* per ton, about 30 per cent. dearer than in Paris; but I believe I am correct in saying that this plaster, when fresh, may be mixed with an equal quantity of sand, cinders, or ground brick, and answer the purpose in question. The cost of grouting in England must therefore be considered as double that of Paris.

| Bearings. | Depth of Joist. | Depth of Floor complete. | Weight per Square. | Iron Work, per Square. | | | Including Grouting. (12 Shillings) per Square. | | |
|---|---|---|---|---|---|---|---|---|---|
| ft. in. ft. in. | inches. | inches. | lb. | £. | s. | d. | £. | s. | d. |
| 10 0 to 11 6 | 4 | 7⅛ | 370 | 2 | 19 | 5 | 3 | 11 | 5 |
| 11 6 to 13 0 | 4¾ | 7⅞ | 420 | 3 | 6 | 5 | 3 | 18 | 5 |
| 13 0 to 16 6 | 5½ | 8⅜ | 465 | 3 | 14 | 4 | 4 | 6 | 4 |
| 16 6 to 20 0 | 6¼ | 9½ | 510 | 4 | 1 | 9 | 4 | 13 | 9 |
| 20 0 to 23 0 | 7⅛ | 10¼ | 605 | 4 | 17 | 6 | 5 | 9 | 6 |
| 23 0 to 26 0 | 8⅜ | 11¾ | 700 | 5 | 12 | 4 | 6 | 4 | 4 |

The accompanying table is translated from a tarif of prices circulated by M. Thuasne last year; it also gives the weights and depths of the floors for the various spans.

I regret that I am not in a position to furnish more ample information on this head, and that I am unable to produce accounts of some experiments which might convey an idea of the resisting powers of the floors when complete, though I know that these experiments have been made; but perhaps, the general adoption of one or other of the methods may be received as the best guarantee of their results being satisfactory.

In connection with the subject of the general use of iron in France, much might be said on the French manner of constructing wrought-iron girders, but as the most remarkable of these are to be found in the buildings of the new Louvre; and as we have just heard that all matters connected with that important building will be treated at a future meeting by our Honorary Secretary for Foreign Correspondence, I shall abstain from offering any remarks on the subject.

In conclusion, I would add that I have been induced to offer the foregoing remarks, because I conceive that an invention that is well received in a city so important as Paris, must be practically interesting to us, particularly if in our own country the advantage of that invention be partially wanting; it is true that our mode of building and inhabiting our houses differs generally from that of the French capital, where they are usually let in apartments or flats, but in many instances the same arrangements occur here, and in such cases, at least, we might avail ourselves of the experience of our talented neighbours. Many prejudices and conflicting interests must be overcome before any invention can be generally adopted; those of the Parisian building world seem to have yielded readily to the desire to improve, and the opportunities offered to the development of a new method by the extensive character of their alterations; and though the improvements in our own metropolis proceed with less vigour, we may endeavour to evince as little prejudice as our neighbours in our inquiry into the merits of that principle, which constructively has done its part to invest their newly-erected buildings with stability and refinement worthy of the age.

The Rèvue Generale de l'Architecture contains the following experiment, made upon a floor 16 feet span (Système Vaux) the joists being $5\frac{1}{4}$ inches deep, $\frac{3}{8}$-inch thick, and cambered 2 inches in the 16 feet. Upon the grouting being filled in the camber was reduced to $1\frac{3}{4}$ inch; upon the floor being loaded with 1000 lb. per yard super. it was reduced to $1\frac{1}{16}$ inch, and after forty-eight hours pressure again decreased to 1 inch, the deflection from the load being $\frac{3}{4}$-inch; the weight being removed, the floor resumed a camber of $1\frac{9}{16}$, having lost $\frac{3}{16}$ in the experiment. When filled in with pottery, these floors are lighter, but the filling in with solid plaster forms the whole into a stronger and more solid mass.

*Discussion.*—Mr. G. R. Burnell, C.E. refered to a paper read by himself in 1849, in which he had alluded to Vaux's system. Since that time several works had been published on the subject, —the most recent and the best being one by General Morin, who in the fourth volume of his "Cours de Construction" gave an elaborate set of experiments on the resistance of these floors, and the formula on which their thickness and general dimensions might be calculated. From these experiments it appeared that a floor of 26 feet span showed a deflection of seven centimètres, with a weight of 70 lb. on the square foot, in addition to the weight of the floor itself. It appeared to him (Mr. G. R. Burnell) that one of the great objections to the modern French system of filling in with plaster, was not so much the weight as the expansive action of the plaster. In practice the effect of this was to bring the floor down nearly half the amount of deflection, produced by the extreme load which the floor would bear. The use of pottery was therefore preferable, and it would be especially so in this country, where plaster of Paris was comparatively expensive. The conflagrations which had lately occurred in the city rendered it important to devise some incombustible flooring; and it was to be much regretted that in England insurance from fire was a tenant's tax, instead of being a landlord's tax, as in France, because there was no inducement to builders and landlords in this country to construct fireproof houses.

Mr. Donaldson, observed that the rent was regulated in each case with reference to this fact, and Mr. Godwin considered that the prevalence of short leases, instead of freeholds, might equally explain it.

Mr. Papworth, referred to a house in Hinde-street, Manchester-square, built by Dr. Gillies, the Scottish historian, the roof of which was made of cast-iron bars, little more than $4\frac{1}{2}$ inches deep, with a sufficient flange, and filled in with flower pots, precisely as in the French method, but cambered so as to form a vault. This had always stood exceedingly well until the walls began to settle; there was then a fracture which had caused considerable trouble; but that had been remedied, and the roof still stood very well indeed. With respect to the expansion of the plaster, mentioned by Mr. G. R. Burnell, he could not understand why it should press downwards, when there was no abutment above to prevent it expanding in an upward direction.

Mr. Fowler observed that it had an abutment above; being turned up against the joist, in a form equivalent to a curve; and, therefore, if expansion did take place, it must press downwards.

Mr. Piper stated that the plaster would expand in all directions. The floor at Messrs. Clowes's printing office was of the ordinary construction, with timber joists; but a plaster of Paris ceiling was attached to it, or a sort of flat centering was fixed and secured below the joists, and the plaster was filled in from above the laths; the laths being of oak, and stronger than usual, both in material and scantling, and placed at a wider interval. The plaster therefore passed through and formed the ceiling below, and a sort of pugging above: it consisted of two parts of sand to one of plaster. The floor was constructed of three courses of plain tiles, in order to make it a perfectly fire-proof and air-proof chamber, used as a drying-room; no bad effects had arisen from the expansion of the plaster. With reference to the use of cast-iron in floors, he had had great experience in those constructed on Fox and Barrett's principle; and it had always occurred to him that cast-iron was an unsound material to be subjected to a permanent set, and to be strained as a floor was liable to be; and therefore the introduction of rolled iron joists, which were produced so successfully at the Butterley Works, was a great advantage. Six floors had been constructed with cast-iron joists in the Albert-buildings, Spitalfields; and at the top of the building a defective joist broke, and fell down vertically, striking out one joist in every floor as it fell, without disturbing the rest—an illustration of the extreme brittleness of the material. Regarding the concrete as an addition to the weight, without being any addition to the strength, or having any natural cohesion or connection with the iron, he had not been prepared to expect a very firm floor as the result of the combination, in a span of 18 to 20 feet, in a coach manufactory in Regent-street; but on the contrary, he was surprised to find that, when the mass became set, it was rigid to an extraordinary extent, forming a kind of uniform landing, in which there was a good brotherhood between the concrete and the iron, the whole forming a trustworthy mass. With regard to the cost, his experience had shown him that in Messrs. Fox and Barrett's construction it was equal to that of an ordinary floor, with the addition of the price of the floor boards; but the present state of the iron market would somewhat interfere with that calculation. From the actual rigidity to which he had referred, he was disposed to think the French floors described would have a great amount of strength. Alluding generally to the facilities for the spread of fire in houses, by means of skirtings, staircases, quarter partitions and roofs, as at present constructed, he illustrated the power of an ordinary plaster ceiling to resist the action of fire, by referring to a severe fire on his own premises, which began in the shop, and spreading upwards by the staircase ignited the roof, and then burned downwards. The first-floor was however left entirely perfect, and the second nearly so; the only obstacle to the fire reaching them being the plaster ceiling of the ground-floor, where the fire commenced.

Mr. Barrett said that, from the remarks made that evening, he was more convinced than ever that the use of iron in the construction of floors was only a question of time. With regard to these French floors, their liability to deflection was a radical defect, as no finished floor ought to be liable to the slightest deflection or want of rigidity. The system described could moreover prevail only where plaster was abundant—as in Derbyshire, Leicestershire, Nottinghamshire. Objections were also raised to plaster on the ground of its imparting a disagreeable smell, and of its tendency to swell. He had adopted rolled iron in his own method in consequence of the prejudice against cast-iron joists, and he proceeded upon this safe principle: that, taking the concrete as so much dead weight, his joists were so proportioned that that dead weight, together with the extreme load which could subsequently come upon the floor, should not exceed the elastic limit of the iron. He used rolled iron joists for spaces not exceeding 24 feet. On reference to the table of weights used in Paris, he found that the French floors had not more than half the strength of his own; thus, with a bearing of from 16 ft. 6 in. to 20 feet, the French used a weight of iron of 510 lb. per square, whereas he should use 8 cwt., in addition to the difference in the weight of the grouting; and therefore, if the French floors were safe with 5 cwt. of iron, his floors must be more than safe with 8 cwt.; and the cost of the latter, in joists 18 inches to 2 feet apart, as compared with a timber floor, was about 7 to 10 per cent. additional. The thickness of concrete, on his plan, in a floor of 20 feet span, would be 7 inches from the flange of the joint, the whole substance being 12 inches thick, including 2 inches for the floor itself; and as a question of expense, it would be very easy to reduce the strength of the iron (and with perfect safety), so as to bring down the cost to that of an ordinary timber pugged floor.

Mr. C. H. Smith stated, for the consideration of the members, the fact that no material could be more destructive to iron, especially wrought-iron, than plaster of Paris. The girders might be coated with some material to protect them, but in moving them about it was liable to be chipped off; and if the smallest pinhole were exposed to the plaster of Paris, the iron would be corroded. On the contrary, lime tended to preserve iron; and therefore a coating of 2½ inches of ordinary mortar next to the girders, before using the plaster of Paris, might be desirable.

## APPARATUS FOR ASSAYING PRECIOUS METALS.

J. A. Staffel, *Inventor.*

This invention is intended to supersede neither the solution by fire, nor the various chemical tests which have been brought to a state of great perfection: it is simply designed for practical purposes, when neither acids nor fire can be made available. The apparatus is constructed on the principle of *specific gravity,* which has been extended to *specific volume.* The great difficulties to be contended with were, 1st, the elasticity of the air; 2ndly, its temperature; 3rdly, capillarity; 4thly, the closing of the apparatus hermetically; and, 5thly, the furnishing a scale for various weights; but after four years of unwearied study and labour Mr. Staffel overcame these difficulties. The apparatus consists of a glass tube, fixed in a brass case, the bottom of which forms a cylinder, which receives its movement by means of a screw. An annular dial, furnished with a *hair,* for an indicator, shows the degrees from 0 to 99, and controls the motion of this screw. The degrees, from 100 and upwards, are indicated on a plate, fixed at the side, which plate stands in connection with the dial.

The glass tube is closed hermetically at the top with a glass cover, to which is annexed a capsule, a perpendicular glass cylinder, and two brass bars, serving as a scale.

By the side of the apparatus is a bar, by means of which the dial is brought to zero, and at the same time the fluid in the cylinder is reduced by means of a handle to the normal point. The object to be tested is then weighed by means of weights adapted to the purpose; after which the object is placed in a grate suspended within the fluid, and the capsule carefully closed. The handle is then set in motion and turned, until the weight, previously ascertained, is indicated upon the dial, while the fluid in the perpendicular cylinder will rise to a degree corresponding with the figure on the dial. The figure thus obtained gives the alloy, the remainder the amount of pure metal. For example, if it be required to test an object weighing 24 grains, it will be necessary to stop the dial-hand at 24, and of the fluid in the cylinder, then 8, the result will be

$$24 - 8 = 16,$$

which will give the standard of the gold.

If the gold be alloyed with silver and copper, which will be indicated by the paleness of the colour, it will be necessary to refer to the brass bar for the purpose of showing the alloy. The differential weights of the alloy between gold and copper, and between gold, silver, and copper, are indicated by various scales.

If the object weigh 39 grains, and the cylinder show 11, then the result will be

$$\frac{39 - 11 \times 24}{39} = 17{\cdot}23 \text{ proof.}$$

The volume of fine silver or gold is marked ............... F;
The volume of copper, or any other alloy is marked ... C;
The volume of specific difference is marked ............... D;
The volume of weight is marked .................. 1, 2, 3, &c.

If a fusion of $28\ F + 11\ C$ is to be made, the figure must be $F = C - D$, of $F + D = C$, or $28\ F + 11\ C = 39\ F + 11\ D = \frac{11}{39}$ copper or alloy.

The practical utility of the instrument will chiefly be—

1st. The determining the quantity of gold or silver used in manufacturers' wares from either of these metals, and thereby enabling the employer to ascertain whether the finished article contains the exact amount of metal furnished to the workmen.

2ndly. In ascertaining, if required, the value of a chain, though the gold used in the several links be of a different standard.

3rdly. In previously ascertaining the standard of a fusion, when various sorts of silver, of unequal size and weight, are to be melted together.

4thly. In ascertaining the value of coins with the greatest accuracy and dispatch.

## THE PUMPING ENGINES AT THE BIRMINGHAM WATER WORKS.

By W. S. Garland, of Soho, Birmingham,

(*With an Engraving, Plate* VIII.)

[*Paper read at the Institution of Mechanical Engineers.*]

These water works were established in the year 1830; the Company then erected two engines, having cylinders of 61 inches diameter, and 8 feet stroke, each working two pumps of 18 inches diameter, and 6 ft. 8 in. stroke, respectively to the lower levels of the town, or working one pump only when raising water to the upper reservoir. These engines were of sufficient power until the year 1850, when the company erected an additional pair of pumping engines, manufactured by Messrs. James Watt and Co. of Soho. The cylinders of these engines are of 72 inches diameter, and 10 feet stroke, working a pump of 23 inches diameter, and 10 feet stroke, under a head of 252 feet, which with the heads in the main and friction, is equal to a total resistance of 285 feet, and to a load upon the plunger of 124 lb. per square inch or upon the steam piston of 13 lb. per square inch. The weight upon the plunger required to overcome the load upon the air-pump, the friction of the engine, and to maintain a velocity of 10 strokes per minute. is nearly 26½ tons, which is equal to 142 lb. per square inch upon the area of the 23 inch plunger, and 14½ lb. upon the piston. The power, therefore, of each engine when making 10 strokes per minute, is equal to 180 horses; and the total power which the company now have for supplying the borough is equal to 530 horses. The steam cylinders A, A, have steam cases, and are enclosed in a covering of felt having an outside casing of wood, B, B, to prevent the radiation of heat; the tops of the cylinder and upper nozzle are covered in a similar manner.

Fig. 1 Plate VIII., is an elevation of the engine and pumps; and fig. 2 a section on a larger scale of the main pump, suction and delivery pipes, and air-vessel. Fig. 3 is a vertical section of the cylinder, with its piston and rod, and side section of the nozzles. Fig. 4 is a front section of the nozzles; showing the steam-valve C, equilibrium-valve D, and exhaustion-valve E. These valves (on a larger scale in figs. 5 and 6) are 13, 15, and 18 inches diameter respectively, and of the double-beat construction; by which the principal part of the pressure that the common conical valve is subject to, is removed. The steam governor valve F, is made of the single conical form (there being no necessity for making this valve upon the double-beat principle), and is regulated by a screw and wheel handle.

The load upon these engines is a variable one, to the extent of the difference of the dead level of the upper reservoir and the amount of friction of the water *in transitu,* and it sometimes happens that the water is being drawn off faster than the engine supplies it, and the velocity of the water beyond where the great draught occurs is consequently decreased, and the resistance proportionably diminished.

To prevent any accident to the engine by going out too suddenly, in consequence of this diminished resistance, a throttle-valve G, is placed between the upper and lower nozzle, and in the pipe communicating with the top and bottom of the cylinder, which is regulated by a screw and wheel handle in a similar manner to the steam governor or throttle-valve; and by thus contracting the passage, or wire-drawing the equilibrium, the equalisation of pressure between the top and bottom of the

# PUMPING ENGINE, BIRMINGHAM WATER WORKS.

J.R. Jobbins

cylinder is more slowly formed, during the time the plunger is descending, to the extent the weight is in excess of the diminished resistance, acting like a break without absorbing any power or causing any disturbance to the working of the engines. The piston is represented in fig. 3 as descending, making its in-door stroke, the steam and exhaust-valves are open, and the equilibrium-valve closed. In fig. 4 the steam governor-valve F, and the equilibrium governor-valve G, are represented as wide open.

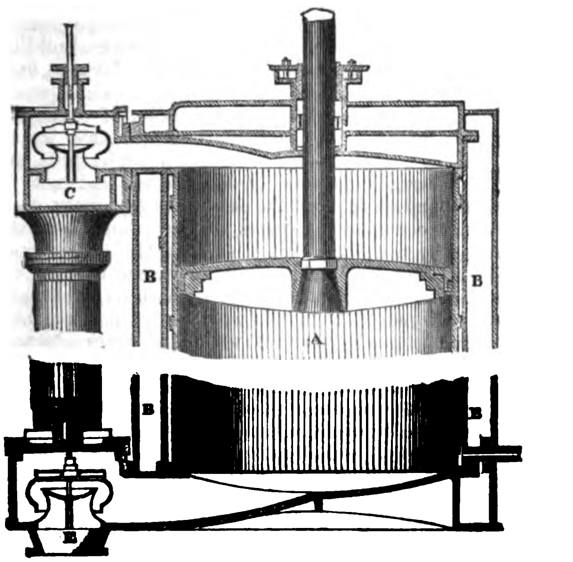

Fig. 3.

The opening of the steam, injection, and exhaustion-valves is regulated by a cataract, and the speed of the engine is thus under the control of the engine-man. The equilibrium-valve is opened by quadrant catches, and is dependent upon the closing of the exhaustion-valve, the former being opened upon the closing of the latter, and is shut in the usual manner by a tappet upon the plug-rod.

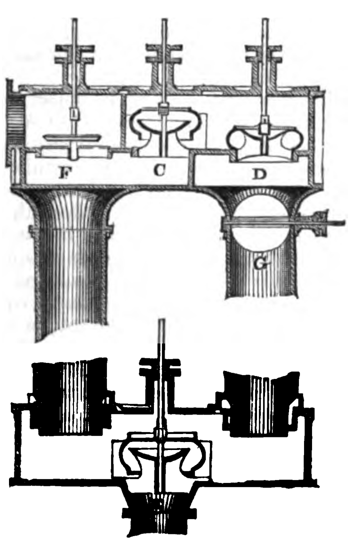

Fig. 4.

The injection-valve is also made upon the double-beat principle, to render the strain upon the exhaustion-valve spindle as little as possible, by relieving it of all unnecessary pressure, the underside of it being open to the condenser.

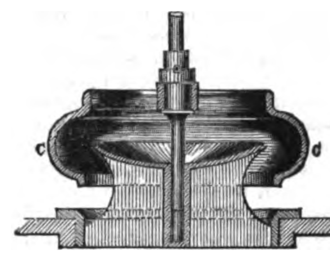
In the event of the bursting of any pipe in the main, and the resistance to the plunger being suddenly removed, a detent is fixed upon the plug-rod, to prevent the repetition of a blow upon the spring beams by the catch pins. This detent comes into action upon the engine when making more than its usual length of working stroke, by holding the steam-handle down, and thus preventing the opening of the steam-valve. This adjunct to the hand gear, though it may never be brought into operation from such an occurrence, would evidently be of great value in such a case.

In fig. 1, H, is the air-pump, and I, the condenser; both of 34 inches diameter and 5 feet stroke. The air-pump bucket is fitted with a brass annular or ring valve, and the delivery and foot valves are of the usual construction, or what are termed flap valves. A vacuum is obtained varying from 27 to 29 inches, according to the state of the atmosphere.

Each engine has its separate condenser cistern, formed of cast-iron, which is supplied by a cold-water pump of 13½ inches diameter and making 5 feet stroke.

The feed-pump W, is of 6½ inchos diameter and 2 ft. 6 in. stroke, fitted with an air-vessel. The plunger K, is 23 inches diameter and of the same length of stroke as the steam piston. The suction-valves L, L, and the delivery-valves M, M, (shown enlarged in fig. 6) are of the double-beat kind, and fitted in pairs to give additional security to the action of the pump in the event of one of them sticking or becoming otherwise deranged. They are of cast iron, and their beating faces are composed of a mixture of tin and lead, which is run into a dovetail recess turned in the cast-iron seat, and thereby becomes perfectly fixed. The water-way through these valves is of the same area as the plunger, and the lift of them is about 2 inches; the blow, when shutting, being scarcely perceptible.

Fig. 5.



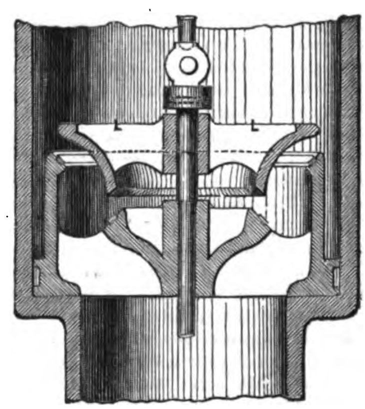


Fig. 6.

The air-vessel N, is 7 feet internal diameter and 18 feet high, or 15 feet high above the delivery branch into the main, and it is replenished with air by a separate pump O, of 6 inches diameter and 3 ft. 6 in. stroke. An air-cock P, is fixed upon the suction pipe of this pump, by which the necessary quantity of air to be supplied is regulated. This cock only requires to be partially open, and when closed entirely, the pump lifts water only.

The air-vessel is of great importance, as by its equalising action the motion of water in the mains is rendered continuous, and a less weight in consequence is required to give the necessary velocity to the descent of the plunger in the out-door stroke. At the top of the pump-plunger is fixed the pole case, containing the necessary weights to overcome the load or resistance, and, as before stated, is equal with the plunger and rod to about 26½ tons.

Upon the first delivery pipe joining the air-vessel is fixed a safety discharge-valve of 6 inches diameter, loaded by a lever and weight a little above the pressure upon the main, to prevent any undue force being thrown upon the pump from the accidental shutting of the sluice cocks between the engines and the town.

The main lever or working-beam R, R, fig. 1, is 30 feet long, cast in two plates, each of 3 inches in thickness, and the depth of it in the middle is 6 feet, and at the ends 2½ feet. Each of the plummer-blocks has saddles of cast-iron between them, and the wooden spring beams S, S, which latter are 30 inches deep and 20 inches wide, of the best Memel timber, and formed of 6 pieces in section, bolted and bound together with wrought-iron straps. These beams are carried by the lever wall T, and by the end walls of the house.

The catch pins U, U, are of wrought-iron. The parallel motions V, V, are of the usual kind, which require no further explanation than what is shown in the drawing of the general elevation of the engines.

The quantity of water lifted by every stroke of each engine is equal to 180 gallons, or 1800 gallons per minute, and 108,000 gallons per hour, weighing upwards of 483 tons lifted in each hour.

## JAMES TRUBSHAW, C.E.*

Mr. James Trubshaw was born at the Mount, Colwich, Feb. 13, 1777, and was therefore four years and a half senior to another eminent member of the same Society (of Civil Engineers) whom in after-life he was proud to call his friend, and to whom he looked up with sincere respect and affection, the late George Stephenson, Esq., by whom, in turn, as also by his distinguished son, he was met, on all occasions of intercourse, with the most kind attention and courtesy. And here, it may be observed, that (allowing for individual diversities) there were many points of resemblance between that very remarkable man and himself, both in character and in career. Both were strictly men of original genius, of great natural talent, and persevering energy; both were of simple, open, manly bearing; both had been subjected to the discipline of actual work in younger days; and both were the makers of their own eventual reputations and positions of life. It may be added, that both were equally esteemed and respected, wherever known, as men of unblemished integrity. But it is not intended to run parallels where neither comparison nor contrast is needed, and where the celebrity of each rests on its own solid foundation. The points of resemblance have been alluded to only because they were fellow-labourers of the same generation, for the benefit of their country, in a common department; and because in Mr. Trubshaw perhaps the last is gone of the old school of engineers, whose works will be handed down to posterity as records of intuitive genius combined with singular practical skill. For Mr. Trubshaw, like his great contemporary, had few advantages of education; but in its stead he seemed to be gifted with an instinctive perception of all great mechanical principles, uniformly guided by excellent common-sense.

In earlier life his abilities became gradually known, chiefly within his own county, where he acquired the favour and esteem of many of its aristocracy. His first special patroness and friend was the then Mrs. Sneyd, of Ashcomb, to whom he himself always attributed his start in the world; but throughout life he received unremitting encouragement and kindness (and even posthumously) from other members of that much-respected family. The late Sir Thomas Cotton Sheppard and his father may be mentioned as other constant friends; and, at a latter day, Sir Geo. Philips; by all of whom his tried worth was consistently appreciated: but his name was well known and esteemed through the county generally. At a later day, Mr. Trubshaw became Engineer of the Trent and Mersey Canal Company, in which capacity his services and works were of the most valuable kind, whether in the way of construction, repair, or supervision. The various reservoirs, feeders, railways and other works which he directed for that company, bear equal witness, in one form or other, to his judicious management or able contrivance.

As an architect, Mr. Trubshaw was naturally without classic pretensions; but his designs were always cleverly arranged for purposes of convenience and comfort. It was, however, as a builder that his talents were most conspicuous. Among his domestic works in that department, Ilam Hall, near Ashbourne, and Weston House, in Warwickshire (which he built for their respective owners, after designs of Shaw and Blore), may be quoted as specimens of first-rate execution. In another line, by a bold and original conception of great simplicity withal, he accomplished a very remarkable work. The lofty tower of Wyburnbury Church, in Cheshire, had declined more than five feet from the perpendicular. At a small cost, and by no other process than that of carefully removing the earth on the higher side, by means of gouges adapted to the purpose, until the fabric above might gradually sink and settle by its own weight, Mr. Trubshaw restored the tower to its upright position without damage to a single stone of the whole building.†

In the outset of his career, however, his great fancy had been for bridges, and as his earliest works of any magnitude were in that branch of art and science, so were his latest and greatest. Perhaps the "Grosvenor Bridge" over the Dee, at Chester (so named by her present Majesty, then the Princess Victoria, at its formal opening in 1832), is, and will remain, his master-piece of ability. An elegant design for the structure had been produced by the late Mr. Harrison of that city, and its cleverness and beauty were readily acknowledged. To design, however, is sometimes easier than to execute; and where was to be found a man bold enough to undertake a work which—if ever completed—was to stand unrivalled in the annals of bridge-building? A single arch was to be thrown across the river, of a span exceeding 200 feet. Telford and other celebrated engineers had pronounced the feat almost impracticable; and the terms of contract alone, amounting to 36,000*l.*, was sufficiently formidable, for a work attended with so many possible yet undefinable hazards, at a day when the gigantic contracts of later time had not become familiar. Nevertheless, Mr Trubshaw courageously undertook the work. It occupied six years in the completion; the first stone having been laid in Oct. 1827, and the bridge opened to the public in Dec. 1833. This was of course a term of great anxiety and of severe trial. The perils, both by land and water, were many and great. Demands were sometimes urgent, while supplies were necessarily dealt out with rigid caution by managers who could not afford to listen to pleas of indulgence; turns of adversity now and then ensued, and (as will ever be the case) there were not wanting some who looked upon the undertaking with adverse eyes, or worse, whom predictions of disappointment, or even less worthy considerations, forbade to sorrow for any prospect of failure. Thus he, on whom the responsibility rested, was more than once reduced to very disquieting straits. But he was no vain theorist or random pretender, nether had he calculated his resources loosely; and, after many a fluctuation of cloud and sunshine, bold enterprise and honest perseverance had their reward. The design was achieved in full; and one of the many wonders of this kingdom now remains for a lasting memorial (as is hoped) of the builder's comprehensive genius and sterling courage. The simplicity of construction in the centres of this great arch (an invention of which he was justly proud), and the mode of slackening them to bring the arch-stones to their respective bearings, drew forth great admiration from the members of the society to which Mr. Trubshaw belonged, and by whom he was treated at all times with marked respect. A model of the bridge and centres (with some others of interest) was presented by him to the society, and a problem of no small importance has been solved in bridge architecture by the triumphant issue of this venturous and able work.

Though it be to pass from a greater subject to a less, there are some details connected with a later work of Mr. Trubshaw (also of very considerable magnitude), so graphically characteristic of the man, that this work would be incomplete winhout a reference to them. This was, ~~the erection of the~~ new bridge, called the "Exeter Bridge," over the Derwent, at Derby. More than one disastrous flood occurred in course of its progress, involving damage obviously fatal to all but the credit of the high-spirited contractor, then on the steady side of threescore years and ten. And now comes the characteristic evidence just referred to, as shown on occasion of a public dinner given at Derby, in celebration of the opening of this bridge in October 1850. The health of the builder having been proposed in complimentary and very feeling terms, with an allusion to his ill-fortune in the foregoing respect, coupled with good wishes for "all the enjoyment which intelligence and integrity could give to an old man in the last days of his life," Mr. Trubshaw replied in terms worthy of being recorded, as a specimen of what may be sincerely called "unadorned eloquence." "I am much pleased," he said, "that my conduct has met with your approbation. I have been in the habit of thinking all my life, but not of talking much; and if the bridge which has been opened to-day will carry us all well over, I shall be much gratified. With respect to the cost, it has never given me much trouble. When I was assailed by sudden floods, and by quicksands in the middle of the river, I soon found out where my profits would be. However, I have paid—or shall pay

* From the 'Gentleman's Magazine.'

† The compiler of this memoir conceives the work to have been accomplished as follows:—Supposing the inclination of the tower to have been from south to north (it matters not whether, in fact, it was so, or *vice versa*), a working trench was dug on the upper (or south) side across the breadth of the tower, and from this trench the ground beneath, as far as to the northern foundations, was scooped out, and made a sort of colander, leaving solidity enough, as the work advanced, to resist sudden or violent pressure, yet inviting its gradual subsidence through the weakness caused by the perforations. Whether this, however, be a correct description or not, the fact is indisputably sure.

in the course of a few days—all the expenses incurred; and I shall then burn the accounts and think no more about them. I thank the Mayor, in particular, and the gentlemen present, for the civility and kindness I have received during the progress of the work, and I hope the bridge will do credit to my memory when I am no more." The line in the play forcibly occurs here—

"Was ever tale
With a more gallant modesty rehearsed?"

Mr. Trubshaw's age and comparatively failing health after this period forbade his attempting a further work, to which allusion had been made, and which was at the time under serious consideration—namely, of erecting a monument to Mr. Geo. Stephenson, to consist of "a single stone which should be several feet longer than Cleopatra's Needle." The project was gravely entertained, and he himself was sanguine as to its feasibility; nor did his peculiar skill in the construction and application of machinery for all building purposes, leave much room for doubt that his combined genius and energy would have brought the scheme to a successful issue, had it been actually taken in hand, and life been spared to him. His ingenuity in surmounting difficulties of such kind as would have been involved, had been very conspicuously shown in the erection of a column at Ramsgate, commemorative of the landing of George IV. in 1821, of which he had undertaken the direction, at the request of Mr. Shaw, to whom his abilities had become at that time experimentally known.

In social life, Mr. Trubshaw was cheerful and friendly; abhorrent from every sort of affectation or pretence; and ready at all times to communicate his valuable ideas and stores of practical information. Order was a great feature of his mind, in all ways; and he was carefully deferential to those of higher degree with whom he conversed, without any tincture of servility. It may be added with truth, that as an employer, no master could ever have taken more thought and pains to render to all their dues—as well to those who served him, as to those whom he served. His guiding principle—on either side, and all his life through—was a single-hearted uprightness. As respected the just claims of workmen, his own early experience had made him a highly competent judge; and so great was his anxiety to do them justice always, that at an early period of his business—which he commenced at Stone, with very slender resources—neither he nor his very estimable wife would ever allow themselves any indulgence until the workmen's wages and all trade debts had been made secure. Many, at that time, were the long and weary walks he undertook in collecting his own dues for such purposes; and greatly distressing was it to both whenever those exertions happened to prove unsuccessful at the moment. And other like traits of honesty might be adduced in abundance, did such mere personal anecdotes belong to such general outline of character as the present.

In person, Mr. Trubshaw was of a commanding figure, tall and athletic, as may be judged in part from the somewhat singular fact of his having been one of seven brothers, whose aggregate height was not less than forty feet. He was married on the 21st Jan. 1801, to Mary, youngest daughter of Thomas and Mary Bott, who survives him, and with whom he truly found and shared, during a term of more than half a century, "that mutual society, help, and comfort, which the one ought to have of the other in married life, both in prosperity and adversity." A more thoroughly united pair cannot have been often met with. Forty-four years of their happy union were spent at Little Haywood, where he settled in 1809, and where they had the satisfaction of receiving from friends, in 1851, some little memorials of their wedded jubilee. Three sons and three daughters, of whom five remain, were the issue of the marriage; his eldest son, Thomas, an architect of considerable promise, died prematurely in 1842. His eldest daughter is the wife of Thomas Johnson, Esq., architect, of Lichfield.

It is pleasant to add, that Mr. Trubshaw eventually realised a handsome independence, although moderate in proportion to the extent of his labours and unfailing industry. He died calmly, on the 28th Oct. 1853, at Little Haywood, Colwich, Staffordshire, aged seventy-six, after a short actual illness, and was buried in the churchyard of Colwich, on the 4th Nov., having died as he had lived, a faithful and humble member of the Church of England. His death occasioned deep sorrow, and received, in his own immediate neighbourhood, that highest testimony of sincere regret —namely, of being felt as a private and personal loss in many houses beyond the circle of his own family.

## FORM OF CONSTRUCTION OF LIGHT-VESSELS AND BUOYS.*

In these go-a-head days, when steam and even sailing vessels are rivalling the speed of railways, observations on the construction of light-vessels may appear to carry us back to the dark ages, or to any other period of "no progress." Certainly, the task of devising the best means for preserving a fixed station in the midst of this turmoil of locomotion is not a very attractive one and by no means in accordance with the restless spirit of the age. But it is a subject, nevertheless, of great importance;—the safe arrival and departure from this country of our almost innumerable marine being dependant on an efficient stationary *light* flotilla.

The great public advantages arising from an improvement in the form and moorings of light-vessels and buoys has escaped the attention of our naval architects, who have been occupied by the more attractive consideration of that construction by which ships may pass through the water with the greatest possible velocity; and as the ship has thus became the sole mistress of the waves, she has been and is still in use for the purpose of stationary floating beacons.

A moment's reflection will, however, raise doubts whether the two opposite requirements, of speed through the water and of a stationary position upon it, can be best attained by the same form of floating body; and further consideration will show it is wholly incompatible with the nature of these requirements that such can be the case. It may, at first, appear that the form which is best adapted to pass through the water with the least resistance is also the form best adapted to permit the water to pass by it, but this condition is only a portion of the case and the remainder wholly deprives the argument of its force. It must not be forgotten that the stationary floating body is fastened to the ground beneath it in the midst of the moving waters. A consideration of this part of the subject will show that the above condition is only apparent, other circumstances not being the same.

The present form of a light-vessel being that of a ship, we will first notice in what respects this mode of construction may be considered disadvantageous. It is taken for granted that the present form of ship is the best possible for the purpose for which it is used and presents the least objectionable features; but notwithstanding this is the case and though she is moored with 1½ inch chain cable, estimated to be strong enough for a sailing vessel of 700 tons (a light-vessel being not more than 170 tons), yet the power of the sea over the vessel is such as to occasionally snap these heavy chains. Now when we consider that the sea when not opposed is harmless,—as witness, the bottles which have floated unharmed upon its surface over half the world,—it is clear that the immense power brought into operation to snap these strong cables must proceed *from the vessel herself*, and the power of the waves to break a vessel's moorings may be considered to arise principally from the leverage upon the chain, which her form necessarily brings into action. This action in ordinary weather may be harmless, but when the sea becomes rough it is then felt, and with a power which, under certain circumstances, is irresistible. Suppose, a heavy strain upon the cable from the weight of many tons at the end of a lever, as above mentioned, and the bow of the vessel struck by a sea at the same moment,—the chain breaks; for nothing can withstand the combination of these forces.

With respect to buoys the leverage is very evident, and it is this alone which causes them to break their cables. A buoy, having a displacement of about one ton, is moored by a ⅞-inch chain, calculated to hold a sailing vessel of 130 tons burthen; yet this small body will break such a cable. Buoys are generally moored from their lowest part. The lowest part is, in different sized buoys, at different depths below the surface of the water; but at whatever depth it may be below the surface (the axis upon which the buoy moves being upon the line of flotation), that depth is the length of the lever acting upon the chain, which, in its turn, reacts upon the buoy by the same length of lever. It is this lever which gives the sea power over the buoy to force it out of the perpendicular, the angle of inclination varying with the strength of the tide, and presenting an inclined surface to the sea, *to run up it* and act upon the upper part of the buoy;—thus bringing into play another lever. In very

* From the 'Nautical Magazine.'

violent weather these joint powers will cause a small body of one ton to break a ⅞-inch chain cable.

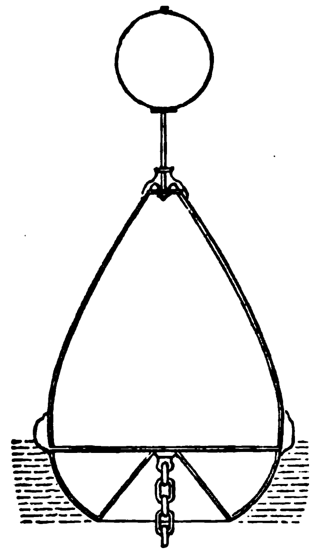
It results from these considerations that leverage action may be regarded as the chief cause of insecurity in our buoys and light-vessels, and that before improvement can be effected in the construction of these bodies this radical evil must be remedied. Nature generally points out the road by which the accomplishment of any object may be best attained, and naval architects have availed themselves of the beautiful lines which fishes afford them to construct their swiftest sailing ships. In like manner, let us notice the method by which nature moors her own stationary floating bodies. We shall find on referring to the floating leaves of aquatic plants; especially to the magnificent leaves of the Victoria Regia and to those of the Lotus and others, that the mooring is in the centre of a circular body, and that in these leaves the centre of the floating body and the centre of gravity are coincident upon the line of flotation. Now here appears the principle to guide us in the construction of light-vessels, buoys, and other *stationary* floating bodies. In a circular floating body of weight the bottom of it will be below the surface of the water; if, therefore, the bottom of the body be hollowed out and raised up, and the mooring attached to the upper part of the hollow cone thus formed, we shall be able to accomplish the results which nature points out as necessary to be attained, viz., the mooring from the line of flotation, from the centre of the floating body, and from the centre of gravity; which, with a due attention to the distribution of material, may be made nearly coincident, and a light-vessel or buoy thus constructed will ride upon the waves in the most violent storms without any leverage action whatever being brought into play.

The action of the waves upon a circular floating body moored from its centre of gravity will be very different, almost wholly so, to that which takes place upon light-vessels and buoys of the present construction, although it requires some little trouble to divest the mind of the habit it may have acquired of contemplating the action of the waves upon floating bodies having a head, stern, and keel.

A light-vessel of the proposed construction must be from 30 to 40 feet in diameter. A circular vessel of this size will appear at first sight to present a larger surface to the action of the wind and waves than a vessel having only 20 feet beam and 80 feet length, but this is apparent only, not real. It rarely happens that the wind blows from stem to stern of a ship; it usually blows upon the bow and slantwise upon the whole length of the vessel, the stern being borne up by the tide or the cross sea. The sea bears the ship up against the wind while the wind is forcing her back again upon the sea, and thus an antagonism takes place between these two forces, each exerting more power as it is more opposed by the other, the ship being to them the handle to wrench and tear her from her chain. In a circular light-vessel, moored as proposed, this cannot occur; the wind may blow upon it and the sea may heave it up, but there can be no combination of opposing powers. If the wind be very strong a certain known power will act upon the chain, and no more from that source; if the sea run very high the vessel will rise with it, and the only strain arising from the action of the sea (apart from the tide) which the cable will be subject to will be that which will result from the "scend" of the wave, which will be found inconsiderable. It is not supposed that the cable will be subject to no strain, but it is assumed that it will be liable to no sudden jerks and also to no strain that has not been previously considered and compensated.

Among the many advantages which will result from this mode of construction will be that arising from the absence of all pitching and rolling,—by which is meant any movement a vessel may make in excess of the angle of inclination of the surface upon which it floats. It may, possibly, be thought that because the mooring is attached to the centre of the vessel that it will oscillate upon its mooring point as upon a fulcrum, but this cannot take place; the weight of the chain bearing down from the centre of gravity, together with the body of water in the hollow bottom, will impart very great stability to the whole of the structure, and to whatever angle the vessel may incline it will be dependent upon the angle made by the body in which it floats and will not relate to the point by which it is moored. From these considerations it will necessarily result that a vessel of the proposed construction can never be struck by a sea. This is evident: the body will be simply borne upon the waves, it will offer no resistance to them, and there will be consequently nothing for them to strike,—in fact, the vessel will ride over the waves instead of the waves over it.

These advantages, claimed for a vessel of 30 feet diameter, have been found to result practically in the use of buoys of 6 feet diameter. The Trinity House has adopted buoys constructed upon this principle, and which are found to be superior to any yet tried. The accompanying figure is a vertical section of one of these buoys constructed of iron for them by Messrs. Brown, Lennox, and Co. On inspection it will be evident that the tide can have no power over the buoy to force it from the perpendicular by any haulage of the mooring upon it, or otherwise; indeed, the strongest tide has no effect in causing it to deviate from its perpendicular position, for whatever tendency there may be to produce a lean over by the tide pressing upon any side of it, it is directly counterbalanced by the pressure of the same tide upon the further or opposite side of the hollow cone.



There can, we think, be no question as to the correctness of the principle of mooring any stationary floating body from its centre of gravity, and there can be but little doubt that the more distant the mooring is from the centre of gravity, the less steady and the less secure is the floating body. A glance at the construction of bodies ordinarily used for stationary floating purposes will immediately convey an idea of their unsteadiness and insecurity; the centre of gravity is in one part and the mooring is attached to another far distant.

## ROTARY ENGINES AND BOILERS.

WILLIAM ANDREWS, *Patentee*, April 24, 1851.

THESE improvements have reference to—Firstly, a method of constructing rotary engines of two revolving parts, so arranged, that the steam having acted to propel one part, passes into and acts upon the other rotary part of the engine. Secondly, the construction of steam-boilers in such manner that the flame and heated gases arising from combustion shall pass up through a series of tubes placed vertically over the furnace, and communicating with a generator or combustion chamber, into which atmospheric air is admitted for the purpose of igniting the gases, &c., and thereby economising fuel and consuming the smoke of the furnace. The combustion chamber communicates with the smoke-box by a series of horizontal tubes. In the bottom of the smoke-box is placed a damper, regulated by means of a lever and rod. Thirdly, to the construction of pumps with two buckets, the piston-rod of one bucket passing through the hollow piston-rod of the other bucket. The foot and delivery valves are dispensed with. Fourthly, an improved safety-valve, consisting of a ring of metal, fixed concentrically in an annular opening by bridges or ribs. The ring and inner edge of the opening form the valve seat; the valve is formed of a solid circular piece of metal, and a solid ring, also connected by bridges or ribs. The solid piece fits into the ring of the valve-seat, and the solid ring of the valve fills the interval between the ring of the seat and the inner edge of the circular opening. By this arrangement, two or more concentric rings of escape are provided, instead of only one, as usual, thereby affording greater area of escape for the steam, and consequently greater safety on any occasion of sudden generation of steam. Fifthly, a method of welding on to the ends of railway axletrees a coating of iron, the grain of which runs around the axle, thereby rendering them less liable to heat than when the grain of the iron runs in a direction lengthwise of the axle.

## LIGHT FOR THE GOODWIN SANDS.

SIR—I observe in the *Edinburgh Evening Post* of to-day, that Mr. Sinclair, C.E., has proposed to erect a lighthouse on the Goodwin Sands, on a cone of rubble stones, constructed on the principle of the Plymouth Breakwater. The great importance of this matter to the maritime interests of the country induces me to ask the favour of your inserting this note, to afford me an opportunity of saying, that after very mature consideration, I came to the conclusion, so far back as 1848, that the plan which Mr. Sinclair has lately brought forward was the only practicable one by which the object desired could be obtained. In accordance with this view, there were made by my assistants in 1848, a detailed plan together with an estimate (amounting to 121,536*l.* 16*s.*) of the proposed works; and I had several communications with Captain Washington on the subject in January of that year.

The paragraph in the *Evening Post* states, that Mr. Sinclair proposes a rubble cone of 600 feet diameter, with a foundation platform at the level of 10 feet above high water, and 60 feet diameter. In my plans, dated 10th January 1848, I proposed a circular cone of rubble 610 feet diameter, and a platform also 10 feet above high water, of the diameter of 50 feet. The paragraph does not state what slopes are proposed by Mr. Sinclair: my plans show the slopes of 6 to 1. I proposed, before constructing the permanent stone lighthouse, to construct the first light on an open framework of timber, so as to allow time for the due settlement of the materials. The extreme height of the lighthouse was 67 feet above high water.

Being confident of the success of such a work as I proposed, and also that it is the only practicable method of overcoming the difficulty of the situation, I should be gratified to find that it is carried into execution. I send you herewith a description of the peculiar advantages of such a plan for a lighthouse on the Goodwin Sands, drawn up by me, some years ago, for an unpublished treatise on harbours.

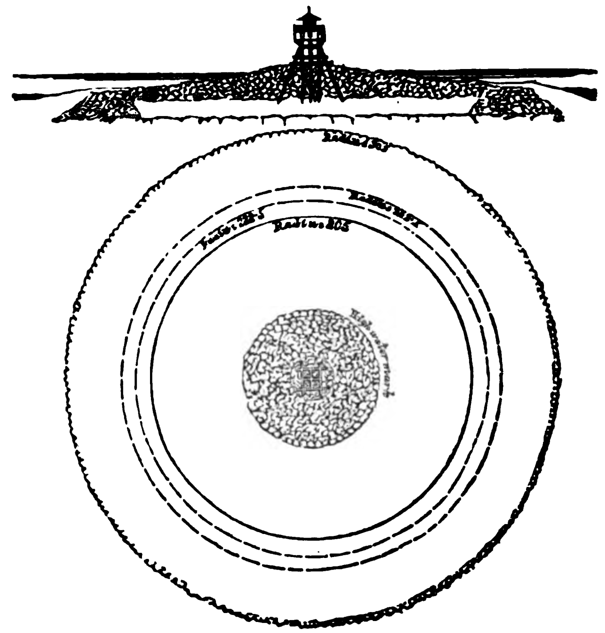
I regret I have not, as yet, had an opportunity of seeing Mr. Sinclair's pamphlet.

84, *George-street, Edinburgh,* THOMAS STEVENSON.
*Jan. 7th,* 1854.

---

*Remarks relating to Proposed Light on the Goodwin Sands; from* Chap. III. *of an unpublished Treatise on Harbours, by* THOMAS STEVENSON, F.R.S.E.

This chapter may perhaps be best concluded by an example of the application of the principles it contains to a case of known difficulty. The case we shall select is, the long-talked-of light on the Goodwin Sands. We do not know any other similar case where so much ingenuity has been shown, and even carried into practice, as the light for the Goodwin Sands. Of the propriety or impropriety of having a light in such a situation we know absolutely nothing, and we have merely selected it as a type of a certain class of works in which ingenuity has been greatly more conspicuous than practical judgment. Our readers are no doubt familiar with the disinterested exertions of Mr. Bush in attempting to erect the "Light of All Nations" on this celebrated quicksand, as well as most of the chimerical designs which have from time to time appeared in the public journals,—not one of which seem in any way suited to the position. The question, then, may well be asked, whether there be any possible way of surmounting the difficulties of the situation. Before attempting to settle the point, we must first discover what is the objection which may fairly be urged against all the plans which have been proposed. These are, the adoption of the principle of mechanical fixture in preference to weight, and the too great disregard of the reaction from the structure against the sand-bank. There does not appear to be any special difficulty connected with the situation. Suppose there were no sand at all, the case would be in no material degree different from the light which is on the end of the Plymouth Breakwater, or any other light which is erected at any of our harbours of refuge. If we conceive the end of the Plymouth Breakwater placed on the Goodwin Sands, and suppose the quantity of rubble to be somewhat increased, the problem would be solved. Without abandoning the well-known and fully-tried principles of marine engineering, the object,—if it be one, for we express no opinion on that point,—could be accomplished by merely repeating that exceedingly simple operation which mainly consists in the throwing of stones into the sea, and allowing them to form their own slope, so as to form ultimately, after some years of labour, and the expenditure of 150,000*l.* or 180,000*l.* an island of *pierres perdues.* In this there is neither novelty nor should there be any doubt as to success, providing the principle be fully carried out. A similar plan was proposed in 1835 in America, but whether adopted or not we have no means of knowing. In the Appendix there will be some reports on the American proposal by Mr. Hartman Bache, and the engravings represent a plan of what was proposed. Such a plan, *if fully carried out,* possesses the following advantages over all the other plans for the Goodwin Sands' light:—first, absolute certainty of a successful result; secondly, the employment of a principle of construction which has already been successfully employed in many situations of as great difficulty and of greater exposure; thirdly, the impossibility of sudden total destruction.



PLAN OF PROPOSED LIGHT FOR THE GOODWIN SANDS.

The requisites for such a situation, which this plan only fulfils, are:—

1. Flexibility of the mass of material employed, by which it can adapt itself to the changes of form consequent upon unequal settlement.
2. That the structure shall rise out of the sand at a low angle, so as to reduce the effects of a reaction against the quicksand.
3. That that part of the structure where reaction must take place shall be far distant from the place where the light apparatus and residence for the keepers are situated.
4. That long before the work is completed, so that a light could be shown or residenters established, a beacon could be erected.
5. That no cofferdams, or caissons, or diving-bells are required in the construction.
6. That the greatest quantity of the material employed shall be of the cheapest construction.
7. That the structure shall not depend upon mechanical fixtures.
8. That if any partial damage ensues while the works proceed, the very ruins shall act as a defence against further encroachment.
9. That the sea cannot impinge with destructive violence at any place near the site of the light apparatus.
10. That it is not absolutely necessary that the structure shall reach the chalk *strata* under the sand.
11. That the great extent of the work can be done by untaught workmen, so that convict labour may be employed. And
12. That no iron or timber, which are so liable to decay in the sea, are required.

## ON THE WARMING OF CHURCHES.*

By J. H. Bigge.

It is very clear, from the more luxurious habits of the present age, as compared with the past, some artificial warmth is required, to render tolerable any lengthened attendance in those sacred edifices where our forefathers worshipped, without any contrivances for such a purpose. Since, therefore, it has become a matter, not only of importance to the comfort of those who are strong and healthy, but absolutely essential to the safety of the sick and the infirm, who are frequently precluded altogether, by the prevalence of damp or cold, from attending the services of our Church, it cannot be a useless inquiry to ascertain the best means for effecting this object in the least objectionable manner. It may be observed, however, that every attempt at warming a church will be found to be completely ineffectual, unless proper care be taken, in the first place, to remove those dilapidations which have been caused by time, or those deficiencies which have crept in through neglect.

Perhaps there is a decayed door; the windows may be badly glazed, and here and there a broken quarry; or the pavement may be damp or defective; these are the certain and self-evident sources of cold, which is thus fruitlessly and injuriously counteracted. The best method of preventing the annoyance arising from the cold air is to hang a curtain over the door, which is in every way more suitable than the red baize doors which we sometimes see, reminding us more of the entrance to a theatre than to a sacred edifice. A kind of thick felted cloth is manufactured for the purpose by Mr. French, of Bolton, in Lancashire (of which some specimens were shown).

Let us glance for a moment at some of the different contrivances which have already been resorted to for obtaining artificial heat. Cast-iron stoves of every kind, and size, and denomination, have been successively adopted, and as often thrown aside; it would be quite a task to discuss the respective merits of each, as it would be sometimes a difficult one to analyse the names they bear. There are the Phœnix, Vesta, Pyropneumatic, and Patent Chunk Stoves; there are stoves with descending flues; Joyce's stove without any flue; and the patent calorifiére gas stove, which requires no pipe, and will burn for twelve hours without any attention whatever.

No one can enter a church in which some one of these iron stoves has been placed without being forcibly struck with their unsightly and unecclesiastical character, and the great disfigurements which they generally occasion to all parts of the building. Pipes of every variety of shape, and size, and hue, are extended in every direction, either suspended by chains from above or supported by legs from below; they pursue horizontal, zigzag, and perpendicular courses above the pews or under the galleries; they are thrust equally through the bare walls or richly-traceried windows, violating all principles of correct taste, and in defiance of all ecclesiastical propriety. But, besides these evils, there are two great defects which will be found to exist in most of the iron stoves in common use. The first is especially to be noticed in churches and buildings with stone floors. However large the fires may be, and the heat they emit, there will always be, in winter, a current of cold air from the doors and windows, sweeping along the floor towards the fire, so that the few who are in a situation to feel the influence of the heat are, at the same time, inconvenienced by the cold. The greatest amount of heat will rise to the space above, whilst the air least warmed will remain on the lowest portion of the building, and always keep that part cold. Hence, though a person may feel warmth to his face, his feet will suffer from the cold of the pavement, and that part of his body will be chilled where warmth is most needed. The other defect is, the great waste of fuel in proportion to the heat obtained. It has been calculated that at least eleven parts of every twelve of the heat generated, passes in waste up the chimney.

Another objection to iron stoves is, that the heat, being transmitted through a metallic substance which expands under the influence of fire, carries with it any impurities existing in the coal which are evolved in combustion; producing that stifling and oppressive sensation which every one must have experienced who has come within their reach. I am bound to notice favourably, although it is an iron stove, one that has been placed in the churches of Brampton Ash and Wenford, since I am informed that it has answered its purpose, and because it is different in its construction from those I have mentioned. A well is sunk in the floor, 10 feet long, 2 ft. 6 in. wide, and 2 feet deep. In this is placed a cast-iron stove, about 1 ft. 6 in. square, with a pipe 6 feet long, having a closed ash-pit, into which drains are conducted from different sides of the building to supply the stove with cold air. The well is covered over with an iron grating, through which the hot air ascends into the church. The smoke passes away by means of a flue under the pavement, and is carried up the tower, and thus there is nothing visible in the building. The system of warming by hot water, conveyed in pipes along the walls, and on a level with the floor, is free from most of the objections just stated, and is effective in its operation; but the expense of laying it down, and afterwards maintaining it, is too great to admit of its being employed in ordinary cases.

Some years ago, the Cambridge Camden Architectural Society, in order to avoid the unsightliness of an iron stove and pipes, recommended an open brazier, filled with *coke*, to be placed on the floor of the nave or chancel, and raised on a stone plinth about six inches high, so that the whole might be about 18 inches altogether. This was to be lighted for an hour or two before service, and afterwards removed, when sufficient heat had been obtained to warm the church. This plan, however, has been very rarely adopted, since the dust and smoke which were unavoidably created would be with difficulty removed without the introduction of cold air.

I am informed that in Salisbury Cathedral, during cold weather, two or three large braziers full of live *charcoal* are placed on the floor in different parts of the building. Its great size, no doubt, prevents any prejudicial effects from the carbonic acid gas emitted, though it frequently produces a sensation of drowsiness, and, in a smaller area, it is clear that this method would be attended with dangerous consequences.

At Durham Cathedral, upwards of a dozen patent Phœnix stoves, which consist of an iron cylinder, about five feet high and a foot in diameter, are placed about the edifice; the pipes thrust out at the windows nearest to them; and the result, though unsightly enough, is tolerably successful.

In the Church of St. Stephen, Westminster—better known as that which has been built at the sole cost of Miss Burdett Coutts—a most complete system both of warming and ventilation is adopted, by means of which hot air, from a large furnace outside the building, is forced into flues constructed in the floor and walls. Cold air is admitted in a similar manner, and both can be regulated according to circumstances.

By the kindness of J. W. Hugall, Esq., architect, of Cheltenham, I am favoured with a descriptiou of a gas stove, which has lately been constructed with good results. It consists of an earthenware chamber, within which the gas-burners are placed. Around this there is another chamber, of the same material; between these two the fresh air is admitted, and is heated by coming in contact with the heated surface. A foul-air tube carries away any unwholesome vapour into a chimney.

The question of open seats in our churches having been at length decided by the general voice of public opinion pronounced in their favour, it becomes a matter of some importance to ascertain what is the best method of making them as conducive as possible to the comfort of the occupants, so that the objection to their being *open* may not operate in a manner prejudicial to their adoption. The object to be attained, therefore, in warming a church is to provide that a body of heat should arise from the pavement, which shall traverse as large a portion of the unoccupied area of the building as possible.

This principle of heating from below, under various modifications, was well known to the Romans, and seems to have been admirably adapted for the purpose. Rooms and baths heated on this system appear to have been provided in every Roman villa; and they have been discovered in England wherever the remains of Roman habitations are to be found. A short notice of them, therefore may not be uninteresting, as a record of their skill and contrivance in providing for the internal warmth of their houses.

The Roman hypocaust (from a Greek word signifying literally *fire or heat underneath*) was constructed in the following manner, as will be observed from the ground plan and section of one which has been discovered at Lincoln:—It consisted of a paral-

* Paper read before the Architectural Society of the Archdeaconry of Northampton.—This Society have appointed a sub-committee to draw up a report on church warming, describing some of the methods hitherto adopted, stating the expense of construction and of fuel, the area heated, the degree of heat gained in each case, with any further remarks they may think advisable.

lelogram 25 feet long by 10 feet wide, containing four rows of brick pillars, some square and others round, 2 feet high, standing 1 foot apart, upon a foundation of tiles. The ceiling was formed of large tiles 2 feet square; upon these was laid a stratum of cement or lime and pounded bricks, in which was set the ornamented Mosaic pavement, composed of small tesseræ or cubes of different colours, the whole being 10 inches thick. The fire-hearth was at one end, constructed under an arch in the outer wall, below the level of the ground, and the flame passed through the arched cavity or throat of the furnace directly into the hypocaust. The furnace was probably approached from without, in the same manner as the stoves of hot-houses at the present day. In addition to these supporting pillars, there were frequently rows of flue tiles, with a hole on one side, placed near, and built into the walls above, so as to admit and distribute the hot air over different parts of the building. The floor of the furnace was 18 inches below the level of the hypocaust, in order that the heat might thus rise to the roof; the large space which the furnace occupied was provided for the admission of air, and was also necessary for conveying a heated current through the flues, as the Romans were unacquainted with the use of a chimney for creating a draught. The hypocaust is well known to the Chinese and is in common use near Pekin, where the winter is very severe. The houses of the better class of persons are built with double walls, and with hollow flues extending beneath the floors. The fire-place is constructed against the outer wall of the room to be heated, by which means the annoyance from dust and smoke is avoided. The floor consists of flat tiles or flag stones, set in cement, so as to prevent the escape of smoke into the room. By this means, the heat coming in contact with every part of the floor is uniformly diffused over the apartment. The ingenious economy of the Chinese (from which we might often borrow a useful lesson) prevents the flues being choked with soot. Instead of employing coal of good quality, they use the inferior or refuse coal for this purpose, and mix it with clay, earth, or any decayed vegetable matter, and then form it into balls, which are dried in the sun. They find that these balls, during combustion, give out very little smoke. This method is not adopted from any scarcity of coal, but the Chinese know how to use it to the best advantage.

I have thought it necessary to carry these remarks upon the hypocaust to some length, because the description will almost entirely apply to the system which I am about to recommend. It will be evident, from what has been just stated, that most of the objections which have been made to the ordinary iron-stoves may be, in a great measure, obviated by the Roman plan, with such modifications as will adapt it to our requirements. By a reference to the plan of Rockingham Church, it will be seen that the furnace is constructed three feet below the level of the floor, at the north-west corner of the building. It consists, as the section will show, of an arched chamber, for the fire, 2 feet deep and 1 ft. 6 in. high, and 10 inches wide, from which a flue, 1 foot square, conducts the smoke and hot air, by a gradual rise of six inches in a foot, or, where practicable, the flue may be brought up immediately to the surface. The throat of the furnace is contracted, by the insertion of a bridge at the top, in order to cause the consumption of as much smoke as possible in the fire, before it enters the flue. This portion of it, viz. nine feet, is constructed with fire-bricks and tiles, and it is here that the greatest amount of heat is produced. The flue starting from the dimensions of 1 foot square, gradually *increases in width* to 2 feet, but *decreases in depth* to 4 inches when it reaches the level on which it is to proceed. The flue is then conducted along the passage between the seats, the pavement itself forming the roof. Blue and red Staffordshire tiles laid alternately, lozenge-wise, form the pavement; they are set in cement, resting upon common blue slates, which are supported at intervals of 6 inches by thin bricks set on edge in the middle of the flue, the whole forming a solid substratum, and by no means unsightly. Staffordshire tiles are used because they will best stand the fire, and from the difficulty of obtaining any stone which will answer this purpose. Supposing the passage to be 5 feet wide, and the flue 2 feet, there remains a space of 1 ft. 6 in. on each side from the wood-work of the seats, thus preventing any danger from over-heating. The flue proceeds along this passage to the extent of 60 feet, when it enters a chimney, formed by circular 9-inch tiles inserted in the wall, and carried up through the parapet.

I have also exhibited a plan of Weldon Church, showing the position of two furnaces, which, in this case, are required from there being a larger area to be warmed. It is of importance that the furnaces should be constructed in such a position that a certain rise may be obtained for the flues. The best place, in general, will be found to be under the porch; the ground underneath which being excavated, and a vault formed, easy access is obtained to the furnace, as well as a convenient receptacle for the fuel. An important advantage is gained by this position of the furnace; every time the door is opened, and a current of cold air enters, it is immediately warmed by coming in contact with the heated tiles just above the furnace; and then it is carried on, provided there are open seats, without doors, in the first instance to the feet, which are thus kept comfortably warm. It will be seen that from the length of flue no heat is wasted, and the higher the chimney is carried, the greater certainty there will be of ensuring a good draught. Where practicable, the tower, therefore, is the best place in which to construct the chimney. In churches where one furnace cannot produce sufficient warmth, an ingenious contrivance has been adopted, consisting of a circular hole made in the floor to the depth of 1 ft. 6 in., 1 foot in diameter at the bottom, and 8 inches at the top, lined with fire bricks, and having a flue at the bottom running into the main flue, at the distance of about 3 feet. From the plan it will be seen that the shape of it is somewhat similar to that of a coffee-pot. This fire-hole is suitable for warming a vestry, or for portions of a church which may be too distant from the main flue. The principle on which it acts is that of a downward current; the coals are placed at the bottom, then some smaller sticks, and shavings at the top; these are lighted, and the flame is carried downwards by the pressure of the air above, igniting the wood and coals, and consuming the smoke in descending.

The superiority of this plan of warming over that by means of iron-stoves, consists in the purity of the heated air which ascends from the furnace, and, being filtered, as it were, through the tiles, rises into the space above, purer than when contaminated by passing through any heated metallic substance. Other advantages are, the beneficial way in which the heat is produced at the lowest point in the building, its safety from fire, the only access to the furnace which is on the outside; the absence of dust, smoke, and dirt; and the economy of fuel. The person who has executed the work at Rockingham and Weldon, is Mr. Bradshaw, an intelligent builder at Leamington, who has warmed several churches and schools in that neighbourhood, on this system. The cost of it for the length and extent I have described, amounted at Rockingham to 35*l*.; at Weldon, to 65*l*. The materials were supplied by Mr. Arnold, tile and brick manufacturer, Tamworth.

Before concluding, I must not omit to notice one other method of keeping our churches warmed and aired, and which cannot fail to be attended with beneficial results, and that is, to open them as frequently as possible for Divine Service. Let this simple method be adopted, in addition to the artificial means already recommended, and we shall not have to complain of cold, which may, in some measure, be the result of a want of zeal and devotion in ourselves.

## ARCHITECTURAL INSTITUTE OF SCOTLAND.

The Fourth Session of this society, which has just closed, has proved highly successful, and augurs well for the future advancement of art and architecture in Scotland.

During the Session many highly interesting papers were submitted to the consideration of the members. Amongst others may be mentioned those of Mr. E. Sharpe, F.I.B.A., on 'The History of the Progress of Church Architecture in England, from the Heptarchy to the Reformation;' Mr. J. Lorimer, on 'The Peculiarities of the Church Architecture of the Rhenish Provinces;' Mr. R. W. Billings, on 'The Ancient Architecture of Scotland;' Mr. J. Baird, on 'The Chapel of St. Blane, in Bute;' Mr. Thomson, on 'The Materials used in Building by the Ancient Romans;' and a highly useful paper, by Mr. Lancefield, on 'The Drainage of Edinburgh.'

The success of the exhibition of models, drawings, and calotypes of architectural subjects, given in the Edinburgh hall of this Institute in March last, warrants the Council in announcing that a similar exhibition will take place this year in Glasgow.

## LOCKS AND KEYS.—BOX-STAPLES AND STRIKING-PLATES.

Michael Leopold Parnell, *Patentee*, November 6, 1851.

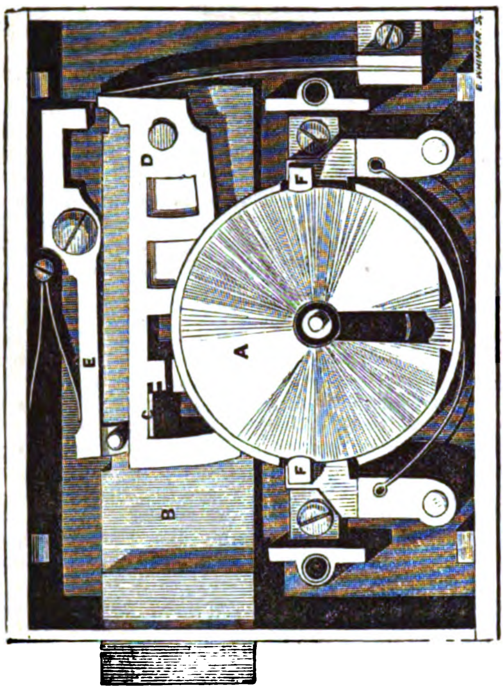


Fig. 1.

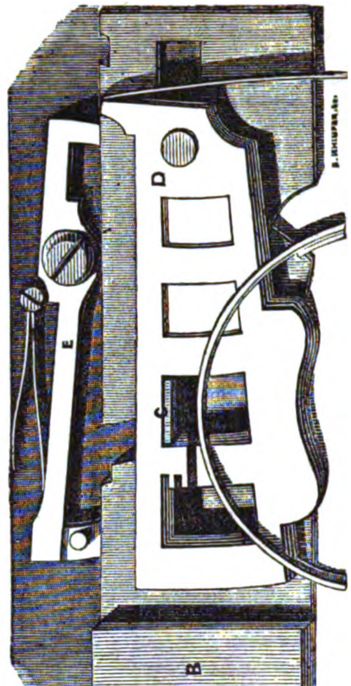

Fig. 2.

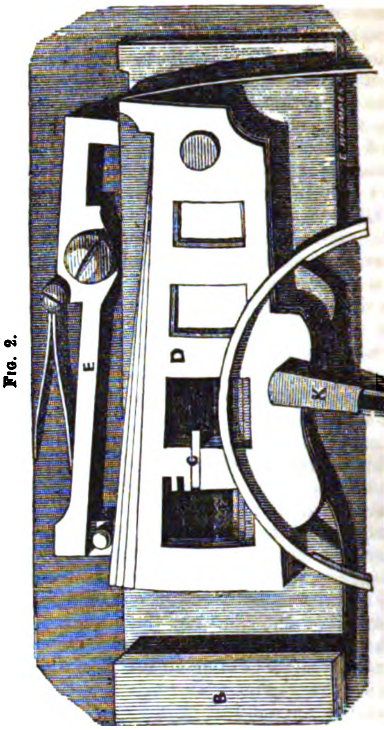

Fig. 3.

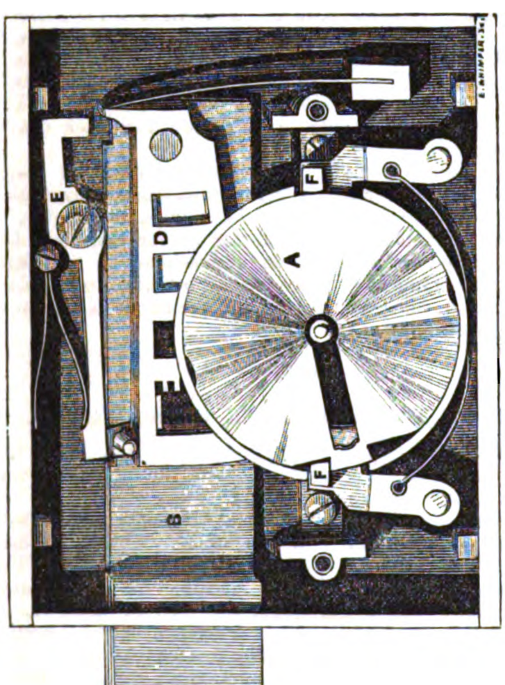

Fig. 4.

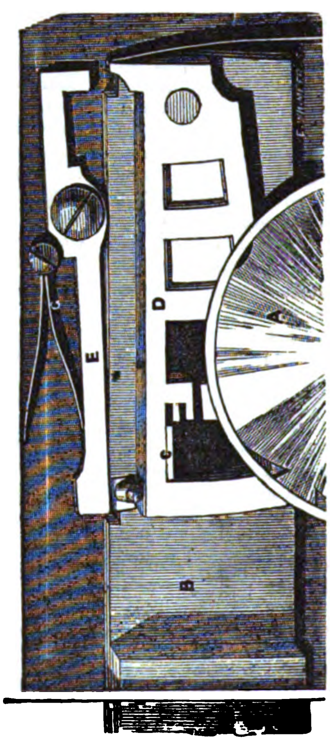

Fig. 5.

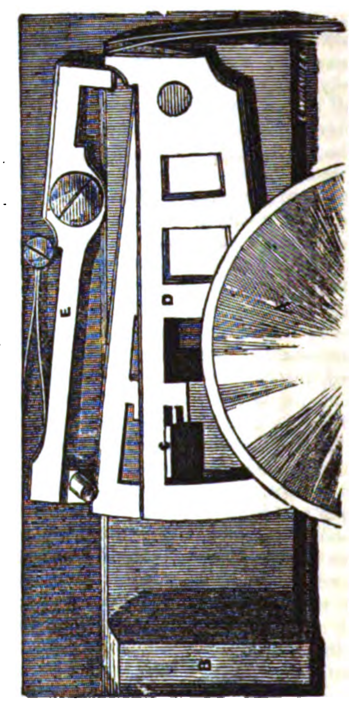

Fig. 6.

The lock, the subject of this invention, which the patentee calls the "Defiance Lock," is one of the best and simplest that has yet been brought before the public. There is no costly and complicated delicate mechanism; all the different actions of the lock work smoothly, with very little strain, and require no oil. All its parts, including those for protection or detection are brought into action every time the lock is used.

Fig. 1 of the annexed engravings shows the lock with the cover removed. A, is a metal cylinder, which revolves with the key or other instrument introduced into the lock, blocks up the key-hole, and thereby prevents the egress of any second pick or tool, and prevents any tampering with the internal works; B, is the bolt, and C, a stump or stud on the face of the bolt; D, the levers; E, the double-action latch; and F, the upright or vertical bolt.

The stump C, being shut up in the chambers of the levers, prevents the bolt from being moved by the pressure or strain of the key, until the levers are raised by the true key to the exact elevation to allow of the passage of the stump through their slots or gratings, when the bolt becomes amenable to the key, and the lock opens. In fig. 2 the stump is shown shut up in the levers; and in fig. 3 in the act of passing through the gratings. Should any instrument but the true key be introduced into and worked in the lock, it will, on making a quarter of a turn, come in contact with the sentinel or upright spring-bolt F, which takes into a notch or rack in the cylinder, and effectually prevents any further movement of the key, as shown in fig. 4. Fig. 5 shows the double-action latch E, above the bolt, working on its centre pivot, and pressed into a notch in the bolt B, by the spring G. Should any false instrument be brought to strain on the bolt, the stud on the latch E, sustains the whole pressure, to the relief of the stump and levers. In the event of the latch being lifted too high, the tail of the latch locks into the tail-catch of the bolt, thereby protecting the levers as effectually as by its first or primary action, and preventing the backward movement of the bolt, as shown in fig. 6.

On the shoulders of the lever are notches to receive the stump, which is made of steel, plain on its face and narrow. This stump, the moment the double-action latch is raised, glides into the notches in the levers, and prevents their being removed, to enable the bolt to pass them; at the same time the latch E, locks into a secondary notch or rack in the bolt, as shown in fig. 7.

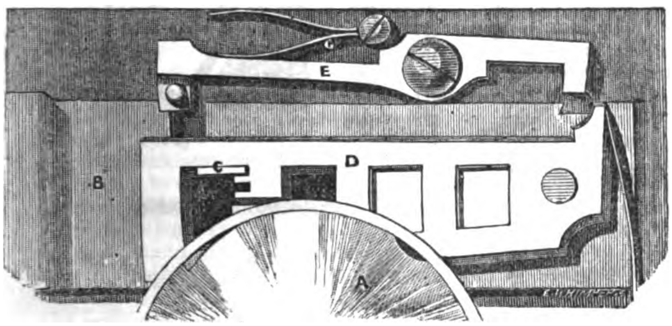

Fig. 7.

In addition to these several securities in the lock, the key is made in the peculiar manner shown in fig. 8, a view of the key as it appears when out of the lock; and fig. 9 the same when in the lock acting on the bolt and levers. It will be seen that the key, when not in use, appears like a highly polished "blank," or key before the wards or bits are cut in it. In this form it enters

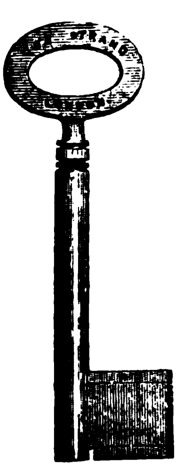

Fig. 8.

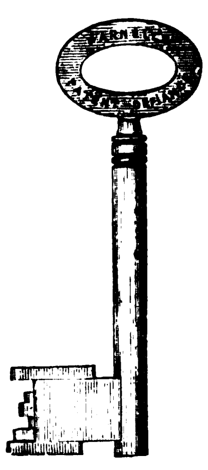

Fig. 9.

the lock, and fits on the edges of an eccentric steel-plate at the bottom of the pin. The moment the key begins to turn, the bits corresponding to the levers are gradually forced out by its action round the eccentric plate, so that when it has made a quarter of a revolution it has become slightly elongated, which enables it to pass the sentinel bolt, and by the time it has arrived at the levers it has expanded about one-third of its length; it then lifts the double-action latch E, adjusts the levers, and shoots the bolt. This construction of key prevents a duplicate being made from sight, as when out of the lock the bits or wards are secreted from view; or should a key be made capable of acting on the levers it could not enter the keyhole, so that the false key that can get in cannot work, and the key that can work cannot get in.

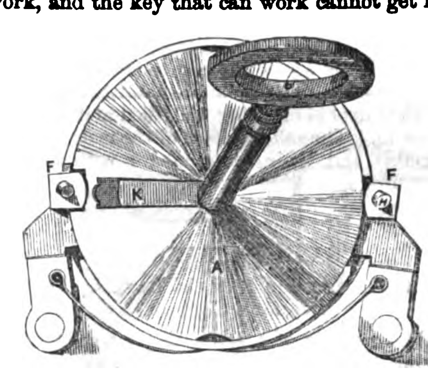

Fig. 10.

By a slight alteration in the cylinder, and the addition of a steel stud on the top of the sentinel bolt F, riveted on a spring underneath, a new arrangement is introduced (shown in fig. 10), which the patentee calls the Detention Cylinder or Detector. The effect is such, that should a false key be attempted to be worked in the lock, the upright or sentinel bolt F, will lock into the notch in the cylinder A, and the studs on the top of the sentinel bolts will be propelled into holes in the cover plate. By these contrivances the false instrument will be seized so firmly that it cannot be released without breaking the door or lock. This principle is peculiarly applicable to locks of safes, strong rooms, or other places where articles of great value are deposited.

There is also a supplementary arrangement, called the Master Key Detachment, whereby the possessor of the master key is enabled not only to open any number of locks of the same suit, where a variation of keys may be necessary, but also to throw them all "out" at pleasure, so that none of the ordinary keys can be of the slightest use until the master key, by its insertion in the lock, puts it into working order for them again. The mode by which this is effected is as follows:—By a simple contrivance, one of the levers in its ordinary position is held up or suspended; to render the key useless, it is only necessary to let it fall. By pushing a small square block that protrudes to the outside of the lock, about the sixteenth of an inch in, this lever is dropped. A small stud screwed into the block or kept apart, or a strong pin, will equally effect this purpose. To restore the action of the ordinary key, the master key has but to be turned in the lock to put the lever up again, and place it in its ordinary position for the key to act on it. This is an exceedingly clever and simple contrivance, rendering unnecessary any operations of "short locking," "double-locking," or the trouble of collecting and distributing a great number of keys, as is the case in banking-houses, prisons, or other large establishments.

This patent also includes a noiseless box-staple and striking-plate, the one adapted to rim locks and the other to mortice locks. The box-staple consists of a moveable plate, which yields to the pressure of the bolt, and offering little or no resistance, allows it to enter the chamber without the bolt being forced back into the lock. When the bolt is in the chamber the moveable plate being loaded at one end, falls noiselessly back into its place, and secures the bolt. The striking-plate acts in a similar manner, only rising to allow the bolt to pass instead of slipping to one side. This contrivance prevents all noise in opening or shutting the door, and all damage to the lock or jambs of the door.

## ARTIFICIAL STONE.

Juste Giret, *Patentee*, June 21, 1853.

This invention relates to the manufacture of artificial and malleable stones from all kinds of sand, earth, stone, and metallic earth. These materials are first submitted to the action of a strong heat in a peculiarly-formed furnace, and when the substances are at the point of red heat, they are impounded in cast-iron or granite mortars, and reduced to an impalpable powder. When thus triturated, fluxes, such as oxide of lead, boracic acid, potash, and soda, are added to the powder, for the purpose of more easily fusing the same. It is then put into a second melting furnace, from whence the products of the fusion are precipitated into a vessel containing cold water, when they are instantaneously transformed into the form of naturally-coloured sand. Different metallic oxides may be added to the mixture when in the melting furnace to vary or increase the colouring of the same. The matters, when cool, are again reduced to an impalpable powder, and placed in fire-clay moulds, and submitted to the action of the oven, for the purpose of being solidified and shaped into the form of the mould. The solidification of the materials being complete, the moulds and their contents are withdrawn from the oven, and deposited in cooling vessels.

## SASH FASTENER.

William Westley and Richard Bayliss, *Patentees*, December 23, 1852.

This invention consists of a self-acting fastener, applicable to windows having one or two sliding sashes, and to all window sashes with intermediate sash-bars, as the apparatus is so arranged between the bevil of the meeting bars, as not to project beyond the face of the sash, and therefore the sashes can pass each other without catching the other bars.

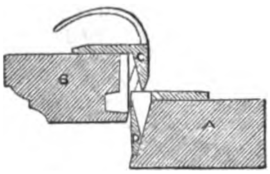

Fig. 1.

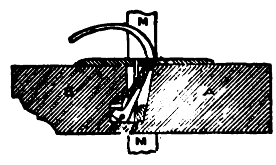

Fig. 2.

Fig. 1, is a section through one end of the fastener, as affixed on a sash (the sashes being a little way open) showing the inclined faces C, D. A, is the meeting bar of the top sash, and B, that of the lower one. When the window is being closed, the inclined face D, on the upper sash, comes in contact with and slides over the inclined face C, on the lower sash, and thereby draws the bars closely together; thus preventing the shaking of the sash, and also the admission of draughts, dust, &c. Fig. 2, is a section through the centre of the fastening, showing the sashes when closed, with the position of the bolt or lever securing the window. M, is the parting bead between the faces of the sashes.

When the window is quite closed, the spring-bolt or lever G, is forced forward by a spring H; the projecting piece I, falls under the shoulder K, on the opposite bar, and is there retained by the spring H, until released by pressing down the finger-piece L.

This self-acting fastener allows the window to be secured by simply raising or lowering either sash; and by passing a cord through a hole in the finger-piece, and drawing the lever L, forwards, windows of any height may be opened without mounting a stool or chair. In windows of upper floors that do not require to be locked, the spring and levers may be dispensed with, the sashes being clasped together by the inclined faces C, and D.

## OBTAINING MOTIVE POWER.

William Henry Fox Talbot, *Patentee*, December 13, 1852.

This invention is a new kind of electro-magnetic machine, consisting of a heavy iron cylinder, made to roll upon a long but narrow metallic table or plate, close beneath which a row of horse-shoe electro-magnets is placed. These magnets stand vertically, with their poles uppermost, so that as the cylinder rolls along the plate it unites the two poles of each magnet consecutively. The magnets are placed close together and level with each other. The cylinder is attracted forwards until it reaches the end of the row of magnets; the action is then reversed, and it returns in the opposite direction. The whole distance traversed by the cylinder makes one stroke of the engine. The cylinder communicates its force and motion to the rest of the machinery by its axis being attached to a crank and fly-wheel. The motion of the cylinder sets in action a commutator or rheotome, which magnetises the magnets that are before the cylinder, and non-magnetises those behind it; and is so arranged that the cylinder is not attracted by the poles of the magnet with which it is in actual contact, but by the poles of the next magnet.

*Claim.*—The general arrangement and construction of the engine.

## MASTS AND SPARS.

Robert McGavin, *Patentee*, October 23, 1852.

This invention relates to the so combining wrought-iron and timber in the construction of the masts and spars of ships, that great strength may be secured, with economy in first cost, and a reduction in weight and bulk.

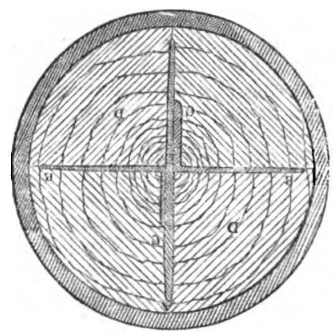

Fig. 1.

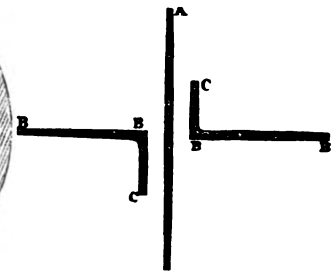

Fig. 2.

In building a mast or spar on this principle, the core or main centre is made of malleable or wrought-iron, of cruciform transverse section. One long plate of iron is taken, of a breadth equal to the requirements of the intended spar, and two other plates are attached at right angles thereto, one on each side along the centre. These two additional plates are each of half the breadth of the main single plate, the attachment or combination being effected by rolling or shaping an angle on one edge of each of the two narrow plates, so that the whole can be riveted together. The four spaces thus left between the four projecting edges or wings of the skeleton mast or spar are then filled in with pieces of wood glued up together with marine glue, or other adhesive substance; and the whole being hooped round with malleable iron hoops or rings, a light and strong structure is produced at a moderate cost.

Fig. 1 of the annexed engravings is a horizontal section of an improved ship-mast; fig. 2 shows the iron plates before fastened together.

In constructing a mast in this way, a long main centre-plate A, is first rolled and prepared to suit the required dimensions of the mast—the width of the metal being considerably less than the diameter of the finished mast. B, B, are the two additional side-pieces necessary to make up the intended cruciform section of the wrought-iron core. Each of these pieces B, has an angle C, rolled along one edge, so that when the two pieces are disposed on opposite sides of, and at right angles to, the main plate A, rivets can be passed through the angle-pieces B, and through the main plate along its centre line, to combine the three pieces into one frame, piece, or core. The four spaces or divisions D, are then filled with wood, so as to form a mast of completely solid cross section. The wood so filled in is not relied upon as a direct means of support or strength; its essential office being the filling-up of the divisional spaces to form a solid mass, and strengthen the buckling of the plates of the core. For, as the presence of a solid body between each two divisional pieces or wings A, B, prevents either of such wings from swerving out of its normal plane, it follows that each plate A, B, is disposed in the best possible manner to meet lateral strains—that is to say, all lateral strain is directed through each plate in a line parallel with the plane of such plate, where there is the greatest resisting depth of metal. Hence the filling-in wood may consist of short small pieces, as, provided the wood is sound, such short pieces, when well joined by marine glue or otherwise, so as to leave no objectionable openings along their central surfaces, are quite as efficient as longer ones.

This system of constructing masts and spars is suitable for a variety of works, and especially for the jibs of cranes where a combined longitudinal and lateral resistance is required. The filling wood may be made either to fill up the divisional spaces entirely or partially, but when filled up throughout, as in figs. 1 and 2, metal hoops E, are passed upon the structure to bind the whole well together.

## STUFFING BOXES.

Messrs. Weatherley and Jordan, *Patentees*, May 26, 1853.

This invention consists of a combination of several split or divided metal rings, with angular or wedge-formed sections, placed in succession round the piston-rod, and within a stuffing-box, the cover of which is kept down by screws and nuts, or springs.

Fig. 1 shows a half vertical section of a stuffing-box, showing the metal stuffing-rings, *a, a, b, b*, arranged alternately, according to this invention; the rings *a, a*, have their widest surfaces outwards, and incline inwards; and the rings *b, b*, are widest on their inner surfaces, and are bevilled towards their outer edges.

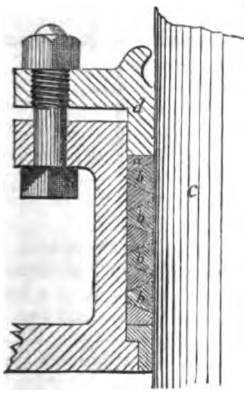

Fig. 1.

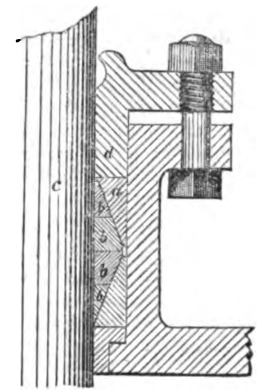

Fig. 2.

When the cover *c*, of the stuffing-box is pressed down upon the rings *a, a*, they tend, by reason of their widest parts being outwards, to force the other wedged-formed rings *b, b*, inwards, and cause them to closely embrace the piston-rod *d*. Fig. 2, a half vertical section of a stuffing-box, shows a different form and arrangement of the metal rings, acting on the same principle as those already described. The patentees prefer making the packing rings of tin.

*Claim*.—The mode of constructing stuffing-boxes by combining a series of split or divided rings, as shown and explained.

## ROTARY ENGINES.

Bristol and Underwood, *Patentees*, May 20, 1853.

These improvements consist—First, in so supporting the outer cylinder of a rotary engine that it is capable of rocking or moving in any direction necessary to preserve it in the proper position in relation to the inner rotating cylinder and the working parts attached thereto.

Secondly, in an arrangement for forcing out or withdrawing the sliders or wings which are acted upon by the steam, gas, or other fluid contained in the inner cylinders of rotary engines.

Thirdly, in a method of forming tight working joints between the outer and inner cylinders, and the working parts attached thereto.

Fourthly, in economising fuel in boilers for generating steam or gas, by increasing the radiating surfaces of the tubes or plates by corrugation, indentation, or abrasion.

Fig. 1 is a section of a rotary engine constructed on this principle. There is a quadrangular framing, having on two opposite sides plummer-blocks, which receive the journals of the main shaft S, to which the inner cylinder or steam-wheel D, is secured. C, is the outer cylinder, which is bored true and faced at the ends; it is surrounded by a double steam-space E, and has two lugs F, F, on opposite sides of its axis; the lower faces of these lugs are convex, to admit of the rocking or vibrating of the outer cylinder, and rest on suitable bearing faces *a, a*, on the top of the framing, at a suitable height to keep its axis in line with the axis of the shaft S. The steam space or band (seen in fig. 2, which is a half section of the engine taken through the steam-ports) has two passages *b*, $b^1$, both entirely encircling the cylinder C; the former communicating with the interior of the cylinder through openings *c, c*, and *d, d*, and the latter through the openings $c^1$, $c^1$, and $d^1$, $d^1$, seen in dotted lines in fig. 1. The passages *b*, $b^1$, are connected with the steam-chest G, by means of the ports *e*, $e^1$, which can be opened or closed in the ordinary manner by the slide-valve H, and handle I; *f*, is the exhaust port; F, the steam-pipe; K, the exhaust-pipe, fitted with a valve L. The inner cyliner D, is connected by four radial arms *h, h*, with its hub *g*, which is keyed to the shaft S. The heads M, M, of the same bore as the outer cylinder, are tightly secured by bolts to

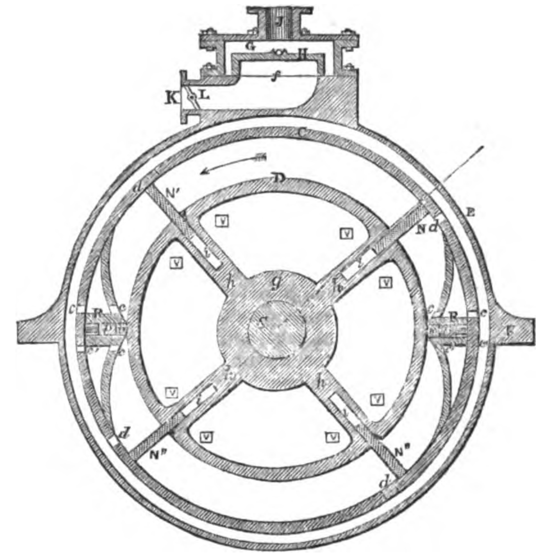

Fig. 1.

the ends of the inner cylinder D. The arms *h, h*, have radial slots *i, i*, to receive the sliders or wings N, $N^1$, $N^2$, $N^3$; corresponding slots are made in the heads M, M, O, O, and other heads, secured by bolts *v, v*, to the heads M, M, having flanges P, P. Q, Q, are metal packing-rings, which are pressed tightly

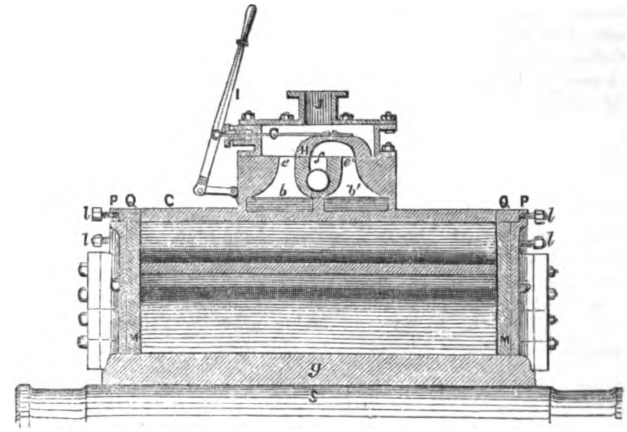

Fig. 2.

against the ends of the outer cylinder by means of set screws, and form a steam-tight joint. R, R, are the cylinder abutments; *m, m*, the face-packings, made in two pieces, and kept tight to the face of the inner cylinder by suitable means. T, T, (fig. 3) are

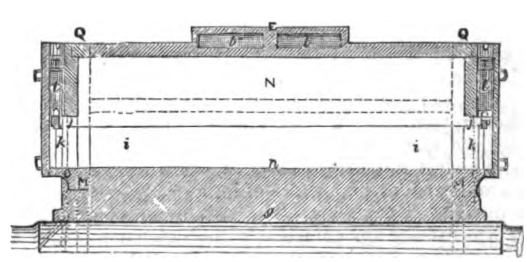

Fig. 3.

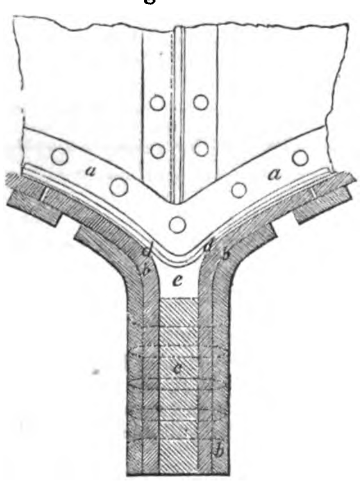
small pistons, working in radial cylinders U, U, and connected with the sliders or wings by the rods *t, t*, and arms *j, j*. When the engine is required to be started, the valve L, is closed, and steam admitted, which fills all the steam space within the engine, and forces out the sliders or wings N, $N^1$, $N^2$, $N^3$. The valve L, is then opened, and the passage or pipe *b*, filled with steam, which enters the cylinder C, through the openings *c*, *c*, and *d*, *d*, and acting on the wings N, and $N^2$, causes the inner cylinder D, to rotate in the direction of the arrow. The spaces between the sliders $N^1$, $N^3$, and the abutments have had the steam exhausted from them, so that there is no pressure on these sliders, nor on their pistons; they will therefore, as the rotation of the cylinder D, proceeds, be drawn in, by coming in contact with the rising parts of the abutments, without any resistance other than their weight and friction. To stop the engine, both steam ports are closed by the valve H; and to reverse it, the port $e^1$ is opened, and *e* brought into communication with the exhaust port.

*Claims.*—1. Supporting the outer cylinder of a rotary engine upon lugs or rockers, or in any other way whereby it is made capable of rocking or moving in any direction necessary to enable it to preserve its position in relation to the working parts contained within it; 2. The manner herein described of moving the sliders or wings outwards by the steam, gas, or vapour, and causing a joint to be formed between their edges and the interior of the cylinder, by its pressure acting upon pistons or their equivalents; 3. The manner herein described of making the moving joints between the ends of the outer cylinder, the rotating heads of the inner cylinder, and the steam and exhaust sides of the ends of the sliders, by means of adjustable metal rings, and by making the sliders exceed in length the space between the heads, such excess being formed of soft metal; 4. The employment in boilers or other vessels for generating steam or gas, of tubes or plates, having their radiating surfaces corrugated, abrased, chased, impressed, indented, raised, or made otherwise uneven.

## IRON SHIPBUILDING.

John Getty, *Patentee*, July 1, 1853.

These improvements in shipbuilding have reference to the construction of the lower parts of iron vessels, and consist in so arranging and shaping the frames or ribs and the garboard strakes of the vessel as will insure an uninterrupted passage to the pumps from stem to stern of the vessel for any water that may collect in its hold or bilge.



The annexed drawing represents a cross section of part of the hull of an iron vessel, built in accordance with these improvements. *a*, *a*, are the frames or ribs, which are bent or curved at their lower portions in the manner shown, in order that they may not touch the keel in any part; *b*, *b*, are the garboard strakes, which, for the purpose of strengthening this part of the vessel, are formed of two plates of iron on each side of the keel *c*, bolted or riveted together. The two inner plates forming the strakes are carried up sufficiently high above the keel to catch or touch the frames or ribs at the points *d*, *d*, and together with the keel form a watercourse or open channel *e*, running the entire length of the vessel; at the same time, the frames or ribs being bent across or bridging over the keel offer no impediment to the free passage of any water that may be contained in the channel *e*. Or, instead of the frames or ribs being curved or bent as above described, they may be brought to a point at their lowermost portions; the garboard strakes being made sufficiently deep to prevent the frames from touching the keel, and thereby destroying the continuity of the channel.

*Claim.*—The formation of an uninterrupted channel or watercourse from end to end of iron vessels, in the manner above described.

## GAS AND AIR ENGINES.

Fabian Wrede, *Patentee*, July 11, 1853.

This invention consists in causing a quantity of gas or other fluid to be moved backwards and forwards between two chambers in such manner that it undergoes no changes in its volume. During its passage from the one chamber to the other, the gas is alternately heated and cooled by a suitable apparatus, by which means its elasticity is alternately increased and diminished. Connected with the chambers is an ordinary working cylinder, with which the gas is in constant communication, and exercises an alternately stronger or weaker pressure upon its piston, thereby causing it to move backwards and forwards in the same manner as ordinary steam pistons. The motive power thus generated is applied to machinery in any convenient method.

## SCIENCE AND ART, PAST AND PRESENT.

By George Harding.

[*Address delivered at the close of the Twenty-Third Exhibition of American Manufactures, held by the Franklin Institute of the State of Pennsylvania.*

The Committee on Exhibitions have invited me on this occasion to deliver the closing address. Deeply sensible of the honour thus conferred, and feeling the warmest interest in the success of our Institute, I have ventured to accept their invitation. I fear that you will have reason to regret that their choice had not fallen upon one better fitted by age, occupation, and experience for the performance of this duty; or that a personal sense of unfitness had not, on this occasion, constrained me to decline.

With regard to the exhibition about to close, I need speak little. To tell you that it surpasses its predecessors, and has elicited the admiration of the community, is but to say that the mechanics of Philadelphia have displayed the fruits of one more year of labour and of genius; and that this has been appreciated by a discriminating public.

The promotion of the mechanic arts is the object for which this Institution was organised. Its agents in accomplishing that purpose are the stimulus of rivalry excited by annual exhibitions, and its provisions for systematic instruction in the application of science to the arts and manufactures. I have thought, therefore, that a sketch of the progress of the mechanic arts, as fostered, in times past, by these means, would be an appropriate, and, perhaps, not an uninteresting subject. My principal aim in this will be to show that the present advancement of our arts and manufactures results from, and their future progress is dependent upon, the intimate union of Science with Art.

The world was nearly six thousand years old before philosophy assumed her true position and became the handmaid to the arts. From the time of Socrates down to the middle of the sixteenth century, philosophy despised and neglected art, and art pined and dwindled for want of her aid. Philosophy preferred rather to devote herself to vague and impracticable theories of moral perfection, to subtle and unmeaning disputations. When she did deign to study natural and physical objects, such study was regarded merely as a mental exercise or diversion.

It is curious to observe to what extent this aversion of philosophy from art was carried under the sway of the lofty intellects of Socrates, Plato, and Seneca. Plato considered geometry as degraded by being applied to any useful purpose. Archytas, who lived about four hundred years before Christ, constructed machines of great ingenuity and considerable power upon mathematical principles, and is even said to have made a mechanical pigeon which could fly. Plato remonstrated with his friend Archytas, telling him that he was degrading a noble intellectual exercise into a low craft, that the true office of geometry was to discipline the mind. From that time all the mechanical arts were considered as unworthy the attention of a philosopher.[1]

Archimedes far exceeded all other men of ancient times in mechanical ingenuity. He was familiar with the doctrine of specific gravity, and practically applied it in detecting the fraud of King Hieros' jeweller, in debasing the crown. When Marcellus besieged Syracuse, Archimedes, from the walls of that city, raised out of the water and destroyed the hostile galleys, or hurled great stones into and sunk their ships; and by means of mirrors he so concentrated the rays of the sun as to burn the fleets of the enemy at a distance. So highly was this man esteemed for his mechanical construction, that, when Syracuse was taken and sacked, his house alone was ordered by Marcellus to be spared. And yet, such at that time was the disposition of philosophy towards the mechanic arts, that Archimedes expressed himself ashamed of these great works; and it was with difficulty that he could be persuaded to divert his mind to them, from mere speculations and abstractions. He regarded his great mechanical works as trifles, with which a mathematican was permitted only to amuse himself.[2]

A distinguished writer, in the time of Cicero, once ventured to enumerate among the humble blessings which mankind owed to philosophy, the discovery of the principle of the arch, and the introduction of the use of metals. Seneca regarded this as an *insult* to philosophy, repelled it, and indignantly replied to him that philosophy had nothing to do with teaching men to rear arched roofs over their heads; the true philosopher does not care whether he has an arched roof or any other roof; to impute to a philosopher any share in the invention of a plough, a ship, or a mill, is an insult.[3]

Such being the state of ancient philosophy, it is not to be wondered at that, for nearly six thousand years, the mechanic arts, despised and neglected, made but small advances. While Greece and Rome, in poetry, eloquence, statuary, and painting, attained to a degree of perfection unsurpassed in modern times, their mechanic arts remained almost stationary. Homer and Virgil are models for the poets of the present day. Men still revert to the glorious age of Athenian eloquence. The fame of Phidias, the sculptor, and of Apelles, the painter, have survived the shock of time which has destroyed the canvas and crumbled the marble. But the natural philosophy of Aristotle and Plato vanished before the light of modern science as suddenly as their moral theories did before the blaze of Christianity.

The human mind was misled by this false doctrine of philosophy until the close of the 16th century. It was then for ever overthrown and demolished by Bacon. He taught a new doctrine. He exhorted men to consider the true end of knowledge, and not to seek it for the gratification of their minds, or for disputation, or that they may despise others, or for emolument, or for fame or power, or such *low objects*; but for its *intrinsic merits* and the *purposes of life*. "The greatest error of all the rest," he said, "is the mistaking or misplacing the last or furthest end of knowledge, for men have entered into a desire of learning and knowledge; sometimes, upon a natural curiosity and inquisitive appetite; sometimes, for ornament and reputation; sometimes, for victory of art and contradiction; seldom, sincerely to give a true account of their gift of reason to the benefit and use of men......But it is that which will, indeed, dignify and exalt knowledge, if contemplation and action may be more nearly and straitly conjoined and united together."[4]

From Bacon, men first learned that science and the arts should walk hand in hand together, and since his day they have so journeyed. The good of mankind, thenceforth, became the aim of Philosophy. Deep was the root which the new doctrine took in the minds of men, and from it has grown the tree of modern science.

Bacon died in 1626. The tumults and troubles of the reign of Charles I., the revolution of 1642, and the disorders which ensued, for a time delayed the progress of science; but immediately after the restoration, in 1660, it began to advance with rapid strides.

About the year 1660, the Royal Society commenced its operations. This Society was originally founded directly upon the motto and the philosophy of Bacon.[5] The earliest records we have of its sessions date in the year 1664, and these show that much attention was given by it to the mechanic arts. During the very first year of its existence, one member was directed to bring in an account of iron from the ore to the bar; another, to inquire into the manufacture of hats; another into the making of lead; a fourth, delivered a full and elaborate report on the history of the manufacture of cloth, as then in use. Tracts were read on the art of marbling paper, and on the refining of gold. Much of the time of the Society, however, was devoted to researches in agriculture and medicine, which had been also neglected under the old philosophy.

The barbarous state in which science had been left by the alchemists, greatly embarrassed their early investigations. Many fables and falsehoods had been bound up with a little true knowledge, and a large portion of their time was occupied in investigating subjects which now excite our ridicule when mentioned. Thus, their recorded transactions inform us that on one occasion a member was ordered to provide some fresh hazel-sticks to try the experiment vulgarly called the divining-rod. Another member was subsequently ordered to bring his box of little animals called the death-watch; and at the next meeting, there were accordingly produced before the Academy two of these for inspection and experiment.

On the 5th of June, the Duke of Buckingham was enrolled a member, and presented a piece of unicorn's horn. The Society proceeded to try an experiment with it, recorded in the minutes as follows: "A circle was made with powder of unicorn's horn, and a spider set in the middle of it, but it immediately ran out. The trial being repeated several times, the spider once made some stay on the powder."[6]

The instrumental collection of the Society appears, during the first year, to have been limited, showing the low state of experimental science at that day. An air-pump, presented by Boyle, a rude microscope, and a loadstone, seem to have comprised their collection. With these, however, they conducted a great variety of experiments. Every thing that was deemed worthy of investigation was either placed under the air-pump, or was submitted to the microscope. The Academy were, nevertheless, proud of their instruments; their experiments were tried with great solemnity, and foreign ambassadors and princes were taken with pomp to see them.[7] Two mechanical inventions were before the Academy that year. One was the scheme of an improved engine for carriage, of such a one as goes by one wheel, and is drawn by one horse. The Society ordered a model made of it, and at the next meeting was produced the modern wheel-barrow made in pasteboard. The second invention was a bow-gun for shooting whales, subsequently abandoned. During the same year, information was received as to the state of one of the arts in the American colonies, then in their infancy. The process reported upon has probably been lost in the lapse of years; it was the art of killing rattlesnakes in Virginia. The outline of this process is thus recorded: "Some leaves of the wild pennyroyal were bruised, and these were tied in the cleft of a long stick; this was then held to the nose of the rattlesnake, who, by turning and wriggling, laboured as much as he could to avoid it; but he was killed with it in less than half an hour; and, as was supposed, by the scent thereof."[8]

At the same meetings at which these, to us, apparently so trivial subjects were discussed, investigations were presented which resulted in our present form of the barometer, in a portion of our present theory of heat and cold, and in improved modes of making lenses. This, too, it will be remembered, was only six years before the immortal Newton, in the 23rd year of his age, communicated to the Society his theory of light, and commenced that brilliant career which during sixty years shed such lustre upon their proceedings.

[5] The Royal Society was an attempt to reduce to practice Bacon's fiction of the New Atlantis. The influence of Bacon was not limited to England—it extended to France, and eventually throughout the Continent. In 1621, Bacon corresponded with Beranzon, an eminent professor in Savoy, in reference to his project for scientific investigation and discovery. And Descartes, who was one of the original founders of the French Association, the basis of the present National Institute of France, shows by his letters to Mersenne, in 1642, that he was familiar with, and entertained the most profound respect for the works of Bacon.
[6] Birch's History of the Royal Society, pp. 26, 84, 270, 338.
[7] Macaulay tells us, that Chief Justice Hale and Lord-keeper Guilford stole a portion of time from their judicial labours, to write treatises on hydrostatics. King Charles spent much time in his laboratory at Whitehall. "It was almost necessary to the character of a fine gentleman to have something to say about air-pumps and telescopes; and even fine ladies, now and then, thought it becoming to affect a taste for science, went in coaches-and-six to visit the Gresham curiosities, and broke forth into cries of delight at finding that a magnet really attracted a needle, and that a microscope really made a fly look as large as a sparrow." Macaulay, Hist. of England, p. 380. Pepy's Diary, May 30, 1667. [8] Transactions Royal Society, No. 3, p. 43.

From our present height of science, we can look back and behold these pioneers clearing the plain below, now gradually surmounting the obstaclès in their course, now wandering backwards for a space, oft-times delayed by the accumulated rubbish of old philosophy, but still steadily advancing, having truth—real, substantial, beneficial truth—for their object, and the omnipotent philosophy of induction for their guiding strength; until, in the lapse of time, we behold their Gregory, Davy, Wollaston, Cavendish, Brewster, Daniels, Faraday, and their compeers, fixing the utmost verge of earth for their bounds; and Newton and Herschel, the highest heavens for their resting-place.

The Royal Society subsequently devoted its attention more especially to the advancement of science, as distinguished from its application to the useful arts, and there sprung up in London, about a hundred years ago, another society, formed for the purpose of effecting a more direct union of science and art. That society was arranged much upon the same general plan as the Franklin Institute. It had its library, collections of models and machines, distributed premiums for inventions, improvements, and superior workmanship; and for nearly seventy years has published an annual volume of transactions. It was the first society which thus brought home to the practical mechanic the means of intellectual improvement in his profession. By its agency the position of mechanics was elevated in England, and the arts greatly advanced. This society arose at a fortunate era in the history of the Mechanic Arts—the era of the steam-engine. At that time James Watt was fifteen years old; fourteen years afterwards he gave to the world his immortal discovery.

And here let me remind you how far he thus contributed, beyond all other men, to the lasting comfort, happiness and glory of his race. In 1769 he converted a simple fire-pump into an engine of boundless power. Nearly a hundred years have elapsed since then, and yet it remains, substantially, unchanged. For eighty years that engine has toiled with the strength of millions of horses, for all men, in every land. Above the wreck of electro-magnetic and hot-air engines, the fame of James Watt, in undiminished splendour, towers proudly eminent. To his genius the hundreds of thousands of our fellow-men in the manufactories of Great Britain, France, and Germany, owe their daily bread; on every navigable river, lake, and sea, on the mountain top and in the deep mine, his engine is working out man's purposes. It has caused towns and cities to spring up and flourish on the barren rocks of New England; it melts, pounds, and rolls the iron of Pennsylvania, and gladdens our ears with the hum of a hundred workshops. It has given to the South a world-wide and insatiable market for its staple; it has filled the Valley of the Mississippi with vigorous life and abundant wealth, carrying its harvests to the East, and bringing back in return the products of manufacture and the rich spoils of commerce. The iron-road, which is but its pathway when it moves upon the earth, binds together the people of our thirty-one States by a tie as strong as our Federal Constitution. To that engine the works of Arkwright, Fulton, Fitch, and Whitney owe the exigency which brought them forth, and the energy which gave them life. Itself the greatest of inventions, it has called forth the highest ingenuity in others. Itself the strongest of mechanical powers, it has rendered available the greatest human strength. If Bacon gave to science the word of truth, Watt gave to art the arm of power.

Fidelity to my subject would require me to trace the organisation of associations similar to the Royal Society throughout Europe; to narrate how the great Colbert, at the instigation of Louis XIV., founded in 1666 the Academy of France; that Society which, in the words of David Brewster, "has stood unshaken and active amid all the revolutions and convulsions which so long agitated that noble, but distracted country; a common centre of affection, to which antagonistic opinions, rival interests, and dissevered hearts have peacefully converged." It would further be my duty to show how, in rapid succession, there sprung up at St. Petersburg, at Stockholm, at Berlin, Edinburgh, Dublin, Copenhagen, Brussels, and Turin, similar academic bodies, bright towers of science, whose light illumined the whole continent, and was, in time, reflected back by many stately halls reared to industrial art. Passing thence to our own country, and later days, I should call to mind the origin of the the American Philosophical Society, and the establishment of our own Institute in 1824; her early struggles, her subsequent prosperity, and how, for thirty years, she has laboured strenuously to unite the interests of the professor and the mechanic. The distinguished success achieved by many of her members—by many, whose presence here forbids my further speaking of them—her reported experiments on water-wheels, on boiler explosions, on the strength of metals, and others in high repute throughout the scientific world, her large library, her crowded exhibitions, and her able Journal, testify how faithfully she has carried out the purposes for which she was organised.

I fear, however, that this detail would become tedious to you; the encouragement of mechanic arts through the medium of Exhibitions, demands, moreover, a brief attention.

The Marquis d'Aveze was appointed Commissioner of Royal Manufactories in France, in 1797. He found that two years of neglect had reduced the workmen almost to starvation, and he then conceived the idea of converting the Chateau of St. Cloud into a bazaar, for the exhibition and disposal by lottery of the tapestry, china, and carpets, unsold and stored in the warehouses of the principal manufactories. A decree of the Directory, in the same year, however banished him along with other nobles from France. He was permitted to return in the succeeding year, and then carried out his original plan at the Maison d'Orsay. The project was eminently successful, and attracted the notice of the French government. That government then erected a Temple of Industry, which was filled with the most beautiful manufactured objects of France. On that occasion the practice of determining the relative merit of contributors and of distributing prizes by committees, originated. This exhibition was so successful that it was determined to repeat it annually.

The troubles of the French nation delayed its repetition until 1801; the third was held in 1802; the fourth in 1806. The wars of France delayed the fifth until 1819. Six others succeeded at intervals of five years, the eleventh exhibition having taken place in 1849, in the Champs Elysée. To their popularity is the origin of the Society of Encouragement to be traced—a society similar to our own, founded about 1804, and which has greatly promoted French art and manufacture.[9]

These exhibitions, it will be remembered, were all carried on by the government. The attention of the "British Society of Arts" was directed to the importance of the subject, about 1847, when their first public display was made. The Franklin Institute gave its first exposition of American manufactures in 1824.

Thus, it will be seen that this Institute is entitled to the merit of being the first society in this country, and probably in the world, which, by its own unaided resources, established this great fostering agent of the mechanic arts. Her example has since been followed by societies at New York, Boston, Manchester, Leeds, Dublin, Baltimore, and Washington. Like the associations from which they spring, they are now generally considered as the necessary incident and legitimate exponent of every manufacturing and mechanical community.

It is to the Society of Arts, of London, whose origin and early history we have already traced, that the world is indebted for an exhibition in which the mechanical industry of all nations was represented. The design of the great fair of 1851, at Hyde-park, was intrusted to a local committee of that Institute, in June 1848; and, after great exertion, they succeeded, with the aid of Prince Albert and the Royal Commissioners, in completing their work on the 1st of May 1851. That exhibition was but a development of our own annual expositions; yet, when we regard its extent, magnificence, and results, it cannot but be viewed as the most remarkable event of modern times.

A space of nineteen acres in Hyde-park was inclosed, and covered by a building 1848 feet long by 408 feet wide, and 108 feet high in the centre. The cost of this structure was 713,900 dollars. The value of the articles exhibited was about twelve millions of dollars. Forty nations contributed to the exhibition, and over six millions of people visited it. From Norway, on the north, down to the Cape of Good Hope, on the south; from China, in the east, to Chili, in the west; from ancient India and Egypt; from Moslem Turkey; from Guinea, on the coast of Africa; from New Zealand, in the South Pacific; and from the solitary Isle of Malta, they were there. *Then*, for the first time, was witnessed the spectacle of ships of war discharged of their armaments, and converted into transports of the mechanic arts. *There*, for the first time in the history of the world, the authorised representatives of thirty nations were assembled on a foreign soil, commissioned on no hostile errand, on no ordinary diplo-

[9] London Art Journal. 1851.

macy. There, for the first time since the Crusades, were the nations of Europe allied together for a purpose which religion deemed worthy of its sanction.

Surely, it seemed that the sword was about to be beaten into the ploughshare, and the art of war to be no longer learned by men. When the Royal Commissioners resigned their commission at the inauguration, the chairman announced the object of their work to be to conduce to the common interests of the human race, by encouraging the arts of peace and industry, and strengthening the bonds of union among the nations of the earth; and to promote a friendly and honourable rivalry in the useful exercise of those faculties which have been conferred by a beneficent providence for the good and the happiness of mankind.[10]

Thus we have seen how science and art, united together, have in times past advanced. Let us turn to the future. A striking lesson which the progress of the arts at the present day teaches us is the high social position which those engaged in mechanical pursuits are assuming throughout the world. As illustrative of this, I need only refer to the fact, that in France the medals awarded to Frenchmen at the Hyde-park Exhibition were distributed by Louis Napoleon in person; and the decoration of the Legion of Honour conferred upon the most successful exhibitors. The Grand Duke of Tuscany has recently, with great pomp and ceremony, established a new order of honour, called the order of "Industry." And aristocratic England has at length discovered that it is high time to abolish the distinction between the industrial and the so-called learned professions. An eminent Fellow of the Royal Society lately held this language: "Industry, to which England owes her success among nations, has never been raised to the rank of a profession. For her sons there are no honours—no recognised or social position. The restriction of learned honours to three recognised professions has a lamentable effect both on the progress of science and industry. Its consequence is, that each profession becomes glutted with ambitious aspirants, who, finding a greater supply than demand, sink into subordinate positions, becoming soured and disappointed, and therefore dangerous to the community. Raise industry to the rank of a profession; give to your industrial universities the power of granting degrees involving high social recognition to those who attain them, and you will draw off the excess of those talented men to whom the Church, the Bar, and Medicine, afford only a slender chance of attaining eminence."[11]

American mechanics, however, need neither legions of honour, orders of industry, or learned titles. The position which they may attain was fixed at an early day. It was fixed when the Philadelphia printer, in 1776, sat with Jefferson and three others to draft the Declaration of Independence; when the same printer signed the treaty of 1778, by which, for the first time, America was recognised as a nation of the earth; when, amid the splendour of the French Court, kings, royal beauties, and learned savans vied with each other in doing homage to the same printer —the conqueror of the forked lightning—our own Franklin. American mechanics know how largely they have contributed to the formation, wealth, and prosperity of this republic; that the want of a government which should protect and render uniform their interests, was a main cause of the adoption of the present constitution; that from that time down to the present their interests have given rise to our great national questions, our division of parties, and have elicited the highest eloquence of our statesmen. They know that the genius of this government, which recognises no titled distinctions, will accord to the exertions of their right arms, and of their intellects, their full meed of social reward.

Another no less striking lesson taught us is the conflict going on throughout the world for precedence in the mechanic arts; and that those nations which would win the struggle must render science more and more subservient to art—that practice and science must join together in a more solemn union. England was forced to admit that France had beaten her, and on her own soil. Eminent Englishmen conceded that France had surpassed them in the display of mechanic arts at Hyde-park. No sensible man doubts where the cause of France's victory lies. That it lies in her Central College of Arts and Manufactures at Paris, in her School of Mines, in her Conservatory of Arts and Manufactures, and in her Industrial Colleges at Ange, at Chalons, and at Aix, where hundreds, nay, thousands, of the most intelligent French youth are annually educated in the practical application of science to the mechanic arts and manufactures. The nations of Europe have looked to this with deep anxiety, and are rousing themselves to the contest.

England thus speaks by Playfair, one of her Commissioners at the Exhibition of 1851: "All European nations, except England, have recognised the fact that industry must, in future, be supported, not by a competition of local advantages, but by a competition of intellect. Their thinking men have proclaimed it; their Governments have adopted it as a principle of State, and every town has now its schools, in which are taught the scientific principles involved in manufactures; while each metropolis rejoices in an Industrial University, teaching how to use the alphabet of science in reading manufactures aright. Were there any effects observed in the Exhibition from this intellectual training of their industrial population? The official reserve necessarily imposed upon me as the Commissioner appointed to aid the Queen need exist no longer; and from my personal conviction, I answer without qualification in the affirmative. The result of the Exhibition was one that England may well be startled at. Wherever, and that implies almost every manufacture, science or art was involved as an element of progress, we saw, as an inevitable law, that the nation which most cultivated them was in the ascendant. Our manufacturers were justly astonished at seeing most of the foreign countries rapidly approaching and sometimes excelling us, in manufactures, our own by hereditary and traditional right."[12]

The illustrious Liebig proclaims from the continent, "that the great desideratum of the present age is practically manifested in the establishment of schools, in which the natural sciences occupy the most prominent place in the course of instruction. From these schools a more vigorous generation will come forth, powerful in understanding, qualified to appreciate and to accomplish all that is truly great, and to bring forth fruits of universal usefulness. Through them the resources, the wealth, and the strength of empires will be incalculably increased."

The venerable Humboldt, with almost inspired authority, thus counsels:—"The most superficial glance at the present condition of European states shows that those nations which linger in the race cannot hope to escape the partial diminution, and perhaps final annihilation of their resources. It is with nations as with nature, which, according to a happy expression of Goethe, knows no pause in ever-increasing movement, development and production—a curse ever cleaving to standing still. Nothing but serious occupation with chemistry and natural and physical science can defend a state from the consequences of competition. Science and information are the joy and the justification of mankind. They form the springs of a nation's wealth, being often, indeed, substitutes for those material riches which nature has in many cases distributed with so partial a hand; those nations which remain behind in manufacturing activity, by neglecting the practical application of the mechanical arts, and of industrial chemistry, to the transmission, growth, or manufacture of raw materials; those nations, among whom respect for such activity does not pervade all classes, must inevitably fall from any prosperity they may have attained, and this, by so much the more certainly and speedily, as neighbouring states instinct with the power of youthful renovation, in which science and the arts of industry operate to lend each other mutual assistance, are seen pressing forward in the race."

In this great struggle between the nations of the earth, what position are American mechanics to assume? Will they scorn these admonitions, and disregard these lessons of experience? Will they not rather call upon science to gird up her loins, and to strike for them in the battle?

In what manner the colleges and schools of our country have been, or may now be, accommodating themselves to this new state of things, it would be presumption in me to say. But I may be excused, perhaps, in addressing a word to the men of my own age, and to younger men, on the facilities afforded by the organisation of this Institute to carry out the principles of the great mechanical progress going on around us.

Elementary science, the practical development of scientific principles in organised machines and processes, and prompt information as to the advancement of scientific discovery, here and abroad, constitute the proper basis of study for the formation of mechanical intellect. To provide these, the organisation and re-

[10] Official Report of Royal Commissioners, at opening of Great Exhibition.

[12] Lectures before the Society of Arts, on results of Exhibition of 1851.

sources of the Franklin Institute are amply sufficient. Its annual course of lectures on elementary science, by professors of acknowledged ability; its large collection of treatises on theoretical and applied science; its committee meetings of learned professors, of experienced practical mechanics, of engineers skilled in mining and metallurgy, of practical chemists, versed in the processes of the arts; its monthly receipt of the scientific journals of this country and of Europe, and its own monthly journal and review —these are its means of usefulness, and to all these the members of the Institute have free access. If the words of Playfair, Liebig, and Humboldt be true, if our daily experience and if our common sense do not deceive us, a proper use of such means cannot fail to advance the mechanical intellect of our community, and better fit us for the great national conflict, now and hereafter to be witnessed.

To all who are interested in the progress of the arts and manufactures of our country, the eloquent appeal of Sir Humphrey Davy addresses itself with force: "You have excelled all other people in the products of industry. But why? Because you have assisted industry by science. Do not regard as indifferent what is your true and greatest glory. Except in these respects, in what are you superior to Athens and Rome? Do you carry away from them the palm in literature and the fine arts? Do you not rather glory, and justly, too, in being, in these respects, their imitators? Is it not demonstrated by the nature of your system of public education and by your popular amusements? In what, then, are you their superiors? In everything connected with physical science, with the experimental arts. These are your characteristics. Do not neglect them. You have a Newton, who is the glory, not only of your own country, but of the human race. You have a Bacon, whose precepts may still be attended to with advantage."

We have a Franklin. He trod the path of Bacon and of Newton; he reached the same pre-eminence. Amid his daily toil as a mechanic, he struggled up the steep ascent of science. The labour of his hands abated not the vigour of his intellect. Loiter not in the path which these great men have opened, lest you be overtaken and vanquished in the strife. Say, rather, that their precepts shall be attended to, and their example followed.

## VULCANISED INDIA-RUBBER RAILWAY-CARRIAGE SPRINGS.

G. Spencer, *Patentee.*

(*With Engravings, Plates* IX. *and* X.)

Our engravings represent a new system of applying vulcanised india-rubber to every description of railway-spring, in which are some features that we think worthy the attention of our scientific friends. We add some particulars of the advantages claimed by the patentee for these springs, together with a descriptive reference to the drawings, which have been furnished by Messrs. Reade, Spencer, and Co., of Cannon-street West, the sole manufacturers of them.

The chief advantages claimed for these springs over those in present use, are—1. Non-liability to get out of order, from their strength and simplicity of construction, and the peculiar fitness of india-rubber as a material for springs (when scientifically applied), to resist the effect of sudden concussions. These springs have been put to very severe tests by means of two powerful testing-machines, which the manufacturers have had constructed for that purpose. By means of one of them, a number of the india-rubber cones have been submitted to very great pressures, and left for a considerable time under pressure; but they were found on removal instantly to resume their original shape, and to be uninjured, and that in all temperatures. The cones used in these springs are equal to a force of five tons, but the power can be increased, if thought desirable, without any addition to the cost. By the second machine, worked by a steam-engine, 100,000 strokes have been given to several of the cones, without producing the slightest injurious effect upon them.

2nd. Extreme lightness in comparison with the springs in present use, by which means a great saving in non-paying weight is effected. Below is shown the comparative weight of the buffer-springs in present use on the carriages on the North-Western Railway, and that of buffer-springs on George Spencer's system:—

| | cwt. | qr. | lb. |
|---|---|---|---|
| Buffer-springs on North-Western Railway, including steel-plates, all iron work used with same, 4 buffer rods, buffer-blocks, plates, buffer-heads and fastening-guides, &c. Total weight .......................... | 10 | 2 | 6 |
| Buffer-springs on North-Western Railway, on George Spencer's plan, including india-rubber springs, 4 buffer-rods, blocks, heads, balls, and fastenings complete. Total weight ................................. | 4 | 1 | 14 |
| Saving of weight in this case ........... | 6 | 0 | 20 |

The total weight of Spencer's set of buffers and springs complete, being only that of the steel in the two springs on the old system, namely, 4 cwt. 1 qr. 14 lb., thus the weight of six passengers is saved in every carriage fitted with these springs, or of sixty in a train of ten carriages.

In the bearing-springs a further considerable saving of weight is effected; the weight of one bearing-spring complete, with all its parts, being only 33 lb. while those on the old system weigh three times, and sometimes four times as much. But a still greater advantage than saving of weight is effected by these springs,—"*they cannot break*," as laminated springs frequently do.

3rd. There is a great saving in the first cost of these springs over all others, owing to their extreme simplicity, and the cheapness of the material used.

4th. Owing to the small space they occupy in the under-frames of the carriages, these springs (buffers) may be in all cases used inside the framing, and thus any length of stroke may be obtained. The manufacturers supply several good and cheap forms of outside buffers (see figs. 1, 2, and 3), of the same powers (5 tons); but they expect that the many advantages possessed by inside-buffers will be a strong inducement to engineers and railway companies to adopt them, notwithstanding the small extra cost of these latter over the former.

These springs have met with very general approbation from the profession, and several eminent railway-carriage builders, both in England and on the continent, to whom they have been submitted, and from whom have been received very flattering testimonials of the merits of the invention, as well as large orders for their application.

*Description of Plates* IX. *and* X.

Plate IX.—Fig. 1 shows a new system of outside buffer of a a very effective kind for use on wagons and trucks; they are shown to a 3-inch stroke, and exert a power equal to five tons when driven home; C, is a corrugated cast-iron block; B, is a strong cast-iron piston; A, A, are the double cones of vulcanised india-rubber; *a*, *a*, are the confining-rings. Fig. 2 is a similar outside buffer, with the buffer-block made of elm. Fig. 3 shows a plan and elevation of an inside truck-buffer; B, buffer-rod; A, india-rubber cone; *a*, confining-rings; C, buffer-block.

Plate X.—Fig. 4 shows a plan of a spring for passenger-carriages. Fig. 5 a new system of bearing-spring. Fig. 6 a double-action draw-spring. Fig. 7 a single-action draw-spring.

## REVIEWS.

*The Museum of Science and Art.* Edited by Dr. Lardner. London: Walton and Maberly. 1854.

The purpose of Dr. Lardner is, he states, to publish a collection of instructive and amusing essays and tracts in a popular and amusing style, on the leading discoveries in the physical sciences, and on their most important and interesting applications to the industrial arts. In this design he does not address himself simply to the uninstructed, but also to those who have been disciplined in the study of the sciences. We think it a very useful feature, that the writer proposes to avail himself of many interesting and familiar details and incidents, which are usually excluded from systematic treatises. The work, too, is to be published in a very cheap form, so that it may be obtained in penny numbers. To conduct such an enterprise, we know no one more fitting than Dr. Lardner. He is as much of a student as a professor; indeed, for part of his life he taught what he had learned only a few hours before. Thus he shows in his writings a full knowledge of the wants of the student; he follows his train of thought, he meets the difficulties that arise, and makes ready the way before him. To the young and to the old reader such a guide is valuable, for the former wants assistance to compass a

new subject, the latter too often needs time to wade through or to elaborate a treatise artificially constructed.

If we are to judge by the first part, the Doctor's description does not do justice to all the merits of his design. This part includes two subjects: "The Planets, are they Inhabited Worlds?" and "Popular Fallacies,"—which, independently of their application, are interesting as illustrations of modes of reasoning, and will be found valuable to the professional student who may have been trained solely in the mathematical process, or only mastered the schemes of the logicians. In the first paper physical facts are made use of in the solution of a moral problem, and applied, by way of analogy, to indicate results. This is a mode of reasoning wanting the rigidity of the mathematical process, but one which is alone available in many cases, and which is of much application in the affairs of life. In the paper called Popular Fallacies, the writer shows that what is called the evidence of the senses is liable to error, and must be subjected in many cases to correction. We call attention to these features because, in the present day, the practice is too prevalent of teaching facts without teaching the mode of reasoning, and of imposing a very extensive course of instruction which includes everything but the art of thinking. We believe the University of London is the only examining board where the medical man undergoes an examination on logic; and, we believe, nowhere else is there such an examination or instruction for the lawyer, who is supposed, above all others, to exercise a profession dependent on dialectics.

The question—"The Planets, are they Inhabited?"—is examined by the light of all those phenomena which the latest and soundest observations have established, and the author endeavours to show that the harmony of conditions of the several planets, as compared with the earth, is in favour of a similar organisation. In developing this from a variety of facts, some interesting examples of analysis are exhibited, and suitable diagrams and illustrations are introduced to assist the reader. We think a more convenient course of arrangement would have been to have considered, first, the harmony of geological conditions; secondly, of botanical; and thirdly, of zoological conditions. Nevertheless, there is a harmony of results from the numerous solutions collected by the author.

In a paper on weather prognostics, Dr. Lardner analyses the evidence as to the supposed influence of the moon on the weather, and controverts the popular doctrine.

The number on Popular Fallacies is, more strictly speaking, an inquiry into errors of the senses; and this will afford an opportunity of giving an extract, which may serve to illustrate the author's mode of treating his subject.

"*Fallacies of Vision.*—Of all the organs, that which would seem to be most exact and unerring in its indications is the eye; and, although in a certain sense this is true, yet there are no impressions which more imperiously require the exercise of the judgment to adjust and rectify them than those of vision. By this sense, we receive the perception, subject however to many qualifying conditions of form, magnitude, brightness, and colour. There is not one of these qualities, however, which is not frequently mistaken or wrongly estimated.

"*Fallacies of Vision, as applied to the Sun and Moon*—Every one, for example, is familiar with the appearance of the sun and moon when rising and setting. The apparently large orb which they present to the senses is an object of familiar notice. Is not every one impressed with a conviction that the apparent magnitude of the sun when it rises, glowing with a redness acquired from the depth of air through which its rays then pass, is much greater than the apparent magnitude of the same object at noonday? and is not the same impression admitted with respect to the rising or setting full moon, compared with the same object seen on the meridian? Yet nothing is more easy to prove, as a matter of fact, that these impressions are fallacious. Let any one adopt any convenient method which may occur to him, to measure the apparent magnitude of the sun on the horizon, and again on the meridian, and he will find them the same. This may be accomplished by extending two threads of fine silk parallel to each other in a frame, and placing them in such a position, and at such a distance from the eye, that when presented to the sun or moon, on the horizon, they will exactly touch its upper and lower limb, so that their apparent distance asunder will be equal to the apparent diameter of the lunar or solar disc. If this arrangement be preserved, and the sun or moon be viewed in the same manner when at or near the meridian, it will be found that the threads will equally touch its upper and lower limbs, and that their interval will still measure its apparent diameter. It will therefore be evident, that whatever be the cause of the illusion, the apparent magnitude of the sun or moon is not greater at rising or setting than in the meridian. Whence, then, it may be asked, arises an impression so universally entertained?

"The explanation of this singular effect, in which all astronomers appear to concur, refers it to mental, and not optical causes; strictly speaking, it is not an optical illusion. The error is one of the mind, and not one of the senses. The estimate which we form of the actual magnitude of any visible object depends on a comparison of the apparent magnitude which that object presents to the eye, with the distance at which we imagine it to be. Thus, if there be two objects—buildings, for example—which have to the eye the same apparent height, but which we know or believe to be at different distances from us, we instinctively, and without any operation of the judgment of which we are conscious, conceive that which is more distant to be the largest.

"To apply this reasoning to the case of the sun or moon, we are to consider, that when either of these objects is in the horizon, a portion, at least, of the space between the eye and it is occupied by a series of objects, with the magnitudes and relative positions of which we are familiar. We are therefore enabled to make some estimate of a portion of the space that intervenes between the eye and the object. But when the object is in a more elevated position in the firmament, no part of the intervening distance is thus spaced out, and we are accustomed to consider the object nearer to the eye.

"Conceding this, then, it will be asked how it explains the universal impression of the enormously large disc of the sun or moon when rising or setting; the answer is, that when in or near the horizon, the mind is impressed with the idea that the distance of these objects is much greater than when on the meridian, and that their apparent magnitude being the same, the real magnitude is judged to be greater in the same proportion as the distance is supposed to be greater. Thus, if we are impressed with the notion that the sun seen in the horizon is twice as distant as the sun seen in the meridian, we shall infer its diameter to be twice as great, since it appears the same; and if its diameter is twice as great, its apparent superficial magnitude will be four times as great.

"The operations of the judgment in such cases are so rapid, and the effect of habit is such, that we are altogether unconscious of them. A thousand examples might be given of bodily actions and motions performed by the dictates of the will, of which we retain no consciousness. It is difficult, in the case we have just explained, for minds unaccustomed to metaphysical inquiries, to satisfy themselves of the validity of the explanations we have given. Yet, if it be remembered that it is capable of unequivocal proof that the illusion is not optical, and that, in fact, the apparent magnitudes of the moon on the horizon and the meridian are not different, it will easily follow that the error must be mental, and the only explanation which has ever been given of it is that which we have here offered.

"There is perhaps no sense which more requires the vigilant exercise of the understanding to rectify its impressions than that of sight. The susceptibility of the organ of vision itself is liable to frequent and rapid change, and the same objects at different times produce upon it extremely different impressions. A situation in which, in one condition of the eye, we shall appear to be in absolute darkness, will present to us, in another state of the organ, sufficient light to render visible the objects around us. If we are suddenly deprived of the illumination of any strong artificial light, we appear to be for the moment in absolute darkness; but when the organ of vision has had time to recover itself, we often find that there is sufficient light to guide us.

'Thus when the lamp that lighted
 The traveller at first goes out,
He feels awhile benighted,
 And lingers on in fear and doubt.
'But soon, the prospect clearing,
 In cloudless starlight on he treads,
And finds no lamp so cheering
 As that light which heaven sheds.'—Moore.

"*Perceptions of Colour.*—The perception we receive of the colour of an object depends often as much on the condition of the eye when the object is seen as upon the object itself. By the action of lights of different colours, the sensibility of the retina may be so modified that the same object will appear at different times to have different colours, and unreal objects will often be perceived. These are called spectra. If we place on a sheet of white paper a red wafer, and, illuminating it strongly, direct the eye steadily to it for a short time, and then look at the paper close beside it, we shall there see a blue wafer of the same size. This object is an optical spectrum. The cause of its appearance is easily explained. By the action of the strong red light proceeding from the wafer, the retina is rendered for the moment insensible to the operation of a more feeble red light upon it, for the same reason as the ear would be insensible to the ticking of a clock immediately after being affected by a discharge of artillery. Accordingly, when the eye, after viewing the red wafer looks at a white wafer beside it, the action of that portion of the compound white light reflected from the paper which is red, fails to produce any perception, and the remaining constituents alone are perceived, which accordingly present a blueish tint. To comprehend this and other similar illusions, it is very necessary to remember that white light is a compound of reds, yellows, and blues, and that if we deprive it of any one of these elements, it will assume the tint produced by the others. Thus, if the eye be insensible to red light, all white objects will appear to it with a tint composed of yellow and blue. If it be insensible to blue light, then white objects will appear orange.

"Instances have more than once occurred, and are recorded in the works on optics, of individuals incapable, from original defects of vision, of perceiving particular colours. The late Dr. Dalton, of Manchester, was a conspicuous example of this.

"But, as we have above stated, even a healthy and perfect eye will be rendered temporarily insensible to the impression of particular colours by being exposed for a short time to the strong action of coloured lights. Optical illusions are produced in this way in the exhibition of fireworks. When luminous balls, some red and some white, are thrown up into the air, the white appear blue beside the red, and are generally imagined to be really blue. The effect, however, is a visual illusion, ascribable to the cause just explained.

"In the sky, towards sunset, when reddish clouds are arranged with openings between them, the sky at such openings appears green, although it be really blue.

"In astronomical observations on the stars there is a curious case, in which it has never been settled whether the appearance is real or illusive. Many of the stars, which to the eye appear individual objects, prove to be double when examined with powerful telescopes. The two stars, thus composing a double star, are frequently of different colours, and it is found that when one is red the other is of a blueish tint. Now, we know that it would appear of this tint, even though it were a white object, by reason of the presence of the red star. Whether, in these cases of double stars, the blue one would be really blue, or is rendered so by the optical effect adverted to, has not been decided, it being impossible to view it except in juxtaposition with its red companion.

"*Fallacies as to Number.*—One of the most curious and most incomprehensible illusions of the senses is the singularly-erroneous estimate which we make of the number of objects of any kind that are presented to us. A striking example of this is presented by the impression made upon the eye by the view of the firmament on a clear starlight night. The number of visible stars is always immensely over-estimated. Although it be true that the stars are, strictly speaking, countless in number, yet the number distinctly seen by the naked eye at any one time, unaided by the telescope, is not great. Any one can satisfy himself of this by examining any good map of the stars; yet, when we look at the firmament on a clear night, these objects appear to be inconceivably numerous. This illusion is dispelled by examining the heavens through the most ordinary telescope, or even by looking through a long tube, which will limit the view at any one moment to a small portion of the firmament. On the entire sphere of the heavens there are not above twenty stars of the first magnitude, and it is seldom that as many as six or eight of these can be seen at once. The number of stars of the second magnitude does not exceed fifty, and of these twenty are seldom seen at any one time. The stars of the third magnitude may amount to about two hundred, half of which only can be at the same time above the horizon. The small stars are much more numerous, but they are discernible with difficulty, and do not produce upon the mind the impression of multitude that we conceive."

Unless the Doctor reserves it for another occasion, he might have said more about chromatopseudopsis, or Daltonism. Besides Dr. Dalton, we believe the eminent mathematician, John Herapath, was partially affected with colour-blindness. This imperfection of vision as regards colours, is one that interests engineers, on account of its unfavourable influence on those set to watch railway signals. There can be no doubt that, among the thousands of engine-drivers, stokers, guards, and other employees, many cases of the imperfect discrimination of colours must be found, and it is suspected that serious consequences have resulted from this defect. This physical evil is also worthy of consideration by another class of engineers, those connected with lighthouses: and is one reason for which coloured lights for such purposes are open to objection. The gas engineer has too, perhaps, something to learn with regard to the effect of illuminating substances of various colour.

---

*The Human Hair, Physiologically Considered.* By ALEXANDER ROWLAND. London: Piper Brothers. 1853.

This work treats a novel and seemingly a trivial subject, but those who read it will find a mass of learning well applied, and that the volume is by no means too large for its complete treatment. We should, nevertheless, have left it to the physiologist were it not for the evidence it gives in favour of the endeavours now being made for the protection of men in various employments exposed to injury of the respiratory organs. The evidence adduced from theory and practice shows, conclusively, that the old English fashion of wearing the beard and moustaches is the natural and effective safeguard of the lungs, nostrils, and throat, not only against the influence of the external atmosphere, but against the injurious effects of various employments. It is indeed singular, that after the artificial and unnatural practice of shaving had taken root in this country, art was called in, by the application of the respirator, to remedy the evil. The Russians, who are exposed to a cold of 35° below zero, wear no other covering round the throat but the beard. It being found that the German and French masons are less subject to phthysis than ours, Professor Alison, of Edinburgh, recommended the masons of that city, on the score of health and cleanliness, to wear the beard and moustache as a preventative against breathing the fine dust, which so much injures the working-mason and shortens his life. We are informed that now nearly all the masons in Scotland, in the north of England, and parts of Ireland, and many in the south of England, have adopted this advice. It is noted that in Bavaria and Wurtemburg, in particular, where freestone is extensively worked, the masons are fine-looking muscular fellows, with large beards, and such a disease as phthysis is never heard of. The official medical statistics of our army show that the cavalry regiments suffer less from phthysis than the infantry. Steel-grinders, millers, cabinet-makers, and some other trades where dust is inhaled, are following the example of the masons. On many of the Scotch and some English railways, the engineers and guards, who are severely exposed to the weather, are directed to wear their beards, and in some towns the police. A curious practical example of the operation of the natural hair was observed by Mr. Chadwick, in the case of some blacksmiths who wore beard and moustaches, the hair about the mouth being discoloured by the iron dust that had been caught in its way into the mouth and lungs. It is said that the air-passages of a Londoner, or Manchester man, are found to be more or less coloured by the dirt that is breathed.

## RUSKINISM.

THE tide is beginning to turn against Ruskin; his popularity is now ebbing away very fast. The 'Stones of Venice,' and the 'Fall,' have occasioned his own downfall and tumble, and have lately incurred for him, in different quarters, a good deal of strongly-pointed animadversion, no less just than severe. In fact, he may now be said to be,

"Fallen, fallen, fallen
From his high estate;"

for his admirers—real or pretended—leave him in the lurch; no doubt, because conscious that it is impossible either to ignore or to refute the charges now brought against him by those who really do understand something of architecture, and have plainly convicted Ruskin of gross absurdities and inconsistencies, which they themselves were either too ignorant to discern, or else wilfully omitted to point out to their readers.

Abundant was the praise bestowed by reviewers on the 'Seven Lamps,' but with regard to quality it was little better than ordinary off-hand newspaper-puff, to the tune of,

"Long live the Regent and the Duke of York."

They lauded his "eloquence," his feeling, his fine passages fraught with imagination, and so forth, some of them expatiating upon his peculiar merits in that respect,—which at the best were but of secondary consideration,—in a style that seemed to mimic—at any rate to be ambitious of mimicking, his own. One of Ruskin's eulogisers assures us that his architectural writings "cannct be read by any one without improvement to his moral sense and mental discipline." Another has had the hardihood to predict that "'The Stones' will become the most popular of all his productions!" A third hails him as "the first really popular writer we have ever had upon architecture,—the first who has satisfactorily touched upon architectural principles." "His eloquence," says a fourth, "is as rich, his enthusiasm as hearty, his sympathy for all that is high and noble in art as keen as ever." Such is the strain in which pen-wielding donkey after donkey has brayed forth his rather clumsily-feigned raptures into which they profess to have been thrown by John Ruskin's double-distilled sentimentality, and lackadaisical palaver. The substance and ingredients of his books are, moreover, of very "mince-pie" sort, the most heterogeneous matters and topics being mixed up together in them; so that dipping into them at random, we might at one time fancy that we had taken up a volume of sermons; at another, that we had pitched upon some formal dissertation on painting; or else dipped into some work on Venetian history; or into some political treatise, some essay on morals. And in every instance we might read on, page after page, without discovering or even suspecting that such matter—of whichever sort it was—

was merely a long-winded *hors-d'œuvre* in what professes to treat specially of architecture. Not only does Mr. Ruskin touch on very irrelevant matters, but he dwells upon them so long that he frequently seems to forget architecture altogether; or else to make use of it as a mere peg on which he can hang up and display his own peculiar notions respecting things in general.

The consequence is his three bulky volumes ycleped 'The Stones of Venice,' must disappoint even those who are disposed to fall in with Ruskin's architectural fancies and heresies, when they find how very much there is crammed into them that does not relate to architecture at all, but serves only to swell out the work and add to its price, rendering the last almost a prohibitory one in these days of cheap literature. On the other hand, placed where it is, the non-architectural matter is completely buried from those whom it more immediately concerns and is likely to interest, or who, even if they are aware of its existence, will hardly purchase so extravagantly expensive a work, merely for the sake of such portions of it. Therefore, as far as sale is in question, Mr. Ruskin appears to have placed himself upon two stools; which is, however, his concern, not ours.

What he calls his "Topical Index" exhibits the multifariousness in which he indulges, and how much of the exceedingly far-fetched and incongruous he has foisted into his work, thereby rendering it chaotic, disjointed, and fragmentary. Digressions to the same extent might have been excused had they been confined to disquisition bearing more or less upon architecture itself. We are so overburthened with earnest, thoughtful, intelligent, searching, many-sided criticism on the subject of it, as to render any addition either unnecessary or unwelcome. We must not, however, look to Ruskin for it, he being a man of such extreme prejudices as better qualified for the office of a *hangman* than a judge. Neither does he show himself to be the most skilful of advocates; since after all, according to him, his idolised Venetian Gothic is the best style only because all others are decidedly bad and worthless, so "base," "detestable,"—such mere "clouts" and "rotten rags," that they deserve to be flung aside at once without examination. Therefore, instead of being represented as supreme among the noble and the glorious, it is made to appear little better than a mere *pis aller*.

More energetic than gentlemanly in the language he employs on that occasion, Ruskin shows himself also to be no less foolhardy than foul-mouthed, flying in the face of, and scornfully trampling upon, all established authority whether as regards theory and criticism, or practice. Singularly inconsistent he most certainly is, and not least of all so upon one most important point, for how is it possible to reconcile his professed abhorrence of Romanism with his love of symbolism and the practices of the unreformed mediæval church? Not only is he avowedly Pre-Raphaelite in his taste, but covertly Pre-Lutheran in his sentiments. When he charges the Renaissance period with infidelity he surely forgets that it was also that of the great Protestant Reformer,—forgets, too, that classical literature helped to dispel the superstitions of monkish lore. Now, his Pre-Raphaelitism and Pre-Lutheranism go well together, yet the latter is altogether at variance with the puritanical strictness he affects when touching upon matters of belief and religion; and he not only frequently touches, but sometimes dwells upon them in a very strange fashion.

That there is a very great deal in 'The Stones of Venice' that no one cares to countenance, is tolerably evident, there being a very great deal which even his admirers deem it advisable to take no notice of whatever, notwithstanding that much of it is not a little startling. A writer in Parker's 'National Miscellany' qualifies his commendation of "Mr. Ruskin's delightful book," by pointing out certain "defects," and among them a gross mistake relative to the Doge's Palace; but he winks at his depreciation of our English Gothic, his sneering at the towers of York Minster as no better than "confectioners' Gothic," and his rabid denunciation of the classical styles, both ancient and modern,—which reference surely partakes of dishonesty. Let those who really admire Ruskin, and are willing converts to his doctrine and teachings, show their sincerity by boldly standing up in defence of his vital and most vulnerable points; instead of which they deck him out with gaudy plumes, when they ought rather to supply him with an impenetrable breastplate.

CANDIDUS.

## RECENT AMERICAN PATENTS.

[Reported in the Journal of the Franklin Institute.]

*Method of Generating Steam.* J. B. Moinier and P. H. Boutigny.

The generator is formed so as to cause a direct production of steam at high temperatures (500° and upwards) by means of injecting water at the top or near the top of the generator, when the same is in a heated state, and causing the water to come in small quantities in contact with the surfaces of perforated metallic diaphragms (arranged one above another within the generator) and also to come in contact with the sides of the generator.

*Claim.*—Subdividing the water and at the same time increasing the evaporating surface of the generator, the water being gradually heated and subdivided in its passage through the apertures or meshes of the diaphragms, before it comes in contact with the more highly-heated surface of the generator.

*Steam Boilers.* B. Irving.

The improvements in this invention are, chiefly, to secure a more perfect combustion of the gases generated by the consumption of fuel, and to present a large extent of heating surface without subjecting any part of it, when working properly, to a very intense heat; to guard against explosions of the boiler; to gain more compactness and strength in structure, and to diminish the necessary weight of metal and quantity of water. The results claimed are, economy in amount of fuel and in expense of construction, safety from explosions, increased strength and durability, and adaptedness for the use of coal or wood to propel engines on railroads, and for all other purposes.

*Claims.*—1, a boiler composed of an external water-jacket, of cylindrical or other form, with a steam-chamber at the top, and with or without one or more inner water-jackets connected with the outer water-jackets, when either water-jacket contains one or more vertical coils of steam-pipe, whose lower ends connect with one of the water-jackets, and whose upper ends discharge into the steam-chamber; 2, drying the steam by passing it through a coil within or between the water-jackets.

*Regulating the Speed of Steam-Engines.* R. Fraught.

This invention consists in causing the "cut-off" valve to move with the slide-valve, by means of friction produced between them by the pressure of the steam in the valve-chest, and by plates compressed to the valve-rod by a spring, or by other suitable means. The "cut-off" is attached to a pendulum, or other contrivance, capable of offering to its movement a resistance which causes it to move a shorter distance than the valve, and thus close the steam-openings of the valve, and cut-off the steam before the termination of the stroke of the engine, and which resistance increases or diminishes with the increase or diminution of speed of the engine, so as to close the passages and cut-off the steam earlier or later, as may be required, and thus regulate the speed of the engine.

*Stoves.* T. S. Gore.

An inner cylinder or chamber of the stove is surrounded with spiral flues, so arranged or connected to the base that the heat which passes down the spiral flues will meet or unite with a main flue or pipe connected to the ordinary smoke-pipe. By this arrangement of the spiral flues and base, a large heating surface is obtained, and a space formed for the admission and heating of cold air.

*Apparatus for Purifying Gas.* W. Wigston.

This invention consists in what is termed a scrubber, which is a float of wood or other material, of circular or other form, of sufficient buoyancy to float in the purifying liquor, with an interior cavity above the surface of the liquor, and with passages leading from the said cavity through its sides, and the gas enters through the inlet pipe which rises through the liquor, and opens into the cavity above its surface, escaping through the passages through the sides. These passages are so arranged that they are almost or entirely submerged, when there is no pressure of gas; but that when there is a pressure, the float will be raised so as to bring a small portion above the surface, to allow the escape of the gas in very thin streams, to produce a diffused contact with the fluid.

*Machines for Making Railroad Chairs.* R. Griffith.

*Claim.*—1. Hanging the fulcra of the clipping and bending levers eccentrically in boxes made capable of circular movement, for the purpose of adjusting the said levers to their work with facility and accuracy. 2. A method described of adjusting the angular set of the clipping and bending levers, by pivoting and adjustably connecting them to outer operative levers, essentially as set forth, and whereby a varied inclination may be given to the cutting and bending of the clip, to suit different thicknesses of blanks or forms of chair required.

*Magneto-Electric Machines.* C. Carpenter, jun.

This invention consists in the combination of one or more series of permanent magnets, radially arranged; the poles of each series being in one plane, and in two concentric circles, with a disc or discs of helices arranged in three sets, in such manner that the three sets may be acted upon successively, at nearly equal intervals of time; one set by the inner circle of poles, and the other two sets by the outer circle of poles; the currents of the several sets of helices being thrown into one constant or uninterrupted current by means of the current dischargers and springs, or theire quivalents.

*Metallic Piston-Packing.* Henry L. Russell.

This invention consists in expanding a number of metallic bands which encompass a drum, by means of levers secured in the periphery of the drum, and operated upon by a ring within the drum. The ring is prevented from casual movement by means of a coil-spring, ratchet and pawl, or their equivalents.

*Machine for Dressing Stone.* E. G. Matthews.

This invention relates, firstly, to arranging the driving-wheel and friction-wheel, forming the cutting apparatus, in the frame attached to the driving-rod, by means of which rod a reciprocating motion is imparted to the frame, which causes the driving-wheel to rotate backwards and forwards, on and over the heads of the cutter-stocks, thereby causing the cutters to make the desired cut in the stone; the friction-wheel, meanwhile, rolling on the periphery of the driving-wheel, and also in a groove in the cross-bar. Secondly, combining the rocking-bar, which has inclined planes at each end, with the cutter-stocks and roller, or its mechanical equivalent, attached to the frame of the driving apparatus, for the purpose of rolling or striking on the inclined planes of the bar as the driving-apparatus reaches the end of its stroke, so as to rock or tip the bar, thereby causing the inner edge of the bar to catch or stroke under the shoulders in the cutter-stocks, and raise them up in position for the driving-wheel to act upon them on its return-stroke.

*Machine Hammers.* D. Noyes.

This invention consists in a novel arrangement of mechanical contrivances for hammering or forging iron, whereby it can be brought into any desired shape or form much more expeditiously, and with greater regularity, than by any of the modes commonly practised in trip-hammers for the purpose. This result is effected by means of hammers which are so placed and actuated as to strike the iron to be shaped, both on the top and on the two sides; the upper hammer having motion imparted to it from a crank on the main driving-shaft, and the two side-hammers moving horizontally so as to strike the sides of the piece to be forged.

*Claims.*—1. A hammer for giving the blow upon the upper surface of the iron, acting in conjunction with two hammers, which simultaneously strike the sides of the iron; these two side-hammers operating as specified, whether in connection with the upper hammer or without it. 2. So arranging the relative position of the fulcra of the hammer-beams, and the ends of the connecting-rods attached to these beams, and to the crank-shaft and gears from which they derive their motion, as to bring the said fulcra and connecting-rods in nearly a straight line at the time of giving the blow for the purpose specified; the opposite ends of the connecting-rods just before giving the blow, moving in opposite directions, so as to give a rapid and powerful blow. 3. Causing the anvil to descend from the iron just before the blow of the side-hammers, and to ascend just before the blow of the upper-hammer, by means of a rod attached at one end to the under-side of the hammer-beam, and at the other to a tilting-arm which embraces the anvil.

## INSTITUTION OF CIVIL ENGINEERS.

*Jan.* 10.—JAMES SIMPSON, President, in the Chair.

THE proceedings of the evening were commenced by an Address from the President, on taking the chair for the first time after his election. After expressing his sense of the distinction conferred on him, by his election to the post of President, he embraced the opportunity of acknowledging the debt of gratitude he, in common with many other members of the profession, owed to the Institution of Civil Engineers, where they had first found a field for the exhibition of their talents, and had there formed the valuable and lasting friendships to which might be attributed the good feeling prevalent in the profession. He then alluded to the difficulties formerly experienced by young engineers, at the commencement of their career, chiefly from want of opportunity of contact with, and experience of the proceedings of the older practitioners; contrasting it with their present freedom of communication with the seniors at the meetings of the Institution, where all met on a footing of equality and with a predisposition to afford the aid or advice that might be requested.

He then gave a slight sketch of the professional career of his father, who entered the metropolis as a millwright in 1778, and before his decease had raised himself to eminence as a civil engineer, and was the coadjutor of Smeaton, Jessop, Watt, Rennie, Telford, and others. Under him Mr. James Simpson commenced his practical career, of which he gave a rapid outline. As a very old member of the Institution, having been elected in 1825, and chosen a Member of Council in 1826, he ventured to give some sound practical advice on the subject of agitation in societies.

He then gave a succinct account of the great engineering works in progress in India, Egypt, Sweden, Norway, Denmark, Canada, Australia, Cuba,—on the European continent generally, and Russia; chiefly under the direction of Members of the Institution. The maritime works on the Thames, the Tyne, the Severn, the Clyde, the Avon, &c.—the harbours and docks at Harwich; at Dover, at Guernsey, Jersey, Alderney, Portland, Holyhead, Plymouth, Leith, Hartlepool, and other places; the works at the Norfolk Estuary, the reconstruction of Bishop's Rock Lighthouse, and other important labours of civil engineers, were also noticed.

He also alluded to the subject of screw propulsion, and the valuable and hitherto unrewarded labours of Mr. F. P. Smith, as triumphantly demonstrated in the late naval review at Spithead, and the general adoption of the system for an improved class of steam and sailing vessels. The new system of propulsion invented by Ruthven, and introduced by Mr. Clark, for the Deep-Sea Fishing Company, was also mentioned.

The improvements in the supplies of gas and water, particularly of the latter, were noticed, in contradiction to assertions made "by authority" that little or no amelioration had taken place. A short history of the waterworks of the metropolis was given, to show that the extensions and ameliorations of filtering and high service had closely followed the facility for obtaining cast-iron pipes, in large quantities and at a reasonable rate; and that the improvement in steam-engines and pumping machinery had also produced corresponding advantages.

Attention was directed to the present state of the sewerage of cities and towns, and also that of the drainage of farm lands; for the former it was urged, that more had been done than was generally admitted, and for the latter, the partial steps hitherto taken were contended to be inefficient, unless the system was introduced on a larger scale, and extended to arterial and trunk drainage, and the improvement of the principal drains and watercourses in the low-lands.

The regulations for the prevention of the nuisance of smoke from steam and other boilers were noticed, and the various trials already made were examined.

The present general employment of members of the profession was alluded to with pleasure, as demonstrating that the science and practice of engineering had not experienced any check; and with a tender, to the junior members of the Society, of any advice or assistance in his power, the President concluded his address, which was unanimously voted to be printed and published with the minutes of proceedings.

*Jan.* 17.—The discussion was renewed on Mr. Harrison's Paper, "On the Drainage of the District, South of the Thames" (*ante* p. 35). After reviewing the objections to the proposed main sewer of 8 feet diameter, and its tributaries or feeders, it was explained that the general dimensions had not been assumed as fixed, but only as data to argue upon; the practical area, as well as the ultimate direction, remaining to be settled by more careful investigation. It might be preferable to construct two parallel sewers, to be used and cleansed by flushing, or otherwise, alternately; or used for fecal matter, or for rain water alternately.

As to cleansing, it was objected that the velocity of 1¼ mile per hour would be insufficient, and a scouring power of 3 miles per hour was demanded by one authority, whilst another stated that a sewer constructed on a dead level, on account of the difficulty of obtaining outfall, was effectually flushed by having gates at intervals of 1600 feet. At Eton, the main sewer was stated to be horizontal, but having a good supply of water constantly running through it no deposit occurred. The quantity of water that could be brought to bear on the Lambeth main-sewer being unlimited, and used at each tide, it was argued that the velocity of 1¼ mile per hour would suffice to keep it clear.

The plan of the double reservoirs for the discharge of the sewage into the Thames would obviate any objections. One reservoir would be filled at low water, to that level, from the river, ready to receive the sewage; the other would be filled with the sewage, to a height of 2 feet to 6 feet above that level; into this latter, as the tide rose, the water would be admitted, the gates at the upper end being closed; at the turn of the tide, the lower gates being opened, the contents of the reservoir would be permitted to flow freely out, carrying away the whole of the sewage matter accumulated during the past 12½ hours, and commencing its exit at the turn of the top of the tide, the matter would never return to within half-a-mile of the spot whence it started. The capacity of the reservoirs being regulated accordingly, there would be no objection to discharging at low water in cases of heavy rain, as then both reservoirs would be used simultaneously for receiving the well-diluted sewage.

Even admitting certain valid objections to a flushing system, it was agreed to be more simple and quite as effectual as the pumping system, whilst it was decidedly more economical and less liable to derangement.

Allusion was made to the present comparative levels of the River Thames and the Lambeth district, and it was suggested whether the bed of the Thames, like that of the Mississippi, the Po, the Arno, and other streams, had not been artificially raised by alluvial deposit; and if so, whether a certain extent of embanking of the shores, so as to restrict the channel, without too much reducing the area for flood waters, would not deepen the centre, and afford a better outfall for the sewers at any given point.

Instances of the employment of the liquid sewage for agricultural purposes were mentioned, and it was urged that the introduction of water supply for habitations should always be followed by utilising the sewage from them, and that thus a valuable interchange might be established. To this it was replied that the comparative value of the rental of agricultural land and of that of the same area covered with buildings would show, that no parallel existed between the water supply to houses and that of pumping liquid manure for agricultural purposes, and that the schemes for that purpose were, with few exceptions, fallacious.

As to the general question of the drainage of London, it was argued, that with a good system of intercepting sewers, the gravitation plan could be adopted for the upper districts on both sides of the river, and on the north side, the whole sewage might be so disposed of; but on the south side, on account of the deficiency of fall, it would probably be necessary to resort to a system of pumping the low sewage, at some point, say at Deptford Creek, and there lifting it to such a height as to give the requisite fall from thence, by a sewer, into reservoirs, as proposed by Mr. Harrison, whence the matter should be delivered into the river, without any deodorising, at a point low down at the first turn of the tide from high water, so as to preclude the possibility of any pollution of the stream above the point of the admission of the sewage. It was contended, that the same skill by which steam power was enabled to be continuously used for long sea voyages, could preclude any but very remote chance of casualty from a derangement of the pumping apparatus, and that in the cases of excessive rainfall, flooding might be prevented by permitting the present outfalls into the river to be used.

As to the general question of deodorising, it was argued, that like the employment of the diluted sewage for agricultural purposes, the schemes might be feasible for small towns, but that the immense quantity proceeding from such an area of houses as in London, appeared at present to preclude the general adoption of the system.

Up to the present time, it appeared that all the plans proposed for the drainage of the southern district were defective in providing capacity of main sewers for conveying away the excessive rainfall, the amount of which was quoted to the meeting from returns supplied from the Royal Observatory at Greenwich.

It was shown, that at present, when a heavy rainfall occurred simultaneously with a high tide, the districts by the York-road and along the river side down to Bermondsey and lower down, were flooded from the river which flowed over the surface and down the gullies into the rivers, whence it flooded the houses. Therefore a greater pumping power would be required than had been mentioned, if the habitations were to be guaranteed from casualty, as they should be under a new and expensive system. It was contended, that the outfall should be extended even below Greenwich, as any system of sewerage for the southern districts should be permanent, and allow for any amount of extension of buildings to the eastward.

It was hoped that the facts elicited by the discussion would be found serviceable in determining the ultimate system to be adopted, and that special care would be taken to avoid the fallacies, which it was contended had been promulgated in some of the documents emanating, "by authority," from the General Board of Health; particularly in the "Minutes of information, collected with reference to works for the removal of soil water, or drainage of dwelling-houses, public edifices, etc." (1852.) Numerous errors, both of theory and practice, contained in those documents, were pointed out; and it was contended, that they set at nought all the received laws of hydraulics, the formulæ of De Buat and other experimenters of acknowledged scientific skill, and even the "Principia" of Newton, and only substituted fallacies for those rules which had hitherto formed the basis of the best practice. The tendency of such publications was contended to be very mischievous, and it was incumbent on practical engineers to furnish an antidote, by a careful examination of the published statements and an exposition of the errors; this was undertaken to be done, and was promised to be laid before an early meeting of the Institution.

Specimens were exhibited of Mr. Austin's *perforated bricks and blocks*, with dovetailed joints, for straight work and for circular or oval culverts; their merit was stated to consist in imparting great strength and solidity to the work, with the parallel joints, using less mortar, or cement, and enabling great speed to be employed in laying the blocks. The larger perforations were stated to be intended for ventilation, for channels for warmed air, or for passing holding-down bolts where the bricks were used instead of stone, for masses to resist impact or strain.

A simple and effective trough, with a cover, for containing the underground wires of the electric telegraph, was also on the table, and in the ante-room there were several ingenious sewer-grate traps, and other accessories for sewerage works, the invention of Mr. Austin and of Mr. Jennings.

*Jan.* 24.—On the reading of the abstract of the proceedings of the last meeting, regret was expressed that any remarks on the experiments published in the "Blue Books" emanating from the Board of Health, should have, apparently, been considered to have a personal application; nothing could have been more opposed to the intentions of the speakers, and they were convinced that if the authors of the "Blue Books" had consulted the engineer alluded to, the necessity for making the remarks would not have existed. This view was confirmed by the published results of an experiment, on a large scale, made under the direction of an engineer of the Board, so recently as December 16th 1853, at Alnwick. The line of earthenware pipe was 770 yards long, 18 inches diameter, and lying at an inclination of 1 in 400, with a square culvert 20 × 20 inches leading from a flushing chamber and stop-gate adjoining the weir from the river. In the first experiment the sluice was only sufficiently elevated to fill the pipe, when the results were:—

Velocity 3·581 feet per second, or 2·441 miles per hour.

Discharge 2367·78 gallons per minute, or 3,409,603 gallons per day of 24 hours.

Depth at delivery end 12½ inches.

In the second experiment the sluice was entirely taken out, causing the water to accumulate to a depth of 13 inches above the top of the pipe; when the results were:—

Velocity 3·915 feet per second, or 2·67 miles per hour.

Discharge 2588·04 gallons per minute, or 3,726,777 gallons per day of 24 hours.

Depth at delivery end 15 inches.

The second experiment gave the most decided results; the water being 13 inches above the top of the upper end of the pipe, and 3 inches below at the lower end; allowing for the hydraulic height due to the velocity, a working inclination was given of about 1 in 340; and assuming, in accordance with the received rules, the resistance to be as the square of the velocity, and, as a corollary, *cæteris paribus*, the velocity in pipes being as the square root of the mean hydraulic height —*i. e.*, as the square root of the diameter of circular pipes,—the velocity stated being about 235 feet per minute, and the real inclination being about 1 in 340, would, with these data, give for a pipe 6 inches diameter, at an inclination of 1 in 100, a velocity of 255 feet per minute.

According to the "Blue Books," the velocity stated from the original experiments of the Board of Health, at an inclination of 1 in 100, would be 325 feet per minute. The results of this experiment, in fact, coincided much nearer with those given by the formula, even as stated in the "Blue Book," than with the results of the pretended experiments therein.

For a similar pipe, with an inclination of 1 in 800, the velocity would be 88 feet per minute instead of 240 feet per minute, the formula giving a velocity of 75 feet per minute.

It was therefore contended, that whilst the recent experiments at Alnwick confirmed the accuracy of the results of the formula, they as clearly demonstrated the inaccuracy of the experiments and the erroneous deductions stated in the "Blue Book," which could not therefore be recieved as authority.

The Paper read was a *"Description of an improved Inclined Plane for conveying Boats to and from different Levels of a Canal."* By J. Leslie, M. Inst. C.E.

After alluding to the successful inclined plane, established by the author, at Blackhill, near Glasgow, on the Monkland Canal,* and describing the difficulties to be overcome, and the points essential for the good-working of such lifts, the paper proceeded to propound, as the simplest modification, in cases where there was a scarcity of water, and where vessels would bear being taken out of the water, to have two uniform inclined planes, descending each way, from a culminating point or summit placed at a suitable elevation above the water in the upper reach. Each of the inclines was cut down, for a distance from the

* See *Journal*, Vol. XV. 1852, p. 201, 270.

summit equal to the length of a carriage, fit to carry the largest boat, and a railway laid on a lower level in a segment of a circle vertically; the segment being traced from a centre so placed, that lines parallel to and equidistant from the inclined planes, should each be a tangent to the circle at a point half-way between their summit or apex, if produced, and the terminations of the segmental rails.

On this curved railway there was a lower or subsidiary carriage, running on a number of rollers; so as to have no friciton on the axles, and having straight rails and ratchets on its upper surface. When the lower carriage was at either end of the curved railway, its upper surface formed a direct continuation of one of the inclined planes; and being exactly one half of the length of the curved railway, the uppermost point of the rails fixed on the carriage coincided exactly with the apex of the two inclines.

The principal carriage with a boat on it was then run forward so as to stand on the lower carriage, by a rope attached to a drum on the shaft of the fixed engine, and was held in its place by palls dropping into the ratchets, when the lower carriage, with the travelling carriage and the boat on it, was moved forward by a wheel working in a rack under the lower carriage, which was thus made to traverse the apex or summit, and descended until the surface of the rails in the lower carriage and on the incline became identical, and the upper carriage was lowered into the water by the rope motion and the boat was allowed to float from it into the next reach of the canal.

This plan was first proposed for removing vessels from a small dock by the side of the Vistula, at Warsaw, so as to be out of the reach of floods and of ice, and whenever there was a scarcity of water for lockage, or for working caisson inclined planes, it was admitted to be a desirable modification.

In the discussion, after paying a just tribute to the ingenuity and skill of the author, it was admitted, that inclines of this nature were only applicable for certain exceptional situations; that in general it would be cheaper to pump up the water for lockage, using over again as it might be required, and that in general the competition between railways and canals had ended in the partial abandoning of the latter, in spite of all attempts to use steam propulsion and traction.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated August 13.*

1900. J Gwynne, Essex Wharf, Essex-street, Strand—Improvements in the preparation of a black powder from coal, and the application thereof to the manufacture of paints, blacking, and various other purposes.

*Dated August 29.*

2004. J. H. Johnson, Lincoln's-inn-fields—Improvements in the preparation and application of gluten. (A communication from F. Durand, Toulouse, France.)

*Dated October 18.*

2404. E. Rider, Coleman-street—Improvements in the manufacture or treatment of gutta-percha; being improvements upon the invention secured to him by letters patent dated the 20th July, 1852. (Partly a communication.)

*Dated October 25.*

2456. C. R. N. Palmer, Amwell, Hertford—Improved mode and apparatus for preventing accidents on railways (including improvements in signalising apparatus.)
2462. A. V. Newton, Chancery-lane—Improved construction of railroad carriage axle. (A communication.)

*Dated November 5.*

2576. J. Barlow and T. Settle, Bolton-le-Moors, Lancashire—Improvements in power-looms for weaving.

*Dated November 17.*

2667. W. Hunderwood, Handsworth, Staffordshire—Improvements in cooking-stoves.

*Dated November 21.*

2701. A. Parfitt, Newbury, Berks—Improvements in the construction of certain descriptions of vehicles.

*Dated November 22.*

2712. R. Adams, King William-street—Improvements in fire-arms.

*Dated November 25.*

2741. A. A. V. S. de Montferrier, Paris—Improvements in wheels for vehicles on common roads and railways.

*Dated November 28.*

2771. J. C. Ramsden, Bradford. York—Improvements in apparatus or the mechanism of looms for weaving a certain class of plaids, checks, and fancy woven fabrics.

*Dated November 29.*

2776. E. J. Hughes, Manchester—An improved method of purifying and concentrating the colouring matter of madder, munjeet, spent madder, or any preparations thereof, however they may be made.

*Dated December 1.*

2793. T. Garnett, Low-moor, near Clitheroe, and D. Adamson, Duckinfield—Improvements in generating steam and in consuming smoke.
2794. A. E. L. Bellford, Castle-street—Improvements in machinery for manufacturing horse-shoes. (A communication.)
2795. A. I. Jones, New Oxford-street—Improved cigar-light.
2796. J. Dilworth, Preston—Improvements in escape-valves and safety-valves.
2797. T. Hollinsworth and J. Hollinsworth, Winwick, near Warrington—Improvements applicable to alarm-whistles, to be used upon railways, or as signals where otherwise required.
2798. J. H. Johnson, Lincoln's-inn-fields—Improvements in the treatment or manufacture of caoutchouc. (A communication.)
2799. J. H. Johnson, Lincoln's-inn-fields—Certain applications of vulcanised india-rubber. (A communication.)

*Dated December 2.*

2800. J. Reilly, Manchester—Improvements in machinery or apparatus for tenoning mortising, and sawing wood, metal, or other materials.
2801. A. W. Callen, Peckham—Improved excavating and dredging machine. (A communication.)
2802. A. E. L. Bellford, Castle-street—Improvements in blocks for ships and other uses. (A communication.)
2803. H. Deacon, Widnes, and E. Leyland, St. Helen's—Improvements in apparatus for the manufacture or production of sulphuric acid.
2804. A. Brown, Glasgow—Improvements in metallic casks and other vessels.
2805. G. Williamson, Glasgow—Improvements in applying motive power.
2806. A. Bain, Paddington—An apparatus for damping paper and other substances, in order to prepare the same for the reception of labels, stamps, and other like articles coated with a gummy or adhesive matter.
2807. J. C. Wilson, Redford Flax Factory, Thornton, Kirkcaldy, N. B—Improvements in machinery for scutching flax, hemp, and other fibrous materials.
2808. G. Collier, Halifax—Improvements in looms for weaving.
2809. R. Reyburn, Greenock—Improvements in sugar refining.
2810. S. C. Lister, Bradford, Yorkshire—Improvements in combing wool, hair, cotton, and other fibrous materials.
2811. H. Bessemer, Baxter House, Old St. Pancras-road—Improvements in the manufacture and refining of sugar.
2812. J. Saunders, St. John's-wood—Improvements in the manufacture of rails for railways.

*Dated December 3.*

2813. C. E. Green, Blandford-street, Portman-square, and J. Bayliss, Parliament-street—Improvements in machinery to save persons and property in case of fire; which machinery may also be applied for the purpose of raising and lowering weights of any kind; also for the purpose of compression, and for other useful purposes.
2814. A. Rogers, Bradford, Yorkshire—Improvements in ventilating sewers, mines, or other subterranean works.
2815. C. Buck, Wellington—Improved apparatus for retarding or stopping the progress of wheel carriages.
2816. W. Dray, Swan-lane—Improvements in the construction of portable houses and buildings.
2817. J. Gwynne and J. E. A. Gwynne, Essex Wharf, Strand—Improvements in the manufacture of fuel; its preparation and applications for the reduction of ores, fusing and refining metals, cementation or making steel, and treating salts. (A communication.)
2818. H. J. Iliffe and J. Newman, Birmingham—Improvements in the construction of metallic bridges and other similar structures.

*Dated December 5.*

2820. S. Cheavin, Spalding—Double-action or belt filterer.
2821. B. Skillman, Crosby-hall Chambers—Improved mode of preparing sheets of paper suitable for postal communication.
2822. W. Simons, Glasgow—Improvements in propelling and steering vessels.
2823. M. A. Muir, Glasgow—Improvements in check and fancy weaving.
2824. J. Patterson, Beverley—Improvements in reaping-machines.
2825. T. Storey, Phœnix Foundry, Lancaster—Improvements in the construction and arrangement of apparatus employed in connection with sewers.
2826. J. Robertson, Kentish Town—Improvements in the consumption or prevention of smoke.

*Dated December 6.*

2828. E. Oldfield, Salford—Improvements in machinery for spinning and doubling.
2829. J. C. Haddan, Chelsea—Improvements in the manufacture of cartridges, and of wads or wadding for fire-arms.
2831. A. E. L. Bellford, Castle-street—The manufacture of an artificial tartaric acid, and the application of the same to useful purposes. (A communication.)
2832. G. Ross and J. Inglis, Arbroath—Improvements in looms.
2833. T. Mills, Leicester—Improvement in the manufacture of lined gloves.
2834. W. E. Gaine, Harewood-street—Improvement in treating or preparing paper.
2835. R. C. Witty, Portland-place, Wandsworth—Improvements in the construction of boiler and other furnaces.
2836. J. H. Johnson, Lincoln's-inn-fields—Improvements in printing oil-cloths and other fabrics. (A communication.)
2837. J. Bernard, Regent-street—Improvements in machinery or apparatus for stitching or uniting and ornamenting various materials.
2838. J. Hargrave, Kirkstall, Yorkshire—Improved apparatus for washing and scouring wool.
2839 A. V. Newton, Chancery-lane—Improvements in fire-arms and ordnance. (A communication.)

*Dated December 7.*

2840. W. Slater and R. Halliwell, Bolton-le-Moors—Improvements in machinery for spinning.
2841. L. H. Bates, Bradford, Yorkshire—Improvements in machinery for stamping and cutting metal nuts and other similar metal articles.
2843. J. Getty, Liverpool—Improvements applicable to the plating of iron ships; part of which improvements is also applicable to the construction of boilers.

*Dated December 8.*

2844. W. G. Reeve, Elizabeth-street, Eaton-square—An appendage to horseshoes, to supersede the necessity of roughing them, as hitherto practised.
2845. W. B. Adams, Adam-street, Adelphi—Improvements in railway wheels, their axles and boxes.
2846. W. T. Henley, St. John-street-road—Improvements in electric telegraphs.
2847. T. Morau, Dublin—Improved means or apparatus for the prevention of accidents on railways in certain cases.
2848. B. Solomons, Albemarle-street, Piccadilly — Improvements in telescopes and other glasses in their application to the measurement of distance.
2849. W. C. Jay, Regent-street—An improved cloak.
2850. J. Goddard and C. Yates, Tottenham-court-road—Improvements in machinery or apparatus for obtaining and applying motive power.
2851. J. Robinson, Denton Mill, Carlisle—Improvements in mills for grinding corn and other substances.
2852. J. Nelson and D. Boyle, Selby—Improvements in scutching flax and hemp.
2853. J. Beall, Cheshunt—Improvements in apparatus for applying sand to the rails of railways.
2854. W. E. Newton, Chancery-lane—Improved machinery for drilling or boring rocks and other hard substances. (A communication.)
2855. P. J. T. Bordone, Paris—Improvements in extracting and treating the juice of beetroot and other vegetables.
2856. M. G. Lavertet, Paris—Improved mode of treating photographic pictures.
2857. R. Murgatroyd, Bradford, Yorkshire—Improvements in washing or scouring wool and fabrics composed entirely or partly of that material.

*Dated December 9.*

2858. J. B. E. Ruttre, Paris—Improvements in machines for producing shoddy from woven fabrics, and for sorting the fibres of fibrous materials.
2859. P. M. Fouque, L. R. Hébert, and V. E. D. le Marneur, Paris—Improvements in rudders.
2860. A. James, Redditch — Improvements in counting, measuring, and weighing needles, and in preparing papers to receive the same.
2861. D. Christie and J. Cullen, Bromley—An atmospheric counterbalance slide-valve for the steam-engine, hydraulic, and all other machines in which the slide-valve is used or required.
2862. A. Shanks, Robert-street, Adelphi—Improvements in instruments and apparatus for indicating or measuring weights and pressures.

2863. C. Mackenzie, Bayswater, and A. Turnbull, Manchester-square—Machinery for paring fruit and vegetables.
2864. J. Winspear, Liverpool—Improved mode of coating metals, wood, stone, and plaster, to preserve them from decay.
2865. R. Eccles, Wigan, and J. Mason and L. Kabery, Rochdale—Improvements in slubbing and roving frames for cotton and other fibrous substances.
2866. J. Sutcliffe, Manchester—Improvements in steam-engines, and in apparatus connected therewith.
2867. F. Osbourn, Aldersgate-street—Improvements applicable to the distribution of manure.
2868. J. Chisholm, Holloway—Improvements in the distillation of organic substances, and in obtaining products therefrom.
2869. J. H. Johnson, Lincoln's-inn-fields—Improvements in portable cases for containing provisions. (A communication.)
2870. G. Morley, Birmingham—Ornamenting or producing pictures on japanned goods, panels, canvas, or other material, whereby a vast amount of artistic skill and labour is superseded.
2871. W. Schaeffer, Stanhope-terrace—Improvements in purifying spirit.
2872. J. Bourne, Port Glasgow—Improvements in steam-engines.
2873. J. Bourne, Port Glasgow—Improvements in machinery for the production of iron ships and other similar structures.
2874. J. Bourne, Port Glasgow—Improvements in the construction of iron ships.
2875. H. Bessemer, Baxter House, Old St. Pancras-road—Improvements in the construction of railway axles and breaks.

*Dated December* 10

2876. A. Macpherson, Brussels—Improvements in disinfecting sewers or other drains or depositories of fetid matters or gases, and in converting the contents thereof to useful purposes.
2877. W. Muir, Brittannia Works, Manchester—Improvements in machinery and apparatus for cutting out parts of garments.
2878. C. Coates, Sunnyside—Improvements in and applicable to looms for weaving.
2879. H. L. Du Bost, Rue Neuve des Petits Champs, Paris—Improvements in the construction of locks and keys.
2881. J. H. Johnson, Lincoln's-inn-fields—Improvements in furnaces for the manufacture of steel. (A communication.)
2882. E. Green, Wakefield—Improvements in boilers and furnaces.
2883. N. V. Guibert, Paris—Improvements in forge-hammers.
2884. W. Thornley, Clayton West, Yorkshire—Improved manufacture of woven fabrics.

*Dated December* 12.

2885. E. O. W. Whitehouse, Brighton—Improvements in effecting telegraphic communications.
2886. T. Hollinsworth, Winwick, near Warrington—Improvements in the method of applying breaks to carriages employed upon railways, and in the machinery or apparatus connected therewith.
2887. W. Evans. Myrtle-street, Hoxton—Improvements in obtaining and applying motive power.

*Dated December* 13.

2888. W. Redgrave, Croxley-green, Rickmansworth—Improved safety travelling-cap.
2889. G. K. Hannay, Ulverston—The combination and manufacture of composition grinding-wheels, hones, and other grinding bodies.
2890. J. Wansbrough, the Grove, Southwark—Improvements in the manufacture of waterproof fabrics.
2891. W. F. Plummer, St. Mary's Overy Wharf, Southwark—Improved machinery for grinding or crushing animal, vegetable, and mineral substances.
2892. C. Schiele, Oldham—Improvements in preventing undue oscillation in engines, machinery, carriages, and other apparatus.
2893. A. G. Gueedron, Montmartre—Improvement in or addition to sugar-basins.
2894. A. G. Gueedron, Montmartre—Method of producing plans in relievo.

*Dated December* 14.

2895. P. Grant, Manchester—Improvements in printing-presses.
2896. F. A. Gatty and E. Kopp, Accrington—Improvements in printing and dyeing cotton, wool, silk, and other fibrous substances.
2897. J. A. Coffey, Providence-row, Finsbury—Improved method of evaporating liquids.
2898. E. Beanes, Charlotte-street, Portland-place—Improvements in the manufacture and refining of sugar.
2899. J. Z. Kay, Dundee—Improvements in gas-meters.
2900. B. Fullwood, Abbey-street, Bermondsey—Improvements in the manufactuure of cement.
2901. J. Wibberley, Eagley, near Bolton—Improvements in machinery or apparatus for winding yarns or threads on to spools or bobbins.
2902. R. J. N. King, Exeter—Improved artificial bait for fish.
2903. R. Parrock, Glasgow—Improvements in coats and similar articles of dress.
2904. W. B. Johnson, Manchester—Improvements in machinery or apparatus for making bricks and other articles from clay and other plastic materials.

*Dated December* 15.

2905. E. H. Rascol, Catherine-street, Strand—Improvements in retorts for the manufacture of gas. (A communication.)
2906. S. Messenger, Birmingham—Improvement or improvements in railway, ship, and carriage lamps.
2907. T. Pugh and W. Kennard, King-street, Snow-hill—Improvements in locks and latch-spindles.
2908. J. B. Howell and J. Shortridge, Sheffield—Improvement or improvements in the helves of tilt-hammers.
2909. J. P. H. Vivien, Paris—Improvements in the manufacture of paper and pasteboard.
2910. A. E. L. Bellford, Castle-street, Holborn—Improvement in blasting powder, for mining, and other operations of a similar nature. (A communication.)
2912. J. B. Pascal, Lyons—Improvements in obtaining motive power.
2913. F. W. Branston, Oak-tree House, Clapham—Improvements in certain tablets, labels, and signs, or their surfaces exhibiting letters and designs.
2914. C. J. Morris, Kirby-street, Hatton-garden—Improvements in bookbinding.
2915. B. Whitaker, Brighton—Improvements in the manufacture or production of useful toys.
2916. A. Cochran, Kirkton Bleach Works, Renfrew—Improvements in the application of starch or other substances of a similar nature to woven fabrics, and in the machinery or apparatus employed therein.
2917. F. D. Gibory, Paris—Improvements in instruments for ascertaining heights and distances, and for levelling.
2918. A. B. S. Redford, Albion-place, Walworth-road, and Thomas Cloake, Saville-row, Walworth-road—Improvements in retarding and stopping the progress of railway carriages.

*Dated December* 16.

2919. W. Binnion, Birmingham—Improvements in carriage and other lamps.
2920. W. G. Whitehead, Birmingham—Improvement or improvements in hats, caps, bonnets, and other coverings for the head.
2921. W. Tranter, Birmingham—Improvements in fire-arms, and in bullets and waddings to be used therewith.
2922. A. Limousin, Paris—Improvements in looms for weaving pile fabrics, and in a mode and apparatus for cutting the pile.
2923. A. Médail, Paris—Improved hydraulic machine.
2924. T. Williams, South Castle-street, Liverpool—Improved revolving pistol.
2925. T. S. Truss, Cannon-street—Improvements in breaks for railway carriages and other vehicles.
2926. T. S. Truss, Cannon-street—Improvements in apparatus for communicating between the engine-driver and the guard of railway trains.
2927. J. H. Johnson, Lincoln's-inn-fields—Improvements in dyeing. (A communication from M. Bellancourt, Rheims.)
2928. J. H. Johnson, Lincoln's-inn-fields—Improvements in the treatment or preparation of wool, and of the wash-waters employed in such treatment. (A communication from Messrs. Villermet and Manheimer, Paris.)
2929. S. Norris, New Peter-street, Horseferry-road—Improvements in lighting and extinguishing gas-lamps.
2930. S. Smith, Horton Dye Works, Bradford—Improvements in preparing rovings and yarns of wool.
2931. A. Parkes, Birmingham—Improvements in separating silver from its ores or other compounds.
2932. R. B. Hall, Whitecross-street—Improvements in crushing and grinding quartz, minerals, and other matters.
2934. A. L. Knox, Glasgow—Improvements in ornamenting certain descriptions of textile fabrics.
2935. J. Thompson, Clitheroe—Improvements in machinery or apparatus for stretching textile fabrics as they are wound into laps or rolls. after the processes of bleaching and dyeing, or operations connected therewith.
2936. R. W. Walthman, Bentham House, York—Improvements in belts or bands for driving machinery for use in mines, and for other purposes.

*Dated December* 17.

2937. J. S. Bailey, Keighley, York—Improvements in machinery for operating upon wool, alpaca, mohair, and other fibrous materials, preparatory and prior to being spun.
2938. J. Horton, Birmingham—Improvements in the manufacture of certain kinds of metallic vessels.
2939. G. Anderson, Gas Works, Rotherhithe—Improvements in apparatus used when manufacturing gas, which apparatus or part of which is also applicable when transmitting gas from one place to another.
2940. C. Bedells, Leicester—Improvements in the manufacture of elastic fabrics.
2941. J. D. M. Stirling, Larches, near Birmingham—Improvements in the manufacture of iron.
2942. J. Greenwood, Arthur-street West, London-bridge—Improvements in preventing draughts of air into rooms and places when the doors and windows are shut.
2943. I. James, Cheltenham—Improvements in carts for distributing water or liquid manure.
2944. M. P. Houghton and A. Stewart, Hillmorton—Improved means of preventing accidents on railways.
2946. R. Whewell, Little Bolton, Lancaster—Improvements in machines used for cutting paper.

*Dated December* 19.

2947. H. Milward, Redditch—New or improved machinery for manufacturing needles and fish-hooks. (A communication.)
2948. J. Tribelhorn, St. Gall, and P. Bolley, Aarau, Switzerland—Improvements in the process of bleaching vegetable fibrous substances. (A communication from C. Custer, Alstaetten, Switzerland.)
2949. A. E. L. Bellford, Castle-street, Holborn—Improvements in paddle-wheels for propelling vessels. (A communication.)
2950. W. Crossby, Devonshire-street, Sheffield—The ventilation of granaries, store-houses, or places of deposit for grain whatsoever, and for improvements in the grinding of grain and dressing of grist, and grinding generally.
2951. A. E. L. Bellford, Castle-street, Holborn—Improvements in presses for expressing oil or other fluids from fruits, grains, or other substances. (A communication.)
2952. R. Waygood, Newington-causeway—Improvements in portable forges.
2953. D. Goldthorp, Cleckheaton, near Leeds—Improved propeller.

*Dated December* 20.

2954. A. Paterson, Westminster—Improved cooking apparatus.
2955. J. H. Campbell, King's Arm's-yard, Coleman-street—Improvement in machinery for cutting corks.
2956. J. L. Clark, Chester-villas, Islington—Improvement in insulating wire used for electric telegraphs, with a view to obviate the effects of return or inductive currents.
2957. H. E. F. de Gergy Veuve Durut, Paris—Improvements in the manufacture of bread.
2958. P. Wagenmann, Bonn, Rhenish Prussia—Improvements in the manufacture of liquid hydro-carbons and paraffine.
2959. J. Boydell, Gloucester-crescent—Improvements in the manufacture of wrought-iron frames.
2960. E. M. F. Lemaire, Rue Drouot, Paris—Improvements in tanning.
2961. J. Webster, Cornwall-road, Stamford-street—Improvements in acting on drying oils and preparing varnishes.
2962. J. Burrows, Haigh Foundry, near Wigan—Improvements in the formation of such metallic plates as are required to be conjoined by riveting or other similar fastening.
2963. J. Burrows, Haigh Foundry, near Wigan—Improvements in the construction of steam-boilers or generators, and in the arrangement of furnaces connected therewith.
2965. R. B. Huygens, Holland—Improvements in machinery for crushing, washing, and amalgamating gold and other ores and substances.

*Dated December* 21.

2966. G. Boccius, Hammersmith—Apparatus adapted to the breeding and rearing of fish.
2967. C. J. Farrington, Hampstead—Improvements in signalling and preventing collisions on railways by electrical communication.
2968. H. Kohnstamm, Union-court, Old Broad-street—Improvements in the manufacture of imitation leather.
2969. T. V. Lee, Lockyer-terrace Plymouth—Improvements in the construction of certain machinery and apparatus for the manufacture of bricks and tiles.
2970. J. Dining and W. Inglis, Southampton—Improved apparatus for purifying and filtering residuous water.
2972. J. Jones, Glasgow—Improvements in governors or regulators for steam-engines and other machinery.

*Dated December* 22.

2973. J. Youil, Burton-upon-Trent—Improvements in the mode or method of obtaining power to raise liquids, and of treating the said liquids when raised, and of using them to obtain additional power.
2974. L. A. F. Besnard, Paris—A new system of painting, by means of lithography, without leaving a particle of paper upon the canvas.
2975. P. A. L. de Fontainemorean, South-street, Finsbury—Improvements in constructing and applying connecting-rods. (A communication.)
2976. W. H. Woodhouse, Parliament-street, Westminster—Improvements in the construction of roads, ways, and ducts.
2977. C. Lewis, Hull—Improved lamp for signalling.
2978. B. Murgatroyd, Bradford, York—Improvements in washing or scouring wool, alpaca, and mohair, and fabrics composed entirely or partly of those materials.

2979. T. Berry, Rochdale, J. Mangnall, and J. Chadwick, Heywood—Improvements in winding and twisting wool, cotton, and other fibrous materials.
2980. J. Gibbons, jun., Wolverhampton—Improvements in locks and latches.
2981. J. Shaw, Hatton-garden—Improvements in pianofortes. (A communication.)

*Dated December 23.*

2982. J. Gillow, jun., Northwich, Chester—Improvements in the manufacture of salt.
2983. J. Britten, Birmingham—Improvements in girders, bridges, roofs, and other such like structures.
2984. J. O'Neil, Bury, Lancaster—Improvement in apparatus for drawing condensed steam and air from pipes or other chambers in which steam is used.
2985. F. Bennock, Wood-street, Cheapside—Improvements in coating silk and other yarn or thread with gold or other metal. (A communication.)
2986. J. D. Pfeiffer, Paris—Improvements in machinery or apparatus for cutting paper and similar material.

*Dated December 24.*

2987. R. G. Coles, Cheltenham—Improvements in the locks of fire-arms.
2988. J. Gaulter, Paris—Improved apparatus for washing and bleaching.
2989. G. Goutaret, Paris—A new system of propulsion.
2990. J. Margerison, Preston—Improvements in railway-breaks.
2991. H. Hardinge, New York—Manufacturing liquid quartz or silex, to be used in the manufacture of certain compositions for ornamental and useful purposes.
2992. G. A. Buchholz, Gould-square, Crutchedfriars—Improved machinery for the cleaning and hulling or dressing of rice, wheat, and other grain.
2993. J. Lewis, Salford—Improvements in apparatus for drilling or boring metals and other substances.
2994. T. Cooper, Leeds—An improvement applicable to the binding of ledgers and other books.

*Dated December 27.*

2995. T. W. Makin, Manchester—Improvements in machinery or apparatus for finishing woven fabrics.
2997. F. C. Calvert, Manchester—Improvements in the treatment of naphthas and other volatile hydro-carbons, and in the application of the same to various useful purposes. (A communication.)
2988. G. J. Mackelcan, Lechlade, Gloucester—Improvements in winnowing or corn-dressing machines.
2999. S. Sedgwick and T. Dawson, Piccadilly—Improvements in the moderator-lamp, or in lamps of a similar principle.
3000. T. S. Prideaux, St. John's-wood—Improvements in apparatus for regulating the supply of air to furnaces, and for preventing radiation of heat from fire-doors and other parts of the fronts of furnaces.
3001. T. Molyneaux, Manchester—Improvements in winding and doubling silks; a part of which improvement is applicable to the treatment of other fibrous substances.

*Dated December 28.*

3002. J. Parkinson, Bury, Lancaster—Improvements in governors for regulating the pressure of steam, gas, and other fluids or liquids.
3003. J. Moffat, Heiton, Scotland—Improvements in the means of communication between the guard and the engine-driver in a railway train.
3004. J. Taylor, Britannia Works, Birkenhead—Improvements in raising and lowering weights.
3005. W. U. Coates, Ombersley, Worcester—A new or improved rotary steam-engine.
3006. J. Alexis, Avignon, France—Improved railway-break.
3007. R. Green, Flint Glass Works, Brettell-lane, Stafford—Improvements in insulators for insulating the wires or rods employed for conducting or transmitting electricity.
3008. J. Macintosh, Pall-Mall East—Improvement in discharging projectiles.
3009. J. Barnes, Church, Lancaster—Improvement or improvements in dyeing and cleansing cotton, silk, wool, and other fabrics.
3010. Francis Parker, Northampton—Improvement in the manufacture of gaiters.
3012. D. M'Nee, Hillfield, Dumbarton, and A. Broadfoot, Ingram-street, Glasgow—Improvements in printing with colours on cloth; which are also applicable to printing ornamental designs on paper or other surfaces.
3013. T. Phillips, jun., Sparkbrook, and S. Phillips, Birmingham—Improvements in the construction of window-shutters; which improvements are also applicable as an additional security for doors and other similar openings.

*Dated December 29.*

3014. H. Jackson, High-street, Poplar—Improvements in machinery for moulding bricks and other articles of brick-earth.
3015. E. Estivant, Givet, France—Improvements in the manufacture of tubes of copper and its alloys.
3016. M. Phillips, Birmingham—Improvement or improvements in metallic revolving or winding shutters. (A communication from her late husband.)
3017. A. F. Rémond, Birmingham—New or improved metallic tubes.
3018. J. White, East-street, Red Lion-square—Improvements in friction-joints or fastenings.
3020. C. A. Roux, Belleville, near Paris—Improvements in printing warps of cut pile and similar fabrics.
3021. H. C. Vion, Paris—Improvements in pistons and stuffing-boxes of engines moved by water, steam, or gas.
3022. A. V. Newton, Chancery-lane—Improvements in the manufacture of screws. (A communication.)

*Dated December 30.*

3025. B. Swire, of Ashton-under-Lyne—Improvements in machinery or apparatus for making metal tips for shoes and clogs.
3026. H. C. C. de Ruolz and A. de Fontenay, Paris—An improved metallic alloy.
3027. J. Marlor, Oldham, Lancaster—Improvements in ascending and descending mines and shafts, and in the apparatus connected therewith, by which said improvements the ventilation of mines is increased.
3028. W. Mabon, Ardwick Iron Works, Manchester—Improvements in machines used for riveting together metallic plates.

*Dated December 31.*

3029. I. Holroyd, Sowerby-bridge, York—Improvements in apparatus employed in singeing textile fabrics.
3030. J. Milner, Stratford, Essex—Improvements in connecting the rails of railways.
3031. H. V. Physick, North-bank, Regent's-park—Improvements in electric telegraphs, and in apparatus connected therewith.
3033. J. Pym, Pimlico—Improvements in machinery for grinding auriferous and other ores, and separating the metal therefrom.
3034. W. Tuxford, Boston, Lincoln—Improvements in portable thrashing-machines; part of which improvements is also applicable to fixed thrashing-machines.
3035. A. Trueman, Swansea, and I. Baggs, London—Improvements in grinding, amalgamating, and washing quartz and other matters containing gold.
3036. R. Waygood, Newington-causeway—Improvements in portable forges.
3037. J. Holbrey, Bradford, York—Improved machinery for combing wool and other fibrous materials.
3038. J. Slater, Salford, Lancaster—Improvements in cocks, taps, or valves.
3040. T. Brown and P. Macgregor, Manchester—Improvements in power-looms for weaving.
3041. A. Oppenheimer, Manchester—Improvements in the manufacture of silk-velvet and other such piled goods or fabrics.
3042. B. Hunt, Brighton—Improvements in obtaining and applying motive power.
3043. P. Sonntag, Paris—Improved apparatus for measuring and fitting garments of persons.
3044. F. A. Clerville, Paris—Improvement in the construction of fire-arms.
3045. S. T. M. Sorel, Paris—Improved compositions to be employed as substitutes for caoutchouc, gutta-percha, and certain fatty bodies.

*Dated January 2, 1854.*

1. C. H. Collette, Lincoln's-inn-fields—Improvements in the manufacture of sugar. (A communication.)
2. E. D. Smith, Hertford-street, May-fair—A mode of communication between the passengers, guards, and engineer of a railway train.
3. A. Dawson, Barne's-place, Steyney—Converting small coal or coal-dust, or small coal and coke into solid blocks of fuel.
4. J. Gowans, Edinburgh—Improvements in apparatus for heating and ventilating, and in baths and washing apparatus connected therewith, applicable to dwelling-houses.
5. P. A. Montel, Paris—Improvements in stopping the trains on railways.
6. P. A. de Fontainemoreau, South-street, Finsbury—Improvements in dyeing wool. (A communication.)
7. P. A. L. de Fontainemoreau, South-street, Finsbury—Improvements in water-wheels. (A communication.)

*Dated January 3.*

8. H. L. Corlett, Summer-hill, Dublin—Improvements in caoutchouc springs for locomotive engines and tenders, railway carriages, and wagons.
9. J. Madeley, Walsall, Stafford—Improvement or improvements in the manufacture of certain kinds of tubes, and in nuts for the heads of screws.
10. D. Kennedy, Reading, U. S.—Invention for the use of tanners, being certain compositions of matter to be used in the manufacture of leather.
11. J. Strovold, Barnes, Surrey—Improvements in machinery or apparatus for sifting and washing gravel or other similar substances.
12. F. A. T. de Beauregard, Paris—Improvements in drying cigars and ligneous materials or other substances.
13. E. J. Wilson, Oxford-street—Improved method of making portfolios, music-books, brief-cases, and pocket-books.
14. J. Collins, St. Ann-street, Liverpool—Improvements in the manufacture of vinegar.
15. J. I. Grylls, Murton-street, Sunderland—Improvements in whelps for the barrels of capstans, windlasses, and other machinery.
16. T. Mann, Horsham, Sussex—Improved cinder-sifting shovel.
18. J. Dransfield and W. Robinson, Oldham, Lancaster—Improvements in carding-engines for carding cotton, wool, and other fibrous substances.

*Dated January 4.*

19. D. Hulett, High Holborn—Improvements in gas-regulators for regulating the supply of gas to the burner.
20. J. Taylor, M. Wrigley, and S. Greaves, Oldham, Lancaster—Improvements in carding-engines for carding cotton, wool, and other fibrous substances.

*Dated January 5.*

21. J. Liddiard, Deptford, Kent—Improvements in the construction of furnaces, with a view to the prevention of smoke.
22. E. Schishkar and F. C. Calvert, Manchester—Improvements in dyeing and printing textile fabrics and yarns.
23. B. White, Newcastle-upon-Tyne—Improvements in the manufacture of waterproof fabrics, and of waterproof bags and other like articles.
24. J. H. Johnson, Lincoln's-inn-fields—Improvements in ventilating carriages and buildings; part or parts of such improvements being applicable to the obtainment of motive power. (A communication from J. Chillcott and G. Palmer, Brooklyn, U. S.
25. W. Rigby, Glasgow—Improvements in steam-hammers and pile-driving machinery.
26. L. J. Pomme, Paris—Improvements in reducing the friction of axles and axletrees of carriages.
28. A. V. Newton, Chancery-lane—Improved machinery for crushing or grinding and washing and amalgamating quartz, rock, and other substances. (A communication.)

*Dated January 6.*

29. I. Pearse, Cawsand, Cornwall—Improvements in means for navigating ships or other vessels.
30. H. H. Edwards, Ludgate-hill—Improvements in treating peat and vegetable matters for the purpose of fuel, as well as in the extraction of other useful products therefrom. (Partly a communication.)
31. R. Tait, Glasgow—Improvements in the manufacture or production of ornamental fabrics.
32. J. Radcliffe, Stockport, Chester—Improvements in power-looms for weaving.
33. J. Healey, Bolton-le-Moors, Lancaster—Improvements in spinning-machines known as mules, and in machines of similar character. (A communication from A. Peynaud and E. Paynaud, Charleval, France.)
34. M Poole, Avenue-road, Regent's-park—Improvements in the manufacture of dextrine, glucose, and alcohol, and in employing the products of such manufacture. (A communication.)
35. J. D. M. Stirling, Larches, Birmingham—Improvements in the manufacture of iron.
36. A. V. Newton, Chancery-lane—Improvements in the construction of motive-power engines; part of which improvements is also applicable to the packing of pistons generally. (A communication.)

*Dated January 7.*

38. W. E. Newton, Chancery-lane—Improved machinery for dyeing, washing, and bleaching fabrics. (A communication.)
42. N. M. Caralli, Glasgow—Improvements in the manufacture or production of ornamental fabrics.
44. H. S. Edwards, Paris—Improvements in preparing textile fabrics or materials for the purpose of their better retaining colours applied to them. (A communication.)

*Dated January 9.*

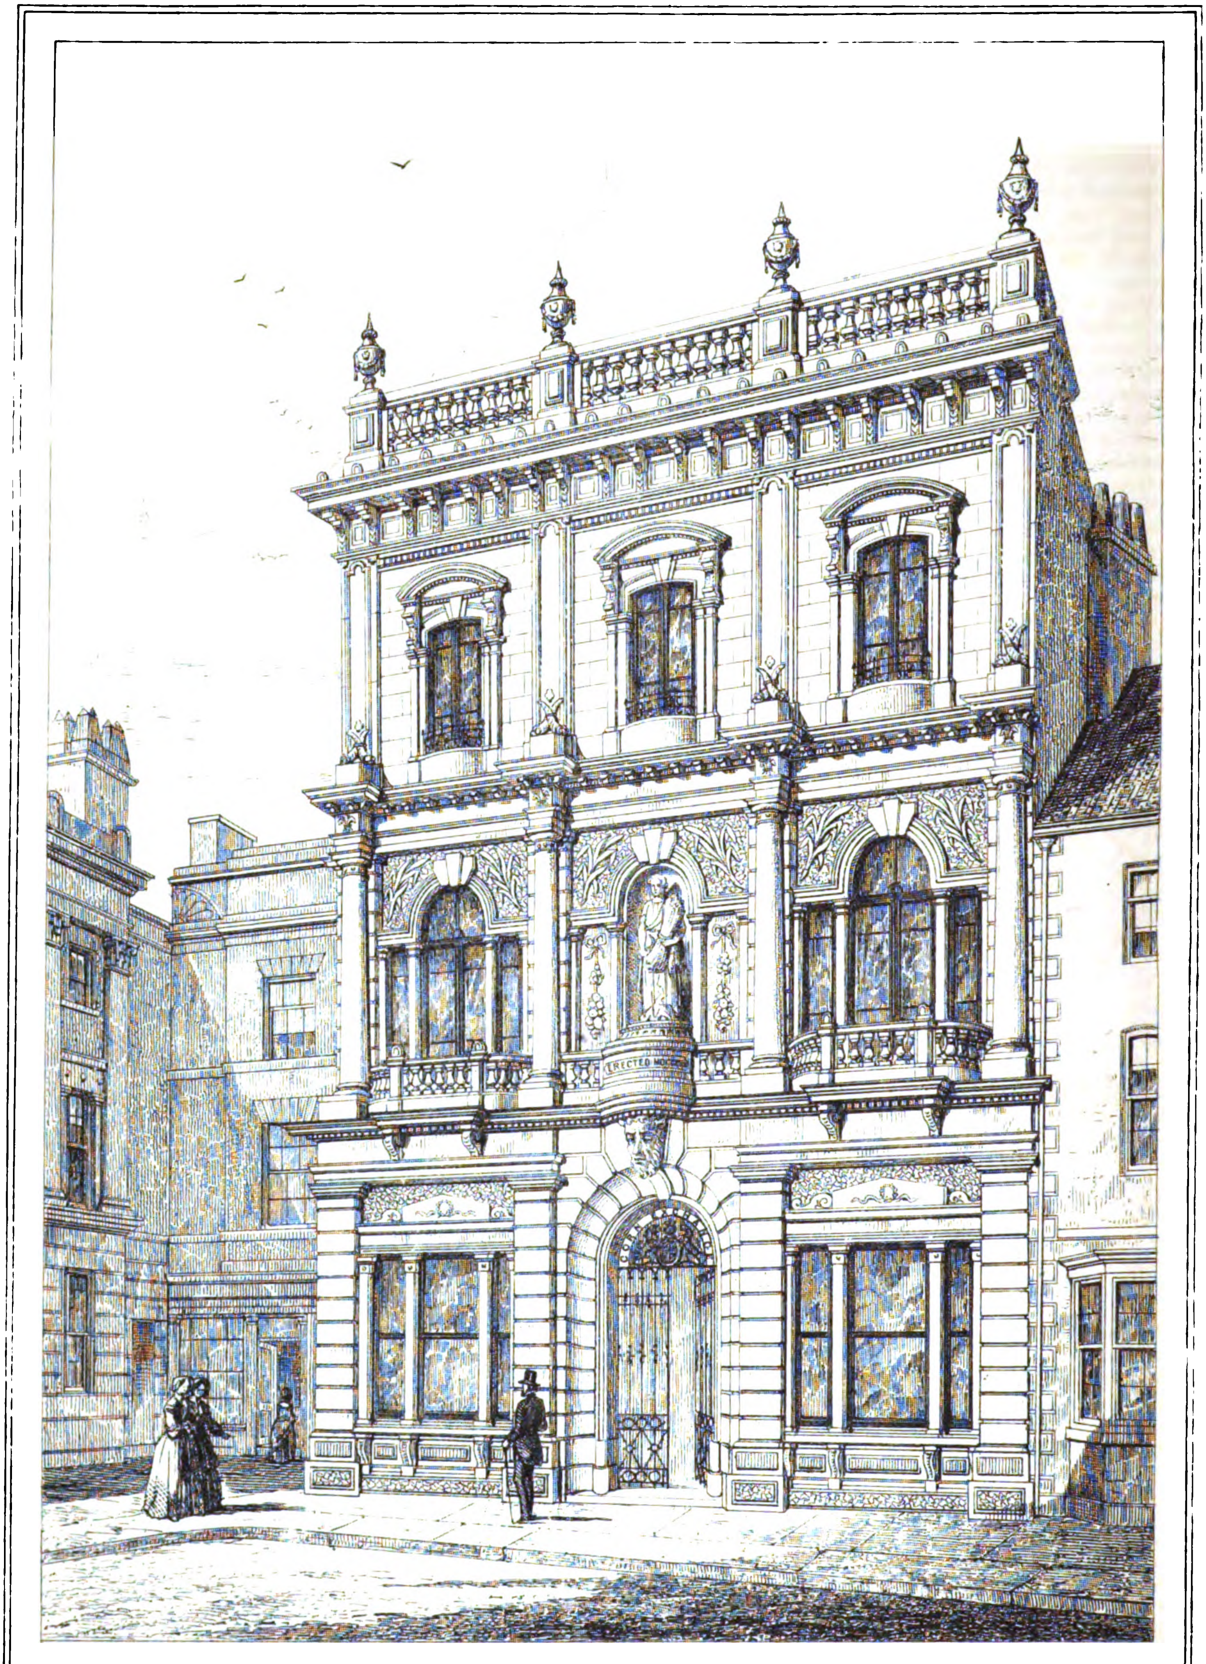
46. Z. Pettitt, Fordham, near Colchester—Improvements in thrashing-machines.
48. R. Husband, Manchester—Improvrments in the method of ventilating hats or other coverings for the head.
50. R. Howson, Manchester—Improvements in screw-propellers.

*Dated January 10.*

52. E. Tyer, Rhodes-terrace, Dalston—Improvements in giving signals on railways by electricity, and in instruments and apparatus connected therewith.
54. A. M. E. Boyer, E. Ducros, and O. Verdeau, Paris—Improved compounds to be used in dyeing.
56. Rev. W. R. Bowditch, Wakefield—Improvements in the purification of gas, and in the application of the materials to be employed therein.
58. A. Mitchell, Belfast—Improvements in propelling vessels.
60. A. Drevelle, Halifax—A new combing-machine, suitable for any textile or fibrous matter. (A communication from A. Morel, Roubaix, France.)

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

3032. C. G. Schönheerr, Chemnitz, Saxony—Improvements in bobbin-machines. — Dec. 30.



J. R. Jobbins

PERSPECTIVE VIEW OF THE NEW CORN EXCHANGE, LOUTH.

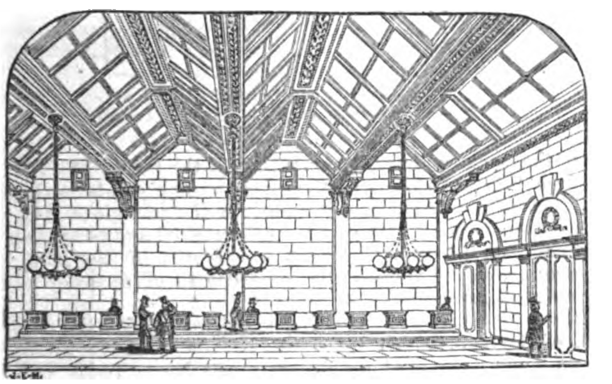
PEARSON BELLAMY, ARCHITECT.

## NEW CORN EXCHANGE, LOUTH.

(*With an Engraving, Plate* XI.)

It is only a few months since the project was conceived of erecting an Exchange in the important agricultural town of Louth, in Lincolnshire; and it is mainly by the exertions of a few spirited individuals that this object has been speedily accomplished. The capital for the purpose was raised in shares of 10*l.* each, the greater portion being held by the directors, of whom Charles North, Esq., an eminent agriculturist, residing at South Thoresby, near Louth, is the chairman, and Robert Norfolk, Esq., of Louth, one of the most influential merchants in the county, is vice-chairman.

The building is in this form, L, one front being 120 feet long, and the side-front 90 feet; total height, 60 feet. The façade a perspective view of which is given in Plate XI., is executed in Caen stone, of the modern Italian style of architecture, consisting of three stories, divided into three bays—the lower story by rusticated pilasters, the middle story by three-quarter Doric columns; in the centre compartment of this story over the arched entrance is a niche containing a figure of Ceres. The upper story is divided by deeply-panelled pilasters, surmounted by an enriched bold cantilever cornice, over which is a balustrade, with emblematical vases thereon. The basement story consists of extensive wine and porter vaults, and other requisite offices, occupied by Messrs. Lucas and Co. On each side of the principal entrance are offices for merchants, from which, rising by a broad flight of stone steps, the level of the Exchange-room is attained, which is entered from a spacious landing. The large room, shown in the annexed engraving, is 116 feet long, 37 feet wide, and 35 feet high. The whole area of the Exchange is covered with Hartley's patent rough plate glass, arranged in the ridge-and-furrow form, supported by enriched beams upon beautiful large carved corbels, modelled by Mr. T. W. Wallis, of Louth.



LARGE ROOM, LOUTH CORN EXCHANGE.

Over the front offices is a large dining-room, 35 feet by 24 feet, with bed-rooms in the attic story for the accommodation of the adjoining inn.

The most essential points (light, ventilation, &c.) appear to have been well considered—the former is extraordinarily good. The design throughout is chaste and original, and reflects credit on the designer, Mr. Pearson Bellamy, of the firm of Bellamy and Hardy, architects, Lincoln and Louth.

The amount of the contract for the building is 2510*l.*, including 400*l.* for the old Town-hall building, which originally stood on this site. The works have been executed by the contractor, Mr. John Levitt, of Louth, in a very efficient manner.

*New Streets.*—On the 15th inst. the new street from King William-street, London Bridge, to St. Paul's Churchyard (through Carter-lane, Doctor's Commons, Old Change, &c.) will be opened. Considerable progress has been made in the extension of Farringdon-street for the opening to Islington, and the new street is expected to be opened for traffic as far as Clerkenwell Green during the ensuing summer. On the Surrey side of the Thames, a new street, extending from the end of Stamford-street, Blackfriars-road, through the borough of Southwark to High-street, near the London Bridge railway terminus, is about to be constructed.

## ORDNANCE SURVEY OF SCOTLAND.

As the battle of the scales has not yet been fought out, so far as we are aware, the papers upon the subject not having been made public, an opportunity presents itself for examining somewhat in detail the much-contested but little understood subject of contour-levelling.

Contouring appears to be a life-and-death struggle with the Ordnance Survey authorities, as at present constituted. Should this mechanical system of obtaining the basis or groundwork for hill-shading the reduced maps be abandoned, they will be driven to the necessity of employing "men who can think and act and use discretion." What a fearful alternative, in an age when thought is beginning to develope itself to such an extent that even official dicta can no longer keep it confined under the rubbish of ignorance, the accumulation of bygone ages, and when the wise are directing the expanding thoughts, the rising genius of the age, into new and more profitable channels, and bringing the action of mind more directly into contact with the multifarious avocations of daily life.

Before entering fully into the subject, it may be as well to explain what is really meant by contour-levelling, and how the operation is performed.

A very clear and distinct idea may be formed by supposing a model of a district of country to be constructed to a natural scale (that is, having the horizontal and vertical scales equal), exhibiting all the undulations and irregularities of surface as they exist in nature. Suppose this model to be placed in a water-tight box, to the side of which let a scale be attached, standing vertically, and graduated to correspond with the scale at which the model has been constructed, and let the zero of the scale correspond to the horizontal base or datum plane upon which the model has been constructed.

Let water be now poured into the box until it reaches any given height upon the scale (say 25 feet), and draw a line around the model corresponding with the surface of the water. This line will be parallel to the datum plane upon which the model has been constructed, and will represent the first contour line. By the same process, any number of parallel lines may be drawn upon the model, and at any required vertical distance from each other.

The water being removed, the model will exhibit a number of lines or planes, all parallel to each other and to the datum plane of the model.

It will be observed, that if those lines are projected to the plane of the datum—which would necessarily be the case in order to represent the contour lines upon a plan—the horizontal distances between them would differ materially, according to the nature of the ground; the flatter the ground the greater the distance, and the steeper the ground the less the distance, would be between the contour lines upon the map.

It is essential that a series of levels, extending over a whole country, such, for example, as Ireland or Great Britain, should all proceed from one fixed point in each case, otherwise it is useless to expect anything but confusion, and the natural concomitant, "Revision."

As there is no fixed natural datum plane to which all levels can be referred, a single datum point should be adopted, and this point may conveniently be chosen as near as possible to the best natural datum plane. In the case of Ireland, for example, the low water, even if accurately ascertained at a great number of points round the coast, would not afford a natural datum from which a considerable number of starting or initial points could be adopted, and closing-in in the interior of the work, as these points would differ several feet from a true datum plane, and there would be no means of ascertaining the amount of this difference. This would also be the case if the high water at several points were used as starting-points; but the mean of high and low water, if accurately ascertained at several points round the coast, would be much nearer to a true datum plane than either the low or the high water. It would still however be extremely injudicious to make use of several initial points, even although based upon the most careful tidal observations, for the same series of levels, inasmuch as one extremely useful problem to be solved by these levels would be to ascertain accurately the relative height of high, of low, and of mean tides in all the harbours, estuaries, and numerous indentations round the whole coast. It would, in fact, be assuming as correct one important problem to be solved by the levels.

A reference to the "Report from the Select Committee on the Map of Ireland, 1853," will show how these important matters have been attended to.

Sir J. M'Neill, who is an uncompromising advocate of the Ordnance six-inch map, and of contouring, states, in answer to Question 78, that the figures would be all above the datum "*if there were one datum line established.*"

79. "Do not the figures indicate the altitudes of the different trigonometrical stations of observation?"—"Some are put in by levels, I believe; I believe the datum line is not uniform throughout."

Capt. Gossett was applied to in this dilemma, who does not much mend the matter; for, in answer to Question 80, he states, that "When the survey was in *its infancy*, the subject had not received the same experience which has since dictated uniformity throughout."

This answer suggests very important inquiries, which lie at the very root of the expenditure of vast sums of public money in the production of imperfect, or rather erroneous public documents. If the duration of this helpless, infantile state of things is to be estimated by the length of time during which the altitudes placed upon the engraved maps were derived from angular measurements, depending upon numerous ill-defined, low-water starting-points not in the same datum plane, we must conclude that the survey was in its infancy at least twelve or fifteen years after its commencement—about three-fourths of its entire existence, and was then only rescued from this helpless condition by Professor Airy.

81. "Is not the datum point for the altitudes which have been placed upon the six-inch map the same for every part of Ireland?"—"No, not precisely; we have *improved upon the map as years went by:* at first many of the altitudes were obtained only by vertical angles; we now make use of the levelling upon which Professor Airy's tidal calculations are founded. All our *revisions* of the map will be relative to one datum plane."

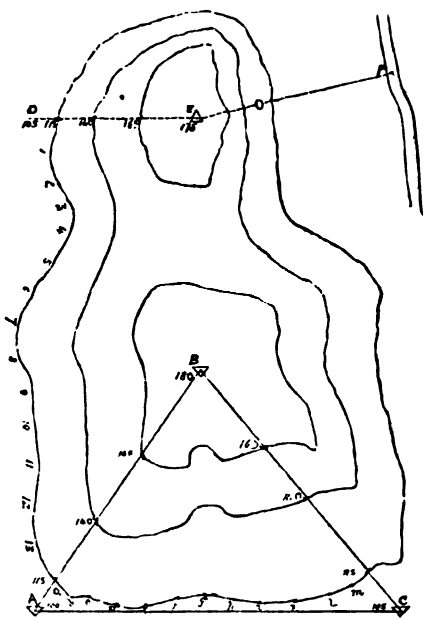
It is not quite clear from this answer whether the whole of the levels exhibited on the six-inch map of Ireland at the period of its completion in 1846, must be replaced by an entire new set of levels which shall refer to one datum plane, or whether there are some portions of the original maps with the levels referred to the new datum.

Ought there not be some effort made on the part of the government to fix the meaning of this mysterious term, "*Revision,*" as made use of by the Ordnance Survey authorities? It is doubtless frequently employed to mean an entire new survey, or an entire new set of levels, as the case may be.

Whatever claim to indulgence the Irish survey authorities may have with respect to a state of *infancy*, *childhood*, and *incipient manhood* in the production of a detailed survey for civil purposes, they can have no claim to the same indulgence in reference to the trigonometrical points and the levels with which they must have been familiar for forty or fifty years before the survey of Ireland commenced. These ought therefore to have been perfect from the commencement, and without calling in this much-abused term, "*Revision.*"

The accompanying engraving will sufficiently explain to our scientific readers the mode in which contour-levelling is performed. In order that the contour lines shall be surveyed and laid down upon a map with the same degree of accuracy with which the details of the map itself have been laid down, it is necessary that the principal lines of the triangles forming the trigonometrical basis of the survey shall be laid out and chained, to fix the several points where the contour lines cross the lines of the triangle. But as this would entail a second laying out and a second measurement of these lines, the detailed survey and the contouring should be combined (when the above accuracy is considered essential) into one and the same operation. In the triangle A B C, the altitude of the trigonometrical points A, and C, having been obtained from a system of accurate bench marks, derived from the initial starting or datum point, the lines A B, and C B, are laid out, chained, and levelled, and pickets driven into the ground at the points 115, 140, and 165, where these lines are crossed by the contour lines, and such other marks made as may be necessary for the survey of the detail to be shown on the map.

In commencing the contour-levelling at the point 115, on the line A B, the spirit-level is placed in the most convenient position to level along the line *a b c*, &c.; the staff is held upon the picket 115, which becomes the back station; the height is then read off and the staff is carried along the ground to the points *a*, *b*, &c., which give the same reading on the staff as the back station, and which points are consequently in the same datum plane. These points are marked by pickets or by marks cut into the ground so as to be easily discovered in subsequently surveying them. When as many points have been fixed as can conveniently be fixed from one position of the instrument, a forward station is selected, which will become the back station when the instrument has been carried forward to another position; and the same process will be carried on until the contour line is closed upon the point 115 on the line C B, and the accuracy of this close will be a test of the accuracy of the contour line from the point of starting.



In the same manner, commencing at the points 140, 165, on the line A B, and closing on the corresponding points on the line C B, the three contour lines included in the triangle A B C, will be completed; and if these lines are surveyed and plotted on an original plan in connection with the details of the map, the contour lines will possess the same degree of accuracy as the several matters exhibited on the map itself.

When, however, the contouring is carried on after the publication of the map, which is the case on the Ordnance Survey of Ireland, and when it would be too expensive to re-lay out the lines of the several triangles, the following process is adopted. From the bench-mark 105 at D, a line of levels is carried to the trigonometrical station E, and thence to the bench-mark F. These lines must be chained, in order that the levelled points may be plotted on the plan, and pickets are driven into the ground at 115, 140, and 165 on the line D E, and also at corresponding points of altitude on the line E F, when confidence can be placed in the party contouring, but if not, the check points are placed on the line E F, at some distance from the point at which the contour line would strike.

Commencing the contouring at the point 115 on the line D E, and proceeding along the line 1, 2, 3, 4, &c., as above described, and passing along the same line to the point O, on the line E F, as if the more accurate process described in reference to the triangle A B C, did not exist on the diagram. When the contour leveller has his check-points given him, he would ascertain on closing at the point O, if his work was correct; but if the check-points are retained, he must level to the point F, and send the height which he makes the point O above the point F, to the keeper of his conscience at a considerable distance, who informs him of the state of his work, which, if satisfactory, he may proceed to survey.

From this very brief and imperfect description, those who are acquainted with levelling will easily understand the process of contouring and the manner in which it is checked. In surveying the contour lines thus marked out upon the ground after the map has been completed, the survey is made to depend upon angles of fences, buildings, or any convenient object on the map. In mountain districts where there are no details upon which to base the survey, traversing must be resorted to.

It must be obvious that to contour accurately through dense woods, over steep precipices, through demesnes and pleasure grounds with high walls and other obstructions, is all but impracticable; and to attempt contouring in a town where the levels can only be placed upon the streets and the intermediate portions sketched, is a pure absurdity and calculated to mislead.

To attempt to get at the exact cost of contouring as executed by the Ordnance, is in reality to search for knowledge under difficulties. In the Report of the Committee on the Ordnance Survey (Scotland), pages 230-231, Capt. Yolland distinguishes between what he calls "Instrumental Contours" which "would be run at 25, 50, 75, 100, 150, 200, 250, 300, 350, 400, 500, 600, 800, 1000, 1200, 1600 feet (in altitude), and increases by 400 above that limit;" and below 1200 feet, the contours at every intermediate 25 feet not shown by the instrumental lines are what are termed "Sketch Contours," run with a water-level in lieu of a spirit-level.

It is difficult to account for the circumstance of so very imperfect an instrument as a "*water-level*" being employed by the Ordnance in the execution of a national survey. One of the great boasts of the Ordnance over Civil Surveyors, has been the possession of superior instruments, but this superiority can no longer be claimed after the adoption of a miserable make-shift instrument such as that described by Capt. Yolland, who states—"Suppose my body to represent the stand of the instrument, and my two arms held in a horizontal position, a hollow tube passing from one elbow to the other elbow, and the hands to represent two phials or bottles, and these being filled with water, that constitutes a water level."

It is subsequently admitted that this instrument "will not give the same degree of accuracy as the spirit-level will do, because in the one case it is read by telescopic sight, and in the other it is not." But if the same degree of accuracy cannot be attained by this imperfect instrument, why in the name of common-sense make use of it at all?—for anything introduced upon a map as data for important ulterior operations, not having even the pretence of being accurate, had much better not be introduced at all; and it is well known to practical levellers that if even minute errors are permitted to exist in a series of levels, there can be no certainty as to what extent the errors may run, nor can any confidence be placed in such operations.

In the pages of the report above referred to, Capt. Yolland states the expense of contouring to be 4*l.* per square mile, or 10*s.* per lineal mile, making no distinction between what he calls instrumental spirit-levelling and instrumental water-levelling. He also states that the saving of expense if the water-level interpolated contour lines were omitted, would be about 8*s.* per square mile. With this data as to cost, we must be satisfied for the present, and endeavour by an impartial analysis to work out the most accurate results which this data will enable us to arrive at.

Sheet 147 of the six-inch map of Yorkshire, which being an incomplete sheet, embraces only 14 square miles of country, contains by admeasurement about 65 lineal miles of instrumental, and about 453 lineal miles of water-level contours, making a total of 518 lineal miles, equal to 37 lineal miles per square mile in an average of 14 miles. This at 10*s.* per lineal mile, amounts to the sum of 18*l.* 10*s.* per square mile. But the water-level interpolated contours amount to about 32 lineal miles per square mile, and if these were abandoned, 8*s.* per square mile would be saved, consequently, the cost of these 32 miles of interpolated contour lines is 8*s.*, or at the rate of 3*d.* per lineal mile; and as this distance must be twice walked over, once for levelling, and once for surveying, the mere field operation will be reduced to 1½*d.* per lineal mile.

This is certainly a cheap age, but we think it will be difficult to reconcile this estimate with the facts of the case, if these facts could be fairly got at. Let us imagine the cheapest possible "human machine" in the shape of a surveyor, with the cheapest possible mechanical machine in the shape of a "water-level," and two labourers commencing the important operation of contour levelling: with the extravagant expectation of realising 1*s.* 6*d.* per diem for the surveyor, and 1*s.* per diem for each of the labourers,—not a very extravagant amount considering the price of provisions,—we find that the party must level or survey 28 lineal miles per diem. But by dealing even thus liberally with the field parties, there would be nothing allowed for plotting the survey of the contours, for field examination by a superior party, for fixing the numerous levelled starting-points and the check-points to close upon, or for the loss of time, which must be considerable in sending to a distant head-quarter office to ascertain if the work closing upon the various check-points are satisfactory. The superior superintendence, and many other obvious contingencies, are also unprovided for.

But let us take another example, which proves more favourable to the above estimates. Sheet 151 of Yorkshire, being a complete sheet, contains 24 square miles of country: a portion of this sheet has the contours at a fair average distance from each other, but a considerable portion being above the 1200 feet contour line, where the number of contours rapidly decrease, this sheet, as a whole, may be considered to give a minimum quantity of contour lines. This sheet contains by admeasurement, 97 lineal miles of instrumental and 540 lineal miles of water-level contours, making in all 637 lineal miles in 24 square miles, or about 27 lineal miles per square mile upon an average of 24 square miles of country. This, at 10s. per lineal mile, will amount to 13*l.* 10*s.* per square mile, and that on a large average of country.

Any one acquainted with the process of contour levelling, as above described, must admit that 10*s.* per lineal mile is a very low estimate, and we are therefore driven to the conclusion, that either the amount of 4*l.* per square mile must be greatly increased, or the quantity of contouring must be limited to 8 lineal miles per square mile. This amount of contouring in an undulating country, such for example as Ireland and Scotland and the northern counties of England, would seldom amount to more than two or three parallel contours in each square mile, which would be altogether inadequate to develope the features or physical relief of the country, or to afford any considerable assistance in the prosecution of engineering works or of agricultural improvements.

The advocates of contouring, and indeed the Committee on the "Map of Ireland," appear to think that a contoured map would enable an engineer to lay out a railway or other engineering work in his office, as if there were no point of importance to be attended to but that of levels; and seem to fancy that a map which would enable an engineer to do very imperfectly in his office what he could only execute perfectly by a careful study of the ground in walking over it, would be a very great saving to the country. Poor, deluded, well-meaning mortals! as if engineers charged for their various operations in proportion to the length of time in which they are occupied upon them. If a surgeon amputated a limb successfully in ten minutes, and another hacked away without ultimate success for two or three hours, according to these sages, the latter laborious individual would be entitled to a reward in proportion to the time occupied and not to the quality of the work performed.

By a careful examination of the contour lines on Sheet 151, Yorkshire, it will be observed that the instrumental lines show numerous sharp salient points, giving a rugged angular appearance to the ground, which nature never exhibits unless in the most sterile regions where the rock formations crop out to the surface: but wherever the surface is covered over with vegetable earth and verdure, the protruding angles of the bare skeleton are rounded off into the most pleasing undulations.

The water-level contours exhibit no such unnatural angles, and are so far preferable to the instrumental contours. It will also be observed that the contour lines pass over abrupt precipices, which are brought out by shading, without deviating in the slightest degree from the symmetrical form assumed on each side of the precipice, which is a self-evident proof of error. This sheet also contains several large patches of woodland through which the contours are carried with a great amount of uniformity and freedom, evidently at the discretion of the draughtsman, as it would be impossible to contour accurately through a wood without destroying a great portion of it.

One most remarkable circumstance connected with this sheet of the six-inch map, is the fact that by as careful an estimate as can be arrived at without the field notes, of every feature upon the map which has been surveyed, the average of the whole sheet gives about 12 lineal miles of surveying to every square mile of area, whilst the amount of contouring is 27 lineal miles per square mile; and as contouring must first be levelled and then surveyed, the actual amount of work would be 54 lineal miles of contouring, as compared to 12 lineal miles of detailed survey. There is, therefore, more than four times as much contouring work upon the plan as there is of every description of detailed survey; and consequently, if a square mile of contouring can be executed for 4*l*., a square mile of detailed survey can be executed for 1*l*. per square mile, being about ⅜ths of a penny per acre.—These few rough notes may amuse and perhaps edify our readers until the promised Treasury papers appear.

## THE AQUEDUCTS OF CONSTANTINOPLE.*

As water is the only beverage generally used by the Turks, and as moreover the Koran prescribes seven ablutions of the body every day, aqueducts and fountains are objects of an almost religious bearing in the East. Their number in the towns and along the roadsides is constantly increasing, and water is often brought to them from great distances. They have, of late years, been built in a somewhat better style than formerly, and are always pleasing on account of their great utility.

The chief sources which supply the consumption of Constantinople and its suburbs on this side of the harbour are situate on the outrunners of the Balkan (Hæmus) mountains, which terminate on the Canal of the Black Sea near the castles of the Dardanelles. The height of these mountains, at the spot where the sources are situate, is about 800 feet, the distance from Constantinople three miles, and from the shores of the Black Sea three-quarters of a mile. The slopes of this mountain are covered with fine forests of oak and chesnuts on the side towards Constantinople, and are very rich in sources of pure water. The slope towards the Euxine must have been once similarly wooded, but is now quite naked. On the former side, near the village of Belgrad, most stringent regulations for the preservation of the timber, &c. are in force, and for not obstructing the flow of these most valuable springs.

The lateral mountain chains, on which Constantinople is built, divide the western valley of fresh water from the Sea of Marmora, and end at the point of the Seraglio. This chain of mountains has one plateau and two slopes, and on both these deep and extensive plains. It was from the position of these three slopes and the situation of Constantinople, that three systems of water conduits have been established. Part of the supply has also been derived from Dshebedshe-Kioi, which unites itself with that of Alibeg-Kioi about 1½ mile from the Justinian Aqueduct. The situation of the Turkish capital demanded, moreover, that the waters were to be taken up as high as possible, that they might be conveyed, at the minimum expense, to the different points of distribution. Another feature in this hydraulic problem to be solved was, to find on the water-shed in the direction of the great Bend (reservoir) from Belgrad to the Takssim of Egri-Kapu, a point, which was situate on the incline required for the flow of the water,—a point, to which both the waters of the valley of Belgrad and Aiwat-Bendi could be conducted, and whence it could be brought to the Takssim of Egri-Kapu. This object was achieved by the construction of a reservoir of circular form (Bash-Hawus), situated in the embouchure of a small valley sloping towards the Alibeg-Kioi valley. The valley of Pyrgos was crossed by means of an aqueduct called the long one, extending to 2000 feet. The waters of Belgrad stream forth at the end of the valley from three sources; they soon, however, unite, and fall into a very handsomely built reservoir. The little valley of Pasha-Deressi has also its reservoir and aqueduct. Two other aqueducts take up the waters of the Belgrad and Aiwat-Bendi, and conduct it to the Bash-Hawus of Pyrgos. A third conduit, which starts from the same Bash-Hawus, brings these united streams to the heights of the Alibeg-Kioi valley, where they are carried over to the Aqueduct of Justinian. The latter is a superior work of hydraulic architecture, and undoubtedly the finest left us from the middle ages.

The Takssim at Banari is connected with the Aqueduct of Valens; it lies 53 feet below the upper part of the latter, consequently these two aqueducts belong to two quite different systems. Most writers, amongst whom is Gyllius, who has been continually copied, assert that the Aqueduct of Valens receives the water coming from Belgrad, which is erroneous.

The Takssim of Sta. Sophia furnishes the seraglio of the Sultan with water. After the stream has passed underneath the Hôtel of the Mint, it fills a cistern in one of the courts of the Harem, whence it is raised by what is here called a "Norin," and then discharges itself at Tap-Kapussi in a basin, which is said to be 170 feet long and 150 feet broad, and on which plies a boat for the private recreation of the Sultan.

These various streams are carried to the metropolis through a number of aqueducts, of which the following may be mentioned. The Crooked Aqueduct, the Long Aqueduct, and that of Justinian, are situate near the village of Pyrgos. Their plan forms an equilateral triangle, of which that from the Long Aqueduct to that of Justinian forms the base, upwards of 2½ miles long, while the other two sides, which unite in the Crooked Aqueduct, have each a length of nearly two miles.

The Crooked Aqueduct of Pyrgos receives the water coming from the valley of Belgrad. It consists of two branches, the one 400 feet long, and the other branch, forming nearly a right angle with the previous one, and passing over the valley of Pyrgos from one slope to the opposite one, is 720 feet long. The latter branch consists of a triple row of arcades, whose openings widen and enlarge towards the top, obviously imparting to the building a greater strength than if the arches were placed perpendicularly above each other. The height of the aqueduct from the level of the water in the valley to the top is 114 feet, and above the third tier of arcades is the canal, covered with slabs of stone to exclude the rain water. This aqueduct cannot be of very ancient date, as the lower tier of arches is pointed. Although this structure has no fine external appearance of dressed stones, &c., it still presents a pleasing view from the proportion of its parts and the regular arrangement of its materials. The pyramidal shape of the walls from below upwards, has contributed to effect in all parts of the aqueduct that equilibrium of resistance with the least vertical pressure,—so much so, that all accessory iron bands have been dispensed with.

The Long Aqueduct is, perhaps, of a more imposing character, on account of its great length, but is far inferior to the former, as well in the grace of design as in the choice of materials, and has moreover experienced considerable damage. This aqueduct has probably been rebuilt by the Turks, after the decay of the previous structure. It consists of two tiers of pointed arches, forty-eight in the lower and fifty in the upper story. Its length is 2327 feet, and height 84 feet.

Reservoirs or basins are called at Constantinople Bash-Hawuss, which, mostly of a circular form, are placed in ravines for collecting the waters which have strayed away from their course, and for giving them the direction they have to take. The waters are collected in vaulted viaducts, and by such they flow off, and a third similar conduit brings the water to the natural stream, if the basin is full. The waters of the Crooked and the Long aqueduct flow to the Bash-Hawus of Pyrgos, in two vaulted conduits, and pass combined into one stream to the Justinian Aqueduct.

The Justinian Aqueduct is led over a valley, in which flows the Kydaris of the ancients, and consists of two tiers of large pointed arches, those of the lower being 16·88 mètres in the clear; those of the upper tier have a span of 13·11 mètres. These arches are divided by pillars, which are pierced at three different heights by small arches, which, without endangering the solidity of the structure, diminish the expense of construction, and impart an air of great lightness to the monument. The pillars of the second tier are, moreover, pierced in the whole length of the aqueduct by a vaulted passage 1·3 mètre broad, which has also for its object to make the structure lighter, and to be used as a communication from one side of the valley to the other. The length of the Justinian Aqueduct is 833·88 mètres, its height 35·08 mètres, and the pillars at their base are 16·56 mètres thick. The canal is 0·65 mètre broad, and 1·23 mètre high, and also covered by stone slabs, sloping at each side. This aqueduct is built in an exceedingly solid manner, and although the Turks have paid but very little attention to its preservation, it has now withstood the action of many centuries. This and the Crooked aqueduct are the most remarkable works left by the Greek emperors. Although this aqueduct is now called the Justinian, it does not appear that it was built by that monarch, as Procopius, in his work 'On Buildings,' which dilates on those erected by Justinian, does not mention the aqueduct. Other authors have ascribed it to Andronicus Comnenus, who was elected Emperor in 1183, but did not reign more than two years.

The Aqueduct of Valens (Aquæductus Valentianus) transects the valley formed by two of the hills on which Constantinople is built. It consists of hewn stones, and is of a very imposing aspect. Originally it had two tiers of arcades, the upper, however, being removed for the sake of obtaining a better view of the

* Abridged from the 'Allgemeine Bauzeitung.'

Mosque of Sheh-Sadeh. What remains of that aqueduct extends to a length of 2040 feet, and its height is 74 feet. It is conjectured, that the structure when complete, extended to the length of three-quarters of a mile. This aqueduct was begun by the Emperor Hadrian, before the foundation of Constantinople, re-constructed by Valens, destroyed by the Avares, and re-erected by Soliman the Splendid.

Conjointly with these aqueducts there are a number of reservoirs, by means of which the water is distributed in the different quarters and districts of Constantinople. The most important and most handsome is that of Dsheni-Bagtshi. We were astonished, at first, that those buildings, some of which are under ground, and form walls against which the silt water is constantly exercising its influence, have not experienced any deterioration during the many centuries since they have been erected. Their inner walls are so smooth, the courses of stone so well united, the vaults so complete, that they appear as if cut in one piece; and it is difficult to conceive how this has been the case without any care whatever having been bestowed on these buildings by their present Moslem owners.

## COMMISSION FOR THE PRESERVATION OF ARCHITECTURAL MONUMENTS IN AUSTRIA.

The honour of having appointed an official commission for the preservation of monuments, belongs to the government of Louis Philippe, which first instituted the Paris Commission des Monuments. Austria has now followed in the same course, although both the extent and value of its historical monuments, and its financial means, are much inferior to those of France. The seat of the central commission is in Vienna, while conservators are to be appointed in the capitals of the provinces, Buda-Pesth, Prague, Milan, &c. The conservators have to obtain information on all architectural monuments of their district, and to collect all documents, drawings, and engravings relating thereto. For this purpose they have to keep a register of all architectural monuments of their district which possess either an artistic, scientific, or historical interest. Then follow some instructions as to the preservation of such structures, and also the precautions to be observed in the search after and discovery of hitherto unknown monuments. All moveable objects discovered in excavations, &c., are to be purchased from the owners by the Imperial Museum of Antiquities, at Vienna. In all cases where grants of money are required, for either the preservation of or search after historical or art monuments, the conservators have to apply to the central commission, which, being part of the Ministry of Public Works, will take the necessary steps in furthering such objects of public utility.

## DECORATIONS OF THE NEW PALACE, AT WESTMINSTER.

A Return to an Address of the House of Commons has been printed, giving an "Account of the Amount of all Commissions for Works of Art to various Artists for the Decoration of the New Palace of Westminster, from its Commencement to the Present Time, with the Estimate for each Work; also, a Return of the several Salaries to Artists holding Appointments under the Royal Commission for Decorating the New Palace of Westminster." The return also shows the Receipts and Expenditure of the various Exhibitions which took place, under the direction of the Commissioners, in Westminster Hall and elsewhere, in order to distinguish certain premiums and purchases, the cost of which was furnished from the receipts of such Exhibitions, from the amount provided for similar objects by the Treasury.

House of Lords.—The decorations in the House of Lords, executed under the direction of Her Majesty's Commissioners on the Fine Arts, included six Fresco Paintings for the end walls, and eighteen Metal Statues of Barons and Prelates for the niches on the four sides. By adopting the modern invention of casting statues in zinc, coated with copper by the electro process, and chemically tinted as required, an invention carried to great perfection, consistently with cheapness, in Berlin, a saving may be effected on the estimate. It is proposed that such surplus be carried to a fund for "Sundry Works," the Commissioners having, in some instances, been unable, for want of such a fund, to institute experiments, or to meet the cost of unforeseen alterations without increasing the first estimates.

The superintendence of the Commissioners, with regard to the Stained Glass Windows, was limited to the selection of the Royal Personages represented, and, in consequence of a competition (June 1844), to the recommendation of the artists. The style of design and colour in the windows, in its required adaptation to the place, and as affecting the light, was left to the architect.

*Fresco Paintings.*

| Religion ... ... ... | J. C. Horsley | The "Baptism of Ethelbert," the first fresco executed in the House of Lords and in the Palace of Westminster, was completed August 1846.<br>The frescoes of "Chief Justice Gascoigne" and "Justice," the two last executed in the House of Lords, were completed Dec. 1849.<br>Estimated at 800*l.* for each entire work; 400*l.* for the cartoon, and 400*l.* for the fresco. |
| Justice ... ... ... | Daniel Maclise, R.A. | |
| The Spirit of Chivalry ... | Daniel Maclise. R.A. | |
| The Baptism of Ethelbert | Wm. Dyce, A.R.A. | |
| Prince Henry, afterwards Henry V., acknowledging the Authority of Chief Justice Gascoigne | C. W. Cope, R.A. | |
| Edward the Black Prince receiving the Order of the Garter from King Edward III. ... ... | C. W. Cope, R.A. | |

*Remarks.*—Of the six artists above named, commissioned to furnish designs for these subjects, and whose works were exhibited in Westminster Hall in 1845, four were thus selected. This afforded an opportunity of preserving a uniformity of style in the two outside frescoes on each side, such frescoes having been executed respectively by one artist.

*Metal Statues of Eighteen Barons and Prelates who co-operated in obtaining Magna Charta.*

| SUBJECTS. | ARTISTS. | DATE AND ESTIMATE. |
|---|---|---|
| 1. Stephen Langton, Archbishop of Canterbury. | *Gilder*—F. Draycott.<br>J. Thomas, *Modeller* | The model for the statue of Wm. Earl of Arundel, was the first completed, December 1848.<br>The model for the statue of William de Mowbray was the last completed, May 1851.<br>The statue first cast was that of Hubert de Burgh, July 1850.<br>Eleven remain to be cast.<br>The price of the eighteen models was estimated at 150*l.* each, making 2700*l.* The price of casting, after the cost of the first experiment, was estimated at 110*l.* each statue, making 1980*l.*; that sum was accordingly appropriated for the purpose from a Parliamentary grant. But as the estimated cost at 110*l.* each statue, would not include the gilding, various metal founders were consulted, and various methods tried, with a view to diminish the expense of casting. The Commissioners ultimately agreed, May 1852, to pay Messrs. Elkington 80*l.* per statue, the material being zinc, coated with copper by the electro process, and bronzed. By this arrangement more than sufficient will remain from the original estimate to cover the cost of gilding, estimated at 10*l.* 10*s.* per statue. |

Upper Waiting Hall.—The decorations are at present limited to Frescoes. The object was to test the powers of artists, otherwise eligible, in the treatment and execution fitted for fresco-painting. With regard to the choice of subjects, it having been originally proposed to place eight statues of poets in the apartment, the illustration of each poet by a scene from his works at once suggested itself, while the scope thus afforded to the artists would, it was thought, enable them to make their trials with advantage. That advantage, it must be confessed, is more than counterbalanced by the very imperfect light in the room, a defect most apparent at that season of the year when the works can be carried on with least interruption. Most of the artists have, in consequence, been compelled to paint there by gas-light.

The "Remarks" on the subject of the metal statues for the

House of Lords, as to the expediency of providing a fund for "Sundry Works," in order to meet the cost of occasional alterations, and that of works which might be set aside, are applicable in the present instance.

*Frescoes.*

| SUBJECTS. | ARTISTS. | DATE AND ESTIMATE. |
|---|---|---|
| Chaucer: "Griselda's First Trial of Patience." | C. W. Cope, R.A. | The fresco of "Griselda" and that in illustration of Milton were completed respectively in October and November 1848.<br>The fresco in illustration of Pope was completed November 1852.<br>Those in illustration of Scott and Byron were not completed when this Return was called for, Aug. 1853.<br>The cost of each painting was estimated at 400*l*., 200*l*. for the cartoon, and 200*l*. for the fresco. The amount would therefore be 3200*l*. But one artist, after having completed his cartoon, for which he received 200*l*., was not invited to execute the fresco. Another had completed his cartoon, when the Commissioners thought it advisable to change the subject, and a compensation of 100*l*. was, under the circumstances, accepted by the artist.<br>The sum of 300*l*. was therefore added to the original estimate, making 3500*l*. |
| Spencer: "St. George overcoming the Dragon." | G. F. Watts. | |
| Shakspeare: "Lear disinheriting Cordelia." | J. R. Herbert, R.A. | |
| Milton: "Satan touched by Ithuriel's Spear." | J. C. Horsley. | |
| Dryden: "St. Cecilia."... | J. Tenniel. | |
| Pope: "The Personification of Thames." | E. Armitage. | |
| Scott: "The Death of Marmion." | E. Armitage. | |
| Byron: "The Death of Lara." | C. W. Cope, R.A. | |

St. Stephen's Hall.—The decorations proposed are Statues and Frescoes. The decorations are at present limited to Statues. The Commissioners have expressed the opinion, "that as St. Stephen's Hall stands on the spot where the House of Commons was, during many centuries, in the habit of assembling, it should be adorned with statues of men who rose to eminence by the eloquence and abilities which they displayed in that House. Twelve personages selected on this principle were accordingly named in the Fourth Report of the Commission to Her Majesty."

In this, as in others cases, the estimate is limited to works actually commenced. The statues in St. Stephen's Hall being by various artists, the entire series (consisting of twelve personages) may be completed without interruption or not, as may be thought advisable.

The Commissioners have determined that the chronological order of subjects, or of personages, in the corridors or halls connected with the Central Hall, should begin from that hall. In the ultimate arrangement of the statues in St. Stephen's Hall, the figure of Selden will therefore be the first on the right in quitting the Central Hall.

*Marble Statues.*

The Prince's Chamber.—The decorations proposed for this apartment are Statues, Bas-Reliefs, either in wood or in some more durable material, portraits of the Tudor Family, and Tapestries. The decorations are at present limited to Statues and Bas-Reliefs.

This apartment was first called the Lobby to the House of Lords; then the Victoria Hall; and finally the Prince's Chamber (the ancient designation of a corresponding room). According to the architect's first design, the apartment did not exist, as it formed part of the Royal Gallery, first called the Victoria Gallery. The earlier Reports, in alluding to the decorations of the Victoria Gallery, consequently comprehend a portion of those of the room now called the Prince's Chamber.

The previous remarks on the expediency of providing a fund for "Sundry Works" are again applicable in the present instance. The Commissioners had proposed to fill certain narrow panels in this room with portraits of the Tudor Family, 28 in number, executed in a style corresponding with the peculiar form of the compartments, and with the periods to which the personages belonged. The specimens submitted did not, however, meet the views of the Commissioners as to the requisite treatment. The sum of 50*l*. paid by agreement for one of such portraits, afterwards set aside, might have been included in "Sundry Works."

*Statues.*

| SUBJECT. | DATE AND ESTIMATE. |
|---|---|
| A Statue of Her Majesty, with Figures of Justice and Clemency, and with Bas-reliefs on the Pedestal.—J. Gibson, R.A., *Artist*. | The small model was approved by the Commissioners, July 1850. The statues, to be executed in Rome, are not yet completed. Estimate 3835*l*. |

The place which this work of sculpture is to occupy is the recess on the north side of the apartment.

*Models for Bas-Reliefs, and one experimental Portrait.*

| SUBJECTS. | DATE AND ESTIMATE. |
|---|---|
| In the two compartments on the East and West sides:<br>1. The Field of the Cloth of Gold.<br>2. The Visit of Charles V. to Henry VIII.<br>In the three compartments on the South side, West of the door:<br>3. The Escape of Mary Queen of Scots.<br>4. The Murder of Rizzio.<br>5. Mary looking back on France. (The Escape of Mary occupying the centre panel.)<br>In the three compartments on the South side, East of the door:<br>6. Queen Elizabeth Knighting Drake.<br>7. Raleigh spreading his Cloak as a Carpet for the Queen.<br>8. The Death of Sir Philip Sidney. (The subject of the knighting of Drake occupying the centre panel.)<br>On the North side:<br>9. Edward VI. granting a Charter to Christ's Hospital.<br>10. Lady Jane Grey at her Studies.<br>11. Sebastian Cabot before Henry VII.<br>12. Catherine of Arragon Pleading. | Wm. Theed is the Artist to whom the series of models is entrusted.<br>The model No. 8, the "Death of Sir Philip Sidney," was completed July 1852.<br>Nos. 3, 5, 7, 9 and 10 are also completed. Another artist had been previously commissioned to execute the work; but after furnishing three models, he was not invited to proceed, and the specimens were set aside.<br>The cost of each model was estimated at 50*l*., the amount for the 12 would therefore be 600*l*. But the three models furnished by the artist first employed, and for which he received 150*l*., having been set aside, the cost of the entire series requires to be estimated at 750*l*.<br>The models referred to will ultimately be executed, either in wood or in some more durable material. The estimate for such ultimate works will depend on the material. |

The Queen's Robing Room.—The decorations proposed by the Commissioners for this apartment are limited to Fresco Paintings. A Committee, consisting of nine members of the Commission, observe in their Report (adopted by the Commission generally), that, "influenced by the considerations before expressed as to the expediency of varying the character of the decorations proposed," they "were of opinion that a series of paintings illustrating the Legend of King Arthur would be appriopriate in this locality; and your Committee unanimously agreed to recommend to the Commission that the execution and entire superintendence of such decorations should be entrusted to Mr. Dyce, who had already executed a fresco in the House of Lords."

*Fresco Paintings.*

| SUBJECT. | DATE AND ESTIMATE. |
|---|---|
| The Legend of King Arthur, W. Dyce, R.A., *Artist*. | The agreement dates from July 1848. The work is in progress.<br>The agreement provides that the artist shall receive a salary of 800*l*. a year for six years, making 4800*l*.<br>The artist would also by the agreement have been entitled to the above amount had the work been completed in less than six years. |

The term of six years, dating from the 1st July, 1848, was at first fixed, as the introduction of a work in sculpture in a compartment on the west side of the room was then contemplated, and such an arrangement would have reduced the number of fresco paintings; but the Commissioners having subsequently decided that the whole of the available wall-space should be filled with frescoes, the time was prolonged, by the conditions of the agreement, accordingly, and it may be necessary to extend it still more.

Mr. Dyce is the only artist employed in the decoration of the Palace of Westminster, who for a limited time, receives a salary.

THE PEERS' ROBING ROOM.—It is proposed that the decorations in this apartment (as yet not built) shall be limited to Fresco Paintings. The Committee before referred to, after expressing their opinion "that Scripture subjects, as affording scope for the highest style of design, and as being especially eligible on other grounds, should by no means be excluded, considered that the above-named locality, in which the principal compartments intended for painting are of considerable magnitude, would be well adapted for such subjects. Your Committee were of opinion that the illustrations should have reference to the idea of Justice on Earth, and its development in Law and Judgment, and that the following subjects would be appropriate."

The foundations of the Peers' Robing Room have been only recently built; but as in fresco-painting a considerable time is required for the preparation of designs, cartoons, and coloured studies, the Commissioners deemed it expedient to engage and employ the artist at the period mentioned, so as to give him ample time for such preparatory labours.

*Fresco Paintings.*

| SUBJECTS. | DATE AND ESTIMATE. |
|---|---|
| In the single compartment, on the West side:<br>1. Moses bringing down the Tables of the Law to the Israelites.<br>In the two small compartments on the East side:<br>2. The Fall of Man.<br>3. His Condemnation to Labour.<br>On the South side, in the larger compartment:<br>4. The Judgment of Solomon.<br>In the two smaller:<br>5. The Visit of the Queen of Sheba.<br>6. The Building of the Temple.<br>On the North side, in the larger compartment:<br>7. The Judgment of Daniel.<br>In the two smaller:<br>8. Daniel in the Lions' Den.<br>9. The Vision of Daniel. | John Rogers Herbert, R.A., is the Artist to whom these works are entrusted.<br>The agreement with Mr. Herbert was concluded in July 1850. His first design for the subject of the Judgment of Daniel was approved by the Commissioners, May 1851.<br>The work to be completed in nine years, or less, dating from the 1st April 1851. Estimate 9000*l.* |

THE PEERS' CORRIDOR.—The decorations proposed for this corridor, containing eight compartments, are Historical Oil Pictures. The Committee before referred to "were of opinion that the corridors which join the two Houses might properly be decorated with paintings illustrative of that great contest which commenced with the meeting of the Long Parliament, and terminated in 1689. It will be seen that the subjects have been selected on the principle of parallelism, and that an attempt has been made to do justice to the heroic virtues which were displayed on both sides.

*Oil Paintings.*

| SUBJECTS. | | SUBJECTS. |
|---|---|---|
| 1. Charles erecting his Standard at Nottingham. | Opposite | 2. Speaker Lenthal asserting the Privileges of the Commons when the attempt was made to seize the Five Members. |
| 3. Basing House defended by the Cavaliers against the Parliamentary Army. | Opposite | 4. The setting out of the Train Bands from London to raise the Siege of Gloucester. |
| 5. The Expulsion of the Fellows of a College at Oxford for refusing to sign the Covenant. | Opposite | 6. The Embarkation of a Puritan Family for New England. |
| 7. The Burial of Charles I. | Opposite | 8. The parting of Lord and Lady Russell. |

The artist at present invited to undertake this work has not, as yet, furnished the design required by the Commissioners.

The estimate is 3650*l.*; 500*l.* for the first picture, and, in the event of the artist being commissioned to execute the remainder, 450*l.* for each remaining picture.

THE COMMONS' CORRIDOR.—Consisting of eight compartments, in which Historical Oil Pictures are proposed to be placed. See the observations of the Committee before quoted in reference to the Peers' Corridor.

On the chronological order of the subjects, *see* the remarks on St. Stephen's Hall. The picture of the Execution of Montrose will be fixed in its place when the artist shall have completed that of the Sleep of Argyll, on which he is now employed, in order that the two may be seen together. The picture of the execution of Montrose, the first executed, was completed March 1853. The Estimate is 3650*l.*; 500*l.* for the first picture, and 450*l.* each for the remainder. Edward M. Ward, A.R.A., is the Artist.

*Oil Paintings.*

| SUBJECTS. | | SUBJECTS. |
|---|---|---|
| 1. Charles II. assisted in his Escape by Jane Lane. | Opposite | 2. Alice Lisle concealing the Fugitives after the Battle of Sedgemoor. |
| 3. The Executioner tying Wishart's Book round the neck of Montrose. | Opposite | 4. The Sleep of Argyll. |
| 5. Monk declaring for a Free Parliament. | Opposite | 6. The Acquittal of the Seven Bishops. |
| 7. The Landing of Charles II. | Opposite | 8. The Lords and Commons presenting the Crown to William and Mary, in the Banquetting House. |

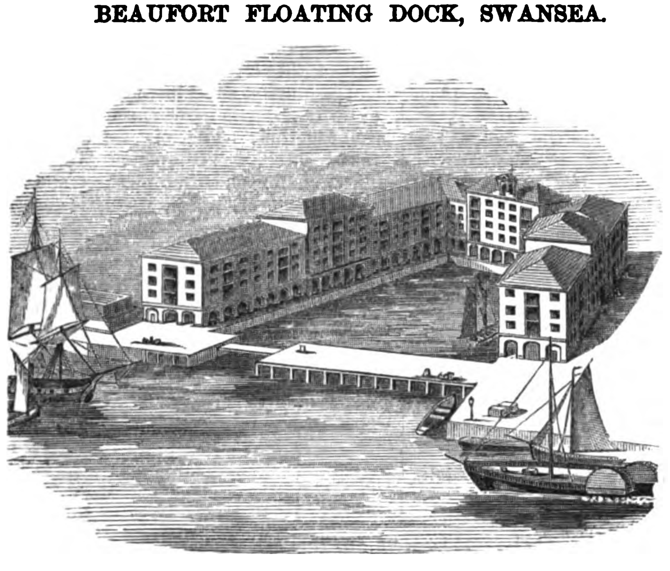
*Sundry Works.*—This item in the estimates is intended to provide a small fund for experiment or extra works, in order to avoid, as far as possible, the alteration of more important estimates. It has been seen, in the case of the frescoes for the Upper Waiting Hall, and in the case of the bas-reliefs for the Prince's Chamber, that works may from various causes sometimes be set aside. Under such circumstances, it would be desirable to meet the additional outlay by means of a fund of the above description. Such an arrangement has been only recently proposed; it appears for the first time in the Estimates for the year ending 31st March 1852, but it is only in the Estimates for the present year that part of the sum required, happening to come within the usual vote, has been granted: that sum is 100*l.* The Commissioners had already set apart the sum of 120*l.* for the same object from a grant for the year ending 31st March 1851. The only payment hitherto made under this head was in September 1852, when 50*l.* was paid to an artist as a remuneration for his time, according to agreement; a sketch which he had been invited to submit not having been approved. The fund for "Sundry Works" amounts therefore at present to 170*l.*

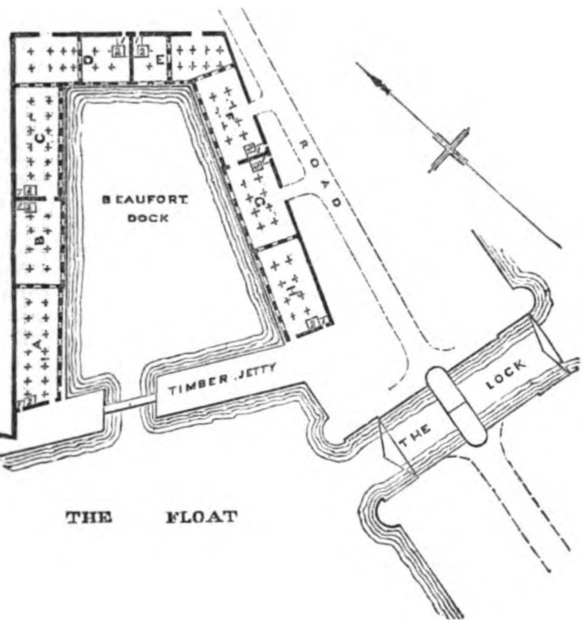
*Salaries to Artists.*—Referring to that part of the requisition calling for "a Return of the several salaries to artists holding appointments under the Royal Commission for decorating the New Palace of Westminster," it has been already stated in the Return relating to the Queen's Robing Room, that William Dyce, R.A., is the only artist employed in the decoration of the Palace of Westminster who, for a limited time, receives a salary. No other artist, in any way connected with the Commission, has a salary, except the secretary, who had the honour to be appointed by her Majesty. The secretary at present receives 750*l.* a year, out of which he pays an assistant and clerks.

## THE MUNICH PALACE OF THE GREAT INDUSTRIAL EXHIBITION.

AFTER many preparatory studies and investigations of the Committee appointed for that purpose, it has been proposed and accepted that the Munich Crystal Palace shall be erected on the north side of the botanical gardens. The locality is well chosen, as it is lighted on all sides by the uninterrupted rays of the sun, the whole area extending to 480,000 square feet. As it is intended that the building should be converted, after its temporary use, into winter, or rather botanical conservatories, the construction has been adapted thereto. The area of the Industrial hall is calculated at 160,000 square feet. The plan has been designed by M. Voit, the architect of the new Pinakotheka. The chief entrance will be from Arûr-street, which lays in a line with the north entrance of the transept. The building is to be completed in June next, reckoning thirty days for the erection of the ironwork, and as many for the glazing. The outer circumference will be constructed of a solid wall, and the lateral naves will be formed of iron columns, supported by a foundation of brick and cement.

## BEAUFORT FLOATING DOCK, SWANSEA.





The Trustees of the Harbour of Swansea have lately formed a part of the port into a floating dock, and have impounded for that purpose an extent of water of between nine and ten acres. The Duke of Beaufort, as the owner of a piece of land bordering on the above float, has caused a side excavation to be made to the same depth of water as the floating dock, fronted by a timber jetty, leaving an open water-way 40 feet in width, and having access from the general float, thus forming a private berthage for six or eight first-class vessels, entirely out of the way of the general traffic of the float. This private dock is surrounded on three sides by eight stacks of substantial warehouses, each stack being provided with a staircase, and inclosed with brick partitions the whole height; the upper floors are calculated to carry the weight of any goods usually stored on timber floors. The total contents of the warehouses, exclusive of the wharfage on the timber jetty, are 1,239,257 cubic feet, and 116,200 feet superficial area. The ground story or quay is paved with Pennant stone, grouted and bedded on river shingle, filled-in on a bed of concrete. The walls stand on a mass of concrete, in some places upwards of 16 feet deep. They are built in rubble-work, with excellent sandstone from the local quarries, the facing being random-range work, with ashlar angles, reveals, piers, and arches, all hammer-dressed. A moulded string runs round the top of the arcade, and divides the ashlar work of the piers and arches from the random-range work of the face of the walls above, which are crowned by a bold but plain cornice. The lime used throughout the building is blue lias, from the sea beach at the Abershaw quarries.

The floors are carried by fir solid girders and iron stanchions, the bases of which are bedded on the caps of those next immediately beneath. The window-sashes are of iron. Messrs. Haward and Nixon, of London, are the builders.

Swansea, as is well known, is the chief seat of the copper smelting business, and has already a large trade with Australia, and other foreign parts, and is connected with the Glamorganshire iron works, and steam coal collieries at Aberdare and Merthyr, by the South Wales and Vale of Neath Railways. It has also a communication with the tin-plate works and works for smelting silver ores in Swansea Valley, by a canal of sixteen miles in length.

The Port of Swansea offers great facilities for repairing vessels, having already one patent slip and three dry docks; there are also in progress eighteen acres of wet docks, consisting of a half-tide basin and inner dock, which will be completed in about eighteen months.

The annexed engravings represent a general view of the Beaufort Docks, and a plan of the same, together with the float; the figures 1, 1, are staircases, and 2, 2, counting-houses.

## IRON ROOF FOR SMITHFIELD MARKET, MANCHESTER.

F. R. Wheeldon, *Engineer*, Derby.

(*With Two Engravings, Plates* XII. *and* XIII.)

The space to be covered over by the iron roof is 440 feet long by 244 feet wide. It is composed principally of wrought-iron, and consists of two central spans of 72 feet each, and two side spans of 50 feet each. The whole is supported by cast-iron gutter-girders, of an average length of about 23 feet each, resting on columns about 25 feet high. At the apex of each roof is a skylight 15 feet wide on each side of the ridge, running the whole length of the market, and supported on louvre framing, by which ample ventilation is secured. The total area of glass is upwards of 60,000 square feet. The rain-water is conducted down each column into drains laid for the purpose; the girders or gutters are provided with an outlet at each end, for the discharge of the rain-water into the columns. And in fixing on the columns a space of a quarter of an inch is left between each, so as to allow of the expansion and contraction of the metal, and obviate the continual leakage from the breaking of joints, so common in long lengths of metal guttering. The meeting of the ends of the gutters on the columns is concealed behind cast-iron shields bearing the City Arms. One side of the market is bounded by a line of shops looking into the market, the other side will be an open arcade, consisting of 18 arches, resting on columns with foliated capitals. Each end of the market is finished with four ornamental elliptical arched screens, filled in with rough plate-glass, and springing from square open pillars with enriched capitals. The gable ends of each roof are finished with antefixes.

Mr. James Haywood, of Derby, is the contractor, and Mr. Wm. Fairbairn has been appointed by the Committe consulting engineer.

*Pendulous Reciprocating Steam Engine.*—A novel and cheap steam engine has lately been invented under the above title. It is "an eccentric revolving on its own diameter," in a "cylinder" or steam chamber suspended as a pendulum, the shaft on which the eccentric piston is keyed, being the main or driving shaft, and makes upwards of 100 revolutions per minute in a thirty horse engine. The principle of this engine is similar to the ordinary engine but it works with much less friction; a thirty horse high pressure will work with one pound of steam. "An eccentric revolving on its own diameter" contains the two motions of the ordinary engine, viz., rectilinear and revolving, though so amalgamated as to be hardly distinguishable. It has been received favourably by the Lords of the Admiralty, being especially adapted for screw propulsion, from the small space it occupies and the speed that can be obtained direct. The inventors and patentees, Messrs. Shiptons and Simpson, engineers, Manchester, obtained a medal at the Exhibition of 1851, since which great improvements have been made by them.

## STANDING ORDERS OF PARLIAMENT.

During the present session, an important question is engaging considerable attention before the examiners of petitions for private bills in the House of Commons. This question relates to the deposit of plans and sections, where it is sought to continue or amend an act passed for making a railway. It is well known, that during the period which has been emphatically called that of the "Railway Mania," a great number of acts were passed, the powers of which have never been executed, and the consequence is, that about this time, the powers have either expired or are about to expire. In consequence of this numerous bills have been brought into Parliament, both in this and in the last session, to revive the powers of certain acts which have either expired or are about to expire, and hence the question has arisen,—whether new plans and sections are required for such bills? In order to make this question intelligible, it must be explained, that according to the Standing Orders of the House of Commons, all private bills are divided into two classes—the first class comprising those for which no plans and sections are required to be deposited, and also comprising bills for *continuing* or *amending* acts passed for any of the purposes included in this or the second class, where no further work than such as was authorised by a former act is proposed to be made. The second class includes all those bills for which plans and sections are required to be deposited, including railways, canals, roads, &c.

Now, in all railway acts, the powers for the compulsory purchase of land, and the power to make the railway, expire after a certain number of years; and there can be no doubt, if the act for continuation be introduced while the powers of the original act are still in force, the object being merely to extend those powers during a further term of years, such a bill would undoubtedly come under the first class, and no plans and sections would be required in respect of such bill. But the case is widely different when the powers of the original act have expired, for then the new bill can scarcely be called a bill for *continuing*, but really appears, to all intents and purposes, to be a new act intended to confer new and original powers.

The decisions of the two houses with respect to this intricate point are not yet complete, but as far as they have gone hitherto, the decisions are at variance with each other.

In the House of Commons, it was held last year by the examiners, that when powers for the compulsory purchase of land had expired, but when powers to make the line still existed, a bill of the first class might be brought in to amend and continue the original act. In the House of Lords, however, this decision was directly reversed in the case of one special and as well-known bill—that of the South Staffordshire Railway. In this case, when the powers of compulsory purchase had expired, but powers to make had not expired, the Lords' Committee held that the bill was of the second class, and actually rejected the bill because the plans and sections applicable to bills of that class had not been deposited. So far, the decisions of the two houses are entirely at variance; but during the present session there are several bills before the examiners in the House of Commons where *all* the powers of the original act have expired, and the parliamentary agents are endeavouring to force these through as bills of the first class, not requiring plans and sections. Whatever may be the fate of these bills in the House of Commons, the result which will follow in the House of Lords is sufficiently obvious, since the decision of the latter being directly opposite to that of the Commons when any part of the powers have expired, will be still more strongly opposed to allow the bill to rank of the first class when all the powers of the original act have expired.

Seeing that this remarkable difference exists at this moment between the views of the two Houses of Parliament, let us consider for a moment which view appears to be most reasonable and consistent with justice and common-sense.

The entire powers of an act generally expire in five years, and, on application to the Board of Trade, it is possible to obtain a certificate extending the duration of these powers for a further period of two years, making in all a term of seven years. Now, if it be conceded that these powers may be revived at any time within the seven years without the deposit of new plans and sections, surely this is sufficiently liberal, without giving a company powers to come at any time after the seven years for revival of powers.

Most persons at all conversant with surveys, and accustomed to compare plans with the ground, will admit, that even in a much less period than seven years the face of a country, especially in an improving agricultural district, or even in a town, may be very much altered,—often so much altered as to make the original plans worthless.

The least therefore that a company can do, after the expiration of the seven years, is to deposit new and correct plans and sections, showing the accurate configuration of the country at the time of making the deposit. Remarks of the same nature apply to the Book of Reference, which undoubtedly ought to be new, as it is well known that tenancies or occupations frequently alter to a very great extent in less than seven years.

In fact, if the principle which is now advocated in the House of Commons be carried out, there is nothing to prevent a company coming to parliament twenty and even a hundred years after the expiration of their powers, asking for a revival under the name of a continuation, and claiming to bring in their bill without depositing plans and sections, or complying with any of the forms applicable to bills of the second class. We often hear complaints of the injustice and annoyance inflicted by too rigid an adherence to the mere technical formalities of the Standing Orders, but here is a case where a strict carrying out of the Standing Orders is a necessary measure for the protection of the landowner and others interested in the country to be traversed by the railway.

It is a case where immense injustice would be done by dispensing with the necessary plans and sections; as no one could otherwise know how his land is to be affected, or what is intended by the railway company. While we hope earnestly, that the question, as one of practical importance, will be speedily settled by an agreement between the authorities of the two houses, we cannot doubt, that in the present instance the House of Lords is correct in its decision.

Since the preceding remarks were written, one of the examiners has decided, in the case of an act passed in 1846, when a bill is brought in during the present session to continue that act, the whole of the powers having expired, that plans and sections ought to have been deposited, and in consequence has declared that the Standing Orders have not been complied with. This decision will probably be confirmed by the Standing Orders Committee; and so far the practice of the House of Commons will be assimilated to that of the Lords. The only point of difference now remaining between the two houses will be in the case of bills where all the powers have not expired.

## ON THE ACTION OF SAILS AND RUDDERS.

At a meeting of the Royal Scottish Society of Arts, the Rev. J. Brodie gave the results of some inquiries he had made into the principles on which the action of sails and rudders depends. After showing the importance of distinguishing between the overturning and impelling influence of the wind, he gave, as the result of his calculations and observation, the following rule. The faster any vessel sails in proportion to the velocity of the wind, when the wind is on the side, the more acute should be the angle which the sail makes with the line of the vessel's motion, in order to produce the greatest impelling force; and, on the other hand, the slower the vessel's motion in proportion to that of the wind, the more obtuse should that angle be made, in order to prevent at once a diminution of the impelling force, and a dangerous increase of the overturning influence of the wind.

He then directed attention to the alteration which should be made on the position of the after-part of the sail, in consequence of the wind rebounding from the anterior portion of it, and showed that the effect of the air rebounding from the fore-part of the sail would require the general angle of inclination to the line of the vessel's motion to be more acute than it would otherwise have been, and that all fore and aft sails should be drawn as tight as the strength of the materials will permit. In regard to the action of rudders and other appliances for steering a vessel, he showed the different forces on which that action depends, and directed attention to the fact, that the action of a sail near the stern not only resembles that of the rudder, but, being independent of the vessel's motion, might in many cases be advantageously substituted for it; and suggested, that in tacking sharp-built vessels the mizen-sail should be brought round much further to windward than is usually done, in order to prevent them missing stays.

## ON THE FRENCH AND OTHER METHODS OF CONSTRUCTING IRON FLOORS.

By Mr. Barrett.

At a meeting of the Royal Institute of British Architects, on January 23rd, Mr. Barrett requested permission to read a Paper in continuation of that read by Mr. H. Burnell at the previous meeting (see *Journal*, *ante* p. 54), containing some further explanation of the system of fireproof construction with which he was connected, and which was known as "Fox and Barrett's Patent;" and stated that the objects accomplished by this system, whether applied to public buildings, dwellinghouses, warehouses, mills, or other structures, were as follows:—

To make each floor, as well as the roof of the building, fireproof, so that fire can neither be communicated from one story to another, nor be introduced into the building by burning away the roof;

To avoid all lateral thrust or weakening effect upon the walls, and to distribute the weight over them, instead of concentrating it on certain points;

To secure the building from the attacks of dry rot;

To give increased solidity, firmness, and durability to the structure;

To render the floors practically sound-proof, when finished with a boarded surface;

And to combine these advantages with great simplicity and economy of construction, and a much less thickness of floor than is usually required.

These objects are accomplished by forming the floors of the buildings of materials as imperishable as the walls themselves, the leading features of the system being, the substitution of girders and joists, either of wrought or cast iron, for those of timber, and the employment of layers of incombustible materials, supported by and consolidated with the joists; the whole, when combined, forming a solid fireproof foundation, adapted to receive a finished surface, either of cement, asphalte, tile, slate, stone, or other material; or upon which foundation the ordinary boarded surface, upon light sleepers or bevilled fillets may be laid down.

The principle of construction, as applied in its most simple form, is shown in drawing No. 1.* The joists are fixed as the building proceeds, the ends being firmly built into the walls; and the floor is afterwards formed by light strips of wood, being first laid across from joist to joist, bearing on the bottom flange, and having narrow spaces between them. Upon these is spread a layer of coarse mortar, which is pressed down between the strips, so as to form with them a rough and uneven surface for the pricking-up coat of the ceiling; the subsequent application of which thoroughly imbeds the strips in mortar. A layer of concrete is then applied, of the requisite thickness to ensure the necessary rigidity in the floors. This thickness is determined by the nature of the building, the width of bearing, and the required degree of strength. The ceiling is applied of such a thickness as to perfectly imbed the flanges of the joists, and thus protect them from the action of fire from below. A fireproof foundation is thus formed, which, when thoroughly consolidated by the perfect setting of the concrete, is of great strength and rigidity, while the pressure upon the walls is *strictly vertical*. The finished surface of the floor is applied when the concrete is set and dry.

The joists are made of a form combining strength, lightness, and economy; their section depends upon the nature and uses of the building to which they are to be applied, and in all cases they are proved, before they are fixed, to an extent more than equal to the greatest load that can ever be brought upon them, care being taken that this proof is within one-third of the breaking weight in the use of cast-iron, and within the elastic limit of the material in the use of wrought-iron. This precaution may perhaps be considered unnecessary with the latter material, more especially as the mode of construction is one which, in effect, ties the whole of the ironwork together. It is, however, more satisfactory to prove the joists, and it is done with a lever at the most trifling cost.

The strips, which answer the double purpose of a foundation for the concrete and a key for the ceiling, may be made of any non-combustible material instead of wood; but it will be seen that these strips are so placed that their ignition is impossible, as they are completely imbedded in the mortar, and have a superincumbent mass of concrete, which prevents the establishment of any current of air, and renders them practically proof against fire. This has been proved on several occasions. Amongst other materials that can be substituted for these wood strips, small draining pipes may be mentioned, and if made of a triangular form they give an excellent key for the ceiling.

The concrete is formed of the materials most readily obtained in the locality of the building, such as fine gravel or ballast, burnt clay, or broken brick, mixed with a proper proportion of good stone lime, the whole being laid on moist, and well trodden in.

For the finished surface of floor, besides the ordinary flooring-boards, cements of different kinds, such as Portland, Keene's, and Parian, may be used. Asphalte, metallic lava, slates, and tiles in cement have also been employed as a finished surface, both for floors and roofs.

In applying this system to dwellinghouses and similar buildings, the joists are first tested singly to bear weights equal to from 120 lb. to 150 lb. per square foot of floor; that test being in the case of the employment of cast-iron one-third of the breaking weight, and in the case of wrought or rolled iron, the elastic limit of the metal. For buildings of a different character, and requiring stronger floors, the strength and the test are increased so as to meet the requirements of the structure. The joists are then fixed on the walls, and when built upon they form a series of ties, which greatly strengthen the building. A considerable accession of strength is given to the joists by their ends being thus firmly fixed in the walls, and every successive step in the process of construction tends both to develope additional strength, and also to protect the joists from the effect of impact or concussion. The strips or pipes are the groundwork of a continuous strut, which is completed by the subsequent application of the mortar and concrete, the latter completely imbedding the whole of the ironwork, which is pressed equally on both sides, and the concrete well trodden under the upper flanges of the joists. Thus it will be seen that the force of compression acts upon the joists only through the medium of the concrete. What the actual addition is to the original strength of the joists by, in the first place, firmly fixing the ends, and then by the perfect union and combination obtained in the process of construction, has not been ascertained; but an idea of the enormous weight that would be required to break down a floor may be thus obtained:—Supposing the room to be 18 feet square, thus containing 324 feet in area; the joists, having an original working strength of 120 lb. to 150 lb. per foot, the *average ultimate* strength is 405 lb. per foot, and if it is assumed that an increase of 25 per cent. only is obtained by the fixing and the consolidation of the entire mass, the breaking weight is 500 lb. per square foot, which, multiplied by the number of feet (324), gives 1446 *cwt.*, or upwards of 72 *tons*, as the load required to break down the floor of a room 18 feet square; and this, it should be remembered, is not a floor in which extra strength is provided, but merely the room of an ordinary dwellinghouse, which if packed with 200 people, or as full as the "Black Hole" at Calcutta, would only be loaded with 15 *tons*, or about one-fifth of the breaking weight of the floor. In assuming 25 per cent. as the gain in strength, a low estimate is taken, for an increase of twice this, or 50 per cent. is commonly reckoned as due to the firmly fixing of a beam alone; while the great principle of this system is the gradual development of strength and firmness; the effect of the load being transferred, through the medium of the concrete, to the walls or other vertical supports; the entire floor becoming in effect *one large beam with iron ribs*. This calculation has reference to the use of joists of cast-iron; with joists of wrought or rolled iron the ultimate strength would be considerably greater.

There is of course a limit to which single joists can be carried on this system, but as rooms 24 feet in width have been constructed with them, and without the use of main girders, it is very rarely that the latter are required for dwellinghouses and buildings of the same class. When, however, the span much exceeds 20 feet, the adoption of girders with minor joists bearing upon their flanges is the most economical method. In this way, floors of 60 feet span have been constructed, the girders having an intermediate bearing on columns placed 20 feet apart. Floors of 30 feet, 36 feet, and 42 feet span have also been constructed with girders and joists, without the aid of columns.

It may be said therefore that there is scarcely a limit to the application of the system as regards the space to be covered,

* The drawings referred to were exhibited at the meeting, but we are unable to publish them in our present Number: the discussion on the subject being again adjourned, we hope, however, to be enabled to illustrate the various systems referred to by Mr. Barrett, in our report of the discussion next month.

while there is probably no kind of building to which it is not capable of being adapted. Besides public buildings of different kinds, such as hospitals, lunatic asylums, and workhouses; buildings for records, railway offices, banks, hotels, exhibition-rooms, baths and wash-houses, training institutions and schools, &c., the system has been extensively adopted in private buildings, such as mansions, dwellinghouses, offices and chambers, and dwellings for the working classes. It has also been employed in the construction of warehouses and mills.

This system of construction is not therefore to be regarded as a mere theory, but as one which has been very extensively applied, and has moreover stood the test of an experience of twenty years: I mention this first to disclaim all merit whatever in having originated it. It is to a member of the medical profession, recently deceased, Dr. Henry Hawes Fox, that we owe the introduction of this principle of construction. That gentleman erected, in the years 1833-4, an extensive private lunatic asylum in Gloucestershire, and built it entirely upon this principle, and ten years afterwards, in the year 1844, at the urgent solicitation of his friends, and as the only means of bringing a valuable invention, which had on several occasions saved the building from destruction by fire, into general use, he was induced to patent it. My own connection with it dates from the year 1848, since which period it has, as I have said, been applied successfully to almost every description of building. Another reason for my mentioning the early employment of this mode of construction, and the date and object of its being patented in England, is, that it has struck me that some persons may possibly imagine that the principle may have been borrowed from the French system, described in Mr. Burnell's paper. Nothing could be more erroneous than such a supposition; a comparison of dates, indeed, at once sets this question at rest, the patent having been taken out in 1844, ten years after its successful employment by the patentee, while, as I gather from Mr. Burnell's paper, the employment of the French system is comparatively of recent date.

In 1850, I visited Paris myself, with letters of introduction to various architects, only one of whom referred to the use of iron there. He told me that a building was then in course of erection, and recommended me to see it, which I did: it was the Hospice de la Republique, near the Northern Railway Station. The floors were formed by means of girders of wrought-iron, consisting of two rectangular bars, the lower one straight, and the upper one arched or curved, both placed on edge, and the two occasionally tied together by vertical straps. These were placed about 5 feet apart; cross-bars 5 feet apart were carried at right angles with the girders, and three smaller flat bars on edge ran between each girder: spaces of about 4 feet × 15 inches were thus formed, and these spaces were filled in with pottery, slightly wedge-shaped, imbedded in plaster; dwarf walls were built on the top of the pots to receive timber-joists, upon which the floor-boards were laid. The whole appeared to be a very expensive mode of construction, occupying a depth of about 18 inches for a span of 3½ mètres, or 11 ft. 6 in. This was the only instance I heard of, at a period six years subsequent to the date of the patent. But independently of priority of date, it will be seen on close examination that the two systems differ both structurally and economically, the only point of resemblance being the form of the joists, which are alike, except that the French joist is made to taper towards the centre or neutral axis. The peculiar form of intertie adopted in Paris is available where plaster is abundant, the chemical constituents of this material enabling it to set so rapidly that a considerable open space can be filled in without any intervening support. These interties however are necessarily much more expensive than the strips upon which the concrete is laid in my system, and which are the mere refuse of a builder's yard. The material used for filling-in is different, both as regards its thickness, its tendency to expand, its possible effect on the iron, and the strong affinity of gypsum for ammonia; and the final results of the two modes of construction are different,—the one producing a finished floor, admitted to be subject to deflection with an ordinary load, and the other producing a floor of very great rigidity.

In illustration of the method of applying this system in cases of extended bearings, where the use of girders is necessary, the drawings Nos. 2 and 3 and from 7 to 11 are exhibited. No. 2 is a section illustrating the application of the system with both girders and joists of cast-iron, and shows the method of construction employed at a large flax mill at Newry, the plan of one floor of which is given in No. 3, an Ironmongery Warehouse at Bristol, St. Mark's College, Chelsea, the Metropolitan Convalescent Asylum, and various other public and private buildings. The girders, a section of which is shown, bear either upon columns or walls, and the joists, which are shown in elevation, run at right angles to the girders, and are cast with a shoulder to drop over the flange of the girder, and form a tie. The depth of the girders is of course in all cases adapted to the span, and when this depth is greater than the thickness of the floor, an intermediate flange, supported by side feathers, is cast upon the girder. The projection below the ceiling line should be covered either with plaster or fireproof cement, and take the form of a moulded beam, as shown in the figure, drawing No. 2. The thickness of the floor in this construction rarely exceeds 10 or 12 inches, and the saving of space as compared with the iron girder and brick arch system, will be understood from the fact that a depth of 20 inches is required at the springing line of the arches. This difference, in a mill or warehouse several stories in height, will either economise 3 or 4 feet of walling all round the building or give an increased height in the different floors. Drawing No. 7 shows the combination of wrought-iron boiler-plate girders and cast-iron joists, as adopted at the recently erected extensive additions to Guy's Hospital, where the rooms are from 21 feet to 30 feet wide. The main girders have cast brackets riveted to the web to receive the joists, which are of cast-iron with shouldered ends, to drop into the brackets: considerably more than an acre of floor has already been so constructed in this building. Drawing No. 8 shows the application of wrought-iron exclusively; both girders and joists being of this material. The girders, which are also of boiler-plate, have an additional or intermediate flange of angle-iron, to give the requisite bearing for the joists; which latter are of rolled iron, and are occasionally tied to the girders by small angle-plates, bolted or riveted on. This application of the principle has been adopted in various public buildings (amongst which may be mentioned, the Foundling and Brompton Hospitals, the New Offices of the London and Brighton and the Bristol and Exeter Railway Companies, Her Majesty's New Highland Residence, Balmoral, &c.), 42 feet being the extreme width of bearing to which it has been at present carried; but there is no difficulty in extending it much beyond this, as the adaptation of boiler-plate girders to this system of construction, combined with joists of rolled iron, provides for every possible contingency, whether as regards width of bearing, strength of floors, or liability to impact or vibration. In cases, however, where the use of columns can be admitted to shorten the bearings to 9 or 10 feet, the same advantages may be secured by the adoption of rolled iron, for both girders and joists, thus avoiding the use of riveted plate and angle-iron girders, the labour on which necessarily makes them somewhat expensive. Diagrams illustrating this double application of rolled iron are shown, drawing No. 9 being the plan of a floor 63 × 28 feet, with a row of cast-iron columns running down the centre: these columns support a line of rolled iron girders, which pass through a hole left in the top of the column, as in drawings Nos. 10 and 11. The joists are carried over the backs of the girders, and are rolled of a length to span the full width of the building, including the bearing on each of the side walls. The advantage of having the joists rolled in long lengths, and fixed with an intermediate support on the main girders, is a most important one, not only as affording an efficient tie to the building, but as greatly increasing the strength of the floor; this is an advantage which is peculiar to the use of wrought-iron. The ends of the joists may be either pierced and secured to the walls by a rod or S piece, or they may be bolted to a plate of iron built into the wall. The extreme ends of the girders being also secured to the walls, a tie in each direction is given, and the whole forms a framework of wrought-iron, possessing immense strength, each part affording efficient aid to the rest. In buildings of greater width, the addition of another line of columns would enable the same arrangement to be adopted; the joists being in that case rolled in long and short lengths, placed alternately so as to break joint, and bolted or riveted together at the points where they take a bearing on the girders.

I have already remarked, at the former Meeting, that from prejudice against cast-iron joists, though they have been very extensively and successfully used, I was induced three or four years ago to turn my attention to wrought-iron. But here I had to break entirely new ground, to institute experiments, and to overcome many obstacles from the manufacturers. The main question was as to sufficiency of strength in a section of a form best adapted for the purpose—the ═ shape—but for the manufacture of which no rolls were in existence. Experiments were therefore tried on ⊥ shaped bars, and a formula deduced from these, and acted upon by my having rolls prepared from 4 to 8 inches deep of the ═ section. Subsequent experiments on these had fully verified the correctness of the formula, but I had not carried my experiments more than 60 per cent. beyond the limit of elasticity, this amount of strain producing a permanent set of only $\frac{3}{40}$-inch. I had heard that iron joists were coming into use in France, but knew nothing of the strength they employed, and have never seen either the joists or floors to this day. I have however recently obtained some information as to the strength considered sufficient in Paris: a friend who is about to build there had sent me some particulars obtained from the engineer of the company manufacturing the joists, and a printed statement of experiments on their strength. This information and these experiments are important as bearing on the question of cost, to which I will almost immediately refer. It seems that under no circumstances, and except in a very extraordinary case, would they place the joists less than from 70 to 80 centimètres apart; and for a floor of 6 mètres, joists 12 centimètres deep, and weighing 14 or 15 kilogrammes per mètre, would be used.

I think the first point to establish is the sufficiency, or rather the actual strength, of the joists, of the scantling used in Paris, and the table of experiments enables us to examine this:—

Joists of 12 centimètres deep, and weighing 15 kilogrammes per mètre, were proved at bearings of 4, 6, 8 and 10 mètres. Converting these into English dimensions, we have for the bearing of 6 mètres, 19 ft. 8¼ in.; for the depth of the joists, 4¾ inches; for the weight per feet run, 10 lb; and for the mean distance apart, 75 centimètres, or 30 inches. From the table I find that a joist of these dimensions was proved at 6 mètres bearing with 2000 kilogrammes on centre, which is equal to 4000 distributed, or 8800 lb. English. The area of floor this joist would carry is—

19′ 8″ × 2′ 6″ = 49′ 2″ and 8800 lb. ÷ 49′ 2″ = 179 lb. per foot super.

But a similar joist was proved with the same weight at 8 mètres bearing, which is equal to 5333 kilogrammes at 6 mètres:

5333 kilog. = 11730 lb. English ÷ 49′ 2″ = 240 lb. per foot super.

But even this did not reach its limit of ultimate strength, for the joist was further tested at 10 mètres bearing, until the deflection was increased to the extent of just 50 per cent. beyond the last load. It may therefore be safely assumed, that a load of 300 lb. per square foot of floor, would not have broken the joist.

None of the joists I use have been tested to anything like this extent, for as I have said, I have proceeded upon the principle that the joists should not be loaded beyond their elastic limit. We however easily arrive at the strength of such a joist as I have been referring to (for the purpose of comparison) by adopting the simple and universally received formula, that the strength is as the depth$^2$ × thickness, and I will reduce both this joist and the one I have used (and which forms the basis of my calculations of comparative cost with a timber floor) to rectangular bars, and compare them:

Taking first the French joist—a weight of 10 lb. per foot gives a sectional area of just 3 square inches; and a rectangular bar of this area and 4¾ inches deep, would give the following result:—

15 kilog. per mètre = 10 lb. per ft. = 3 sq. in. = $4{\cdot}75^2 \times {\cdot}63 = 14{\cdot}214$
while the English joist = 16 lb. ,, = 4·8 ,, = $7^2 \times {\cdot}686 = 33{\cdot}614$

And further,—

$$14{\cdot}214 \div \overline{19'\,8'' \times 30''} = {\cdot}289 \text{ per square foot,}$$
$$\text{and } 33{\cdot}614 \div 20'\,0'' \times 24'' = {\cdot}840 \quad ,,$$

Giving the result of a comparison of strength just 1 to 3; while a comparison of weight would stand thus:

French joist carries 19′ 8″ × 30″ = 49′ 2″ weighing 220 lb. = 450 lb. per sq.
English joist carries 20′ 0″ × 24″ = 40′ 0″ ,, 352 lb. = 880 lb. ,,

This gives a result of very nearly as 1 to 2.

Now the conclusion seems unavoidable, that if, as I have demonstrated, the breaking load of the French scantling of joist is equal to 300 lb. per square foot, it is in my case equal to 900 lb. per square foot; but even this is assuming that no strength whatever is derived from the principle of construction, while I believe that with properly constructed floors, that is, with good concrete of the proper thickness, these results, satisfactory as they are, may be increased by at least 50 per cent.

Turning now to the question of cost, the following statement has been prepared of the approximate comparative cost of a floor for a room 12 feet square, and for one 20 feet square, constructed on the fireproof principle, and with timber. The results are as follows:

| | Room 12′ × 12′ £ s. d. | Room 20′ × 20′ £ s. d. |
|---|---|---|
| Fireproof floor, formed with strong joists of rolled iron, and a cement surface | 7 14 10 | 32 4 3 |
| Deduct excess of iron in joists to reduce them to the strength of the French scantling | 1 17 10 | 10 12 1 |
| Cost of fireproof floor | 5 17 0 | 21 12 2 |
| Add difference of cost between 1 inch flooring boards and a cement surface 25s. per square | 1 16 0 | 5 0 0 |
| Cost of fireproof floor with boarded surface | 7 13 0 | 26 12 2 |
| Cost of timber floor pugged | 8 15 4 | 31 12 3 |

These calculations are made with the price of iron nearly 50 per cent. above that of eighteen months ago, and much dearer than for many years past. The details of these calculations are given below:—

*Dimensions of Room,* 12 × 12 *Feet.*

*Fireproof floor formed with strong joists of rolled iron and cement surface—*

| | | |
|---|---|---|
| Five rolled joists, 13′ 8″ long, 8¼ lb. per foot—113 lb. each —5 cwt. 5 lb. @ 15s. | 3 15 8 | |
| Concrete, &c., ceiling and cement surface of floor, 55s. per square | 3 19 2 | |
| | £7 14 10 | |
| Deduct excess of iron in joists to reduce them to the strength of the French scantlings, £3 15s. 8d. ÷ 2 | 1 17 10 | |
| Cost of fireproof floor | ...... | 5 17 0 |
| Add difference of cost between 1 inch flooring boards and a cement surface, 25s. per square | ...... | 1 16 0 |
| Cost of fireproof floor with boarded surface | ...... | £7 13 0 |

*Timber Floor—*

| | | |
|---|---|---|
| 11 joists, 13′ 6″ long, 9″ × 2″ = 18¼ cubic feet @ 3s. | 2 15 6 | |
| Wall plates, 24 feet run, 4½″ × 3″ = 2¼ | 0 6 9 | |
| Herring-bone strutting, 3s. per square | 0 4 6 | |
| Half-brick trimmer and centering, 4′ 0″ × 2′ 0″ | 0 8 0 | |
| 144 feet sup. 1 inch flooring boards, @ 35s. per square | 2 10 5 | |
| 16 yards lath and plaster ceiling, @ 1s. 4d. | 1 1 4 | |
| 144 feet sup. fillets, sound boarding and pugging, @ 20s. per square | 1 8 10 | |
| Cost of timber floor, pugged | ...... | £8 15 4 |

*Dimensions of Room,* 20 × 20 *Feet.*

*Fireproof floor formed with strong joists of rolled iron and cement surface—*

| | | |
|---|---|---|
| Nine rolled joists, 22′ 0″ long, 16 lb. per foot—352 lb. each—28 cwt. 1 qr. 4 lb. @ 15s. | 21 4 3 | |
| Concrete, &c.—ceiling and cement surface of floor, 55s. per square | 11 0 0 | |
| | £32 4 3 | |
| Deduct excess of iron in joists to reduce them to the strength of the French scantlings, £21 4s. 3d. ÷ 2 | 10 12 1 | |
| Cost of fireproof floor | ...... | 21 12 2 |
| Add difference of cost between 1 inch flooring boards and a cement surface, 25s. per square | ...... | 5 0 0 |
| Cost of fireproof floor with boarded surface | ...... | £26 12 2 |

*Timber Floor and Ceiling of a substantial kind—*

| | | |
|---|---|---|
| 17 joists, 22′ 0″ long, 12″ × 2¾″ = 85⅔ feet cube, @ 3s. | 12 17 3 | |
| Wall plates, 40 feet run, 4½″ × 3″ = 3¾ | 0 11 3 | |
| 2 wrought-iron ties, ¾″ diameter with screws, &c., 40 feet @ 7½d. | 1 5 0 | |
| Herring-bone strutting, 3s. per square | 0 12 0 | |
| Half-brick trimmer and centering, 6′ 0″ × 2′ 0″ @ 1s. | 0 12 0 | |
| 4 squares 1¼″ battens, @ 42s. per square | 8 8 0 | |
| 44½ yards lath and plaster ceiling, @ 1s. 6d. | 3 6 9 | |
| 4 squares fillets, sound boarding and pugging, @ 20s. | 4 0 0 | |
| Cost of timber floor, pugged | ...... | £31 12 3 |

Mr. Barrett stated, in reference to the practicability of reducing the scantlings of the joists on his principle, that although it might not be desirable to reduce them to the French standard, he had no doubt rolled iron joists of an intermediate strength between those used in Paris and his own, might be employed with safety, and thus bring down the cost of a fireproof floor with a boarded surface to that of an ordinary pugged timber floor. M. Thomas, an eminent Parisian builder, had adopted Fox and Barrett's principle in several houses in Paris, using joists of the strength generally employed there, and he had found the floors superior to the French system, which was defective from its want of rigidity, and from allowing the transmission of sound when the hollow pots were used in combination with the plaster. Mr. Barrett concluded by observing, that it might be considered that he had a personal interest in advocating the English system. Undoubtedly as the proprietor of the patent, to a certain extent he had; but his interest in the patent was for a limited period,—

a period which would be totally inadequate to repay even one-half of the very large sum which had been sunk in establishing it. Independently of personal considerations however, the subject was one of general interest; and as the losses by fire in this country were reckoned by millions of pounds annually, he might say it was one of national interest. Certainly, the general introduction of a system which must promote the use of iron (a material for the production of which our resources were unlimited, and in the manufacture of which native skill only was employed) should be encouraged in every possible way.

*Discussion.*—Mr. MOCATTA (the Chairman) said, that as architects they must feel the importance and advantage of an incombustible and imperishable floor. With reference to cost, it appeared desirable to ascertain the degree of lightness which would be free from vibration and deflection, in order to avoid a very expensive mode of construction. Mr. Barrett's system was, he believed, the development of that executed some years ago in Gloucestershire by Dr. Fox, which excited much interest at the time. With respect to one matter of detail in Mr. Barrett's system,—namely, the small laths placed between the joists to receive the concrete, he inquired whether those laths were not very slight to carry so great a weight, as if they were liable to become bent, the consequence would probably be a cracked ceiling.

Mr. BARRETT stated that these laths were merely used as a support to the concrete, till it became set. They were 1 inch square by 24 inches long, between the bearings on the iron joists; the weight upon them being only $\frac{1}{16}$th of their breaking weight. As the concrete became set, the structure became wholly independent of these strips, and if it were practicable to remove them, the structure would for any purposes of strength be complete without them. He had constructed many acres of flooring in this way, and not the slightest difficulty had arisen from the cause suggested.

Mr. TITE, said, it appeared to him that the present question was a little involved in a discussion raised some time ago by the late Professor Cowper, who had brought before the Institute the wonderful merits of construction adopted in the Crystal Palace, and told them that they were behind hand in all inventions, and had to learn everything from the engineers, especially the use of iron. Now he, Mr. Tite, freely admitted the ingenious application of familiar principles which the French system of flooring displayed; but the question of cost, referred to by the Chairman, was probably the main reason why iron joists of this character had not been more extensively used. Architects had certainly been taught by the engineers to be more extravagant than they used to be, but to an architect the question of cost must be one of the gravest consideration. It was true that in Paris they had seen a great deal of the application of wrought-iron joists by Visconti and others, but he felt bound to claim a perfect acquaintance with this matter in his own experience of some twenty-eight years. There was, in fact, nothing new in the principle, either as respected the iron or the concrete. Mr. Tite then adverted to the early methods of forming floors: first by a row of beams placed side by side, the least dimensions downwards, and of an uniform substance, and afterwards by means of strong heavy girders or bearing beams of oak, producing the greatest possible rigidity. This system, introduced in Italy, was adopted by Sir C. Wren, and when (after the fire of London) oak became scarce, fir was used in the same way. This however, being more elastic, was found to bend, and a system of trussing girders by the insertion of iron was adopted, and gradually carried to a great extent. (Mr. Tite described, and illustrated by sketching, several of the varieties of trussed girders formerly in use). Sir Robert (then Mr.) Smirke at length introduced the cast-iron girder, and the use of concrete (the latter in the foundations of the Penitentiary, which had failed). Feeling the defects of the old systems of flooring, and believing that they might be remedied by the employment of cast-iron girders, Sir R. Smirke, after consulting Mr. John Rennie, introduced the use of them, and had told him (Mr. Tite) that the first he used was of the extraordinary length of 34 feet, without a support between the walls. The next step was made by Mr. Farrell, a smith, who was employed under Sir R. Smirke at the Custom House, and he, regarding cast-iron as a very brittle and dangerous material, proposed the use of wrought-iron, for which he took out a patent; and between that system of Mr. Farrell's, and the systems now under discussion, there was in fact no difference whatever, except in the ingenuity of the means which had been brought to bear upon the latter. In France earthern pots or plaster were used with iron rods between the joists, in England concrete and wooden laths; but these were merely improvements on the patent of Mr. Farrell, who suggested that the space between the joists might be filled in with any fireproof material. The joist adopted by him was of this form ⊥, and as he could not get rolled iron, he riveted the parts together. Mr. Tite stated, that he had used the system described, many years ago in a large public school, where a cheap fireproof floor was required, with complete success, and when he last saw this construction it was as perfect as when first erected. The space between the joists was in this case about 4 feet and filled in with 4 inch and 6 inch Yorkshire landing; which gave a good upper as well as under surface, the interstices being filled with Roman cement, and the ceiling formed of the same material. This was applied to a space of 300 feet long, and on an average 15 feet wide. Important as this subject was, Mr. Tite proceeded to express his opinion, that the systems of flooring referred to were not applicable to architecture in its more important forms. They might do for a range of offices, an hospital, or any building where plain ceilings were sufficient; but the architect had to consider decoration, and must apply his means accordingly; and it would often happen that the ordinary mode of construction introduced by Sir R. Smirke, with subsequent improvements, was better adapted to such purposes, than novelties of more recent invention. With regard to fireproofing, the world was not satisfied with actual safety, but required that no part of a building should be combustible, even if no danger could arise from its becoming ignited. Thus, at the Royal Exchange, where he had employed cast-iron girders, with arches in cement, the improper substitution of a new stove for the one fixed by his directions, had caused fire to communicate to the frame of a blank window. This frame however might have been entirely consumed without the slightest injury to the building, but the public was not satisfied: an inquest was held as to the cause of the fire, and great complaints were made that the building was not incombustible in every part. With regard to the safety in the use of concrete, as a protection from fire, especially when the concrete was only a few inches in thickness, Mr. Tite expressed much doubt, considering it inferior to the York landings employed by himself as above mentioned. Mr. Farrell had sent to Sir R. Smirke a description with drawings of his method, and the reply of Sir Robert was that he had done the same thing himself for twenty years, only turning the girder with the flange upwards T, instead of downwards. Whether Sir Robert had done this in cast or in wrought iron however, and to what extent, did not appear. He, Mr. Tite, should have used wrought-iron joists upon Mr. Farrell's plan more generally, but for the improvements and popularity of cast-iron girders; and should certainly have employed iron much more extensively, but for the great question of expense. He was very glad the subject had been discussed, as it would be of the greatest possible advantage, if a cheap and durable floor could be constructed, which should be fireproof in the honest sense of the word.

Mr. T. H. WYATT considered that the present was not a question of precedency, but of general applicability; and as he had been one of the first to use Messrs. Fox and Barrett's system extensively, and had employed it to the extent of 1400 or 1500 squares, he begged to say a few words in its favour. In the Wiltshire Lunatic Asylum, erected by him, it was essential that the estimates should not be exceeded. Originally a judicious system of pugging had been contemplated, but by the adoption of Fox and Barrett's system, not one shilling had been added to the cost, and the results had been most satisfactory. He had tested the deflection of the joists employed, and found it very slight indeed; and he was convinced that any sound wall would bear the weight of this construction, amounting as it did to not more than 78 lb. for each superficial foot of flooring. Mr. Wyatt confirmed the experience of Mr. Piper as to any needless doubts which might be felt respecting safety of the construction until rigidity was imparted to it by the concrete filling in. This desirable result however was obtained in a most remarkable degree. In the building referred to, he had used joists up to 16 feet bearing, but others of larger bearings since employed had been equally satisfactory. He had felt some misgivings as to the possible decay of the wooden strips resting upon the joists, but he believed that, as Mr. Barrett stated, they might with safety be removed as soon as the concrete had set. The only serious doubt was, as to the action of any damp which might arise from the concrete, supposing the wooden floor to be laid covering it before it had had time to become thoroughly dry. He had used a boarded surface of floor with this system, though if he were building a house for himself, he would prefer one of cement. There were, he believed, no wooden floors in the asylum built by Dr. Fox. With respect to the depth of the iron joists, he had examined Mr. Barrett's calculations, and was convinced they were free from all possible risk, and might be made from a considerably reduced formula, and yet be within the mark of safety. Mr. Wyatt then adverted to the action of a body of flame upon ordinary plaster, and described some experiments made by Mr. Hardwick at the St. Katherine's Docks, in which plaster slabs 1⅛ inch to 1¼ inch thick, screwed to the underside of the wooden joists, were exposed to violent flames from tar barrels, and showed that very little fear need be entertained of the effect of fire upon a ceiling, even if the whole contents of the room were to become ignited. From this he inferred that the laths employed in Fox and Barrett's system did not constitute any objection to it; and he added that he considered it one which was really well deserving the attention of the members of the Institute.

Mr. I'Anson also spoke in favour of Fox and Barrett's system, and considered that although both that and the French system might have some analogy to the old methods described by Mr. Tite, they showed a great advance upon those methods. The concrete and other substances were superior to York landing, inasmuch as they tightened up the joists, and gave its chief value to the construction. The elasticity of the joists, until they were filled in was most remarkable, but in about six or eight months after completion the floor became perfectly rigid. He had employed Mr. Barrett's system in a large dwellinghouse 45 feet by 26 feet in dimensions, and the cost of iron did not exceed 90*l.*; the whole of the timber being saved.

Mr. Tite explained that the York stone in Mr. Farrell's plan was perfectly connected with the iron by means of the cement.

Mr. Boulnois stated, that it had been asserted by Mr. Brunel, that the concrete was very liable to become disintegrated, and so to part from the joists in Fox and Barrett's system, and to leave them hanging up like so many laths. He had used the system for a 19 feet bearing three years ago, employing joists without any upper flange, but the floor was subject to considerable vibration, which might be increased beyond the control of the architect—for instance, if used for dancing. He wished to know if the concrete formed a rigid slab equivalent to the stone employed by Mr. Tite, and whether in Mr. Barrett's experience, he had ever found the concrete shaken off from the joists.

Mr. Barrett said that he had not. The concrete could not be acted upon from below, nor from above except by a complete disruption of the upper part. He considered that Mr. Boulnois was altogether begging the question, by assuming the fact of vibration, which he could not allow to be taken for granted. After an experience of twenty years with bearings of as much as 18 feet, subject to all the ordinary wear and tear of a dwelling-house, he could not conceive the possibility of such a result as the concrete becoming loose.

Mr. Boulnois could confirm Mr. Barrett's opinion by his knowledge of the floor at Messrs. Nurse's coach factory, in Regent-street. There was a sag in that floor, in consequence either of the joists not being cambered, or not being supported in the middle; but that sagging had never increased, although the floor was subject to very great vibration from carriages being moved over it, nor had the concrete been disintegrated. These, however, were matters which patentees ought to be able to speak to, without leaving architects to find them out.

Mr. Barrett said that he had no means of finding out such a fact, which was not necessarily correct simply because Mr. Brunel had asserted its possibility. He must be content with referring to his own experience, confirmed as that had been by Mr. Boulnois himself.

Mr. Tite called attention to the question of Mr. Boulnois as to the degree of strength and rigidity of the concrete taken alone; and objection to a wooden floor over the concrete on the score of expense.

Mr. Piper said that his own gateway was covered with rolled iron joists, filled in with common York paving, and then (to meet the requirements of the old Building Act) covered with concrete, so as to make a thickness of 14 inches. He had, however, ceased to use this method, observing that York paving was exceedingly destructible by fire, and that practically it did not furnish a fireproof floor. With reference to the doubt suggested by Mr. Boulnois, he believed the patent floors would be found to move altogether, if at all; that there was in fact a close union between the concrete and the metal, and no distinction in the amount of vibration of each. A floor over a stable, subject to all the wear of a loft and granary, had stood for six years (covered with Portland cement) without the slightest disintegration. Mr. Piper concurred with previous speakers as to the resistance of plaster to the action of fire, and therefore considered the laths used by Mr. Barrett were perfectly safe.

Mr. Tite inquired what experience there had been of the action of fire on concrete. He apprehended if there were flint stones in it the concrete would split, and yield under the action of fire.

Mr. White referred to the fire at Mr. Ald. Humphrey's warehouses, in February 1851, where, he believed, the concrete alone prevented the spread of fire to the vaults, which were filled with valuable and combustible goods.

Mr. Barrett read an extract from the *Times* newspaper of the 21st February, 1851, in confirmation of this statement. He added that several fires had occurred in the building erected by Dr. Fox. On one occasion all the furniture in a room, and on another occasion a four-post bedstead and furniture, had been reduced to ashes without injury to the ceilings. Mr. Piper could probably explain the circumstances attending the fire at Messrs. Collard's manufactory at Camden-town.

Mr. Piper said, that there the upper floors were on iron girders, but not fireproof. The basement was covered with a light ceiling on Fox and Barrett's patent, and with ordinary care on the part of the firemen it would have preserved the property below. The firemen, however would not interfere, and what was termed a second fire took place, and destroyed the contents of the basement story.

Mr. Barrett read the official report of Mr. Baker, the district surveyor, to the official referees, describing in detail the circumstances referred to, and which concluded thus:—"From the foregoing statement, there is no reason whatever to doubt the efficiency of Fox and Barrett's patent, when applied as a sound fireproof party structure; on the contrary, I am well pleased with it, and even with its resistance to very great concussion, when the latter is spread over a surface; I only wish it had resisted the single and more *pointed* attacks as well as the combined." These "pointed attacks" refer to the fall of iron columns and girders from a height of 30 feet upon a fireproof ceiling never intended to carry anything but itself.

Mr. Tite contended that York stone would not yield to a fire above it, and again inquired for any proof of the effectual resistance of concrete to the action of fire.

Mr. Barrett said his system had resisted fire in dwelling-houses frequently, but it had not been tested by a fire in any large warehouse.

Mr. Scoles observed, that if the ceilings were plastered where these fires occurred, the concrete had not been tested.

Mr. Hesketh thought the case of Mr. Ald. Humphrey's warehouses unsatisfactory as a proof of the value of concrete. The fire did not get under that floor, and it was protected from above by the rubbish which fell upon it.

Mr. Boulnois contended it was the duty of the patentee to settle this point, which he might easily do by erecting an experimental house and setting fire to it.

Mr. Donaldson: No architect would use such a ceiling without plastering it, and it was in evidence that intense and long-continued heat would not damage the plaster.

Mr. Boulnois complained that insurance companies made no reduction in their charges where the patent was used. If the patentees proved it to be fireproof, this object might be attained.

Mr. Barrett said this rested with the proprietor of the building. The house in which his own offices were cost 3000*l.* or 4000*l.*, and was only insured for 600*l.*, just to cover the little damage that could arise.

Mr. Tite having referred to covenants to insure leaseholds to two-thirds the value, Mr. Wyatt said he had advised the Wiltshire magistrates not to insure their lunatic asylum; and Mr. Barrett said, that in the case of the Royal Porcelain Works at Worcester, where his system had been introduced, the insurance had been reduced from 7*s.* 6*d.* to 1*s.* 6*d.* per cent.

Mr. C. H. Smith referred to the causes which rendered some of the varieties of laminated York stone used for fireproof construction more destructible by fire than others. Those termed self-faced, having been naturally divided, and containing more clay to absorb moisture, which would be converted into steam by great heat, and consequently split, were the most unfit for the purpose. Under ordinary circumstances, he was of opinion that concrete, properly made, would bear a very considerable degree of heat; perhaps more than Yorkshire stone.

Mr. C. C. NELSON, in continuing the discussion on February 6th, observed, that on comparing the French and the English systems, which had been brought under consideration, one great point of similarity was found between them, inasmuch as the main supports in each were the rolled iron joists; on the other hand these joists were much closer together in the English than in the French system, in which latter, however, the iron entretoises, or transverse rods, were placed further apart than the wooden laths in the English system; while the material used for the filling in differed materially, being plaster of Paris, or plaster and hollow earthenware pots in one case, and concrete, formed of lime, sand and gravel, in the other. Neither of the systems under discussion could be considered perfectly novel; and indeed, so far back as the year 1849, a paper was read to the Institute by Mr. Donaldson, describing a mode of construction adopted by an engineer named Thompson, in a bridge over a railway near Glasgow, in which tubular iron girders, of boiler-plate $\frac{3}{8}$-inch thick, were made solid by the introduction of concrete between the plates to render them unyielding and rigid; the girders being then tied and framed together with bars of iron, the space between them was filled in by arched brickwork. With reference to the question which had been raised at the former meeting as to the expansion of concrete, Mr. Nelson referred to the "Essay on Concrete," by Mr. Godwin, in the first volume of the Transactions of the Institute, for which the first medal of the Institute was awarded in 1836, as containing the results of experience on the subject; clearly proving that concrete in setting did expand. As to the nature of the French plaster, M. Delassaux had forwarded the following communication in 1846, describing the difference between that material and the "plaster of Paris" used in this country, from which it would appear that the former was a much better material than the latter:

"The English plaster stone is a sulphate of lime, destitute of water, except a small portion of sulphuric acid; it is in fact an imperfect alabaster. The consequences of the chemical composition of this stone are, that burnt and reduced to powder in the usual way, it is not capable of resisting the vicissitudes of the weather, and the small quantity of sulphuric acid it contains prevents its setting quickly or becoming hard. It can consequently only be employed for interior plastering, and generally for works requiring but little solidity—its employment in construction is thus very limited. The stone of the French plaster of the environs of Paris is a sulphate of lime composed in the best proportions, the acids being almost equal to the bases; properly burnt it preserves all its acid properties, and reduced to powder and mixed it becomes very hard in one day. Unlike the English plaster there is no need to grind it very fine, on the contrary for strong work it is better to be rather coarse; it is only in decoration that it is employed as fine as the English. In France, along the borders of the Seine, the houses are constructed with this material; for solid construction, grouting the joists of stones, for exterior and interior decoration, and masonry generally, plaster of Paris is employed; for the latter purpose the powder is used rather coarse; mixed with water it forms a factitious crystallisation, which adhering to the materials employed gives them greater rigidity—thus a vault formed of stones badly dressed and ordinary mortar would have but little strength, but the use of plaster with its properties of adhesion and augmentation of volume would insure solid and durable work."

In February 1849, Mr. Charles Barry read a paper describing a system, patented by Mr. Beardmore, C.E., in which the same reliance was placed upon concrete, formed of Portland cement and shingle, for stiffening wrought-iron, as in Messrs. Fox and Barrett's flooring, drain pipes being in some cases introduced with the concrete for the purpose of lightness. For a span of 20 feet, iron plates, 12 inches deep, $\frac{1}{2}$-inch thick, and 2 ft. 6 in. apart, were used, a layer of concrete, 5 inches thick, being placed between them, on horizontal plates of iron, $\frac{1}{16}$-thick, secured by rivets to the sides of the upright bearers. The author thus described the use of the concrete. "The uniform pressure of the concrete against the surface of the web, and under the upper flanges of the beam, produces the effect of a continuous strut, and enables any sheet, however thin, to assume the true character of a beam or girder." For a span of 15 to 18 feet the depth of floor would be $7\frac{1}{2}$ inches; from 16 to 20 feet, 12 inches. Mr. Beardmore "considered his floors to be fireproof from their mode of construction; not liable to disintegration when exposed to fierce flame, as brick arches are by their falling off in flakes, nor to be destroyed by sudden cooling when highly heated. The thinness of the floor, when contrasted with one of cast-iron, and the absence of all lateral pressure, and consequent necessity for tie-bolts, were further advantages; in addition to which the concrete was a necessary element of the floor itself, not a weight independent of it, and it rendered the whole, as it were, one continuous beam, thus making it nearly impossible to accumulate a great weight on any one spot."

Mr. H. H. BURNELL, read the following extracts from letters which he had received from Paris, in reply to questions which he had forwarded since the first evening's discussion. The first was—

1. *A communication from* M. PIOT, *Sub-Architect employed at the works of the Tuileries and Louvre*:

"You ask me for some account of the iron floors we are now using in the new buildings of the Louvre. These floors are generally composed of girders and joists of the ≖ form. The joists are so proportioned that the deflection of the floor under a load of 700 kilog. per superficial mètre, or 143 lb. per square foot, shall not exceed 20 centimètres (or $\frac{3}{4}$-inch), which may be thus explained: We suppose that four persons might stand in the space of a superficial mètre (or $10\frac{3}{4}$ square feet), and that their joint weights might equal 300 kilog. or 661 lb.; we add as the weight of the interties, fantons, pottery, small wooden joists, and floors, 50 kilog., making 350 kilog. We double this load to make it equal to walking or dancing, and thus we arrive at the above-named 700 kilog. (1544 lb.) The following table gives the spans, weights, and depths of the joists employed in the floors of the Louvre:—

| Spans. ft. | in. | Weight of Joists per yard run, in lbs. | Depths of Joists. inches. |
|---|---|---|---|
| 6 | 7 | 18 | 4 |
| 9 | 10 | 22 | $4\frac{3}{8}$ |
| 13 | 2 | 40 | $5\frac{1}{8}$ |
| 16 | 5 | 50 | $6\frac{1}{4}$ |
| 18 | 1 | 54 | $7\frac{1}{8}$ |
| 21 | 5 | 60 | $7\frac{7}{8}$ |
| 25 | 0 | 76 | $8\frac{3}{4}$ |

We have adopted the above-mentioned spans, placing the joists 80 centimètres, or 2 ft. $7\frac{1}{2}$ in. from centre to centre, the interties 1 mètre, or 3 ft. $3\frac{1}{3}$ in. apart; the fantons are placed 20 centimètres, or $7\frac{7}{8}$ inches from each other, and serve to support the pottery in the usual way. The pottery is thoroughly bedded and plastered on both sides, rendering the floor as nearly as possible sound-proof, and infinitely superior in this respect to the ordinary methods. The strength may be judged of by the fact that some have been proved to 1500 kilog. per superficial mètre, or 307 lb. per square foot, and the deflection did not exceed 3 centimètres (or 1 inch) in the middle. In first-class buildings the filling-in is generally of pottery or hollow bricks, but in private houses they usually content themselves with plaster alone; it is considered inferior and less sound-proof. In general the wrought-iron floors are found to be of the necessary strength, and may be regarded as a great improvement, but in France, and particularly in Paris, the spirit of speculation is prone to exact too much from the material it employs."

2. *A communication from* M. LEBAS:

"I received the letter you were good enough to send me, and was glad to hear that you had written to M. Piot on the subject, for he is the most capable of giving the desired information, as he unites great experience with practice, which is better than all the theories. He has no doubt given you all the necessary proportions of the floors of the Louvre. Though it is certain that with these floors there is a small amount of vibration, it is no less certain, that when used with common judgment, they offer the desirable qualities of strength, durability, and incombustibility. Had I to undertake a building of importance, I should unhesitatingly adopt this system, which I consider excellent."

3. *A communication from* M. CHARLES HITTORFF:

"For dwellinghouses, the weight on the entire floor should not exceed one-fourth or one-fifth of the breaking weight, or limits of deflection of the joists, and it should bear the weight of four persons = 300 kilog. (651 lb.) per superficial mètre (66 lb. per foot superficial). When these limits are surpassed, a disagreeable vibration and a disposition to transmit sound is the result. As yet, the floors well filled-in with pottery or hollow bricks have developed no symptoms of failure, either with respect to vibration or transmission of sound; but they are considerably dearer than those of wood, though the manufacturers (quoting the first or cheapest system) pretend the contrary. This kind of economy is much to be regretted, as it may be the means of causing accidents which would tend to create a prejudice against this mode of construction. The difficulties of rolling, render the production of large joists very doubtful, as regards the equality of texture, and in many instances those of from 22 feet to 24 feet long, and from $8\frac{1}{4}$ inches to $10\frac{1}{4}$ inches deep, have broken on being proved; but nothing is to be feared from the employment of these methods for moderate spans. Has never known that these iron floors have been filled in with concrete.

which would load the floor unnecessarily. The ironwork is painted with a coat of litharge, to prevent oxidation; sometimes this precaution is neglected, and without ill effects; for after all, the oxidation can only take place by the double action of the oxygen of the air and water. The iron imbedded in plaster is at once covered with a coat of rust, but this action soon ceases when the plaster is of a sufficient thickness (say ¾-inch) to exclude the air. This fact is sufficiently proved by the fragments of iron we constantly find, while demolishing our old buildings, in a perfect state of preservation, though they have never been painted."

4. *A communication from* M. Dumont:

"Of the two systems of wrought-iron floors that you mentioned, this one is almost exclusively employed here. Prudent builders never allow the depth of the joist to be less than $\frac{1}{16}$th part of the span. The filling in between the joists is generally of pottery or hollow bricks, bedded in plaster; when the builder is not too sparing of his plaster, and the spaces properly filled-in, the necessary rigidity is obtained. We avoid the use of concrete on account of it weight; we find nothing answer so well in every respect as the pottery. We paint our ironwork with one or two coats of litharge, according as the speculator may be disposed. As to the quality of the work, I may state, that up to the present time the ceilings have not suffered from discoloration by the oxide of iron; I believe, that in the first instance, the paint is sufficient to protect the iron from the humidity and the corrosive qualities of the plaster, and at a later period, the plaster in its turn protects the iron from atmospheric influences. It must be acknowledged, that experience as yet can say little on the matter. In twenty, fifty, or a hundred years, we shall be better able to judge of the systems, but at the present moment they are so much in favour with us, that we very rarely have recourse to the old methods. In four houses that we are now erecting in the Rue de Rivoli, we have used these floors, three of them opposite the Tour de St. Jacques, and the other (which is the most important) between the Rue de Bourdomais and the Rue de Deschargeurs; we do not yet know the numbers."

Mr. Burnell continued—From these communications we may briefly sum up the following facts:—That the planchers-en-fer, if properly carried out, succeed, but that they, in common with all other modes of construction, are capable of being executed badly. We learn that the floors of the Louvre, though upon the same principle, are stronger than those ordinarily used for dwelling-houses. That joists of the depth and weight indicated in the table furnished by M. Piot, if placed 2 ft. 7½ in. apart and properly filled in, will produce a floor whose deflection shall not exceed ¾-inch in the centre, under a load of 143 lb. per superficial foot; and that there are others executed in the Louvre that have borne 307 lb. per square foot, with only 1 inch deflection in the middle. That for the floors of dwelling-houses, the weight on the floor should not exceed one-fourth or one-fifth of the breaking weight of the joist, or that the depth of the joist should not be less than $\frac{1}{35}$th of the span, when placed about 2 ft. 6 in. or 3 ft. apart; and lastly, that no ill effects have at present been experienced from the contact of the iron with the plaster. As I have before said, my object in drawing your attention to the matter in question was to induce a due appreciation of that which seemed successful, but not to extol it beyond its merits. I think we must all perceive that a valuable lesson is to be learned by the study of these French methods, when we consider their lightness, and the small space they occupy, when compared with the fireproof floors we have been in the habit of executing. The introduction of interties between the joists must surely be important, when the filling-in is of a material that swells in the process of setting, to say nothing of their use as transverse ties. The ceiling appears to offer its advantages on the score of durability and convenient execution; for how much more easy must it be for the workman to adjust a flat centering beneath the joists, and form the ceiling by the simple operation of pouring a composition in upon it, than the tedious process involved in our own method of lathing, and applying the various coats of plaster, in a very inconvenient position, from the under side. This mode of grouting from above is not peculiar to iron floors, but it requires a material that sets with moderate rapidity, which with us is more costly than with the French. I believe that the rare occurrence of serious conflagrations in France is mainly attributable to the use of solid plaster ceilings. All seem to agree that the frequent losses by fire, the discreditable condition of many newly-built houses, the fall of others, and the threatening aspect of the many more which must inevitably share the same fate, were there not a special Providence over ignorance and knavery, are sufficient causes to justify any attempt to introduce improvement; and when we consider the rapid occupation of very desirable positions by endless piles of mud and bricks, exhibiting little but a disposition to speculate and low cunning, we must all regret that our already great metropolis should continue to extend itself under the guidance of parties so little capable or disposed to develope constructive or artistic talent.

Mr. Christopher felt called on to offer some remarks upon what had been called the English system, as the results of considerable experience. He had spoken warmly in favour of that system when it was first introduced, and still thought well of it, though it had not been so much improved as he had expected. With regard to the kind of finished flooring, used upon the concrete, he observed that Portland cement in connection with elastic iron was objectionable from its rigidity and brittleness; and in many instances within his own knowledge it had cracked. Indeed, he did not know of a case in which it had remained sound for three years. This had been the case both with floors and with flat roofs, after remaining perfect for twelve months; and, as they were aware, when the Portland cement was once cracked, water spilt would penetrate through the concrete, and in the case of a floor would stain the ceiling below, whilst in that of a roof the damage would be much more serious; as there it was impossible to repair effectually the cement. It was difficult to account for this failure, but probably, as one of Mr. Burnell's French correspondents suggested, it might be owing to the expansion of the concrete. Whether the fault was in the cement or in the concrete, he had had failures in three roofs. However, the system admitted of other modes of finish, and amongst these he might observe that he had found the metallic lava of Messrs. Orsi and Armani quite successful after two years trial. The ceilings on the French system were, in his opinion, better than those on the English plan. In the latter there was the want of a good key, and this was a serious objection where the plaster was 1¼ or 1½ inch thick, while under the flanges of the joists and girders there was no key at all, and several serious falls of the ceiling had taken place. In the French system this could not happen, the whole mass being poured in from above; but in the English a separate material was applied to form the ceiling from below. As the object of this discussion was to ascertain the truth, he felt bound to say there had been several instances of ceilings giving way, not only under roofs, perhaps from the faultiness of the cement coating, but also in the floors below, and he had found it necessary very recently to take down the whole of several ceilings, in order to quiet the apprehensions of the tenants on this score. Another serious objection to the English system, especially in London, where expedition was required and ground rents high, was the time necessary for the materials to dry. The drying of a mass of material 8 or 9 inches thick and full of water, if in a confined situation, was indeed almost an impossibility. He had a case in which it had not dried even in two years, and in which it had been necessary to take up the surface of the lower floors entirely, and to employ another material. The floors in that case had been of lime and sand; after the building had been shut up for two months, the workmen (who were provided with slippers) went in to hang the doors, and the surfaces were consequently so worn and broken that they were destroyed. In the lower part of this building Portland cement was substituted for the original finish, and he might observe, as an exception to his former statement, that as a basement finish that material, about 1¼ inch thick, answered exceedingly well, the damp tending to preserve it. In this case the cement was laid on a concrete bed, 4 to 5 inches thick, upon the well rammed earth. As he had remarked some years ago, Fox and Barrett's system admitted of the best plans of ventilation and artificial warming, but this point did not appear to have been much attended to. This, indeed, with such a mode of construction, was more necessary than in the ordinary plan. The floors were so solid from wall to wall that no air could get through them, and therefore a special supply was necessary. From the same cause there had arisen a want of draught to the fire places, and consequently smoky chimneys. Mr. Christopher then proceeded to the question of cost, in which he differed altogether with Mr. Barrett. He had gone into estimates with that gentleman when iron was only half its present price, of 15*l.* per ton, and they could not reduce the price of a floor on his plan to the cost of an ordinary timber floor; on the contrary, it was about the cost of a timber floor of the best description, made in the best way. He objected to the course pursued by Mr. Barrett in his calculations read at the last meeting, and to the deductions he had made from the price of his floors in order to bring the cost down to the lowest possible figure. Thus Mr. Barrett made a deduction for an assumed excess of strength, but he (Mr. Christopher) could not admit that for a moment. To any person employing his patent Mr. Barrett would certainly not recommend any reduction of strength to correspond with this deduction from the price. Indeed, instead of making any deduction from the cost of the patent system, he (Mr. Christopher) thought certain additions should be made. In the first place better foundations were required than for ordinary construction. These would be necessary even in the country, on a maiden soil, and in a second-rate house in Pall-Mall he estimated the extra cost for the foundations, which were essential in using this solid and massive description of fireproofing, at 20*l.* In the Thames Chambers, an extra first-rate building, upwards of 10,000 feet of hoop-iron were used, at a cost of 46*l.*, rather more than half of which, or 25*l.*, he had considered necessary in consequence of adopting Fox and Barrett's system. Then, again, there was the license for the use of the patent to be added, which, in a dwelling-house, would be from 10*l.* to 30*l.* It did not appear, moreover, whether the hoisting and fixing of the joists were included in Mr. Barrett's price. [Mr. Barrett said they were included]. Then expense was incurred in cutting and trimming the joists for chimney breasts and projections, which in the case of the Thames Chambers, where there were fifty-five squares of flooring, he estimated at 10*l.* There was the painting the lower flanges of the joists, which he thought very advisable, and more so after inspecting the result of Mr. Smith's experiments on the table, and which the French architects appeared also to think necessary. [Mr. T. H. Wyatt, the Chairman, said, the statement of M. Hittorff was that the painting might be dispensed with; that its absence did not seem to produce any ill effects.] In all good rooms it would be also necessary to have a wooden fillet for nailing the carpets to. Mr. Christopher's estimates, framed on the result of his experience, would therefore be as follows:—

*For a Room* 12 × 12 ft. = 1 sq. 44 ft.

| | £ | s. | d. |
|---|---|---|---|
| Fireproof floor with cement surface—Mr. Barrett's price, omitting his deduction | 7 | 14 | 10 |
| Add for extra foundation and bond | 1 | 3 | 0 |
| License for use of patent | 0 | 14 | 4 |
| Hoisting, fixing, cutting, and painting—say | 0 | 7 | 10 |
| | 10 | 0 | 0 |
| Add extra for boarded surface | 1 | 16 | 0 |
| | £11 | 16 | 0 |
| Cost of timber floor, pugged—Mr. Barrett's price | 8 | 15 | 4 |
| Excess in cost of fireproof floor | £3 | 0 | 0 |

*For a Room* 20 × 20 ft. = 4 sq.

| | £ | s. | d. |
|---|---|---|---|
| Fireproof floor with cement surface—Mr. Barrett's price, omitting his deduction | 32 | 4 | 3 |
| Extra coat on ceiling, 44½ yds.—@ 2*d.* | 0 | 7 | 5 |
| Extra foundations—@ 7*s.* ℔ sq. | 1 | 8 | 0 |
| Extra hoop-iron bond—@ 9*s.* | 1 | 16 | 0 |
| License for use of patent—@ 10*s.* | 2 | 0 | 0 |
| Hoisting, fixing, cutting, and painting—@ 5*s.* | 1 | 0 | 0 |
| Wood filleting for carpets—say | 1 | 0 | 0 |
| | 39 | 15 | 8 |
| Add extra for boarded surface, with 1½ in. battens, @ 32*s.* | 6 | 8 | 0 |
| | £46 | 3 | 8 |
| Cost of timber floor and ceiling of best description, Mr. Barrett's price | 31 | 12 | 3 |
| Excess in cost of fireproof floor. | £14 | 11 | 5 |

Upon the whole, therefore, he thought Mr. Barrett's estimates were not to be depended upon.

Mr. C. H. Smith called the attention of the Meeting to some specimens in illustration of the effect of plaster upon iron. In these specimens he had placed different materials in contact with iron on the day after the last meeting (a fortnight ago), and the results were now evident. In one specimen plaster of Paris alone was used, in another plaster mixed with sand, and in another mortar, or lime and sand in equal proportions. In the latter not the slightest trace of rust was perceptible, although the interior of the mass was still in a very soft state, whilst in the other specimens, especially with the plaster of Paris, the iron was sensibly affected. Plaster of Paris decreased in hardness in proportion to its age. As an illustration of this, Mr. Smith stated that he was employed some years ago to remove from the residence of Mr. Prince Hoare, at Bath, to London, eight or ten large casts from the antique, which had been there a hundred years, but he only succeeded in removing two of them safely; the rest having fallen entirely to pieces. Lime, on the contrary, increased in hardness with age, and iron in contact with it was not affected. As the specimens proved, plaster was most injurious. Paint would protect the iron, but if it became rubbed off, even in the smallest pin-hole, the plaster would communicate oxidation to the iron, to an extent almost beyond belief, and in fact would in time entirely destroy the iron. He believed it would be found almost impossible to fix iron joists in a building so that the paint or other coating used to protect it should not be rubbed off in some parts, and even galvanised iron was subject to the same objection.

Mr. Garling inquired if the old casts referred to by Mr. Smith had been exposed to damp.

Mr. Smith said they had not; but that there was always a sufficient amount of moisture in the atmosphere to facilitate the decay of plaster.

Mr. Garling referred to some plaster floors which he had seen in Lincolnshire, in the vicinity of the quarries. These consisted of a body of coarse plaster, with about an eighth to a quarter of an inch of fine plaster as a surface, very finely and smoothly trowelled; and although these were from 100 to 150 years old, they were now as hard as marble. He had also occasion to take down the plastering of the walls of some rooms in the same neighbourhood, which was at least 300 years old; this was 30 or 40 years ago, and, speaking from recollection, his impression was that the plaster in that case was quite as hard as in the floors. It was suggested that these floors were possibly of lime, and not plaster, but he was quite sure they were of plaster.

Mr. G. R. Burnell, C.E., referred to the work of Rondelet—'L'Art de Bâtir'—on the different nature of lime and plaster as to durability, in confirmation of Mr. Smith's remarks, and read some portion of his letter to Mr. Nelson:

"I would call your attention, and that of the members of the Institute, to a work I mentioned on the last evening; it is M. Eck's Traité de la Construction, Poteries, Fer, Fonte et Tôle,' in two vols. fol. Paris, 1841; in which will be found many very remarkable illustrations of the application of those various materials to purposes which rarely are thought of in England. It is an extremely valuable work, and if it had been better known here, probably much money might have been saved by preventing parties from taking out patents for systems already largely employed; and at any rate, the study of M. Eck's book would have suggested many valuable hints to both architects and engineers. At the same time, I would also beg to call the attention of the Institute to a note I published myself in the *Builder* of 1849, page 350, in which I gave a short description of the application of the Ꮋ shaped rolled iron: I allude to this because I have reason to believe that the application of this kind of bar iron to flooring purposes has been patented subsequently to the publication of my note in the *Builder*. In Paris, it was used, to my knowledge, in 1848."

The nature and application of compound wrought-iron beams with earthen pots for roofs were described by Eck as known so long ago as 1780, in whose work an account was given of the church of San Vitale, at Ravenna, the dome of which is formed of oil jars, laid horizontally; a fact which would set at rest the question of the supposed novelty of this use of pottery.

Mr. Scoles referred to the use of similar materials, in the Roman period, in Syracuse, and Mr. Donaldson added also that they were employed likewise in the Circus of Caracalla.

Mr. G. R. Burnell read a further portion of his letter to Mr. Nelson:

"The formulæ given by General Morin are as follows: 1st. For the Système Vaux, he considers that the bars are exposed to the action of a load distributed equally throughout their whole length, and that the ends are fixed in the walls; the weights and dimensions are calculated in mètres and kilogrammes

Then, calling the height of the bars, or main ribs $= b$
Their width . . . . . . . . $= a$
The load per mètre lineal . . . . . $=$ P
The clear span . . . . . . . . $=$ C
The coefficient of the resistance of wrought-iron $= 2,000,000$

$$a\,b^2 = \frac{\mathrm{P\,C}^2}{2,000,000}.$$

In practice, the load per mètre lineal usually applied (at least, for the purposes of calculation) is 53·28 kilog., or about 37 lb. per foot lineal; and the joists or bars are placed at distances of about 2 ft. 6 in. apart.

"2nd. In the cases where rolled Ꮋ rails are used, the height $b$, and the projection of the flanges $a^1$ are constant for the same class of rail, and the thickness of the flanges is usually $\frac{1}{20}$th of $b$. The thickness of the centre web $e^1$ is the only element of the problem in these cases which varies according to the resistance to be given to the bars. Then, calling the total load $=$ 2 P, and the total bearing $=$ 2 C, and the resistance for this form of section R, $=$ 6,000,000, we have

$$\frac{\mathrm{I}}{v'} = \tfrac{1}{6}\,e_1\,b^2 + 0{\cdot}0903\,a'\,b^2;$$

in which I $=$ the moment of inertia of the section in function of the height $b$, and $v^1 =$ the height of the neutral axis of the bar. The ordinary formula $\frac{R\ I}{v'} = P\ C$, then becomes

$$\tfrac{1}{6}\, e_1\, b^2 + 0{\cdot}0903\ a' b^2 = \frac{P\ C}{R} = \frac{P\ C}{6{,}000{,}000};\ \text{and from this}$$

$$e_{1,} = \frac{P\ C}{1{,}000{,}000 b^2} - 0{\cdot}54\ a'.$$

When the proportions between the thickness of the flanges and the height differ, the general formula becomes $\frac{I}{v'} = \frac{1}{6}\,\frac{ab^3 - a'b'^3}{b}$, in which $b'$ = the space between the ribs.

"I was not quite correct in the observations I made upon the deflection of these floors, on the occasion of your last meeting, and I therefore send you a translation of an experiment recorded in pages 331 and 332 of Vol. IV. of General Morin's 'Leçons de Mecanique Pratique,' which treats of the resistance of materials:

"'A floor of about 23 feet span (7 mètres), on the system Vaux, with joists 2 ft. 6 in. apart, 7½ inches deep by 0·36 of an inch in thickness, cross ties 0·63 of an inch square, and split rod laths 0·43 of an inch square, the joists bearing about 1 foot on the walls, was loaded with a weight equal to 102 lb. per foot superficial over the whole surface. The iron work was set with a camber of about 2¾ inches when in place; the filling in with plaster brought this down to 1·68 inches; and when the load was applied, the floor sunk to 1·17 inches below the horizontal line, which deflection ultimately became (after 24 hours) 3·17 inches. On removing the load, the floor rose 2 inches, and on further removing the plaster filling the ironwork rose nearly to its original camber, or to 2·36 inches above the horizontal line.'

"General Morin remarks that this experiment proves that the iron retained its original elasticity to a great extent, and that the plastering contributed greatly to the permanent deflection. Mr. Barrett's objection to the use of the French floors—that they were not perfectly inflexible, and his statement that the plaster used in the Midland counties was objected to on account of its organic smell,—seem both to require notice; for, in the first place, a mere augmentation of the scantlings would give any required rigidity; and, in the second, Mr. Barrett appears to have overlooked the fact that the French plaster, both geologically and lithologically, differs from that of our Midland counties."

Now, the French plaster contained carbonate of lime, which the English plaster did not. Possibly English plaster, used in large masses, might give out some odour; but certainly he could state from experience that the plaster used in Paris was not open to that objection. Where French plaster was used in conjunction with brickwork, a remarkable degree of efflorescence took place, which might arise from animal matter either in the bricks or in the plaster, or perhaps in both. At all events animal matter did not exist in the French plaster to any objectionable extent. Mr. Smith's statement that lime protected iron from rust should be received with caution. All the wrought-iron bridges in France had been built upon the principle laid down by Vicat, that no oxidation could take place whilst iron was immersed in slacked lime; and accordingly the tying-down rods of these bridges were bedded in wells, with a paste of chalk lime carefully rammed in. Yet all those bridges had fallen; that at Angers at a time when 600 persons were upon it, more than 400 of whom were drowned. The explanation of this failure possibly was, that the action of the load upon the bridge set the chains in a state of vibration, which, though not perceptible to the eye, was yet sufficient to detach the rods from the lime in which they were embedded; upon which water could get in, and the oxidation would commence. Mr. Smith's principle was correct; but in a floor of any kind there must be some degree of vibration, which would tend to detach the joists or girders from a bed of lime in which they might be placed. He believed, in fact, that concrete or lime in any form was not better than plaster, which being more hygrometric than the mortar would rather protect the iron more securely. Practically, in a house, the plaster was a sufficient defence to the iron, and this was what the French architects meant, when they said they had not noticed any rust in the use of this material.

Mr. SMITH observed that it was not necessary that lime should be absolutely in contact with iron to protect it from rust. Thus the dealers in polished steel goods, such as needles, did not coat every article with lime, but merely placed here and there amongst them a piece of quicklime in paper, which kept them in a polished state as long as the lime continued in a caustic condition.

Mr. G. R. BURNELL said that this remark did not apply to the French bridges. In the case put by Mr. Smith, the caustic lime not being as yet converted into a hydrate, acted by absorbing moisture from the atmosphere.

Mr. GARLING suggested that if the chains of the French bridges were bundles of wires instead of solid bars, the interstices in the wires might have conducted the water into the wells.

Mr. T. H. WYATT (the Chairman) stated that the names of two gentlemen had been given to him as wishing to offer some remarks upon the subject; and that it would be only fair to Mr. Barrett to allow him to say a few words in reply to Mr. Christopher. As therefore the discussion had already occupied the usual time, he proposed that it should be further adjourned till the next ordinary meeting.

Mr. BARRETT, in reference to Mr. Christopher's statement that extra foundations were necessary in using the patent system of flooring, begged to appeal to Mr. Beck, who might not be able to attend at the next meeting. As architect to the Metropolitan Association, that gentlemen had erected a building five stories in height, all the floors as well as the roof of which were fireproof; and he would no doubt bear testimony to the fact that extra foundations were not used there.

Mr. BECK said that this was the fact, and that, in the case referred to, he had not introduced any additional brickwork in the foundations, in consequence of using Messrs. Fox and Barrett's floors.

## SYMBOLISM IN ART.*

THE question of Symbolism in Art is one interesting to artists, but we fear the writer who is now before us is not the one to treat it in a right spirit. It needs a catholic treatment, but the author has chosen to treat it in a sectarian spirit. Professing to treat the subject on first principles, and impartially, he has written in a theological sense, appealing to conventional authorities, and we fear therefore he will raise more opponents than supporters.

In discussing the question of the admission of symbolism in art, we ought perhaps to define what is or is not symbolism, and afterwards how far symbolism is rightfully applicable. Mr. White appeals only to one of his co-sectarians, who is evidently regarded by him as an infallible authority, and indeed great veneration is shown by Mr. White for authority. The canonist appealed to, has, it seems, been pleased to define symbolism as the "having something in common with another by representative quality." How this is applied, and how it is worked out, we are not able to ascertain from Mr. White's dissertations. We can understand that symbolism which appeals to badges, armorial bearings, cyphers, inscriptions, and other types of men and things, but this does not seem to express the views of Mr. White and his coadjutors. He asserts "that the works of *nature* have an inner meaning, cannot be denied," and this, he says, "is acknowledged on all sides;" as a proof of which, he refers to some sectarian tract, called the 'Christian Year;' and then he goes on to adduce a mass of scriptural quotations, and likewise citations, from St. Basil and the herd of schoolmen. Upon such a basis he builds up a system, which he calls Symbolism, but which others would call Mysticism, for everything is made to speak any language, though to the many, we fear, unknown tongues.

On this topic, Mr. White says, "Our Lord may be symbolised by the vine, the lion, or the lamb; and so likewise may be symbolised by Water, cleansing from Sin, 'the waves of this troublesome world,' or the deep sleep of death. Of what an infinity of thought may even water itself be suggestive, whether we contemplate it as filling the ocean, or ceaselessly flowing down in 'the springs and rivers which run among the hills,'—whether we think of it in its vast extent, its motion and life, its obedience to the Sovereign command, 'Here shall thy proud waves be stayed,'" and so on *ad libitum*, and we may say *ad nauseum*, for it is calculated to bring symbolism, and even religion, into ridicule. Lord Burleigh's shake of the head did not mean as much, and Dean Swift's Meditations on a Broomstick could not have been made so diffuse as this one thing—Water—in the hands of a patristic commentator. Water, or any other substance, may mean all these things, and many more, to him who chooses to imagine them; but what are the many, the multitude, likely to understand of all these fantastic applications, as recondite and far-fetched as the gambler's sermon from a pack of cards? This brings us to one test of symbolism, and which points out the distinction between symbolism and mysticism, and the bounds of symbolism. The symbols to be applicable in architecture must be such as will be felt and understood by the many, and not by the few, for it is to the many that architecture in its noblest

* Is Symbolism Suited to the Spirit of the Age? By WILLIAM WHITE. London: Bosworth. 1854.

monuments appeals. The statue may be secluded in a niche, the picture worshipped by a select body of connoisseurs in the cabinet; but the temple, the church, the monument, stands forth in the broad light of day,—to be seen by the lettered few it is true, but to be seen likewise by the thousands who throng the crowded thoroughfares, and, it may be, to be seen by tens of thousands in ages to come. The more educated may better appreciate the excellences, but those sentiments must be complied with which animate the mass of men, and the many have never failed in any age or clime to admire the truly beautiful.

So far, the application of symbolism in architecture is narrowed, but the body of worshippers is enlarged; though, after all, symbols must to a great extent be local and partial in their application, and can only be looked upon as accessories, ranking below those conditions of beauty which are the first requirements of art. In this application, symbolism has certainly been acknowledged in all ages and by all men, each according to the fashion of the time, and in so far, symbols are vital members of the repertory of art. Under these conditions, symbols are commonly and readily recognised, and have their great power; but when symbols are multiplied in number, and still further multiplied in meaning, and when they are converted into logotypes of theological subtleties, Mr. White is no longer justified in applying to them his trite quotation:—

> "Segnius irritant animos demissa per aurem,
> Quam quæ sunt occulis subjecta fidelibus, et quæ
> Ipse sibi tradit spectator."

The whole force of Mr. White's corroborative examples is here lost, because, while the thing itself is conveyed to the mind of the spectator, the hidden meaning makes no impression. When people look at the *Illustrated News*, they do, as Mr. White says, look at the engravings first, and conceive a stronger idea of the incidents recorded than from the perusal of the text; but if they look at the engravings of the rebus in the *Illustration* or any French publication, instead of such clear idea being forthwith conveyed, the mind is puzzled to make out the meaning,—time is lost, perhaps the attempt abandoned, and no impression is communicated.

Mr. White does not however, seem to be of this opinion, for he boldly assumes that symbolism has its offices and supposed uses. "In that symbolism embodies or expresses spiritual truths by material forms (1), it may be made a means of conveying to men's minds a lively and intelligible impression of such truths; and (2) it may remind men of these truths by objects which they continually see around them; so that wherever they go, and upon whatsoever their eye rests, something shall recall to their thoughts one or another of those realities in which man's truest and deepest interest lies." It is not within our province to discuss the theological principles of Mr. White or any one else, because architecture is a catholic and sectarian art, and because our readers here are men of various religions—Christians, Jews, and Englishmen; and abroad others, Parsees, Mahometans, and Brahmins, men of many nations; but we may say, that the principles advocated by Mr. White are, on artistic and natural grounds, fatal to any religion. Its truths should be impressed on the mind, and they will not be confirmed by teaching the votaries to regard every object in an unnatural sense,—for that is the purport of this teaching. We are not to look upon objects of nature in their visible appearance and meaning, but we are to consider them as fanciful records of immaterial and remote doctrines,—we are to look at everything monomaniacally, and under a delusion; nothing is to be what it seems, but anything but what it seems. Architecture certainly does not admit of this treatment, and the attempt, whenever made, has failed. The symbols of the Egyptian temples were plain and direct records, many of the decorations were pictorial representations of events; and the same may be said of the Parthenon; nor in the middle ages did the schoolmen succeed in imparting to the public, by architectural accessories, their fanciful doctrines. The public then, as now, forebore to participate in these mysteries, and the revivalists alone of the present day can adequately appreciate the latent significations of the *vesica piscis*, and the multifarious whimsicalities with which brainsick imaginations have filled volumes of commentaries. The truths of religion must be implanted in the mind; they are essentially immaterial, and theological doctrines cannot be inculcated in their comprehensiveness by the architect. Personages may be commemorated, and personal worship may be symbolised; but that is the limit of the power of the architect and the sculptor, his fellow-labourer, and even when the painter is called in, the domain of interpretation can be but little extended. A fallacy is therefore involved in the deductions from Mr. White's *petitio principii*, and our readers will not therefore be prepared to admit his premises, or his affirmation "that certain truths should be impressed on men by visible objects as well as by words, is advantageous on many accounts; partly because the eye, as well as the ear, thus becomes a means of conveying instruction to the heart."

Starting from such a basis, the author is led to the most fanciful conclusions when he proceeds to expatiate on what he calls the field of sacred art. It might be thought that the dedication of a church is sufficient in itself as an inculcation of religious feeling, but not so thinks Mr. White. It is not enough that he has his congregation in a church,—he is not content with the provision for devotional influences; they are no better off in his mind's eye than in a playhouse,—he would further surround them with an extensive apparatus of devotion, so that he may fully control the thought. The worshippers are to swim to heaven in cork jackets, or the architect is so to minister that the devotee may not rest his eye anywhere without religious sense being fastened upon and enchained; for Mr. White affirms, "Great are the difficulties of disciplining and restraining the thoughts at all times...... But above all other times and places, men have most need to look to their thoughts when they go to church, where, from the nature of the case, they are for the time cut off from natural teaching; yet still they need to be reminded of Him," and so forth; and therefore the architect is to co-operate in the machinery of asceticism.

Mr. White, it is true, does allow the architect to avail himself of the sublime and beautiful, but he wishes for beautiful forms which contain a meaning beneath the outward expression. How this is to be attained we know not, for the sphere of mathematical symbolism is restricted; but the writer in his fervent zeal is adventurous, for he hopes to keep perpetually before us some phase of the heavenly kingdom, and to realise more truly the presence of God and the Communion of the Saints. The writer has not laid down any scheme for doing this, but he gives numerous examples of his system of interpretation. The exterior of a church affords him notes enough for a volume, and in the interior there is enough to occupy him. On entering the porch, says he, the visitants will be reminded of their Lord's saying, "I am the door of the sheep," and of the impossibility of gaining admission to the heavenly kingdom, but through Him, the Door. This we very much doubt, for there is not one in a thousand Englishmen who will call to mind any such thing; nor is there any need they should, for they will be much better reminded by their prayer-books in the due course of the service. But then, says the writer, the font speaks of new-birth, and of being buried with Him in baptism; the nave, of the ark of Christ's church: and this it will be seen is the type of a type, and how the architect is duly to transmit a succession of types and tropes passes comprehension.

In the same spirit, the aisles are to speak of the extension of Christ's kingdom, when the building should not be large enough to receive them; the chancel, of those who are chosen out of the multitude to minister about holy things; and the sanctuary is to teach a further lesson of the same kind. The writer then goes to details: the pillars speak of the firm supporters of the faith; the arches, of the mutual support of all the brethren; the roof, of the shelter from the blast; the windows, of the light shed down from on high; the uniformity of fittings, of the perfect equality of all in his sight before whom all there appear. He even points out meanings in the turnings of the minister and congregation; nor does this exhaust the subject, for he urges upon the architect that not the main features only, but every minute portion of the building may suggest something good, and a lesson may be learnt even from the scraps of rich sculpture which are sometimes observed in the gloom of a retired corner or an unfrequented aisle.

All this is stated in good faith and with perfect seriousness by the author, in a work which is put forward as a sober exposition of symbolism against objectors. When the so-called symbolism is attacked we are warned that we are on privileged ground, and that the subject must be approached with care, deference, and circumspection, paying due reverence to the great authorities who have upheld it. We have therefore thought it useful to allow this exposition of the system to appear, so that it may be seen that it is not we who have thrown it into ridicule, but its advocate, who has even involved religion. We have given this exemplification because the architect is not only expected to carry out the views here expressed, but he is exposed to the peremptory dictation of the ecclesiologists, who require his submission to their mandates. In obedience to them the artist is to be deposed from his proper directing functions, and is to accept new canons of art, and it becomes him to consider whether he will so submit. He has before him the formula to which his adhesion and subscription are required.

We lay down this position thus clearly and thus broadly, because, as in Mr. White's work, we are required by the ecclesiologists, first to admit symbolism as a recognised catholic principle and practice in art, and when we have done so we are are invited to accept their peculiar theological system in its entirety and its minutiæ; and if we accept we are led to a career of artistic and mental debasement, to the abdication of truth, the abnegation of private judgment, and in the end to blind submission to blind dictators. There is no need, as it seems to us, to accept any such conditions: we may admit symbolism in its principle, and we may carry it out in its just application, without any fear that the cause of art will be lost if we refuse to mortify ourselves in the frock and profession of a barefooted friar.

We believe we have given enough to show the exact tendency of Mr. White's teachings, but we will enforce it by some of his special illustrations. In like manner he says, to architectural details particular forms and proportions, colours and numbers, were suggestive of great truths. Indeed, the two latter, according to him, have ever been considered to contain definite meanings when used in the scriptures, and were much referred to in the interpretation of it by writers of the church in all ages;—granted, but not by the people. Proceeding to colours, he asserts that red, being a symbol of warmth, may remind men of that divine love the fervent glow of which should fill their hearts. Green, being the ordinary colour of the face of nature, is a symbol of coolness or repose, and hence of the usual routine of daily duty when uninterrupted by any festival. White symbolises cleanliness or purity; and black or grey is a fitting emblem of penitence and grief. To all these he attaches further mystic meanings, and he proceeds to speak of certain feelings as being usually associated with particular colours,—black for instance, though we know that white, yellow, purple, and other colours are elsewhere adopted as the garb of mourning. With regard to technical theological emblems, he says that the cross is sometimes irreverently treated in being converted into something that is worn for mere ornament or intended for some common use, as for handles, clasps, and pencil-cases.

## BATHS AND WASH-HOUSES.*

The progress of baths and wash-houses has been referred to by us on occasions when books have been published on the subject, and it is evident there is a growing interest on the part of the public and of professional men, as well as of philanthropists. The architects and engineers first engaged on baths, with great spirit and liberality, published full accounts of their works, and we believe that they, as well as the public, have profited by their liberality. Great improvements have been effected, and such a reduction of expense, as to make a bath an essential and practicable establishment in every country town. Thus a field of employment is opened in the construction of several hundred buildings, of which we hope the beginners will have their fair share. Among the professional works on baths are those of Mr. P. P. Baly and of Messrs. Ashpitel and Whichcord, and now we have before us one by Mr. Cape, which, though not of a professional character, is well calculated to promote the movement; because, besides the necessary constructive information, it enters into the financial and practical workings of the system. Mr. Cape is the Secretary of the Lambeth establishment (formerly the swimming-baths), and he has devoted considerable zeal and intelligence to acquire and impart information on the subject of his employment. Thus his book will be found a very useful manual on baths and wash-houses for towns of all classes, and may be consulted by every one interested in the subject. We see so fully that the subject is an important one, that we think it worth while to devote a larger space to it than we should on the simple ground of Mr. Cape's book, or any novelty of treatment introduced by him. We regard it with a professional eye, not merely as a mode of employment, but as offering opportunities for novel constructive expedients, and for considerable mechanical improvements. It is not a field of routine occupation, but one the successful cultivation of which will, by its experience and example be beneficial elsewhere.

Mr. Cape, in his zeal for his subject, thinks it necessary to go back, like a German, to the beginning, and shows us that the most ancient nations were in the habit of washing, of swimming, and of using artificial bathing expedients. This our readers will be content to take for granted, and even that ducks swim, although Mr. Cape treats his theme pleasantly. He gives likewise a brief sketch of the great baths of the Romans—examples which we have yet to imitate and rival. The author comes nearer home when he appeals to the love of our people for bathing, and the duty of gratifying that habit. As the English are a seafaring people, so also are they a bathing people. They are a people fond of the water, and take to it from boys, whereever they have the chance. We think, nevertheless, that Mr. Cape speaks rather as of the school of mock-modesty, or perhaps as the official of a private bathing establishment, when he says that delicacy has forbidden the use of rivers and streams for public bathing. Delicacy, we believe, has done nothing of the kind, but the new police have. The English people—men and women—when left to themselves, and unmolested by continental influences, are a people having sufficient native good not to be offended with what in itself is not evil, and which has the merit of some good attached to it. It is not so long ago when, before steamers drove pleasure-boats off the Thames, the river was on a fine summer's day covered with thousands of men and women of all ranks, enjoying "the silent highway," while the men and boys gambolled in its waters. There was neither indecency on the part of the swimmers nor indelicacy on the part of the bypassers. For hundreds of years this great thoroughfare was a chosen scence of pleasure; and the pages of our poets and classic writers describe what many of us have seen, and what the pencils of our artists have depicted—the water parties on the Thames, where beauty, wit, and music gave additional charms to the scenes around. In those days, an aristocratic party making the trip by water to Vauxhall or Ranelagh, were no more shocked by the swimmers than by the Apollo and the Venus in the pleasure-gardens they visited. True modesty forbade it, and both modesty and taste would have been wounded by a mock-modesty which would have been too strong an evidence of indelicacy of thought. After the war had ceased, and some of our population had learnt modesty in that great school of outward virtue and consecrated vice, Paris, there was certainly an amazing outburst of propriety,—the legs of pianofortes were then dressed in trowsers; but our transatlantic cousins have long since been in sole and undivided possession of our cast-off forms of prudery.

In the better days we speak of, a noble lord had his address as "Swimming in the Thames opposite Whitehall;" and there was hardly a man in London, young or old, who had not bathed in its stream. Much of the employment of the watermen was derived from taking out bathers to some favourable spot for exercise. In those days, all classes bathed; and the general feeling of the community was sufficient to check any impropriety—which would, indeed, have been attended with summary chastisement. The entry of the up-river steamers, and the interference of the new police, have so much checked the practice of bathing, that the wholesome influence of the better classes is no longer felt; and as it is an act of daring to enjoy a favoured amusement, many of the rougher classes of society take part in what is often a public act of defiance. The love of bathing is however, as Mr. Cape says, as strong as ever, and it has not been without its influence on the public baths. Formerly the public baths were swimming schools, in which practice was gained for the Thames, the Lea, the Wandle, the Ravensbourne, the Serpentine, or the canals. On the river being virtually closed, the baths fell off, and some of them were shut up. The possession of such a noble bathing place as the Thames—one grander than the Baths of Titus—was the reason that London had no great public baths; and when deprived of that, it remained for some time without baths, and making a bad show as against Paris and other cities. Ardent swimmers sought suburban streams and ponds, but the police

* 'Baths and Wash-Houses; the History of their Rise and Progress: showing their Utility and their Effect upon the Moral and Physical Condition of the People; with Copies of the Accounts and Statistics of the Metropolitan and Provincial Establishments, and Practical Hints to those concerned in their Erection, and for their Management, illustrated with Plans, &c.; also a History of the Baths of the Ancients; and a Description (with Plan) of the Lambeth Baths and Wash-Houses.' By George A. Cape, jun., Secretary to the Lambeth Baths and Wash-Houses Company. London: Simpkin, Marshall, and Co. 1854.

beset them and drove them back into the town. In time, a reaction took place; more proprietary baths were opened, and the movement for public baths was powerfully aided by the public feeling. Mr. Cape makes some interesting remarks on the strong love of bathing which is shown, and he points out that most of the existing baths and wash-houses are deficient in adequate accommodation for swimming. At the Lambeth Baths, he has found ragged and seemingly-famished lads pay their twopence to the swimming-bath, when he thought they might have better spent the money on a dinner. Upon this topic of swimming, we shall make some remarks by-and-by, as we consider the claims of the public have been neglected, and that Mr. Cape is rather an advocate for the companies than for the public.

In protesting against Mr. Cape, we have been led into some remarks on the naked swimmers, and we have done so with the further purpose of making a further side-note for the consideration of some of our artistic friends, and that is as to the lessened display of the nude human figure. In the last generation the swimmer came under the eye of man and woman, and the prize-fighter, the sparrer, and the wrestler under observation of all the male community. The love of animal form in the horse, the dog, and in cattle is unlessened; but we are inclined to think that the familiarity with the naked figure, at the period we refer to, had much to do with the enthusiastic reception of the Elgin marbles, the admiration for the Flaxman designs, and the display of the nude in monumental sculpture and historical painting which marked the first quarter of this century, and is in opposition to the buckram professions of an influential body of the middle classes. It is true this display was made under the inspiration of an ill-directed taste, which now commands little sympathy for the *chefs-d'ouvre* of St. Paul's or Westminster, but nevertheless it manifested artistic aspirations as notable as pre-Rafaellitism, and perhaps more lasting in its influence. There certainly is for the nonce a less display of the naked figure, and the manly form divine is now muffled up in quaker garb with nothing picturesque to distinguish it but its incipient beard and moustache, and those who are fond of referring to the influence of the heroic games and gymnasia of Greece as influencing ancient art, may sigh for the change, but they may perhaps be comforted in the hopes of a reaction. The mediævalists and the pre-Rafaellites have given the draped figure a pre-eminence on the canvas, and the pious members of the community may rest self-satisfied with the sober coats and hats which shroud our population, but the population itself is not so satisfied. The women have shown a greater taste in dress than at almost any period, and this is not without its effect on the male population. There is a rather strong conviction that the tailor and the artist are in antagonism, and the public seem only to await a favourable opportunity to break out in open rebellion against their sober elders and the tailors. Sometimes there is a hat movement, now a beard movement, and in a trice we may find the population metamorphosed. Half-a-century ago the nation sacrificed at the shrine of art their wigs, their pigtails, and their cornered hats; and perhaps in the excitement of mind at the present war, the cylindrical head cover and the straight-cut coat may be offered up with like unanimity. The antagonism of the present costume is however most strongly shown when questions of monumental commemoration arise. Shall Wellington, shall Peel be represented as he lived and was, and as we knew him, as an Englishman, a great man in a great country,—or shall he be dressed up in the toga of the effête Roman republic, or the armour of the declining empire? Such is the question which arises, and truthful representation and the artist are in antagonism.

We have thus incidentally touched on an artistic question connected with the great problem of the future in art, which the architect anxiously scans. He looks back, and his ancient landmarks seem to fade from him. The quasi-classical in art has received a fatal blow to its monopolising claims, mediæval restoration is stigmatised as out of keeping with the character and spirit of the age, and there is a new class of structure arising, which will certainly prevail over a large architectural domain. The constructive expedients which have determined the formation of our wide-spanning railway stations and our crystal palaces afford the materials for a new style of art, and in this the bath will take its place. In reading Mr. Cape's work we have been powerfully impressed with this. The present baths, it is true, are relatively small buildings with numerous comparatively small chambers, but, as we have already intimated, he shows that the provision in these for swimming baths is not adequate. The swimming bath, he well states, as compared with the private, single, or plunging bath, is cheap in its construction and cheap in its maintenance. A smaller supply of water and a less rent is needed, and one or two attendants may supervise a large establishment, but a single attendant cannot properly serve more than a dozen bath compartments.

Thus there is scope afforded for large baths for swimming, and these may become of an extent of which at the present time we have no example. In the case of an embankment on the Thames, or in some districts on the shores of the river, it would be possible to form enormous swimming baths, spanned by large roofs, economically supplied with water, and affording ample space for exercise and practise. We may contemplate a bath half-a-mile long with one vast area of roof, the breadth of the building being of less importance than the length. With such a structure—and we know it is within the compass of art—the architect would have the opportunity of producing effects as remarkable in their character as colossal in their extent, and this is only one instance among many promised by the present tendency of progress and improvement. The vast extent of the structures and the novelty of the expedients employed have already resulted in a nullification of the ancient styles, if they have not yet created a new one. The Parthenon cannot be adapted to a crystal palace, nor York Minster to a railway roof, and the new structures will in time create their own styles instead of the styles creating the structures. The basilica grew into the mediæval cathedral because it had received a new impulse and inspiration, and the progress of the mediæval cathedral was largely influenced by constructive expedients. The adoption of glass and the mode of illumination determined the form of the walls, of the openings, and even of the roofs, as compared with the ancient temples of Memphis, Athens, or of Rome; and so too, will the vast glass roofs and walls of the new edifices determine the character of their details. The sturdy, close, and stunted columns of Egypt became impossible in a crystal palace, and will not therefore be repeated, and other forms of ancient art will likewise become obsolete. Thus, by the legitimate force of circumstances, we shall be really and truly led to a modern and perhaps a national style. The adoption of the arch gave its character to Roman architecture; and that of the light and vastly-expanded roof will become the type of the architecture of the nineteenth century in a great proportion of its monumental structures.

We are the more inclined to speculate on the extension of bath architecture, because we can determine that it has practical elements. The attention of architects has been already directed to it, and our readers will recollect in our architectural exhibitions, designs which have shown interiors and features of bath architecture, well calculated to excite the interest of the professional man. There are circumstances too, connected with this class of buildings, which give them a wider scope in their application than would be at first conceived. Bathing is to some degree a summer occupation, but the wash-houses attached to these establishments are in permanent use by the women of the working classes; and there is every probability that as the washerwomen are desirous of using them for trade purposes, they will lead to the establishment of great public lavatories, in their general principle resembling those of the continent. Mr. Cape is strongly of opinion that such application will be profitable, and we think experience and the influence of circumstances are in favour of his views. The employment of the wash-houses by the working classes is however found to be attended with inconvenience to the mothers of families, who cannot be separated from their children and cannot take them into the washing compartments. At the Lambeth Baths they have a kind of temporary infant school, where the children can be left, and which is found to answer.

The hot baths are more or less used in winter, but even a tepid swimming bath has then few votaries, and a large area is therefore left unoccupied for aquatic purposes during several months. Heretofore such places have been used for casinos, public meetings, and even for prize-fights and wrestling matches, but it is easy to conceive that improved structures might be so applied during the winter season as to produce profitable returns. Thus they would be suitable to cattle shows, poultry shows, and in some cases, to vast musical promenades, the more especially if they were originally designed of an ornamental character. On the other hand, in the summer there is a greater demand for open air amusements and less for that which is offered under cover, and by judicious arrangement a bath can always be so adapted as to bring a good revenue.

While we have been descanting on the domain of art, we cannot forget that the new vocation which has been opened for architects is greatly owing to a poor woman, named Catherine Wilkinson, who during the cholera year of 1832, opened a small wash-house in a back street of Liverpool, called Frederick-street, for the purpose of enabling her neighbours to wash their clothes away from their living rooms. In this undertaking she was helped by some charitable ladies, and was thus the means of laying a practical foundation for a useful institution. In Frederick-street a public bath has since been erected, but we should have liked to be able to report that the services of Mrs. Wilkinson had been commemorated on the face of the structure, and that if the opportunity had offered she had obtained employment within its walls.

Mr. Cape necessarily devotes some space to the great model establishment in Goulston-square, which was erected and described by Mr. Baly, and he points out the true worth of this institution as an example in answer to those who have objected to its great cost. The gross expenditure was 26,632*l.*, whereas now an establishment of like capabilities can be erected for half the money; but Mr. Cape shows that this is owing to circumstances of an exceptional nature, and to its experimental character, of which, as it was intended, the public have had the benefit in the construction of similar buildings elsewhere. Without going into details, which constitute large deductions from the above gross outlay, it may be pointed out that one important object was to ascertain the most effectual and least expensive mode of heating the baths, drying clothes, and for which it was necessary to incur much expense in trying various plans; and although the system adopted was necessarily far from perfect, it became, as was intended, the model for like structures throughout the country. The money which was subscribed for such a useful purpose by the Committee, might very properly be reimbursed by the nation; but we need hardly say there is no prospect of this, though the working of the Baths and Wash-houses Act has been greatly facilitated by this benevolent and experimental undertaking.

The economical and mechanical arrangements connected with baths are matters of interest to our professional readers, and are well treated by Mr. Cape, who has a practical knowledge and shows himself observant; but we have not, after the space we have devoted to the artistic considerations, the opportunity for their proper examination. Nevertheless, they well merit the attentive study of the professional man in designing baths, and in the light they throw on many classes of edifices. The arrangement of the apartments and entrances materially affects not only the prime cost, but the yearly outlay, and architects do not always bear this in mind. Many buildings, as churches, take care of themselves, and require small annual outlay, while they admit of great architectural display; but it is not so with many classes of public buildings, and a careless or unskilled architect, while apparently economising, may really ruin the concern by entailing upon it a needless and perpetual expenditure for attendants, fittings, and repairs. Mr. Baly has well shown that it is worth 200*l.* to get rid of an attendant by a constructive expedient diminishing labour.

The influence of bath architecture has been already felt in many trades, but we consider that, on account of the restricted character of the present buildings and apartments, that scope has not been afforded for decoration which is desirable, and which will be presented in larger edifices. A railway platform scarcely admits of decoration, but a great public hall for bathing would have additional attraction in pleasing decorations, which might be economically adapted. The taste of the present day is in favour of such application, and we may yet have establishments which may prove more ornamental to the metropolis and creditable to ourselves.

*Rosso and Verde Antico.*—The quarries from whence these materials were obtained have, it is well known, been for ages quite lost sight of; but the King of Prussia, actuated by a love for the fine arts, recently commissioned M. Siegel, the sculptor, to make researches in Greece, which have been completely successful. The Rosso-antico has been found by him on the southern slope of the Taygotos range of mountains, and the Verde-antico on the north side of the island of Tinos. M. Siegel has succeeded in making these two localities, which are very small in extent, his private property. The king has given orders for several large slabs.

## ON SANITARY IMPROVEMENT.

By Southwood Smith, M.D.

For some years past there has been in the public mind a growing conviction that the physical condition of the labouring classes is mainly dependent on the state of their dwellings. The conviction has become equally strong, that whatever improvement is effected in the physical condition of the people is conducive to a corresponding elevation of their intellectual, moral, and social state.

Investigations into the sanitary condition of populous districts in general, and of the houses occupied by the industrious classes in particular, have been made partly by private individuals, and partly by commissions under the Crown. On the evidence collected under these inquiries, rarely exceeded in extent and value, the Legislature has passed a general measure called the "Public Health Act," granting to local authorities the powers requisite for constructing and maintaining permanent works of sanitary improvement, while a distinct department of government, under the name of the General Board of Health, has been created to administer this Act. Still the acceptance of the Public Health Act is permissive, not compulsory; and therefore the actual extension of sanitary improvement is wholly dependent on the state of knowledge of local authorities, and of ratepayers by whom those authorities are elected.

The evidence which formed the basis of this legislation had distinctly traced to the condition of the houses of the labouring classes, the main causes of the excessive sickness and mortality disclosed by the returns of the Registrar-General;—had distinctly traced to certain definite conditions in and about these wretched abodes the true sources of those constantly-recurring epidemics, which swept away one half of the children born while yet in childhood, destroyed by fever the heads of families in the prime of life, and deprived the whole of this class of the population of more than one-third of the natural term of existence.

But the evidence was not so apparent that this state of things is no necessary and inevitable condition of poverty. While the consequences of bad sanitary conditions were demonstrated, there were presented no very conclusive facts to prove the power of good sanitary conditions to secure to the working man and his offspring the like measure of health and life as is possessed by the wealthier classes. There was, indeed, the strongest conviction on the minds of those who had paid attention to the subject that evidence to this effect was obtainable, and they felt assured that it would be found in the result of residence in houses so constructed as to be fit for human habitation.

It was under this impression that about twelve years ago a few individuals who had taken the lead in the investigations just referred to, formed themselves into an association for the purpose of putting the truth of their conviction to the test of experiment. Their plan was to erect a large building divided into suites of apartments, capable of accommodating a number of families, and provided with the following sanitary conditions:—

1. The thorough subsoil drainage of the site.
2. The free admission of air and light to every inhabited room.
3. The abolition of the cesspool and the substitution of the water-closet, involving complete house-drainage.
4. An abundant supply of pure water.
5. Means for the immediate removal of all solid house refuse not capable of suspension in water, and of being carried off by water.

It also seemed probable that benefit would result from their example; that if it should be found practicable to offer houses well built, well drained, and well supplied with air, water, and light, at no greater charge than is obtained for houses in which no provision whatever is made or attempted, for the supply of any one of these essential requisites of health, cleanliness, and comfort, a public service would be rendered beyond the mere erection of so many better-constructed houses; and that, especially, it might help to render it no longer easy for the landlord to obtain an amount of rent for badly-built, which ought to suffice for well-built houses, and that it might thus indirectly tend to raise the general standard of accommodation and comfort for all houses of this class.

It was found, however, that to acquire the means of erecting a suitable structure for the accomplishment of this object, it would be necessary to obtain exemption from the common law of partnership, without which exemption each member of the Association would have become liable to the whole extent of his property, for all debts legally incurred in the undertaking. It was only by a Charter from the Crown, or by an Act of Parliament, that this liability could be limited to the amount of each shareholder's individual subscription.

The Charter is framed on the principle that the object not being money-getting, but philanthropic and national, the profits, after the payment of a moderate rate of interest, instead of going to increase the amount of the dividend, should be applied to the extension of the scheme. The main provisions of the Charter are—The limitation of the liability of the shareholder to the amount of his individual subscription; Power to make calls; Dividend not to exceed 5*l.* per cent per annum; Capital 100,000*l.*, 25,000*l.* of which to be subscribed before commencing works, and 10*l.* per cent. thereon paid up;* Power to increase the capital with consent of the President of the Board of Trade, and two-third parts in number and value of the shareholders present, at two general meetings especially called for that purpose.

Subsequently a Supplemental Charter was obtained, giving power to establish Branch Associations in the Provincial Districts of England and Wales, and for this purpose to raise a Provincial Capital of One Million sterling, and to apportion the same to different Provincial Districts, the shareholders of each Provincial District being interested in the profit and loss of their own shares only, separately from any other shares of the Association.

Seven years elapsed before these preliminary proceedings, the choice and purchase of the site, and the erection of the first buildings were completed, so that the buildings have been opened for residents only about five years. The Association took the name of the "Metropolitan Association for Improving the Dwellings of the Industrious Classes," and their first buildings, called the "Metropolitan Buildings," are situated in Old Pancras-road, leading from King's Cross to Camden Town.

The Metropolitan Buildings consist of 110 sets of rooms, 20 being sets of two rooms, and 90 of three rooms. Attached to each set of rooms is a scullery provided with a sink, a supply of water at high pressure at the rate of forty gallons per day, and the means of carrying off ashes and other solid refuse through a shaft accessible from the scullery. There is no cesspool on the premises. The water-closet, substituted for the privy, is situated in the scullery, the door of the closet being so hung as, when open, to shut off access to the scullery. Each living-room is furnished with a range, boiler, and oven. By an extremely small quantity of fuel the oven is capable of baking bread, cooking meat, and any other kind of food, and the boiler contains a quantity of hot water always ready for use. The ground in front of the building is enclosed by iron rails, and forms a protected space for the children of the residents, and at the back there is a wash-house, with a drying ground attached for the use of the families.

The sum expended on these buildings, amounts to 17,736*l.* 17*s.* 11*d.* The rooms, which average from 14 feet by 10 ft. 6 in. to 13 feet by 8 feet, are let from week to week, the rent of each set varies from 3*s.* 6*d.* to 6*s.* 6*d.* per week. The total rents receivable from the various establishments of the Association since December, 1847, amounts to 14,630*l.* 11*s.* 7*d.*, of which there has been actually received 14,594*l.* 6*s.* 11*d.*, leaving a deficiency from bad debts of only 36*l.* 4*s.* 8*d.* for five years.

Besides the Metropolitan Buildings in Pancras-road, the Association has erected another set of Metropolitan Buildings in Albert-street, Mile End New Town, capable of accommodating 60 families, at a cost of 10,297*l.* 4*s.* 10*d.* They have also purchased 25 houses, situated in Pelham-street and Pleasant-row, Mile End, capable of receiving about 23 families, at a cost of 5120*l.* 19*s.* 3*d.*; and they have decided on erecting another building in Bermondsey, capable of accommodating 108 families, at a probable cost of from 20,000*l.* to 25,000*l.*†

The lodgings for single men in London occupied by labourers and artizans being in general as unhealthy as the houses for families of the same class, it was conceived that the provision of fit accommodation for single lodgers fell within the legitimate province of the Association. Accordingly a lodging-house for single men was erected, capable of accommodating 234 inmates, at a cost of 13,493*l.* 13*s.* 9*d.*, and another capable of accommodating about 128 inmates, was purchased by the Society for 1422*l.* 7*s.* 7*d.*, being leasehold,* at a heavy ground-rent.

Four Branch Associations have been affiliated with the parent institution, namely, at Brighton, Dudley, Newcastle, and Ramsgate.

The experiment has proved eminently successful with reference to its great object, the protection of health and the diminution of preventible sickness and mortality.

In 1850, the total population in the Metropolitan Buildings, Old Pancras Road, was 560, and the deaths were 7, being at the rate of 12 and a half in 1000 of the living.

In 1851, the total population was 600, and the deaths were 9, being at the rate of 15 in the 1000.

In 1852, the total population was 680, and the deaths were 9, being at the rate of 13 and a fraction in the 1000. The average mortality of the three years in these buildings has been 13·6 per 1000.

But taking together the whole of the establishments of the Association, which had now come into full occupancy, the total population for the year ending March 1853, amounted to 1343. Out of this number there were, during that year, 10 deaths, being at the rate of 7 and a fraction in the 1000.

The deaths in the whole of the metropolis, during the same year (1852), reached a proportion of 22 and a fraction in the 1000; consequently, the total mortality in London generally, taking together all classes, rich and poor, was proportionally more than three times greater than the mortality in these establishments.

The Act entitled "The Labouring Classes' Lodging-houses Act," received the Royal Assent on the same day as the "Common Lodging-houses Act." The "Labouring Classes' Lodging-houses Act" is merely an enabling Act, but it gives most important powers to local authorities for raising loans, procuring lands, and building or buying houses, in order to provide more convenient and commodious dwellings for the labouring classes. Under this Act any town or district may by certain recognised authorities and under certain conditions, erect new structures or purchase' existing tenements unfit for human habitation, and replace them by wholesome dwellings; and such authorities may do this on the principle of a commercial enterprise, though the requisite capital is to be supplied from the rates. By this statute, therefore, local authorities in general are empowered to do what has been done in London by the Metropolitan Association, and the Society for Improving the Condition of the Labouring Classes. (See provisions of the "Labouring Classes' Lodging-houses Act," 14 and 15 Vic. cap. 34.)

## ORNAMENTAL GLASS SURFACES.†

ADOLPHE MARIUS ALEXANDRE IGLESIA, *Patentee*, April 9, 1853.

THIS invention consists, first, in the production of ornamental surfaces in imitation of marble, granite, or any substance capable of a similar polish, by applying, to the under surface of plates or pieces of glass, paper, or any other suitable pliable material, on which may be printed, lithographed, drawn, or coloured, by any of the well-known processes, a design, device, figure, or pattern in imitation of such marbles, granite, or other substanee. Secondly, in ornamenting the under surfaces of glass by applying thereto paper or any other pliable material, on which may be printed, lithographed, drawn, coloured, or otherwise produced by any other suitable process, a design or device which shall have the effect of designs painted upon such surface, or of mosaic or other ornamental work. Thirdly, to a method of consolidating or strengthening the pieces of glass thus ornamented, so as to give them the strength of marble or stone.

The process which the patentee employs for the first and second of the purposes aforesaid is as follows:—He dissolves in a vessel of pure water, by the employment of a water bath at a gentle heat, gelatine or common glue, or any other gelatinous substance, all of which is hereinafter called "glue." In selecting the material to be employed for this purpose he prefers such as is of a white colour, as far as it can be conveniently obtained. He does not limit himself to any particular strength of solution, but that which he prefers usually to employ is of the strength ordinarily used for the purposes of carpentry.

When the glue or gelatinous substance is entirely melted, it

* Shares to the amount of 65,150*l.*, had been taken up to the end of March, 1853.

† This building cannot be proceeded with at present for want of adequate funds, although the ground has been purchased. The Directors have also recently obtained possession of a building in course of erection in New Street, Golden Square, in the parish of St. James, which will accommodate 64 families.

* The other sums before mentioned, with the exception of the one relating to the buildings in Old Pancras Road, include the purchase of the freehold.

† Reported in the 'Repertory of Patent Inventions.'

must be strained through a sieve, so as to remove all impurities; after which it must be warmed to about 80° Fahr., when it will be fit for use. He then takes the piece of glass to which the paper or other substance having the design thereon (all of which is hereinafter called the "paper") is to be applied, and, after washing the glass well with warm water, he lays the paper upon it, with the decorated surface uppermost, and passes the solution all over it by means of a sponge; he then removes the paper from the glass, and wets the glass well with the solution, after which the paper is replaced upon the glass, with the moistened surface undermost, and the solution passed again over it with the sponge, taking care to remove any folds or creases which may show themselves. The piece of glass is then turned over, so as to place the paper underneath it, and after raising the glass with the left hand, he passes warm water over the surface of the glass with a sponge, until all the glue is completely melted. He then, by means of a piece of steel with the edge rounded, presses out the glue from between the paper and the glass; and, lastly, he turns the glass so as to place the paper uppermost, and repeats the same operation until the superfluous glue is removed; after which the back of the paper is cleaned with a sponge moistened with warm water, and it is then left to dry. The temperature of the water employed in this operation should not exceed 80° to 100° Fahr.

This process is applied to the production of patterns made of different pieces of papers of various colours by the following method: The patentee glues the separate pieces, arranged so as to form the desired pattern, design, or device, upon cloth; the design thus composed may, when dry, be fixed on the glass in the manner described above; then, upon moistening the back of the cloth, and carefully removing it, the pieces forming the design will remain and adhere to the glass.

In order to form such a pattern he also sometimes applies the paper which is to form the foundation of the pattern to the glass in one piece, and afterwards cuts out such parts as require to be removed to allow of the introduction of the design, and removes them by means of a little warm water and a brush and any blunt instrument, and fills up the vacant spaces with the paper, which must be attached by the methods before described.

The glass employed may be of any kind, care being taken to select such pieces as are not much curved and are not very brittle.

The third part of the invention, namely, the strengthening of the glass plates prepared in the manner above set forth, is effected in the following manner:—When the paper attached to the glass is quite dry, the patentee applies to the back of it a resinous composition, which is hereinafter called the "mastic," and is made of resin, plaster of Paris, grease, dry sawdust, cotton flock, or, in lieu of the last two substances, of sand. The mixture which he prefers, consists of four pounds of resin, four pounds of plaster of Paris, half a pound of grease, and three-quarters of a pound of sawdust. If it is desired to make the composition very hard, the quantity of grease may be diminished, or it may even be omitted altogether. All the substances may be put on together and melted over a slow fire, and the whole stirred up with a piece of iron until they are well mixed together.

Before applying the mastic the patentee has found it useful to cover the back of the paper with a mixture of glue and whitening, or of glue and plaster of Paris, which should be allowed to get quite dry. The use of this covering is to protect the glass from being cracked by the heat of the mastic, but, if care be taken in the application of the latter, it may be dispensed with. To prevent the danger of the front of the glass being scratched, it is covered over with a similar mixture. The mastic is applied at a temperature just sufficient to keep it melted. In applying the mastic the glass is laid upon an even surface of wood, and if the surface of the glass is not quite flat, weights of about six or eight pounds each are placed upon the edge, at a distance of two or three inches from each other, so as to flatten it; the mastic is then laid evenly with a trowel upon the paper until it is one-eighth of an inch thick, commencing from the outside, and changing the position of the weights as a part is proceeded to where the mastic is dry enough to support them, and applying it gradually, so as not to heat the glass suddenly. When the mastic is quite dry, slips of slate are taken about three inches broad and a quarter of an inch thick, and of a length regulated by the size of the glass, but not exceeding two feet, through different parts of which must be previously pierced a number of holes by means of any common borer. These holes should be larger at the side which is intended to be nearest the glass than at the bottom. The bottom surface of the slate should be slightly warmed, and then a portion of fresh mastic may be applied to that part of the previously covered surface to which it is desired to apply the slate; and the slate is then pressed down upon it, so as to force the mastic up through the holes. When, by this process, one piece of slate is attached to the mastic, another is laid alongside of it, taking care to fill up the intervals between the pieces of slate and the holes in these pieces with the mastic until the back of the glass and paper is covered entirely with mastic and slate. So soon as the mastic is cold, the glass will remain straight and solid, and the decorated surface will be perfectly preserved from injury. If a further thickness be required, it may be obtained by a repetition of the same process. In cases where lightness is required, and where the glass is not exposed to violent blows, backing is dispensed with except the mastic, which is always employed.

In applying the invention to the coating of bricks or stones with ornamented glass surfaces, the patentee does not carry the holes by which the brick or stone is attached to the mastic through the substance thereof, as in the case of slate, but only cuts them a little way into it.

The blocks or slabs, prepared as aforesaid, may be fixed in a wall or used as a flooring with ordinary cement, in the same way as ordinary blocks or slabs of marble, requiring only similar precautions to those commonly used by workers in marble to preserve them from scratches; and pieces of wood, iron, or any other solid substance may be let into the mastic, so as to give facilities for attaching the blocks or slabs.

*Claim.*—1. Ornamenting glass surfaces, as above described, with various devices, designs, or imitations of natural objects by means of paper or other suitable flexible material, on which may be printed, lithographed, drawn, or coloured, the desired device, design, pattern, or imitation; 2. The methods above described of strengthening or consolidating such ornamented surfaces, and rendering them applicable to the various purposes for which they may be employed.

## COMPOSITION FOR COATING MATERIALS EXPOSED TO THE ACTION OF SEA WATER.*

Edward Onslow Aston and George Germaine, *Patentees*, April 23, 1853.

The invention refers to mineral conpositions, prepared principally from sulphur and salts or oxides of copper, which are to be applied in a hot liquid state to metal, wood, stone, cement, and other materials; being used for wood ships, in lieu of coppering, and for iron ships instead of the usual anticorrosive paints and other ingredients employed for coating the same; and may likewise be used as a preventive of the action of the weather or sea-water generally, by coating the surfaces of the exposed materials therewith.

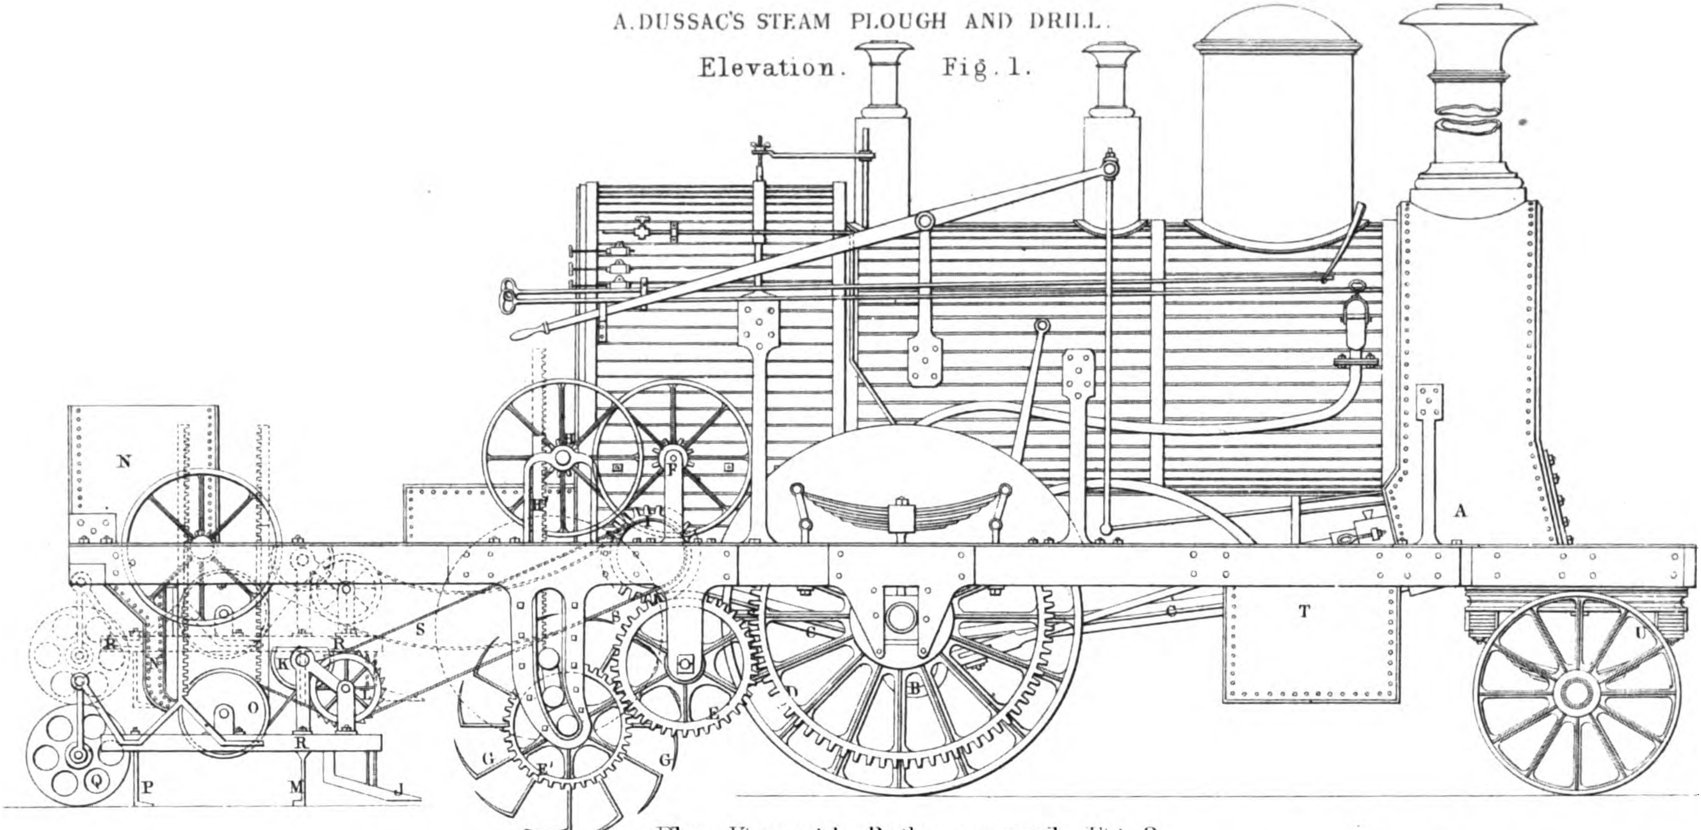
The patentees melt together, and thus combine in variable proportions, sulphur, naptha, and creosote; adding thereto verdigris or acetate of copper. Sometimes substituting for verdigris, copper pyrites, artificial sulphurets of copper, blue vitriol or sulphate of copper, and other combinations of copper with acids or oxygen, either singly or mingled, being first properly ground. The sulphur, naptha, creosote, and sulphuret, or salt or salts of copper, singly or combined, are to be heated together and well stirred, after which the composition resulting therefrom may be poured out into suitable moulds, and when cold broken up and packed in a dry hard state, ready to be remelted when wanted for use.

One of the various preparations that may be thus compounded is made by fusing in an iron pan, or any convenient vessel, three parts by weight of sulphur, and adding one part of naptha heated in a separate pan. When these materials are thoroughly incorporated, one pound of acetate of copper or verdigris is to be added to every eight pounds of the composition, and well stirred into it; after which it may be run into moulds, cooled, and stored for use. Or, the sulphur being melted, the verdigris may be added, then the naptha, and afterwards the creosote, at a boiling heat, to secure the amalgamation of the materials. The same process will apply to the adding of pyrites, they being first well pulverised, and to the salts and oxides of copper generally; all which may be used in variable proportions according to the quality required.

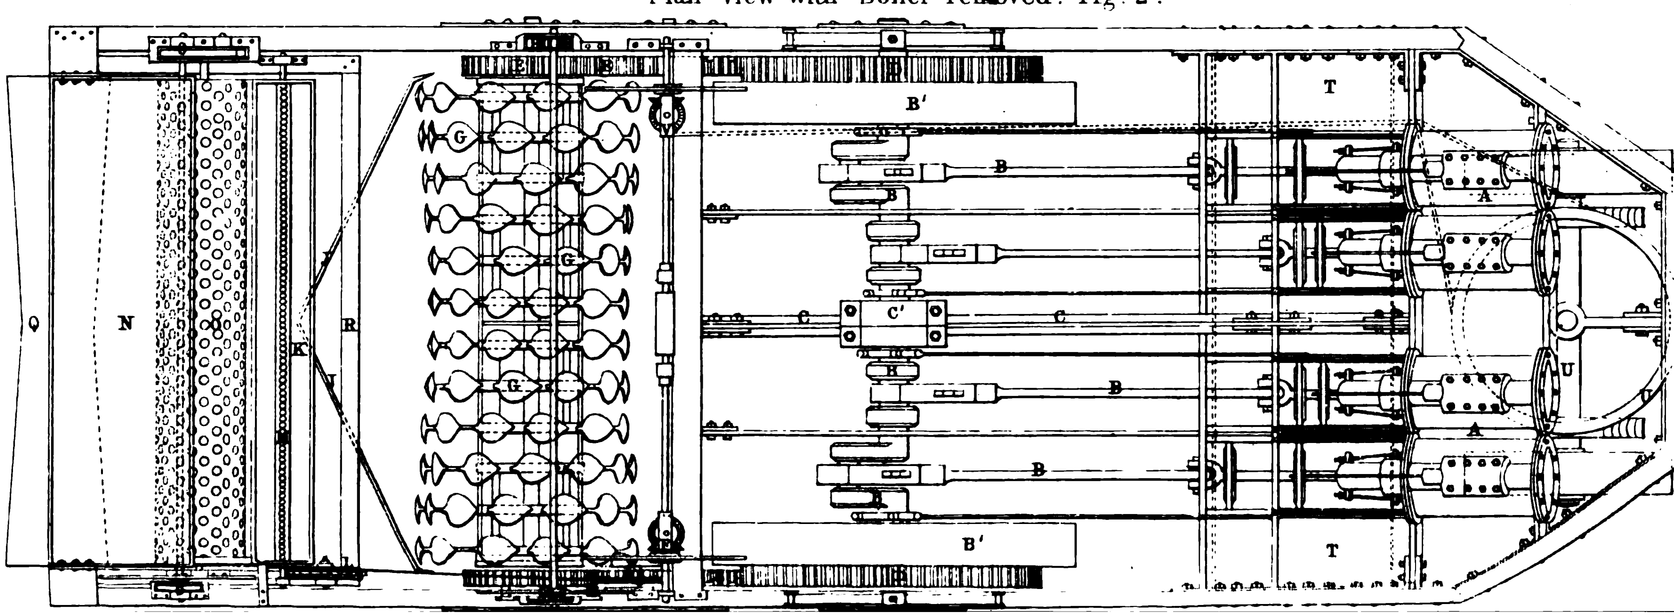
* Reported in the 'Repertory of Patent Inventions.'

A. DUSSAC'S STEAM PLOUGH AND DRILL.

Elevation. Fig. 1.



Plan View with Boiler removed. Fig. 2.



To coat iron with any of the mineral compositions, the patentees recommend the surface of the iron to be first well cleaned by scraping, and then rubbing it over with a stiff brush repeatedly dipped in hot naptha. When a sufficient surface has been thus prepared, a pot of the hot composition is to be provided and spread over the prepared iron, as customary in using pitch. When the sides and bottom of an iron vessel have thus to be prepared, the iron must be first freed from all moisture by common rubbing and firing, or in some cases simply by sanding or dusting it over with any dry ashy absorbent powder; the iron will then be ready for cleaning with the hot naptha before laying on the mineral composition.

To coat wood, and particularly wood ships' bottoms, the surface should be scraped clean, then coated with a boiling compound of naptha and creosote, preparatory to applying the mineral composition, the surface of which may be afterwards smoothed with suitable hot irons.

The mineral compounds may be applied to dry surfaces, with or without the first application of hot naptha, particularly when used for buoys, piles, and all common out-door work; and for roofs to guard them against either moisture or the attacks of insects.

For ships' bottoms, and all exposed iron or wood marine work, these compositions will be found to preserve them from the sea worm, and the adhesion of animal and vegetable products common under such circumstances, in consequence of the well-known action of the mineral poisons. The patentees do not restrict themselves to any particular proportions of the several ingredients.

## MANUFACTURE OF GLASS.*

Robert Walter Swinburne, *Patentee*, May 3, 1852.

The invention consists of a mode or modes of casting or manufacturing glass or other vitreous material in a melted state, by means of cisterns or casting vessels, which are placed in a furnace or kiln whilst being filled or charged from the melting pots, for the purpose of avoiding the diminution of the heat of the melted glass or metal before casting, which is consequent upon the ordinary mode of casting plate glass. The invention is carried into effect as follows:—Near to each melting pot in a furnace a cistern or casting vessel is placed, of such a size that, when filled, it can be conveniently removed from the furnace, and taken to the casting table. Each cistern is placed close to the melting pot from which it is to be filled or charged, in order that the melted glass or vitreous metal contained in the melting pot, or a portion of it, may be transferred without waste, by a ladle or other convenient means from the melting pot into the cistern. When the pots contained in a furnace have been charged, and the glass or vitreous material in them has been melted, and is ready for use, the patentee transfers, by means of an iron ladle or other convenient implement, from each pot, into an adjoining cistern or casting vessel (which must be previously heated in the furnace), a sufficient charge or quantity of the melted material; the cistern into which the melted material is thus transferred remaining in the furnace or kiln during the whole time that the operation of charging it is going on, and until the workmen are ready to take it to the casting table. A cistern or casting vessel being thus charged, and the casting table ready, the workmen withdraw the cistern from the furnace and take it quickly to the casting table, and cast the contents of it upon the table, and roll it into sheets or plates in the usual way, and immediately return the cistern to the furnace, and place it near to the same or some other melting pot ready to receive another charge, to be dealt with as above described.

The patentee continues to transfer the melted material from the melting pots into the casting cisterns, and to cast the same into plates or sheets of glass or vitreous material, in manner above described, until the whole charge contained in each of the melting pots in the furnace has been exhausted, after which the pots are to be refilled and heated until the contents of them are ready for casting as before.

*Claim.*—The mode or modes of casting or manufacturing glass or other vitreous material, by means of casting vessels which are placed in the same furnace with the melting pot whilst being filled in manner and for the purposes described.

* Reported in the 'Repertory of Patent Inventions.'

## STEAM PLOUGH AND DRILL.

Alexis Dussac, *Patentee*, October 17, 1853.

(*With an Engraving, Plate* XIV.)

This agricultural machine consists of an arrangement and combination of apparatus for ploughing, sowing seed, and manuring the land at one operation.

Supported on a suitable carriage is an ordinary locomotive engine, having two pairs of steam cylinders connected to the driving-wheels, which are made to revolve independent of each other, to allow of the machine being turned in any direction; each wheel is connected by cranks and connecting-rods to one pair of steam cylinders. Concentric with each driving-wheel is a large spur or toothed wheel, gearing into an intermediate spur-wheel which actuates the ploughing apparatus. The plough consists of a number of shovel-blades, attached by arms or shanks to a suitable framework. Immediately behind the plough is a follower or iron plate for levelling the surface of the earth preparatory to sowing the seed. The apparatus for sowing the seed consists of an ordinary drill, carried upon a moveable frame, capable of being raised or lowered when required. At the end of the carriage-frame of the machine there is a box or chamber for containing manure, the distribution of which is regulated by a perforated cylinder attached to the moveable framework carrying the drill. Following the manure distributor is an iron roller, which covers in the seed and manure, and smooths the surface of the furrow.

Fig. 1, Plate XIV., represents an elevation of this machine; and fig. 2 a plan of the same, with the boiler removed. A, A, represent two pairs of ordinary steam cylinders, supported on the framework of the machine, each pair connected by connecting-rods and cranks B, B, to one of the driving-wheels B′, B′. C, is an iron frame, carrying the clutch-box C′, in which the inner end of each half of the axle of the driving-wheel works; D, D, are toothed wheels, fixed concentric with the wheels B′, B′, and gearing into intermediate spur-wheels E, E, which actuate the spur-wheels E′, E′, keyed in the axle of the plough G. F, F, an ordinary contrivance of bevil wheels, cords, and rollers, for the purpose of throwing the spur-wheels E, E, into or out of gear with the wheels D, D, when requisite. H, is a small pinion, fixed on a suitable frame, and gearing into the rack H′; the lower end of the rack is attached to the axle of the plough, for the purpose of regulating the depth to which it is desired the cutters should take into the soil, or of raising the plough completely off the ground when the machine is not in action. I, is an iron follower or blade, which prepares the surface of the ground for the reception of the seed, and gives the requisite inclination to the furrow. K, is the seed-box, and L, a ratchet-wheel for shaking the box K. Motion is imparted to the ratchet-wheel L, by means of a band or cord passing over a rigger or pulley keyed on the axis of the spur-wheel L, which gears into the intermediate spur-wheel E. M, are the drills for depositing the seed. N, is a box or chamber containing manure, which falls through the hopper N′, and is uniformly distributed over the furrow by the perforated cylinder O, which is caused to rotate by a cord passing over a pulley on the axis of a ratchet-wheel L. P, is a series of tin tubes, placed in a line with the drills M, for the purpose of covering up the seed dropped by the same. Q, is a cast-iron roller, which smooths the surface of the furrow, and completes the operation of sowing the seed. R, is a wooden framework, which carries the seed-box, drills, manure distributor, and roller, &c. When not required to be in action, the framework R, is raised by the rack and pinion S, to the position indicated by dotted lines, carrying with it the whole of the apparatus attached thereto. T, is a water-tank. U, moveable guide-wheel, to which the fore-wheels of the machine are attached, to admit of their being turned in any direction when the machine is required to be removed or turned round, when arrived at the end of the furrow. This moveable guide-wheel U, is acted upon by a band or cord passing around it and connected to a roller on the axis of the bevil-wheel V. Acording to the direction in which this bevil-wheel is made to rotate, the fore-wheels are caused to rotate either to the left or right; and by this means the machine is capable of being guided with great accuracy.

## CONSUMING SMOKE AND HEATING LIQUIDS.

Samuel Bayliss, *Patentee*, April 15, 1853.

This invention relates—First, to the perfect combustion of the gases arising from the heated fuel in steam-engine and other furnaces, for the purpose of preventing smoke and economising coal; secondly, to the retaining within such furnaces much of the heat which now passes away to the chimney without producing any useful effect; and thirdly, to facilitate evaporation by causing a rapid circulation in the liquids to be heated.

In order to effect a chemical combination between the gases of combustion and the oxygen of the air, the patentee proposes to intercept or retard the gases on their way from the fireplace to the chimney, by dividing them into a number of small streams or bodies, and forcing them into mechanical admixture with the air, which is supplied in small currents.

The furnaces are fitted, in place of the ordinary fire-bridge, with an air-chamber, formed by two cast-iron plates, built in the walls or sides of the furnace, immediately under the inner end of the fire-bar, and provided with a door for regulating the admission of air to the same. One of the plates forming the air-chamber serves as a support for the fire-bars on one side, and the bearing-bars on the other; these bearing-bars are laid lengthwise across the air-chamber, with spaces between them to allow of the passage of currents of air between them. Perpendicular to these bearing-bars are fixed other bars of metal or clay, which serve as "admixers and heat-retainers," and have spaces between them for the passage of the gases of combustion, which, in their endeavour to permeate the numerous channels presented by such an array of bars, and the agitation consequent thereon, are brought into intimate mechanical mixture with the air from the chamber below; the bars also becoming red-hot, form a retainer for the heat of the furnace, and consequently a steady combustion is produced from one end of the admixers to the other. Another modification of the admixers consists in placing a cast-iron vessel on either side of the furnace, and connecting them by metal tubes, which act as admixers. One of these vessels has communication with the force-pump, and the other with the boiler, and thus all the water that enters the latter must pass through the tubular admixers, and by absorbing the heat prevent them from being burnt away, and also, by heating the supply water, greatly economise the fuel.

The second part of this invention relates to extending the admixers and heat retainers to the end of the boiler, or if desirable, through the internal tube or flue of the boiler. These being maintained at a red heat by the passing flame and heated gases, will give off, by radiation, to the surface of the boiler a great quantity of heat, which would otherwise pass up the chimney and be wasted; they will form, in fact, a continuous fire from one end of the boiler to the other, and tend to spread the heat more uniformly throughout the furnace. This arrangement is applicable to evaporating pans, such as those used in the manufacture of salt, for example, where slow combustion and uniform heat under the whole of the evaporating surface are required.

The third part of this invention consists in placing on the bottoms of boilers or evaporating pans a number of hollow cones, open at top and bottom, and supported on legs so as to leave a free passage for the liquid underneath and through them; they should be sufficiently heavy to maintain their positions by their own gravity, or they may be attached to iron bars fixed to the bottom of the boiler or pan—in this case the legs will be unnecessary. On heat being applied, it expands the liquids in the cones, and causes upward currents which carry off the particles of steam as fast as they are formed, the cooler liquid outside the cones rushes downwards to supply the place of that which is ascending, ensuring a rapid and continuous circulation and quicker diffusion of heat.

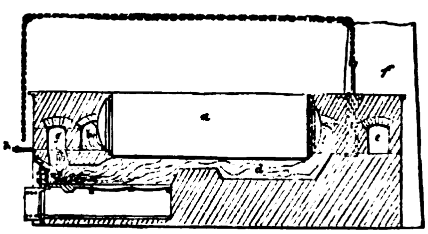
*Claims.*—1. The intercepting the gases in their transit from the fireplace to the chimney, and dividing them into a number of small streams or bodies, and bringing these in contact with a current or currents of air, in such manner as to produce an intimate mechanical mixture of air and gases, in order to facilitate their chemical union; 2. The application of admixers and heat retainers, whether employed in conjunction with the apparatus for preventing smoke, or in furnaces of any other construction; 3. The application of hollow cones, open at both ends, for facilitating evaporation, and preventing the bottom of vessels used in heating liquids from being burnt.

## CONSUMING SMOKE.*

James Bristow and Henry Attwood, *Patentees*, April 28, 1853.

This invention relates to a mode of constructing or arranging the flues of steam-boiler and other furnaces, when two or more are set side by side, or brought into connection with each other, so that the smoke or gases of combustion given off from one furnace may be conducted over the bright fire of another furnace, and be thereby consumed. This object is effected by bringing the several adjacent furnaces into communication with a common flue, provided with dampers, which will permit of a temporary connection being set up between any two furnaces in the range. Thus, when fresh fuel is thrown on to one of the furnace-fires, by diverting the course of the gases generated in that furnace, and causing them to enter the common flue (which diversion may be effected by closing the damper in the exit-flue of the smoking furnace), the smoke and gases may be conducted into a furnace having a bright fire, and be there consumed. When smoke ceases to be given off from the recently-charged fire-place, the gases of combustion are turned into their proper channel, and allowed to escape into the chimney.

Fig. 1.



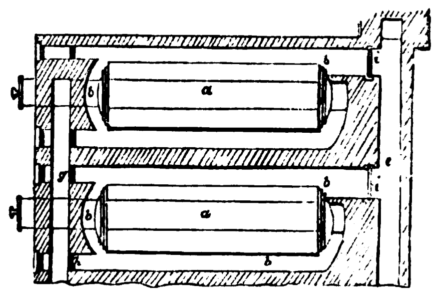


Fig. 2.

Fig. 1 of the annexed engravings represents a vertical section, and fig. 2 a sectional plan of this method. *a*, *a*, are the boilers, which are severally set in brickwork, which forms a flue *b*, around them of the ordinary kind. Into this flue the flame and heated gases from the fireplace *c*, pass, by a flue *d*, which runs under the boiler; and the gases having circulated through the flue *b*, escape into a common flue *e*, at the back of the furnaces, and finally make their exit at the chimney *f*. Immediately over the fireplace *c*, in each furnace is an opening, which leads to a flue *g*, formed in the brickwork, and running from end to end of the series of furnaces. These several openings are commanded by a sliding door or damper *h*, which, when closed, cuts off the communication between the several furnaces and the flue *g*. The flues *b*, near that end which connects with the common flue *e*, at the back of the furnaces, are likewise severally provided with a damper *i*, for cutting off the communication between their respective furnaces and the flue *e*. These dampers *i*, are each suspended by a chain *k*, which passes over carrier-pulleys, and is thereby brought to the front of the furnace, to enable the attendant to raise and lower the dampers with facility.

Supposing, now, a bright fire to be burning in, say, furnace No. 1, and a fresh charge of coals to be required in furnace No. 2, the attendant will, prior to throwing on the coals, close the damper *i*, of the latter furnace, and open the damper *h*, of both furnaces; whereby the smoke arising from the fresh charge will be diverted from its usual course towards the chimney, and thrown back to the front of the furnace. A communication being now established between the furnaces Nos. 1 and 2, the smoke will pass from the latter into the fireplace *c*, of the former

* Reported in 'Newton's London Journal.'

—which contains, as was said, a bright fire—and it will be there consumed. When smoke is no longer given off by the fire in the furnace No. 2, the damper *i*, of that furnace is to be opened; and, supposing the fire to be now burning brightly in this furnace, and a fresh supply of coals to be required for furnace No. 3, the damper *i*, of the latter furnace is to be closed, and a communication established (in like manner to that just described) between furnaces Nos. 2 and 3—the damper *h*, of furnace No. 1 being closed, to cut off the connection between that furnace and the common flue *g*. It will thus be understood that any two furnaces of a series can be connected together at pleasure, for the purpose of diverting the smoke generated in one furnace, on to the bed of bright coals in an adjacent furnace, and thereby effecting the combustion of the smoke. Instead of employing a flue, built up in the brickwork, for producing a passage of communication between the fireplaces of several furnaces, iron or other tubing, having short branch pipes leading to the several furnaces, may with advantage be used; especially when the invention is required to be applied to furnaces already constructed.

*Claim.*—They lay no claim to the principle of diverting the smoke and heated gases generated in one furnace and passing them under or over the bright fire in an adjacent furnace; but they claim the means hereinbefore described, by which any two of a series of furnaces may be readily brought into connection with each other, for the purpose of effecting the combustion of the smoke given off from the successive charges of coal supplied to such furnaces.

## TREATING SEWAGE AND MANURE.*

Thornton John Herapath, *Patentee*, March 14, 1853.

These improvements in the treating of sewage consist in causing the phosphoric acid and ammonia of such matters to be precipitated in a comparatively insoluble state, by the addition of magnesia, or a magnesian compound, at or about the same time that the deodorisation of the sewage is effected by the addition of some deodorising chemical agent, which will not decompose ammonia or its salts.

In carrying out this invention, the patentee runs the matters into a tank or reservoir, and adds to them chloride of magnesium, nitrate, or sulphate of magnesia, or burnt and slacked magnesian limestone, commonly called dolomite, or a mixture of carbonate of magnesia and carbonate of lime, which will slack together. He adds, either before, after, or about the same time, such deodorising agent as may be added without decomposing ammonia or its salts, but will combine with or absorb hydrosulphuric acid, such as metallic sulphates or metallic chlorides, or animal or vegetable carbon. Upon such additions the sewage matters lose their offensive smell, and their fertilising parts precipitate to the bottom. The supernatent clear fluid is allowed to flow off, and either to irrigate the adjacent land or to run to waste. The pulpy sedimentary matters are now dried, either by the admixture of some material capable of absorbing water (such as sawdust, malt combings, ground bones, or coprolites, and so forth), or they are dried by artificial heat of moderate degree; when these matters form a manure of great fertilising power for use, either by themselves or by admixture with other suitable manures.

*Claim.*—The combined employment of magnesia and its compounds, together with deodorants, to sewage matters, so as to precipitate their useful parts, deodorise them, render them readily portable, and manufacture them into manure, in the manner hereinbefore described.

## ROADS AND FLOORS.*

Sir John Scott Lillie, *Patentee*, November 27, 1853.

This invention consists in the formation of blocks and slabs for the construction of roads, footways, and other like surfaces of broken stone, gravel, wood, iron, metallic substances, or other hard material, conjointly or separately, which substances are caused to adhere by means of bituminous compounds or other cements. The moulds may be formed of sand or of iron boxes with moveable sides and ends, and of any convenient size or shape (such as that of a paralellogram), two feet by one, and six inches deep. The moulds are filled indiscriminately with the said materials, or with alternate rows of wooden blocks, with the grain of the wood set perpendicularly, and the intervals filled with the before-mentioned materials cemented together. Metallic sand, borings, filings, or other small pieces of metal, may be added to any ordinary cement or bituminous compound for coating the surfaces of the blocks and slabs, which may be cast with grooves.

For heavy traffic, wooden planks from one to two inches thick should be attached to the bottom of the blocks, on which the small wooden blocks, when used, should rest; and short pieces of wood, imbedded in a concrete or other foundation, to serve as an additional support to the ends and sides of the said large blocks. For footways, floors, and other like surfaces, slabs are formed from one to two inches deep of the same combination of materials, and when great strength is required, they are attached to boards of about one inch in thickness.

*Claims.*—1. The formation of blocks and slabs for constructing roads, floors, footways, and other similar surfaces, as hereinbefore described; 2. Covering the said or other paving blocks with metallic sand, borings, filings, or other small pieces of metal, as hereinbefore described; 3. The application of boards or planks for supporting the said blocks, and also blocks of stone in ordinary use for paving purposes, as hereinbefore described.

* Reported in 'Newton's London Journal.'

## ON DIPPING AND APPARENT LIGHTS.

By Thomas Stevenson, C.E.

The author, at a recent meeting of the Royal Scottish Society of Arts, alluded to the great and well-known difficulties and expense, and, in some cases, the impossibility of constructing lighthouses upon sunken rocks. To remedy such difficulties, he proposed two methods, termed Dipping and Apparent Lights, in order to make lighthouses on the shore answer the same ends as if they were placed on the isolated rocks at sea.

Mr. Stevenson described the plan of *dipping* lights as being applicable to cases where the rocks or shoals, whose position required to be indicated, were surrounded with sufficient sea-room to enable vessels to pass to and fro without approaching near to the rocks themselves. The dipping light, instead of throwing its beam of parallel rays to the horizon in the same manner as ordinary lights, throws it downward at some given angle of depression to suit the distance of the rocks from the shore, so that whenever a vessel crosses the margin of safety, the dipping light is seen, and she has ample time to change her course.

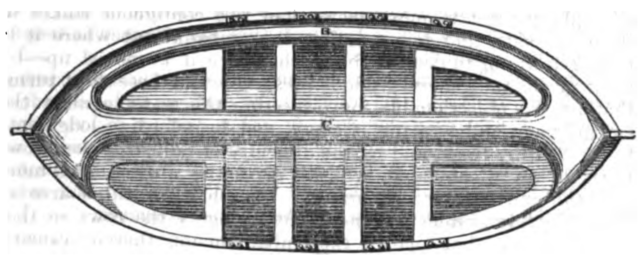
The *apparent* light is useful for sunk rocks in narrow sounds where the fairway is not broad, and where the dangers must be passed very closely; also for pier-heads at the mouths of artificial harbours, and such like situations. The apparent light at the entrance to Stornaway Bay, in the Hebrides, is erected on a sunk rock distant about 630 feet from the lighthouse on the shore, and consists of a hermetically sealed lantern, containing certain forms of optical apparatus, upon which a beam of light is thrown from the lighthouse ashore. The effect of this apparatus is to re-assemble the rays in a focus, from which they again diverge, presenting to vessels entering the bay the appearance of a real light on the beacon, when in fact there is none. So dangerous was this sunken rock, that many thought the lighthouse should be built upon it, instead of on the shore. By means of the apparent light, however, every end has been gained that could have been secured by the lighthouse, while the great expense of construction and of after-maintenance has been saved. From the very small power which is used at Stornaway (a Holofshotral apparatus of only 20 inches diameter, with a burner 1 inch in diameter) the author concludes that such a plan could be applied to very much greater distances. The optical power at Stornaway could, were it necessary, be increased about a hundredfold, if fitted with a Holofshotral apparatus of the first order. If the electric light were employed in connection with such powerful apparatus, the limits of visibility would of course be still further extended. The apparatus necessary for illuminating floating buoys on the same principle was also explained, and the paper was concluded with extracts from letters from ten different shipmasters, who certified to the utility of the beacon light *in all weathers*. The distances to which it had been seen varied from *one to one and a-half* mile,—distances greatly beyond the wants of the locality.

## SELF-RIGHTING LIFE-BOAT.

**William Barrington, *Patentee*, March 7, 1853.**

This invention is intended to supply to boats or vessels, when upset, the means of speedily righting themselves, by constructing them with buoyant chambers or materials unequally distributed, so that one side shall be more buoyant than the other; and also of affording to such boats the means of discharging the water which remains in them after righting, or that may be shipped in other ways, by fitting them with self-acting valves which open outwards.

Fig. 1.



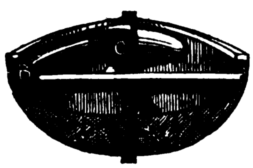


Fig. 2.

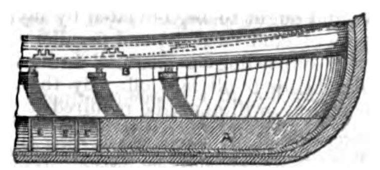

Fig. 3.

Fig. 1 of the annexed engravings represents a plan of a life-boat constructed on these principles; fig. 2 a transverse section, and fig. 3 a longitudinal section of the same. A, is a hollow or buoyant chamber or lining of cork, or other suitable light material, underneath the floor of the boat; it is raised a little at each side, as shown in fig. 3, to facilitate the passage of the water to the valves below. B, is another similar chamber or lining, placed along the top of that side of the boat intended to be made the more buoyant. C, is a third chamber consisting of a mass of buoyant material, extending from end to end of the boat, but placed a little out of the centre towards the more buoyant side; the ends of the boat may also be supplied with similar chambers. The inequality of weight thus produced is counterbalanced when the boat is in an upright position by a weight D, or ballast fixed at the bottom or attached outside to the keel; this weight also operates in righting the boat when upset. The quantity of buoyant matter thus distributed may be varied, as also the mode of its distribution, so long as it is arranged or disposed so as to give a sufficient excess of buoyancy to one side, and to render the boat capable of floating, under all circumstances, with the number of people she is intended to carry. E, E, are self-acting valves, fitted within the tubes or passages *f*, which have a protecting grating G, G, at the upper and lower ends. These valves are fixed on a pivot *e*, open outwards, and are adapted in number and capacity to the dimensions of the boat.

On reference to fig. 3, it will be seen that when the boat is upset, the weight D, acts downward in one direction, whilst the extra buoyant side of the boat B, C, is pressed upwards by the water in the opposite direction; the boat therefore is caused to revolve on the centre of gravity until she becomes restored to her natural position. The valves E, E, are kept closed while the boat is floating by the upward pressure of the external water, but on it becoming filled, or partially so, a downward pressure is produced, and the water contained in the boat forces its way through the valves. The sides of the boat are supplied all round with short rope ladders, to enable people more easily to get into her from the water.

*Claims.*—1. The unequal distribution of the buoyant chambers or materials, so as to act in the manner described; 2. The self-acting valves and their appurtenances in their general features, as constituting means of discharging water from the inside of the boat.

## IRON SUBMARINE TUNNELS.

**Auguste Edward Loradoux Belford, *Patentee*, June 30, 1853.**

This invention relates to the construction of tunnels or ways, having one or more avenues of cast-iron in sections, to be lowered into a bed prepared for them, by excavating the bottom of the river, harbour, or other water, under which the tunnel or way is to pass; the sections to be fastened together when in their bed and suitably weighted; and when all united so as to make the tunnel or way complete, to be pumped out or otherwise relieved of the water within. The improvements consist in the manner of constructing the sections, and in the manner of lowering and uniting them.

Fig. 1 represents a transverse elevation and section of a tunnel, with two main avenues for railways or roads for ordinary vehicles, and an intermediate passage for foot passengers; the elevation being on the left, and the section on the right of the vertical line A, A.

Fig. 2 is a longitudinal section of part of the same tunnel, taken in the centre of one of the main avenues looking towards the central passage.

Fig. 3 is a section of the bottom joint between two sections of the tunnel.

Fig. 4 is a section of the bed-plate, showing the guide-butts on the bottom.

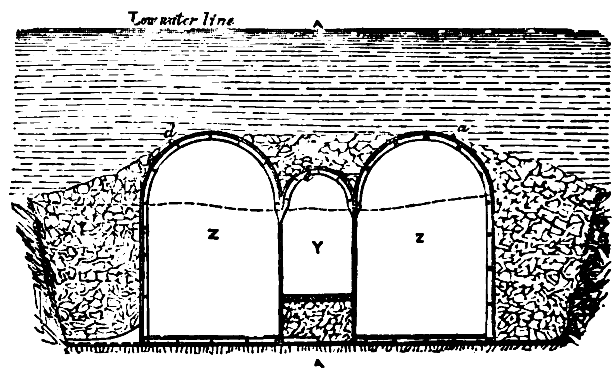

Fig. 1.

Similar letters of reference indicate corresponding parts in the several figures. The sections of the tunnel, are made of such length as is considered advisable, and are furnished with an internal flange *b*, all round, to receive the bolts by which they are secured together. A tongue *c*, is formed all round the outer face of the flange at one end of each section, to enter a recess *e*, in the flange of the next section; the said tongue and recess being packed with a strip *f*, of india-rubber. On the top of each section, two projecting ribs *d*, *d*, are cast, to form a continuous railway when the sections are put together, and it is provided with two grip-pieces for lowering it.

Fig. 2.

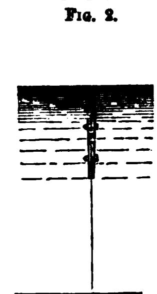

Fig. 3.

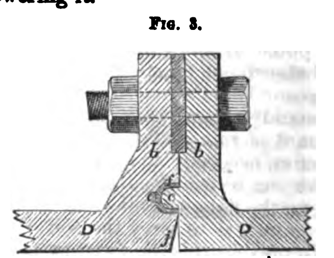

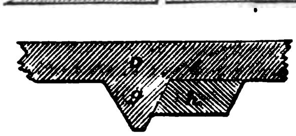

Fig. 4.

The bottom of the river or other water is excavated previous to the sinking of the sections in such a manner as to form a suitable level bed for the sections to rest upon, and to such a depth as to bring the top of the sections to a desirable distance below the low-water line. The line of excavation is marked in fig. 1, where the natural bottom of the river is shown by the dotted line. The first section, or more than one section, may be lowered by any suitable means, either on shore or afloat, and the ribs *d, d*, form a railway for a travelling derrick, by which the other sections may be lowered. The sections are lowered one by one, and bolted together by a diver with submarine armour; the india-rubber packing *f*, being inserted in the recess *e*, previous to lowering. The several sections are caused to come into their proper places, in relation to those previously lowered, by two guide-pieces *g*, of which one is shown in fig. 4 of the form of the letter V, cast on one end of the bottom of each section, and by two butts *h*, which project from the bottom of the next section; the butts *h*, being on the outermost end of the section already lowered, and the pieces *g*, on the innermost end of the section being lowered. When the section is lowered close to the end of that already on its bed, it may be dropped at once into its place. The bed-plate D, is extended beyond the sides of the tunnel to a considerable width, and strengthened by wings to receive a quantity of rubble, for the purpose of keeping the structure sunk when the water is extracted. The inside of the central passage is also filled to a considerable height, and its top covered with rubble, for a similar purpose; the top of the rubble being finished off with rubble and concrete. When the sections are bolted together, and connected with suitable shafts or inclined planes at the ends, and properly weighted down, the water is extracted, and the flanges are all packed from the inside with lead or other metal packing, as shown in fig. 3. The bed upon which the structure rests may be made with gravel, or prepared in any way that may be considered most suitable; and in order to prevent the gravel or earth being scraped up between the joints of the flanges, it is better to bevil off the lower edge of one face, as shown at *j*, in fig. 3.

*Claim.*—The manner herein described of forming submarine or subaqueous tunnels and passages in sections of cast-iron, lowered one by one into a suitable bed, excavated in the bottom of the river, harbour, or other water, and so constructed that those which are lowered form a railway for a travelling derrick to lower the others, and that those being lowered will always drop into proper positions in relation to those which are already in place, and that the whole structure can be properly weighted down.

## AMERICAN HILL-SIDE DITCHING.

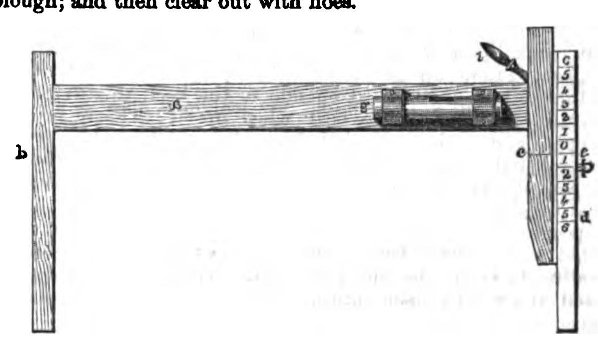
By James H. Forman.

Our soils consist of humus, clay, and sand, the clay generally preponderating. Our subsoil is a fine close clay, which resists the action of water, but when saturated retains it with great tenacity. Humus absorbs water in large quantities, and rapidly; clay pulverised in less quantities, and more slowly; sand in still less quantity, but rapidly. Hence, our soils are well adapted to absorb and retain water; and, wherever there is not a sufficiency of clay for the purpose, the subsoil may be made to furnish th necessary quantity. An ordinary shower gives about half an inch in depth of rain; a hard shower, about 1 inch; and a hard day's rain, about 2 inches. The average annual fall of rain is computed at 45 inches. Our soil, well broken and pulverised, will absorb one fourth of its bulk of water. Hence, if we could keep our land thoroughly pulverised to the depth of 8 or 9 inches, it would seldom wash, always absorbing any but an unusual amount of rain as fast as it falls; but, as this is impracticable, it becomes necessary to adopt some plan by which the unabsorbed water can be conveyed off, so that it shall not settle upon and drown the flats, or collect in such quantities while on its way to the branch as to carry the soil with it.

To prevent this, that system of surface draining called hill-side ditching has been applied; and, although it has in many instances been condemned as worthless, yet we believe that it is the only practical remedy; and we further believe that the cause of every failure has been attributable either to defective location or construction, or neglected repair. We are confirmed in this belief by observing many applications of the system eminently successful. We therefore recommend that these drains should never be more than 250 or 300 yards long without an outlet; and also to increase their capacity, either in dimensions or grade, to accommodate the accumulation of water. Where the subsoil is firm and tenacious, we recommend the latter, and submit a formula, viz: Let the first 50 yards of your ditch (counting from the summit) have a grade of ¼-inch to the yard; the second 50 yards, ½-inch; and so on, increasing the grade ¼-inch every 50 yards. In constructing the ditch thus located, the subsoil should be excavated 3 or 4 inches. This gives a channel for the escape of ordinary showers without wearing away the embankments, and also furnishes material for strengthening said embankments; but where the subsoil is light and porous, the increase of capacity must be in width. In adhesive soils the ditches may be 60 or 70 yards apart; but in light soils, not more than 40 or 50 yards.

In locating, use the spirit-level, as it is obvious that a defect in this operation is incurable. For the description and manner of using a convenient and cheap instrument of this sort, we refer you to the drawing. The inequalities of surface incidental to cultivated land will exhibit a great many abrupt turns in your location; and moving it a little, either up or down, always remembering not to move more than two contiguous stakes to the same side, and to strengthen the embankment where it is moved down, or to deepen the ditch where it is moved up—by these means the general grade is preserved; and these short turns, that are so objectionable, by projecting the water against the embankment and wearing it away, and by affording lodgments to the floating trash, and by the difficulty of adjusting your rows to them, are all obviated, while it gives the work a much more graceful and regular appearance. Another fruitful source of failure in this system is suffered by laying of the rows so that they cross or abut against the embankments, thereby causing them to be trodden down by the horse in ploughing. This may be, and ought to be, obviated by laying off the first row in each space of land close to, and parallel with, the embankments, and every succeeding one parallel to it, until your space to the next ditch below is all laid off. By this arrangement, the horse, in ploughing, will never be required to step on or over the embankment, and your rows will be as well, if not better, situated to facilitate the process of cultivation and draining than by any other means.

We are confident, from observation and experience, that the plan here indicated, if properly executed, will succeed with a very little attention, after construction, as the ditches will keep themselves clean. It will only be necessary to clear them of such rocks, limbs, or large trash, as cannot float off. We are also satisfied, from experience, that the alluvium deposited by these ditches is an effectual reclaimer of our barren glades, and by directing them to such points, the land thus reclaimed will more than compensate for that occupied by the ditches. An expeditious way to make these drains is to open your way with a turning plough, and follow with coulters; and again with a turning plough; and then clear out with hoes.



The above sketch represents an instrument used for locating hill-side ditches. *a*, is a lath, 1 inch by 4 inches, and 12 feet long. *b*, the hinder leg, 1½ or 2 inches square, 3 feet long, and securely fastened to the lath. *c*, the fore leg, 1½ or 2 inches square, 2½ feet long, and securely fastened to the opposite end of the lath. *d*, the sliding leg, 1½ or 2 inches square, and 3 feet long; it is graduated and numbered from zero, 6 inches up and down, and by means of a slit and the thumb screw *e*, may be moved and secured to any required grade, there being a mark on the fore leg that coincides with the zero mark on the sliding leg, when the instrument is adjusted to a level. *f*, a handle, to carry and hold the instrument by. *g*, a small spirit-level, securely fastened to the lath by two screws.

In using the instrument let the operator provide himself with a number of small stakes, 8 or 10 inches long, and an assistant (a small boy will do) to carry the hinder end. Then let him determine his starting point and put down a stake, directing his assistant to place the hinder leg against it; then let him determine the grade he wishes to run, and whether up or down, and adjust the instrument accordingly; then move the fore leg to the right or left until the bubble indicates a level, and put down another stake against the foot of the sliding leg, and proceed as before, directing his assistant to place the hinder foot in the precise spot occupied by the fore one. It will be seen that the instrument can be adjusted to any change of grade that may be required, in a few seconds.

## RECENT AMERICAN PATENTS.

[Reported in the Journal of the Franklin Institute.]

*Coating Sheets of Metal.* E. Morewood and G. Rogers.

This improved apparatus consists of a metallic vessel, having a flange round its top to give it the requisite strength; this vessel should be made of wrought-iron, and of a length somewhat greater than the longest sheets to be coated, and of such a depth that these sheets can be immersed in the bath of molten metal, at least eight or ten inches, when standing on edge.

*Claim.*—The method herein described of coating sheets of metal, by immersing them in other molten metals which are more fusible, by means of rollers; so that with the same machine sheets of metal varying in thickness may be coated, free from puckers, bends, or indentations on their surfaces; thus rendering unnecessary the subsequent operation of flattening, which heretofore could not be dispensed with.

*Improvements in Generating and Condensing Steam.* P. H. Watson.

*Claim.*—The method of recovering the heat of the exhaust steam by passing it through the comparatively cool water in the lower portion of the boiler; also the arrangement of the upper end of the drop-flues in an inclined plate, to facilitate the entrance of the smoke into the flues, and the passage of the steam from beneath the inclined plate into the upper part of the boiler.

*Power-Looms.* J. Greenhalgh, jun.

*Claims.*—1. Suspending each leaf of harness from two jacks, which are of similar form and length, and are geared together by toothed sectors, for the purpose of preserving an uniformity of motion to both ends of the harness; 2. Attaching the knife to the levers, and applying springs to the same, in such a way that it will move on the levers in its descent in closing the shed sufficiently to pass the points of those hooks of the ascending portion of the harness which are in a position to be raised to make the succeeding shed; and after passing the points of the hooks, will slip under them; 3. Suspending the heddle frames or the top rails by means of sheet or hoop iron links, which are pivoted to the jacks, and are furnished with pins to enter slots or notches in the ends of the top rails, by which a simple means of attachment and detachment is obtained.

*Hydraulic Ram.* J. C. Strode.

*Claim.*—The application of the brachystochrone curve to the conduit-pipes of hydraulic rams.

*Burglar Alarms.* E. Brown.

*Claim.*—The inventor does not claim the combination of an alarm-clock with a lamp-lighting apparatus, they being so applied, that on an alarm being sounded by the clock-works, they shall set free the separate machinery by which the lamp and friction match are rotated, the latter being carried against a roughened surface for the purpose of igniting it. In this alarm-apparatus, the spring which moves the match-holder not only performs the operation of moving such match-holder, but elevates the bell and its spring until the slide is brought up against the shelf, which taking place, the accumulated force on the bell causes the bell to vibrate and sound the alarm. The improvement is claimed of so connecting the match-holder and the bell-spring with the slide, that the spring of the slide, on being set free by the opening of the door, shall not only elevate the match-holder, but set the bell in motion, so as to cause the alarm to be sounded by it.

*Improvement in Fluid Meters.* W. B. Leonard.

*Claim.*—The combination in fluid meters of mechanism for measuring the volume of a flowing fluid, however variable; mechanism for measuring the velocity of the flowing fluid, however that may vary; mechanism for multiplying these two quantities together; and mechanism for recording the product in such manner as to show on a register the quantity of fluid that has passed. Also, the combination of a self-acting guard-valve or valves, however constructed or arranged, with the water-wheel or other motor in a meter, in such manner that the flow of water through the meter will be arrested whenever the pressure is not sufficient to give motion to the motor the instant it begins to flow, whereby the escape of water through the meter unmeasured is prevented.

*Improvement in Machines for Straightening and Curving Rails.* G. Williston.

This invention consists in placing over the part of the rail which is bent (by the weight of the train in passing) a curved beam, which has its bearings on the rail near the end of the beam; then, by a contrivance which embraces the rail, a screw is turned, which has power sufficient to raise the bent portion to its original position, where it may be secured.

*Claim.*—The combination of the screw, strap, beam, and slides with the beam placed on the top or side of the rail, for the purpose of straightening or curving rails on railroads, without the necessity of removing the same from the sleepers.

*Machine for Turning or Cutting Irregular Forms.* N. Gear.

This invention consists in making the cutter-heads one or both guides or gauges for the setting of cutting edges of the knives therein, and also guides or gauges to the pattern of the thing to be cut. Also, in the peculiar manner of securing the cutters into the cutter-heads by dovetails, thus avoiding the use of keys, wedges, screws, or any other device than the shape of the ends of the knives and grooves into which they fit.

*Claim.*—The combination of knives with a rotary cutter-head, so that said head shall serve as a guide or directrix to the form or pattern carrying the material to be dressed.

*Blow-Pipes for Enlarging Blasting Cavities.* A. Stickney.

*Claim.*—The inventor does not claim the enlarging a drill-hole by the use of heat or a blast of air thrown upon charcoal or other fuel in a state of combustion; but a process of enlarging the drill-hole by means of an air-blast and charcoal, or other combustible fuel, placed in the hole; the same consisting in the employment of a blast-tube made with lateral projections, and a closed or nearly closed bottom, the same enlarging the hole with a greater saving of labour and time.

*Compound Blow-Pipes for Enlarging Blasting Cavities.* A. Stickney.

*Claim.*—The instrument for enlarging the drill-hole by the employment of gas; and the combination of the two jet-chambers, the perforations or orifices, and supply-tubes, and for commingling the gases and disseminating the flame therefrom entirely round and against the sides of the drill-hole, whereby the enlargement of it into a suitable charge-chamber may be speedily effected. No claim is laid to the use of a blast of air or gas in connection with coal or fuel, and for the purpose of supplying such with oxygen.

*Steam Generators.* A. Shawk.

A tubular generator which has a forced circulation, and which, while it lines the fire-box and is expanded in its diameter from above the fire-box to its termination, is connected to a steam-chamber or receiver outside of or exterior to it.

*Method of Veneering.* C. B. Burnap.

*Claim.*—The method of pressing veneers on to the surface to which they are to be glued or cemented, by means of a fluid hot or cold acting on an interposed flexible substance, such as an india-rubber cloth or its equivalent, which will adapt itself to the surfaces.

*Making Chains.* C. Sleppy.

*Claim.*—The forging and making chains out of a solid bar without the welding process, and which is done instantly as the bar passes between four rollers, with dies on the edges of the same, moulding the links into form, and which may be done out of iron, brass, or any substance suitable to be used as a chain, from the size of a cable to a watch-guard.

---

*Annealing Hollow Ironware.* D. Stuart.

Iron hollow ware is covered inside with a paste made of a composition to exclude the air, and which resists the influence of the heat; when the hollow ware is properly prepared in this manner, it is placed in the oven, and heated to a cherry-red, whereby the chill is taken out of the surface, and rendered so soft that it can be turned bright in a turning-lathe, or otherwise, preparatory to tinning.

---

*Railroad Switches.* J. M. Dick.

*Claim.*—The construction of the sliding-bar, to which the ends of the switch rails are attached, with the depending flanges or side plates, which inclose the slide and cross-piece upon which it works, and afford a certain and effective protection against gravel, dirt, snow, sleet, ice, and other foreign substances, which might otherwise enter between them and derange the operation of the switch.

---

*Ships' Blocks.* C. H. Platt.

*Claim.*—The employment or use of the rods passing through the cheeks, in a direction transversely of their fibre, for the purpose of preventing the splitting of the cheeks; the said rods also securing the plates to the cheeks, and forming a staple for the hook. Also the rods placed underneath the ends of the shaft, for the purpose of preventing the wearing of the cheeks, and thereby forming durable bearings for the shaft.

---

*Hillside Ploughs.* N. Harrison and J. W. H. Metcalfe.

*Claim.*—Curving downward and inward the beam in the rear part, so as to cause it to support the rotary part of the plough, which it performs in combination with the standard.

The entire plough is of wrought-iron, except the mould-board, which is cast.

---

*Treating Metals while in the Molten State.* H. W. Woodruff.

*Claim.*—Treating metals while in the molten state, to expel impurities therefrom, by immersing therein some porous or cellular non-conducting substance or substances containing liquid matter.

---

*Clamp for Laying Floors.* S. E. Parrish.

*Claim.*—The use of the brace having clawed or forked ends, for acting at opposite sides of a beam, in combination with a screw working at right angles to the same.

A brace is made, having a clawed or forked end, with shoulder-pieces attached to the under side thereof, so as to straddle one of the flooring-beams, in combination with a screw working at right angles to the brace, and having on it a ratchet-wheel and lever and pauls for working up the screw against the edge of the plank.

---

*Wheels.* Z. H. Mann.

*Claim.*—The construction of a cast-iron railroad car and locomotive wheel, whose web or portion connecting the hub and rim consists at the hub of broad radiating plates in the plane of the axis; whence turning alternately to the right and to the left, they contract in the direction parallel with the axis, and expand proportionally in the direction of revolution; those of each alternate set uniting as they approach their respective margins of the rim concave, so as to form flanges, having openings left for each intermediate plate on the other side, forming a braced and counter-braced wheel, possessing the requisite lateral stability and continued support at the rim, together with adequate provision for the strain arising from shrinkage, &c. This is claimed whether the said web be formed in a cyma reversa curve, or in any way substantially equivalent.

---

*Throttle-Valve Arrangement.* J. E. Anderson.

*Claim.*—The combination, to serve the purpose of a throttle-valve or regulator, of two hollow cylindrical valves, connected with a lever on opposite sides of its fulcrum, and having slotted openings corresponding with similar openings in the cylindrical valve-seats.

The simplest way of constructing the valve-seat is to cast the cylinders with a short length of pipe, which will constitute a valve-box. The only fitting-up required will then be the boring of the cylinders, and the turning of the valve to fit them. The slots may be so narrow that they would close and open to their full width with the smallest desired amount of motion. On account of the small amount of motion that is necessary, the wear of the valves will be very slight. If slots are made on opposite sides of the valves and cylinders, they will be perfectly balanced in all directions, one balancing the other, and the steam acting equally on all sides of each; thus the friction on every part of the wearing surface will be the same, and the movement being the same, the wear will be equal.

---

*Files and Rasps.* H. Powers.

*Claim.*—The forming of perforations or throats to the cutting edges of files or rasps for allowing the particles cut away to pass through, and to prevent the instrument from clogging or choking.

The invention consists in forming perforations or throats to the fin, feather, or cutting surfaces of rasps or files, for the purpose of allowing the said rasps or files to clear themselves of the material cut away by them, and to prevent their filling or choking, by admitting or allowing the particles to pass through said perforations or throats.

---

*Propellers.* C. T. P. Ware.

*Claim.*—A propeller having one or more blades, the front and rear edges of which are of unequal stiffness; the blade or blades thus constructed being arranged upon an oscillatory shaft.

The blades are constructed of india-rubber, in any of its various forms of preparation, or of any other elastic or pliant material, in combination with elastic ribs or with inflexible parts.

---

*Camphine Lamps.* J. Newell.

*Claims.*—1. The silvering of the perforated metal, or brass, copper, or iron wire gauze used in safety lamps and cans or other vessels, designed to prevent explosions from the vapour of camphine, burning fluid, &c., the silvering being applied for the purpose of preventing the corrosion of the metal or wire gauze by the most economical process; 2. The introduction of perforations in the caps of lamps used for burning camphine, burning fluid, &c., so small as not to admit the communication of flame through them for the purpose of allowing the escape of the vapour formed within the lamp, from camphine, burning fluids, &c., and thereby preventing the bursting of the lamps by the pressure of the vapour. Does not claim the use of any perforations in lamps for burning camphine, burning fluid, &c., except such as are constructed so as to prevent the passage of flame on the principle of Sir Humphrey Davy, relative to the passage of flame through perforated metal.

---

*Ploughs.* C. R. Brinckerhoof.

*Claims.*—1. Combining with the plough-beam, between the plough and the clevis, two wheels, one on each side of the beam, and of different diameters, the one resting on the furrow and the other on the land; 2. Making the tread of the furrow-wheel narrow; 3. Making the said wheels, especially the furrow-wheel, adjustable in the direction of its axis, for the purpose of adapting its position to furrows of different widths; 4. Making the furrow-wheel beviling outward on the side which presses against the land; 5. Making the small wheel adjustable vertically with reference to the shaft and the large wheel.

The invention consists in attaching to any common plough two wheels of different sizes and shapes, the small one to run upon the land, and the large one to run in the bottom of the furrow with its side against the land, by a moveable iron axle passing through holes in the bottom part of two common cast-iron lifters or supporters, which are attached to the beam, one on each side, which have the effect of holding the plough perfectly steady, and regulating both the depth and width of the furrow-slice.

---

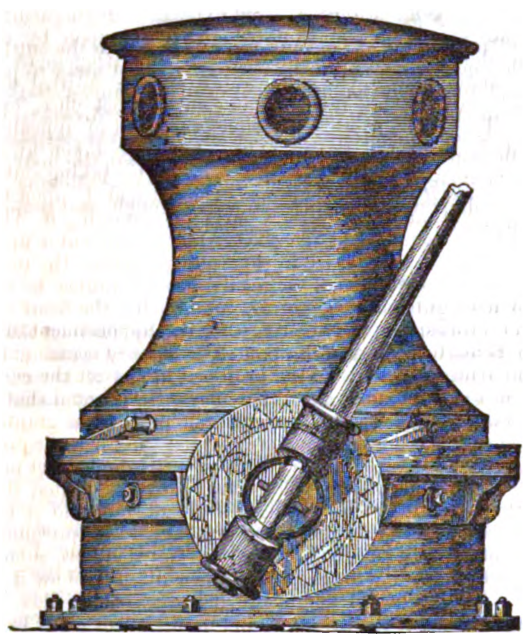
*Air-Engines.* J. A. Woodbury.

*Claim.*—Supplying the air-pump from a receiver into which air has been condensed by a hand-pump, auxiliary engine, or otherwise (the hand-pump or auxiliary engine being used for the purpose of charging and sustaining a uniform pressure in the receiver from which the air-pump is supplied), when the same is done in combination with a second receiver, into which the air is to be still more compressed and maintained at a uniform pressure, or nearly so, by the application of heat to the air on its passage to the working cylinder.

*Ash-Pans for Locomotive Engines.* G. Davis.

*Claim.*—The taking in of air in front of the ash-pan, and introducing it into the fire-box in a direction opposite to the furnace-doors, to protect the fireman from the back-lash of the fire when the said doors are open.

## PERLEY'S PATENT CAPSTAN.*



The improved capstan, of which the above cut represents a general view, has been for some time in very extensive use in the United States of America, but has only recently been introduced into this country. The action is extremely simple, and is rendered sufficiently clear by the above cut, without a detailed description of its construction. The various parts are so arranged as to cause a small amount of friction, not to present any difficulties whatever in practice, and to prevent any injury which might arise from water gathering to the working parts.

The inconveniences of the old form of capstans are too well known to require enumeration. Perley's patent capstan, instead of requiring a large space for the men to "walk" round it, may be placed in any convenient corner. It takes little more room than a ship's-pump. It is, in fact, a powerful and very convenient vertical windlass, worked by pump-handle levers, a more effective mode, as any mechanic knows, than the horizontal working of the common capstan. The capstan may be worked in either direction, by merely reversing the ratchets, and, if required, by the old mode of horizontal levers. It is said, that during the last three years, 475 of these capstans, being about one for every two days, have been sold in the United States, and almost all the vessels sailing from New York to London have one or more of them on board. Certificates signed by the United States navy constructor at Brooklyn, by several eminent ship-builders of New York, Boston, and Portsmouth (U.S.), and by the captains of several well-known vessels, speak in high terms of this capstan, as enabling the men to exert their power to better advantage than any other with which they are acquainted.

* From the 'Journal of the Society of Arts.'

## REVIEWS.

*Report of Commissioner of American Patents for the Year* 1852. Part I., *Arts and Manufactures.* Washington. 1853.

*Financial Transactions.*—The total amounts of receipts and expenditures of the American Patent Office, independent of the moneys refunded on withdrawals and those paid by mistake, were, for the years 1851 and 1852, as follows:—

| | | | |
|---|---|---|---|
| Receipts in 1851 ...... | $81,160 72 | Receipts in 1852 ...... | $90,671 35 |
| Expenditures............ | 72,339 04 | Expenditures ......... | 74,531 92 |
| Surplus ......... | $8,821 68 | Surplus......... | $16,139 43 |

The moneys refunded on withdrawals, which amounted to $21,159 99, were never really available to the office, as also $225 00 moneys paid in by mistake, nor is the payment of them any part of its proper expenditures. During 1852, there was paid—as salaries to officials, $36,674 23; for temporary clerks, $18,992 93; for books for the library, $597 63; for contingent expenses, $13,037 98; and for agricultural statistics and purchase of seeds, $4,831 33.

*Office Labours.* — The extent of the business transacted in examining applications, granting patents, and the like, may be gathered to some extent from the following:—

*Statement of Applications Received and under Consideration during the Year* 1852.

| | | |
|---|---|---|
| Cases on the Examiners' desks, Jan. 1, 1852...... | 155 | |
| Applications received during the year ............ | 2639 | |
| | | 2794 |
| Patents issued during the year ..................... | 1020 | |
| Applications on hand, not acted upon ............ | 481 | |
| Rejections and suspensions .......................... | 1293 | |
| | | 2794 |

Included among these were—patents re-issued, 18; additional improvements, 4; extensions, 3; designs, 107. There have also been filed 996 caveats, and 2 disclaimers. 525 patents expired during the year.

These statements fall far short of exhibiting the amount of labour performed in this department. Each application for a patent is submitted to at least two thorough examinations as to its novelty and utility; most of them receive more, and not a few as many as six. Caveats, which have increased from 760 in 1851, to 996 in 1852, are also examined, no patent being issued until the caveats are thoroughly searched, lest it should conflict with some of them.

The Report urges upon the legislature the necessity of rendering the office of examiner more desirable and permanent; the most eminent skill and science being requisite for this position, and the consequences of frequent changes from dismissals and resignations being most disastrous. The natural result of the great increase in the number of applications and models deposited has been the present insufficiency of accommodation already afforded by the Patent Office building. The eastern wing therefore of the noble structure now erecting is to be appropriated to this department. Some progress has also been made upon the basement of the western wing. The basement of the principal building has been greatly improved by dressing the rough stone of which it was built, so as to make it conform in its general appearance to similar portions of the newly-erected building. In the year 1836, the date of the organisation of the Patent Office, one "examining clerk" was enabled to make all the preliminary investigations required to ascertain whether the applicant was entitled to a patent; but such has been the increase of the business, that six principal examiners and as many assistants are not now able to keep pace with it. The number of models in the office on the 1st January 1836 was 1069; in the beginning of 1851 they had increased to 17,257, and at the close of last year they numbered nearly 23,000. At this rate of increase they would amount at the end of the present century to 150,000, and the whole of the present Patent Office edifice would prove insufficient for their convenient display. To meet this contingency, it is proposed by the Secretary of the Interior to have prepared for publication by the Commissioner of Patents a careful analytical and descriptive index of all patented discoveries and inventions, accompanied by accurate descriptions and drawings, fully explanatory of the principles and practical operation of the subject of the patent. This publication would not only perpetuate the invention or discovery, by avoiding the casualties by fire and other causes, but would be a much safer and more accessible depository for them than the cabinet of the Patent Office, and in a large number of cases obviate the necessity for preserving and displaying the models. This index, if prepared by persons fully competent to the task, would almost entirely prevent the enormous useless expenditure of the time, money, and labour of applicants seeking protection for ideas already anticipated. The expense of such index could readily be paid out of the Patent Fund, which on the 1st January 1853 amounted to $40,292 38. The Commissioner of Patents remonstrates against any portion of the Patent Building being devoted to any other service, alleging as reasons against the occupation of some of the rooms by the Secretary of the Interior, the crowded and confused state of all the Patent Offices, and the delay which arises from their being restricted to such narrow limits. The relation of the Patent Office to the Department of the Interior being one of entire dependence, is attended by serious evils: the results of the scientific and laborious investigations of the corps of twelve examiners and assistants, are subjected to the consideration of the Commissioner of Patents, who, by reason of his numerous other responsibilities, and the multiplicity of patent cases, must necessarily rely, in the great majority of cases, on the fidelity and judgment of the examiners. He therefore cannot feel safe unless he can repose implicit confidence in them, and possesses the exclusive privilege of selecting them. Yet the approval now required from the Secretary of the Interior may be so exercised as to deprive him of an independent choice in this matter. Another mischievous result of the intimate relation of the two offices is, to subject them to the same political fluctuations, whilst every consideration of sound policy requires that the post of Commissioner of Patents should be a permanent one.

The Report of the Commissioner contains several valuable suggestions relative to the re-organisation of the Patent Office and the Amendment of the Patent Laws of America, which if carried into execution would considerably diminish the labour of the patent officials, simplify the routine of application, lessen the cost of protection, and effectually diminish the practice of patent infringements.

The present organisation of the Patent Office is to a great extent the mere result of expedients resorted to from time to time, as the pressure of business required, the result of which is a very ill-digested system of arrangement. Many of the officials, to whom are confided important trusts, pecuniary as well as others, are recognised only through an incidental mention of them in some statute; their duties being nowhere defined. There are also, others, who are charged with responsible services, and designated by courtesy accordingly, but who are known in law only as temporary clerks, whose compensation is discretionary, and liable to the injustice of caprice. No written code even regulates their employments, and their distribution in the offices betrays great want of method.

The department of the machinist especially requires remodelling and enlarging, and an authorised addition by law to the force under his charge, sufficient for the efficient removal, re-arrangement, and repair of the much-damaged models already deposited, the disposition of new ones, and their exhibition to visitors and inquirers.

The need of a new registry law is distinctly commented upon. It is proposed to embrace under one statute, the two analogous classes of articles, as those protected under the law of copyright and those patented as designs. Upon registering an engraving upon paper, or in any publication, with the Clerk of a District Court, at a fee of fifty cents, and depositing a copy with the Secretary of State, it is secured against infringement for twenty-eight years. If the same design is printed on silk, or upon paper-hangings, or a fire-screen, a formal application for a patent must be made, costing $15, besides the expenses attendant on procuring papers, drawings, and models; and, after all, the exclusive privilege in them exists but seven years. These incongruities indicate great want of systematic and impartial legislation, and are to some extent equally observable in the English laws of registrations and copyrights.

The American law now requires that a patent be extended, if at all, before its expiration, previous to which time, whatever controversy arises in such a case must be considered and determined. In deciding the question of extension, the Commissioner must ascertain whether the applicant has already been sufficiently remunerated, and also examine a sworn statement of his receipts and disbursements, which must be made not long before the patent expires, as it might be materially varied by intervening transactions. The usual period for presenting this statement, is not more than three or four months previous to the termination of the patent right, thus inconveniently restricting the time allowed to the Commissioner for his decision. It is proposed to obviate this, by requiring the preliminary proceedings to be closed before the time now fixed for the decision, and allowing the Commissioner such further time as he needs for forming his opinion.

Various emendations of the American Patent Law, intended to afford better security to inventors in their rights, have been brought forward from various sources, by associations interested in the subject, or individuals; others, again, have been proposed by the Patent Office itself. One of these emendations provides that when a patent has been denied by the Commissioner, the applicant, if he still insists upon it, may have one upon his own responsibility. A Patent thus issued would not, like those approved of the Commissioner, be entitled to any presumptions in its favour, nor be regarded as *primâ facie* evidence of the patentee's exclusive title; effectual precautions being taken to prevent the letters patent obtained under this Act being made use of as an official recognition of the claim, and the machinery and manufactures so patented would bear a distinguishing stamp, to preserve any person from being imposed upon by the articles, as though they were protected from infringement as under the existing law. The applicant would be entitled to a mere right to register his invention in some distinct office, or a copyright. To carry out this principle, the right of appealing from the decision of the Patent Office should be taken away. The party aggrieved might have his remedy by taking out a patent or registering his invention as thus provided, upon his own responsibility, and look to the Courts for sustaining it. This arrangement, in fact, would place the American inventor upon the same footing as the patentee in this country, where the mere grant from the Crown is not in itself any guarantee to the inventor of his right to a monopoly.

A second proposition has reference to the appointment of a permanent Board to sit upon Patent Cases, in place of occasionally resorting to arbitrators. It is also proposed to restrict the right of defence in a suit for infringing a patent on the ground that it was not novel, to those who knew before the patent was granted of the invention having been in use; whilst those who acquire such knowledge afterwards, are required to institute distinct proceedings to vacate the patent. This would prove an unjust distinction: the individual who infringes a patent, but who is not cognisant of its invalidity, is, under the present system, presumed to be aware of the existence of the patent, and therefore should be presumed to know its invalidity, and permitted to show it in his defence. The facility of manufacturing proof of like discoveries previous to that of the inventor, and dating them so far back as to render it difficult if not impossible to detect the fraud, would virtually defeat any such restriction as the above. It is further proposed to declare forfeit the machinery employed and the articles manufactured in violation of a patent, and to require of the defendant securities for the payment, in all cases where extra damages and costs might be recovered, before he is permitted to make a defence. A third proposition from the same quarter provided that after one trial establishing the validity of a patent, the patentee might recover treble damages and treble costs, if it is ever contested again; quadruple on a third trial; quintuple on every subsequent trial, with "liberal counsel's fees" in every instance; and it would not be necessary that the defendant should have been a party to the previous suits in order to make him liable to the severe operation of this statute. These several measures would very inefficiently remedy the evils of the present Patent Law, and would prove rather an oppression upon inventors than a protection. The wary and designing speculator would cautiously remove all machinery, &c. forfeited under these statutes, whilst the sequestration would fall with severity upon those comparatively thoughtless and innocent, and who have never taken such precautions. Although it is true that in many cases, irresponsible persons have been put forward to do the ostensible work of infringing, and that for them a judgment has no terror, yet it is equally possible that innocent persons may be sued, and under the proposed statute the plaintiff might entirely debar him from showing his innocence, or even demanding the proof of his guilt. Again, a party infringing a patent may have done so unconscious of any previous trial of the patent infringed, and believing himself to have a *bonâ fide* defence on the ground of having anticipated the plaintiff in his discovery. This would avail him nothing, and should he be unable to provide securities for the payment of the triple or quintuple damages and costs, he would be precluded from pleading, and judgment recorded against him without the privilege of defending himself. Again, these measures would offer temptation to speculators to obtain judgments upon patents by collusion, for the sake of exacting these multiplied damages and costs. Although the statute as proposed provides that the previous judgment must be in good faith, yet the impeachment of a fraudulent judgment is at all times a costly and hazardous undertaking, and when attempted at the risk of such aggravated recoveries, the odds are too great to be risked by any man of prudence who can avoid it. Notwithstanding that the plaintiff, under these statutes, would be liable to treble costs upon a third verdict against his patent, quadruple upon a fourth, and quintuple on all subsequent ones, (not treble upon a second trial, and so on as when he succeeds), and the further provision, that where judgments have been recovered both ways, they shall be adjusted and balanced against each other,—yet it is obvious that the facility with which the plaintiff can obtain amicable verdicts, and the difficulty of exposing them, would make these propositions worse than useless.

Few men could be found who would not make large sacrifices to speculating patentees rather than expose themselves to five-fold damages and costs, with liberal counsel fees, besides being compelled to find security to the amount before being allowed to so much as contest their guilt. Severe and aggravated as are the wrongs and depredations endured by inventors, they do not warrant measures for protection so liable to be abused, and operating with indiscriminate hardship upon the innocent as well as the guilty. The success of those persons who infringe upon patent rights with so much recklessness and impunity, are mainly attributable to the fact, that every valuable invention becomes an object of importance to a large circle, sometimes embracing the entire community, who are therefore strongly tempted to resist a patent for it, and are at once tacitly leagued against it; and also the facility of ante-dating fraudulent evasions of existing patents. Until these are counteracted, there is little hope from legislation, however stringent. The Commissioner suggests that this object may be effected by providing for a final and conclusive determination upon the validity of the patent, at a date so early that people would not have generally become aware of its value, or interested in opposing it and concocting schemes against it; and also while any alleged previous use may be readily inquired into, and its true claims thoroughly scrutinised,—public notice being extensively given of the nature and object of every invention, and all competitors required to show cause against its validity by a specified day. Should any party file an objection or opposition, an investigation to be made into the claims of the invention, and the adverse parties heard: and if the patent survives this ordeal, its validity can never afterwards be contested. It is difficult to understand at what early date this decision upon any invention could be arrived at, other than the period of its first discovery, at which time the statute proposed provides for its promulgation amongst the public, whose ignorance it appears to wish to take advantage of. It is not always on the issue of a patent that its validity is required to be questioned, and it might easily happen that an application for an invention not new, might be allowed, by reason of its value not being then perceived, or of nobody being sufficiently interested in it to oppose its grant.

The Commissioner further proposes to make the wilful infringement of a patent a crime, and punishable as such. But in criminal prosecutions, there is a strong presumption in favour of the respondent's innocence, and the danger is slight of his being convicted unless truly guilty. He is secure where the defendant in a patent suit would be exposed to serious peril; neither would it be safe to use a threat of such proceedings as a weapon of extortion: on the other hand, it would deter many a man from the offence. Hundreds, who have made up their minds to risk a pecuniary loss, would hesitate to subject themselves to the imputation of a crime; and were the stigma of infringing the laws attached to the secret trespasser of his neighbour's patent, the offence might possibly become as rare as others which are committed—not from want, but the mere love of money. Some such arrangement as this carried out in this country would immensely benefit the position of a patentee; but at the same time, it would be necessary to submit the applications for protection to some kind of examination as to their novelty and utility.

The Report enlarges upon the intrinsic importance of the Arts, their bearing upon the prosperity of a country, and the claims of inventive interests upon the attention of Congress to secure a judicious, thorough, and impartial system of patent legislature It also includes both a classified and alphabetical index of patents expired and patents issued during 1852, and the reports of the several examiners, describing some of the most important of the inventions that have passed their respective desks, which reports will become unnecessary should the bill now before the Senate, authorising the publication of an intelligible account of patented inventions, pass. Under the supervision of Examiner Henry B. Renwick, there were granted in 1852, under the diversified class of metallurgy, 115 patents; under the class steam and gas engines, 27; together with many for navigation, civil engineering, &c., making a total of 165 patents granted; 328 were rejected. Examiner L. D. Gale passed 167 patents, and rejected 256; 48 of the patents granted related to chemical improvements. J. H. Lane examined 419 patents, 137 of which applied to household furniture; 81 to mathematical and philosophical instruments; and 68 to leather, &c. The number of examinations by Henry Baldwin was 796, of which 223 were patented and 249 rejected. Examiner F. Southgate Smith patented 134 applications, and rejected, either formally or finally, 293. 141 patents were ordered to issue, and 268 rejections made by Examiner G. C. Schaeffer. The proposal to substitute a succinct and clear digest of every patent in place of the present reports of the examiners, similar to that published by the French Patent Office, would prove a very beneficial guide to the trodden paths of invention in America.—We shall give a further notice next month on the Examiners' Reports.

*Manual of Astronomy: A Popular Treatise on Descriptive, Physical, and Practical Astronomy; with a Familiar Explanation of Astronomical Instruments, and the Best Methods of Using Them.* By JOHN DREW, F.R.A.S., Ph. D. Second Edition.

Our readers will call to mind that Dr. Drew has more than once sent scientific contributions to our pages. We are happy to be able to recommend his treatise on astronomy as a truly scientific work. Though evidently acquainted with the higher branches, he is quite successful in explaining the elementary principles in the clearest manner. The modern discoveries in this science have been numerous and striking: the increase in the number of the asteroids, now amounting to twenty-seven,—the peculiar circumstances attendant on the calculation of the place of the unknown planet, Neptune—and the last particulars respecting Saturn's rings, are all discussed in this volume. In practical astronomy, however, the author shows an originality of treatment, and sound knowledge of his subject, which we have never noticed in any previous work of the kind. Those who wish to view the stars, to use the transit and equatorial, or to found an observatory, will here find clear and practical directions. That class of educated persons who are anxious to keep up with the spirit of the age by obtaining a comprehensive knowledge of the present state of astronomy, without deducting too much time from professional engagements, will here find all they want. For the faithfulness of the representations of the telescopic appearance of the moon, Saturn, the nebulæ, and the double stars, we can confidently vouch; besides these cuts, there are drawings of various instruments, and of the author's observatory. For sea-going persons and intelligent youth the 'Manual' will be invaluable; and we are happy to see that a truly scientific work, by a man of sound knowledge, has been published, at a price which will bring it within the reach of thousands of readers.

Many parts have struck us as being particularly lucid—the tides, the calculation and construction of a lunar eclipse, the account of comets, and of Foucault's pendulum experiment may be specified. In short, the work may be looked upon as a perfect epitome of the science, and as such we strongly recommend it to our readers. The style and printing render it a suitable and elegant present for the young, who cannot fail to derive from its pages both instruction and amusement.

*Outward Bound: being Practical Advice to Emigrants to the Australian Colonies.* By HENRY J. WEBBER, Assayist. London: Darton and Co. 1854.

It is contrary to our custom to notice works of this description, but emigration is such an important and all-absorbing topic, and this unpretending pamphlet so practical and of such great utility to all classes who contemplate adopting this step, that we willingly forsake our usual path to afford it what publicity we can.

Many pamphlets and works have been written on Australia, but not one affords that information and advice which the emigrant stands in most need of, and which 'Outward Bound' so successfully supplies. It is consequently a great boon to the emigrant; it affords him every possible information he can require, from the time he has made up his mind to leave his native land till he settles down in the colony: it is, in fact, the emigrant's *vade mecum*. As the author has but very lately returned from the colony, and has learnt, what he endeavours to teach others, in that dear school, "Experience," he is fully qualified to serve as their guide. He not only gives every requisite information and advice with respect to the voyage, but enters into the various incidents connected therewith; draws a faithful picture of the country, its inhabitants and customs; states who ought to emigrate and who ought not; affords much valuable advice to intending diggers and storekeepers; and shows the various methods of distinguishing gold from other metals. And moreover, the price being so low, it is within the reach of all. We extract that which we think will interest our readers; and, in conclusion, express our candid opinion that no emigrant should leave England without it. With respect to Sydney—

"The streets are spacious, well laid out (with the exception of the pavement which is an absolute disgrace to the city), and lighted with gas; while the houses and shops are as substantial and elegant as the generality in London. Most of the houses and buildings are built of sandstone, which gives them an air of substantiality and elegance. There is a peculiarity about Sydney and Melbourne (the latter more especially) with regard to the buildings: for instance, there will be a handsome stone edifice—perhaps one of the banks—which would be an ornament to London, and next to it a little wooden house or dilapidated shed; then a row of fine shops or houses, and perchance a garden or two struggling for existence; and then more wooden houses or sheds. But this appearance is rapidly declining before the giant strides of commerce. Very few of the houses are built in consonance with the climate. The majority of the superior ones are fitted up with cedar, which gives them a handsome appearance. Most articles of furniture are made of this wood; which is an excellent and cheap substitute for mahogany. The warehouses are numerous and commodious. With the exception of the banks, Government house, and an elegant protestant cathedral, in the course of erection (the first stone of which was laid, I believe, fourteen years ago,—so much for the energy of the people!), there are very few buildings worthy of note."

## FORMULA FOR SETTING OUT EGG-SHAPED SEWERS.

Sir—Two things appear to me as proven by the discussion of questions relative to the drainage and sewerage of towns—viz., that all the main sewers should be brick, and that their cross section should be "egg-shaped," the arch and invert being connected by a circle tangent to both. It may be useful to some of your readers, to know how the radius of this circle can be found.

If the circle which forms the invert touches the circle forming the arch, then if $a =$ rad. of the arch, and $b =$ rad. of the invert, $\dfrac{a^2 + ab}{a - b} =$ rad. of the circle tangential to both.

If the circles forming the arch and invert either do not touch or intersect, then putting $c =$ the distance of the centres apart, $\dfrac{a^2 + c^2 - b^2}{2a - 2b} =$ rad. of the tangential circle.

*Claremont-place, Belfast,*
*February* 11, 1854.

William T. Matier, C.E.

## INSTITUTION OF CIVIL ENGINEERS.

*Jan.* 31.—James Simpson, C.E., President, in the Chair.

On reading the Minutes of Discussion of the meeting of January 24th, attention was directed to the statement of the experiments recently made at Alnwick, on the quantity of water discharged through a "pot-pipe," of 18 inches diameter (*ante* p. 77); for while, on the one hand, the results of the experiment sufficiently confirmed the accuracy of the formulæ of Du Buat, Eytelwein, Smeaton, Prony, Hawksley, and other investigators, and as decidedly contradicted the results published in the "Blue Books" emanating from the Board of Health, these results, nevertheless, differed too considerably from other consistent conclusions to be fully relied upon, and it was therefore desirable that this experiment should not be taken as a datum upon which to found any hydraulic law for the determination of the quantity of water which might be transmitted through tubes. For this purpose, indeed, the cited experiment must be deemed unsatisfactory; because pot-pipes were never of uniform or exact diameter,—inclinations were always more or less vaguely stated, joints were seldom sound, and when the discharge was into free space, the differential level was rarely satisfactorily afforded. Moreover this experiment itself was in some respects contradicted by very carefully conducted experiments, made by Monsieur Couplet, at Versailles, on a pipe 18 inches in diameter, the results of which were extremely consistent with the mathematical determinations successfully resorted to by all practical hydraulic engineers. The experiment by Monsieur Couplet was made on a pipe of 43,200 inches long and 18 inches diameter, the motive head was 145 inches (all French measures), the calculated velocity was 40½ inches, while the observed velocity was 39½ inches, differing from the velocity calculated from established formulæ only about 3 per cent. It was also contended to be extremely undesirable that centralised authorities should continue to exist, as it was uniformly found that these authorities did great mischief by the wide dissemination of errors, apparently under Government influence, and by the consequent repression of scientific and practical improvements.

The Paper read was "*On Macadamised Roads, for the Streets of Towns*," by J. Pigott Smith, Assoc. Inst. C.E.

The lengthened experience of the author, as surveyor to the corporation of Birmingham, having under his charge about 150 miles of street road and 50 miles of turnpike road, enabled him to express confident opinions on the comparative cost, durability, and general qualities of paving and of broken stone, for roads and even for streets, subject to a considerable amount of heavy traffic. The parties chiefly interested in having good roads were shown to be the owners of carriages and horses, and the ratepayers, at whose expense the roads were originally constructed and subsequently maintained. For both these classes, "cheap roads" (*i.e.*, those of small first-cost) were contended, generally, to be the dearest; horse-power being uselessly expended, carriages destroyed, and constant repairs to the surface of the road being necessitated. Any undue increase of tractive power was shown to fall indirectly on all who purchased any commodities conveyed through the streets, and the annoyances and hindrances to commerce arising from ill-paved or ill-kept, muddy, dirty, and noisy streets, were patent to all. The necessity was thence deduced for having the roads and streets so constructed, that the surface should be firm, even, and smooth without being slippery, and be free from mud, dust, or loose stones. To attain this, the foundation should be of firm material, well consolidated, and perfectly drained; then covered with stones broken to uniform dimensions, well raked in and fixed by a binding composition of grit, collected during wet weather by Whitworth's sweeping machine and preserved for the purpose. This binding being regularly laid on, and watered, if in dry weather, would, in great thoroughfares, consolidate the new metal in a few hours, preserving the sharp angles of the stones, which assumed all the regularity of a well-laid pavement, with a considerable saving of material and a firmer crust than by the ordinary method of allowing the vehicle to pass for many days over the uncovered surface of the new stones, grinding off the angles, with a deafening noise, and forming dust or mud, to be carried on to the footpaths and into the houses and shops.

Instances were given of the advantages of this system, of using the grit for binding, which should however be that collected by the sweeping machines, and not mere slimy mud. A street in Birmingham, subject to great traffic, had been thus perfectly made and consolidated in five days, whereas, under the ordinary system, three months would have been required to produce the same effect. The repairs were capable of being effected at any period of the year; under no circumstances were the street surfaces permitted to be worn down, and they were never stopped, as was the case for lifting and repaving.

Rules were then given for keeping the surface in perfect travelling order, for picking off all loose materials, for sweeping and never scraping, for preserving the profile of the surface and getting rid of all lodged water, for light watering in dusty weather, and heavy watering when there was adhesive mud that could not be otherwise removed by the long brushes of Whitworth's sweeping-machines, which were contended to be indispensable for keeping roads and streets in good repair, and for preventing the nuisances of mud and dust.

The system employed in London, of heavy watering without removing the mud; or of scraping and of hand-sweeping and lifting by shovels into carts, was shown to be bad and expensive. The loss of speed, and the extra power required to be exerted by horses drawing carriages over street surfaces in the state of those in London, were shown to be as much as 25 per cent. as compared with the work done in Birmingham. The employment of a better system, combined with the use of the sweeping-machines, had been productive at Birmingham of an economy of nearly one-third of the materials employed for the construction and repairs of the streets and roads.

Instances were given of the actual results of the system of washing and sweeping parts of the Quadrant, Regent-street, where the method had been satisfactorily proved to have produced superior effects; but prejudice had induced obstinate adherence to the old system, to the annoyance of the public and with the derision of all foreigners who visited the metropolis. The actual state of all the leading thoroughfares could vouch for the justice of the criticism on the present metropolitan system.

The greatest amount of wear and tear of macadamised street surface, in Birmingham, was shown to be four inches per annum; the average might be therefore taken at two inches;—the cost of maintenance was fourpence per superficial yard, and that of watering and cleansing was twopence, giving a total of sixpence per yard per annum. Paving cost fifteen shillings per yard, it required to be renewed once in fifteen years, and the cleansing cost about halfpenny per yard. Paving was, therefore, evidently about double as expensive as macadamising, at Birmingham. It was therefore contended, that macadamised roads and street surfaces, if properly constructed and carefully managed, well water-cleansed for mud and watered for dust, brushed or swept by machinery, maintained with an uniform surface, and not permitted to become degraded, were well adapted for towns and cities of average traffic, and for many localities in and around the metropolis.

*Feb.* 7.—In the discussion upon the above Paper, numerous details were given of the comparative prices of the materials in the country and in the metropolis,—the method of laying them down,—the successive employment of set paving stones in large thoroughfares, then in less frequented streets, and ultimately breaking them up for macadamising; thus giving the materials an almost unlimited duration. The use of the grit, as collected by the sweeping machines, was admitted to be advantageous for binding the metalling quickly, and preventing the abrasion of the angles of the stones. It was however shown, that the traffic of country towns was so vastly inferior, in amount and weight, to that of the metropolis, especially since the introduction of the heavy railway and other vans, travelling at considerable speed upon comparatively narrow wheels, that a system of forming streets or roads which would endure well in one case was not applicable for another, and hence the present bad condition of Parliament-street and other streets which had been macadamised, and which it was contended could only be maintained, even in their present state, at a cost greatly exceeding that of the paved streets of the city.

The Paper read was a "*Description of the Navigation and Drainage Works recently executed on the Tidal portion of the River Lea.*" By N. Beardmore, M. Inst. C.E.

The first part contained a general description of the ancient navigation of the River Lea, and of the gradual improvements introduced into the class of barges frequenting it, and the burthens carried by them. Allusion was made to the difficulties and continual delays which had prevailed, up to a very recent period, in the tidal portion, forming the junction with Bow Creek and the Thames at Limehouse; difficulties which were aggravated by the navigation being the common supply for five tidal mills. The new works consisted of stop-gates across the main channel of the Lea, near Old Ford Lock, established for preventing the water from being drawn down by the tidal mills to the eastward; also a lock for a similar purpose and to pass barges on St. Thomas's Creek, near Bow Bridge; and a new overfall, to pass surplus water to the Three Mills.

Three large floodgates, each 18 feet in width, were constructed near Four Millls, with a new tidal lock, adjacent to the spot, in order to pass vessels into Bow Creek; the ancient system being to pass craft by a single pair of gates, only available by drawing down the head water, and frequently during neap tides, the water did not rise high enough to enable the gates to be opened at all.

The remaining new works consisted of a lock at the east end of the Limehouse cut, to retain the water when, in consequence of floods, the Bromley floodgates were required to be opened; the lock being of such a width as to allow vessels of 21 feet beam to enter the cut; the former lock being only capable of admitting barges of 13 ft. 6 in. beam.

In consequence of the treacherous nature of the material at the Bromley end of the Limehouse cut, it was necessary to re-excavate the cut,—to give flatter slopes, and also to build retaining walls of Kentish rag, for the towing path.

The paper concluded by alluding to other considerable works which had been recently executed at the lower end of the navigation, where it formed a junction with the Regent's Canal basin, thus giving access to Armstrong's hydraulic coal lifts and cranes, with the dock conveniences and the wider locks, recently executed by Mr. W. Radford for the Regent's Canal Company.

*Feb.* 14.—The Paper read was "*On the Principles and Construction of Locks.*" By A. C. Hobbs, Assoc. Inst. C.E.

The author's object was to give a brief review of the mechanical principles involved in the construction of locks, and the degree of security hitherto achieved by manufacturers. The paper commenced by asserting as an axiom, that the highest point of security to be attained in the construction of locks must consist in the fact, that the possibility of picking or opening them, without their true keys, should depend entirely on chance; and that notwithstanding the immense variety of locks already invented, there were really but three absolutely distinct principles involved in their construction,—so classed without reference to dates and for convenience of description.

The first principle included all locks having a series of fixed obstructions, or wards, in and about the key-hole, to prevent any instrument except the key being turned in the lock; this principle was shown to be inefficient, however complicated the construction might be, as the wards themselves afforded the means of ascertaining the form of key required to open the lock.

The second principle was that of the letter, or puzzle lock, which appeared to carry out the principle or doctrine of chance, to the fullest possible extent. But in this case, also, a method was shown by which the lock could be opened as easily as in the former; proving, that the inventor of that class of lock had failed to accomplish the object of producing a fastening whose security was dependent only on mere chance.

The third principle, or last class of locks, included all those possessing a series of moveable pieces called slides, pins, tumblers, &c., placed within the case of the lock, and which pieces must be operated upon and moved into certain given positions, by a key, before the bolt could be shot. This principle was illustrated by descriptions of the Egyptian lock, the Bramah lock, the inventions of Barron and of Bird, the Detector of Mitchell and Lawton, and the later improvements of Chubb and of Cotterill (of Birmingham) and others. Allusion was then made to the great reliance which until recently had been placed on these locks, and an explanatinn was given of the principle on which all locks of this description could be as easily picked as their predecessors.

The author then commented on the necessity of devising some simple and effective means by which the defect, common to all the above locks, might be remedied without adding materially to the cost. This desideratum he had endeavoured to secure by the introduction of what was called a moveable stump, which projection, instead of being riveted into the bolt, was fixed to a piece, moving upon a centre or pin at the back of the bolt. The action of that piece was such as to render it impossible to ascertain the true position of the tumblers, for on any pressure being applied to the lock for that purpose, the stump by its motion locked the bolt and left the tumblers at perfect liberty. The author stated his conviction, that this apparently slight alteration rendered it impossible to open such a lock, except by the mere chance or accident of a key fitting it; there being no possible means of ascertaining the form of key requisite to open it surreptitiously. Since the introduction of this lock, several attempts had been made to produce the same result without actually copying the original, but with very little success.

An additional principle of security, devised in America, was then pointed out, in the celebrated permutating bank lock, invented by Robert Newell, of the firm of Day and Newell (New York), of which invention Mr. Hobbs was the proprietor in this country. Previous to the introduction of that system, permutating keys had been used, but they required that the lock itself should be altered, to suit any new adjustment of the bits of the key, whereas, in the American lock, the key alone being altered, produced by its own action the corresponding arrangement in the lock; by this ingenious contrivance, the person using the lock became his own lock-maker, and was able to render the key useless to any other person, by a simple change in the bits after locking the door. Such locks, whose numbers of permutations varied from 720 to 479,001,600, according to the number of bits in the key, were intended principally for strong rooms of banks, and other establishments where large amounts of property were deposited; they were therefore comparatively expensive, and were necessarily of larger size than locks required for ordinary use.

In conclusion, it was remarked that questions would continually arise, as to the violability or inviolability of particular locks and especially of new inventions. The author, however, claimed to have established that any new modification or arrangement of the parts of locks, which did not affect the principle of construction, could have no particular claim to security, or conversely, that if it could be shown that any lock was constructed on a principle not hitherto violated, it might be deemed secure, but certainly not unless such a claim could be made good. In respect to the locks alluded to in the paper, the author justified his statements by the two facts,—that he had not only elucidated the principles on which all such locks might be picked, but that he had actually performed all that had been described. Finally, a hope was expressed, that whatever had been done and said to enlighten the public as to the insecurity of many locks now in use instead of causing any unpleasant personal feelings, would stimulate lock manufacturers to produce what was really required—viz., secure locks, adapted to all purposes, of good workmanship, and at a moderate price.

*Feb.* 21.—The evening was devoted to the Discussion on Mr. A. C. Hobbs' Paper. A succinct description was given of the various recent modifications generally introduced by makers of locks, and it was argued that most of them were simply alterations of form, without materially adding to the security. An exception might perhaps be made in favour of Mr. Denison's lock, which was so constructed that the bolt was shot by turning a handle, without the intervention of a key, which, in fact, was only used for placing the tumblers in a proper position to allow the bolt to be withdrawn or unlocked by the handle,—the keyhole being kept closed during the passage of the bolt; the key might therefore be always retained in the possession of one person, whilst the lock could be closed by any subordinate,—this was important in banks and other similar establishments.

The principle of the bolts being shot by a handle was not new, but the other arrangements were admitted to possess novelty.

Mr. Whishaw's electro-magnetic lock now exhibiting at the Polytechnic Institution was explained, but was admitted not be applicable to all the ordinary uses for locks.

The principle of Mr. Cotterill's "Patent Climax Detector Lock" was then examined, and it was shown to be entirely based upon the Bramah lock, but was less secure in its arrangement, inasmuch as the form of the key admitted of so little variation in the depth of the grooves for moving the slides, that a lock having six slides might be opened by the end pressure of a piece of soft wood, and that any lock on that principle, with any number of slides, could be easily picked by the pressure system.

It was explained, that the American permutating lock, which had been so fully described in the paper, was not intended for ordinary domestic purposes, but for banks and establishments requiring extreme precautions for security, and that the chief object in the introduction of Hobbs' moveable stump or protector lock was to supply a secure lock at a moderate price.

In the course of manufacturing, as might be naturally supposed, the weak points of this lock had not escaped detection, and it was soon discovered, that although the principle was correct as long as the stump remained moveable, if by any means the stump could be held fast, the lock became one of the ordinary tumbler locks, and was as easily picked as the others. For instance, in a till or drawer lock, where the keyhole was parallel to the bolt, it was easy, by the insertion of a piece of watch-spring beneath the lock, to catch and hold the stump, and to open the lock. This however was readily prevented by the insertion of a tongue in the back plate, fitting into a corresponding groove in the back of the bolt, thus cutting off all access to the moveable piece under the bolt; and further, to preclude access to the stump itself, a piece of steel was riveted into the front plate, reaching through the tumblers into a groove in the bolt, thus placing an effectual barrier between the keyhole and the stump. With these slight additions, which were now introduced, it was contended, that locks constructed on the principle of the moveable stump might be considered secure.

It was shown, that Mr. Goater, who was connected with the establishment of Mr. Chubb, had succeeded very ingeniously in picking three of Hobbs' till locks by the means which had been described, those locks however not having the additions for security which had been alluded to. This opening of these locks was admitted to be perfectly legitimate, showing slight defects in the details of construction, but demonstrating the correctness of the principle; and it was argued, that it was only by such means the manufacture of locks could be tested and improved,—indeed, that the lock-makers were greatly indebted to Mr. Hobbs for showing them the weak points of the locks constructed prior to 1851.

The manufacture of locks in this mechanical country had hitherto been conducted in the rudest manner, and with the most primitive tools, and whilst the price of common and insecure locks was incredibly low, that of locks of good construction was much too high to introduce them into general use. It was therefore the object of Mr. Hobbs, by the employment of good machinery, to produce locks of uniformly correct construction on sound principles, and at such a modified scale of prices, as would insure their general adoption; being assured, that whoever might be the maker, the most secure locks at the lowest price would eventually take the lead with the public.

## NOTES OF THE MONTH.

*Proposed Central College of Design, North Staffordshire.*—The design for this building is by Mr. Robinson, of Wolverhampton, and was selected from a number submitted in competition. The style is the Revived Italian. It has an ornamental centre, flanked by two plainer wings. The centre has a rusticated basement, supporting a façade of the Corinthian order, with detached columns and arched windows: the whole is surmounted by a group of figures emblematical of the union of the fine arts. The ground-floor contains an entrance-hall, serving as a statue gallery, and having on one side a large room for a museum of pottery, and on the other a similar one for the purpose of a library. At the extreme end of this hall is the lecture theatre, capable of accommodating from 250 to 300 students, with lecturers' room, &c. adjoining. The remainder of the ground-floor is occupied by the laboratory—a room for the study of technical classes, more especially for those of casting in metal and firing of pottery—and a dwellinghouse and office for attendant. The upper floor is principally occupied by the large studio, which is divided by means of moveable partitions into three compartments, for the painting, drawing, and life classes of the students. When these partitions are removed it will form an additional room for the exhibition of works of art, or for lectures, &c.; adjoining this room are others devoted to ladies' and gentlemen's private classes, head-master's studio, and a room for the study of anatomy.

*New and Repaired Churches.*—The Incorporated Society have made grants of money in aid of the following objects:—Building churches at Wrightington, near Chorley: Crugybyther, near Knighton; Halse Town, in the parish of St. Ives, Cornwall; Pinfold, near Rochdale; Penybontfawr, near Oswestry; the new district of St. James, Plymouth; Aberystwith; Langley Burrell, near Chippenham; and Portsea; rebuilding the parish churches of Llandygwydd, near Newcastle Emlyn; Llanddarog, near Llanelly; and Shrewton, near Devizes; enlarging &c., the churches at Tisbury, near Hindon; Much Dewchurch, near Ross; Wivenhoe, near Colchester; and St. Mary, Princes-road, Lambeth. The committee also increased grants formerly made for re-arranging the seats in the church at Llannor, near Pwllheli; and rebuilding the church at Ringwood, Hants, under the special circumstances represented.

*Congregational Chapels.*—In March last, a society was formed, entitled "the English Congregational Chapel-Building Society," for the purpose of erecting 50 chapels in various parts of England, in five years. Various architects who had had experience in chapel-building were invited to send in designs for model chapels, and out of about eighteen received, the committee have selected five as most in accordance with their views. The designs selected were by the following architects:—One set of Gothic and one set of classic designs, with several elevations adapted to the same plans, by Mr. Andrew Trimen, of London; one set of Gothic designs, by Messrs. Foster and Wood, of Bristol; one set of Italian designs, by Messrs. Bidlake and Lovatt, of Wolverhampton; and one set of Italian designs, by Mr. T. Oliver, jun., of Sunderland. The committee have also commenced the erection of a chapel in Queen's-square, Brighton, of which Messrs. Joseph James and Raffles Brown are the architects. The whole of the chapels are to be erected by voluntary contributions, and there are several donors of 1000*l.* each. The treasurers are Messrs. Joshua Wilson, Arthur Morley, and Rice Hopkins; and the secretary is the Rev. J. C. Gallaway, A.M. A similar society was formed in London, five years ago, and it has aided in providing sixteen chapels in the metropolis. It is now erecting two large chapels, the one at Craven-hill, Bayswater, of which Mr. Trimen is architect; and another at Blackheath. The Lancashire Congregational Chapel-Building Society is engaged to aid in supplying twenty chapels; and there are several liberal contributors to its funds, including Mr. Hadfield, M.P., 5000*l.*; Mr. Kershaw, M.P.; Mr. Barnes, M.P.; and other gentlemen, 1000*l.* each.

*Architecture in Germany.*—The Grand Duke of Weimar has laid the foundation for the chief tower of the Wartburg, which will occupy the same place where anciently stood the central tower which surmounted the whole extent of the old Burg, and separated the two courts.—The Austrian government has ordered the complete restoration of the great antique Temple of Jupiter, at Spalatro. The plans and drawings for this work are by M. Vincenz Andric, architect.

*The Rotherhithe Marshes.*—The Admiralty report on the proposed Wellington Docks, to be constructed at Rotherhithe, on the marsh lands adjoining the Greenwich railway, is of a favourable character. No objection is made to the bill as regards its effect on the navigation of the river, and it is pointed out that, as the site selected is low and unwholesome for houses, the conversion of such a district into docks and quay, besides the facility it would afford to maritime commerce, must prove a salutary measure to the metropolis.

*Comparative Cost of Wooden and Iron Built Ships.* — In a recently-issued circular, by Mr. James Hodgson, consulting engineer, of Liverpool, we find the following comparative annual cost of the working of a wooden and iron ship of 1000 tons each: —"Suppose a wooden ship of 1000 tons to cost 16,500*l.*, or 16*l.* 10*s.* per ton; then suppose an iron ship to cost 13,500*l.*, or 13*l.* 10*s.* per ton, both fitted for the East, we have the following result: *Wood.*—16,500*l.* at 3 per cent. for insurance, 495*l.*; ditto at 5 per cent. for depreciation, 825*l.*; ditto at 5 per cent. for interest, 825*l.*—2145*l.*; deduct 1350*l.*—795*l.* *Iron.*—13,500*l.* at 3 per cent. for insurance, 450*l.*, ditto at 2 per cent. for depreciation, 270*l.*; ditto at 5 per cent. for interest, 675*l.*—1350*l.*; difference in favour of iron, 795*l.* A wooden ship of 1000 tons trading to the East, will not carry more than 1500 tons, which, at 5*l.* per ton for the voyage out and home, will give 7500*l.* while an iron ship of 1000 tons, built from the same external lines, will carry 1800 tons, which, at 5*l.* per ton, will give 9000*l.*; deduct 7500*l.*, and the difference will be 1500*l.*, making a total in favour of an iron ship of 1000 tons of 2295*l.* In the above statement, it will be seen that I have taken the lowest estimated cost for a wooden ship, and also the lowest depreciation of the same; and as regards the iron ship, I have now under my superintendence three large ships for one gentleman, of nearly 1500 tons each (exclusive of others, one of which is 2700 tons, old measurement), which will cost less than 13*l.* per ton, so that the above case is under rather than over rated in favour of iron ships."

*Ericsson's Caloric Engine.*—After so much has been said, and indeed continues to be said, on this and the other side of the Atlantic respecting Captain Ericsson's engine, a few words may not be out of place on a cause which will ever prevent its being commercially useful. Water at the boiling temperature evaporates into steam of about 1700 times the volume of water, and therefore, if one had to pump in water to the boiler against the steam pressure, the loss of power, excluding friction, would be about 1 in 1700. At a temperature of 324½° Fahr., the pressure in the boiler would be about 90 lb. to the square inch, and the volume of steam 325 times that of the water. Therefore, at the available pressure of $90 - 15 = 75$ lb. to the inch, the force lost by the pump to supply water to the boiler would be 1 out of 325, leaving 324 profitable power. Now, at the temperature of 324°, a volume of atmosphere measuring at 32° Fahr. 1000 cubic feet would be expanded to about 1608 feet. The power expended therefore on the feed-pump would be $\frac{1000}{1608}$ part of the power of the engine, supposing it was working against a vacuum; or the useful power generated by the heat is only $\frac{6}{10}$ths, or 60 per cent. of the power employed in working the feed-pump above it, whereas in the steam-engine it is at least 324 times as much, or 32,400 per cent. We have not gone closely into the calculations, but enough has been shown to convince any one of the hopelessness of employing air-engines in place of steam, unless a size of a monstrous character is used.—*Herapath's Journal.*

*Consumption of Smoke.*—The principle adopted by Messrs. James Hume and Co., of the Haymarket Flour Mills, Edinburgh, is that of obtaining more perfect combustion of the smoke, by exposing it to an extensive heated surface, and by the admission behind this heated surface of fresh unconsumed air, which causes its ignition. It is applied to a double-furnace Cornish boiler of an engine of 90-horse power, and the coals used are all Scotch, and consist of one-third dross and two-thirds mixed coal. At the further end of each furnace, the space between the level of the bars and the roof of the flue is divided into eight spaces by seven bricks, each 3 ft. 6 in. long, 4 inches thick at the bottom, and ¾-inch thick at the top; and reaching to the underside of the boiler, so that they vary in depth or height, with the radius of the boiler-flue, from 14 inches in the centre to 6 inches at the sides. From their position at the end of the furnace, these bricks soon attain and preserve a white and and heat, and separate the smoke, which must pass through them to the flue. The fresh air is admitted at the further end of the ash-pit, immediately under the furnace, by an air-valve 15 inches by 5 inches, which is very simply and readily worked by a rod under the bars, terminating with a handle just under the furnace-door. Should the draught admit of it, the air-valve can remain open, or it may be opened only when coaling. The apparatus has been in constant use for the last six months, and continues to give entire satisfaction.

*Sanding Apparatus for Railways.*—Mr. J. Beall, of Effingham-place, Cheshunt, Herts, has patented an apparatus for depositing sifted sand, grit, or other suitable material, on lines of railway, immediately in front of the driving wheels of a locomotive engine, in cases where the rails are slippery, or the steepness of the gradient may render it necesssary to increase the bite of the driving-wheels. The apparatus is so contrived, by means of reservoirs, valves, and tubes, that the deposit of the sand, &c. on the rail can be regulated in any quantity that may be required. When the rails do not require sanding, the closing of a valve prevents the dropping of the sifted sand. Cases often occur in a slippery state of the rails with a heavy train, when it is desirable to increase the bite of the driving wheels, and propel the train forward when behind time or in danger of being run into by a fast train.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated October* 11, 1853.

**2330. C. Rowley, Birmingham—Improvements in ornamental dress-fastenings.**

*Dated October* 25.

**2468. M. Davis, Cloudesley-square, Islington — Improvements in the treatment of fibrous materials other than flax and hemp. (A communication.)**

*Dated November* 8.

2595. G. Shepherd, King William-street—Improvements in the construction of railways.

*Dated November* 14.

**2638. W. Anderson, jun., and A. W. Murphy, Glasgow—Improvements in that class of ornamental fabrics usually termed "Ayrshire sewed work."**

*Dated November* 19.

**2689. A. Castets, Paris—Improved composition for curing diseases in the feet of animals.**

*Dated November* 22.

2707. E. Briggs, Castleton Mills, near Rochdale—Improvements in weaving and manufacturing raised pile fabrics, and in machinery employed therein.

*Dated November* 28.

2778. J. Lord, Farnworth, Lancaster—Improvements in the manufacture of certain articles for ladies' under clothing, and in fabrics for the same.

*Dated December* 5.

2827. E. Lavender, Deptford—Improvements in apparatus for subjecting substances to the action of heat, for the purpose of carbonising, calcining, or combining such substances, or for subjecting such substances to the process of distillation.

*Dated December* 10.

2880. J. H. Johnson, Lincoln's-inn-fields—Improvements in moulding, more particularly applicable to toothed wheels. (A communication from M. de Louvrié, St. Marc, France.

*Dated December* 16.

2933. C. Goodyear, St. John's-wood—Improvements in the treatment and manufacture of india-rubber. (Partly a communicatoin.)

*Dated December* 20.

2964. A. Thomson, Glasgow—Improvements in setting-out and marking the rivet-holes in the plates used in constructing iron ships, boats, boilers, and other vessels.

*Dated December* 27.

2996. E. J. Hughes, Manchester—Improvements in sewing-machines. (A communication.)

*Dated December* 28.

3011. S. Barnes, Oldham, Lancaster—Improvement or improvements in the construction of looms.

*Dated December* 29.

3019. J. W. Crossley, Brighouse, York—Improvements in the production of surface finish to certain descriptions of fabrics composed of worsted, cotton, or silk, or combinations thereof.

*Dated December* 30.

3023. W. Pickstone, Radcliffe, and J. Booth, Pilkington, Lancaster—Improvements in looms for weaving.

*Dated December* 31.

3039. J. Bernard, Regent-street—Improvements in stitching and ornamenting various materials, and in machinery and apparatus connected therewith.

*Dated January* 5, 1854.

27. J. Mason and L. Kabery, Rochdale—Improvements in machinery or apparatus for preparing cotton, wool, and other fibrous materials for spinning.

*Dated January* 7.

37. W. Aspdin, Blackburn, Lancashire—Improvements in looms for weaving.
39. A. B. Baron Von Rathen, Wells-street—Improvements in chimneys and flues of houses, and in stoves to be employed therewith, whereby better draught will be obtained, consumption of fuel will be diminished, smoke, fog, and night-damp will be prevented from entering apartments, more warmth will be thrown out, and whereby fire in the chimney can be readily extinguished.
41. J. H. Johnson, Lincoln's-inn-fields—Improvements in machinery or apparatus for effecting agricultural operations, and in communicating power thereto; parts of the said improvements being applicable to the obtainment of motive power for general purposes. (A communication.)
43. J. G. Taylor, Glasgow—Improvements in writing apparatus.

*Dated January* 9.

45. B. Burleigh, Great Northern Railway, King's-cross—Improvements in railway switches and chairs.
47. R. A. Tilghman, Philadelphia—Improvements in treating fatty and oily matters, chiefly applicable to the manufacture of soap, candles, and glycerine.
49. W. Garforth and J. Garforth, Dukinfield, Chester—Improvements in mechanism or apparatus for retarding or stopping the motion of locomotive engines and other railway carriages.
51. W. Taylor, How-Wood, Renfrew—Improvements in furnaces and fireplaces, and in the prevention of smoke.

*Dated January* 10.

53. W. Brown, Bradford, York—Improvements in preparing to be spun wool and other fibrous material.
55. Rev. W. R. Bowditch, Wakefield—Improvements in economising fuel, and in the more economical production of light and heat.
57. E. Townsend, Boston, U. S.—Improvements in machinery for sewing cloth, leather, or other material. (A communication from W. Butterfield and E. M. Stevens, Boston, U. S.)
59. J. R. Engledue, Southampton, and T. Burningham, Millbrook—Improvements in furnaces.
61. W. L. Tizard, Aldgate—Machinery for stamping, crushing, washing, and amalgamating gold and other ores.

*Dated January* 11.

62. A. A. Masson, Paris—Improvements in the manufacture of thread or wire to be used for making gold or silver lace.
63. J. J. W. Watson, Old Kent-road—Improvements in signalling.
64. H. Bennettsmith, St. Sepulchre's—A machine for mowing or reaping all kinds of corn, grass, clovers, or any other field growth and lawns.
65. D. Semple, 1st Bombay European Regiment of Fusiliers, now at Aden, South Arabia—An improved guide for the finger-boards of musical stringed instruments.
66. W. Watt, Glasgow—Improvements in the application of heat to drying purposes.
67. F. L. Bauwens, Pimlico—Improvements in treating fatty matters previous to their being employed in the manufacture of candles.
68. R. A. Brooman, Fleet-street—Improvements in extracting gold from the ore. (A communication.)
69. R. Lister, Scotswood, Northumberland—Improvements in distilling apparatus.

70. M. Vetillart, Le Mans, France—Improvements in drying woven fabrics, yarns, and other goods.
71. H. M. Leeson, Greenwich—Improvements in gas-burners.
72. F. Tussaud, Paris—Universal pump-press, with continuous action, called "Continuous Producer."
73. A. Ponçon, Marseilles—Obtaining a motive power.

*Dated January 12.*

74. J. W. Wrey, Upper Berkeley-street West—A new and improved method of transmitting motion.
75. T. Waller, Ratcliff—Improvements in register-stoves, and other stoves or fire-places.
76. T. E. Moore, St. Marylebone—Improvements in apparatus to be used for extinguishing fires.
78. J. F. Boake, Dublin—Improvements in and applicable to certain lamps or lanterns, so that either candles or oil may be used therein with facility.
79. J. W. Partridge, Birmingham—Improvements in the manufacture of soap.
80. J. Bethell, Parliament-street—Improvements in manufacturing coke.
81. L. J. Anaer, Paris—Improvements in the manufacture of metallic tubing.
82. T. F. Henley, Cambridge-street, Pimlico—Improvements in the preparation of certain colouring materials.
83. A. E. L. Bellford, Castle-street, Holborn—An improvement in the manufacture of glass. (A communication.)
84. S. Wilkes, Wolverhampton—Improvements in the construction of chairs and rails for railways.
85. J. H. Johnson, Lincoln's-inn-fields—Improvements in the preparation of glycerine, and in its application. (A communication from V. Courboulay, Paris.)
86. R. Maclaren, Glasgow—Improvements in moulding or shaping metals.

*Dated January 13.*

87. W. Eassie, Gloucester—Improvements in trucks used on railways.
88. A. Parsey, Crescent-place, Burton-crescent—Improvements in machinery for obtaining and applying motive power by means of compressed air and other fluids.
89. P. O'Malley, Dublin—Manufacture of a new drink or beverage from certain vegetable and other substances, and the conversion thereof into vinegar.
90. T. B. Foulkes, Chester—Improvements in the manufacture of self-adjusting gloves.
91. J. Wilkinson, Manchester—Improvements in the manufacture of dies for producing printing surfaces for calico printers, applicable also to embossing.

*Dated January 14.*

92. J. Newman and H. Jenkins, Birmingham—Improvements in the manufacture of spoons, table-forks, and other articles.
93. J. Bird, St. Martin's lane—Improvement in taps and cocks.
94. J. Jeffreys, Carlton-villas, Maida-vale — Improvements in the manufacture of mineral charcoal and coke, and in adapting open grates for the combustion of them.
95. A. Dobson, Bolton-le-Moors—Improvements in looms for weaving.

*Dated January 16.*

96. C. F. Stansbury, Cornhill—A new and improved mode of propelling machinery. (A communication from B. Hughes, Rochester, U. S.)
97. W. Crosskill, Beverley, York—Improvements in the constructon of portable railways.
98. J. Newall, Bury—Improvements in machinery or apparatus for stopping or retarding the progress of railway and other carriages, and in the mode or method of connecting two or more carriages with the said apparatus together.
99. P. Grant, Manchester—Improved roller used in the processes of letterpress, copperplate, and lithographic printing.
100. P. Blaker, Crayford, Kent, and W. Wood, Chancery-lane—Machine for crushing coal, and the refuse arising from the combustion of coal used for brickmaking and other purposes.
101. G. F. Wilson, Belmont, Vauxhall—Improvement in the manufacture of candles and night-lights.
103. P. G. Julyan, Bath-street, Birmingham—Improvements in communicating signals to engineers, guards, and others in a moving railway train.
104. J. Spires, Lower Drummond-street, Euston-square—Improvements applicable to boots and shoes.

*Dated January 17.*

106. W. Brown, Camberwell—Improvements in printing machinery.
107. W. Crosskill, Beverley, York—Improvement in the construction of carriage-wheels to run on railways and ordinary roads.
108. E. Highton, Regent's-park—Improvements in suspending the wires of electric telegraphs.
109. H. Holland, Birmingham—Improvements in the construction of parts of umbrellas and parasols.
110. R. Maclaren, Glasgow—Improvements in moulding or shaping metals.
111. H. Corlett, Summer-hill, Dublin—Improvements in springs for railway and other carriages and vehicles.
112. K. Weber, Rechtburg, Wurtemberg—Improvements in the manufacture of boots and shoes.
113. B. G. Sloper, London—Improvements in machinery or apparatus for separating gold from earthy matters.

*Dated January 18.*

114. W. B. Haigh, Oldham, Lancaster—Improvements in machinery or apparatus for tenoning, mortising, slotting, cutting, or shaping wood or metal.
115. E. Lord, Todmorden, York—Improvements in looms for weaving.
117. C. S. Cahill, Greenwich, and Annadown, Ireland—Improvements in submarine, subterranean, and other electric and magnetic telegraphs, and in insulating, laying down, joining, and covering the same.
118. W. Batten, Westbourne-street, Pimlico—Improvement in the construction of a sink, drain, or gulley trap, named the Self-Acting Effluvium Trap, for the more effectual conveyance of all liquids or admixtures in passing into drains, sewers, cesspools, or other receptacles, and the better prevention and exclusion of all vapours, effluvia, or gases arising therefrom.
119. W. Greenshields, Edinburgh—Improvements in chenille fabrics.
120. W. Thomas, Cheapside—Improvements in stays.
121. E. Sharpe, Swadlincote Potteries, near Burton-on-Trent—Improvements in the apparatus used for sifting clay.
122. C. Howard, Trafalgar-terrace, Hoxton—Improvements in the manufacture of iron.
125. J. P. Bourquin, Newman-street—Improvements in or applicable to troughs or vessels for holding liquid substances required in the art of photography.

*Dated January 19.*

127. G. H. Bursill, Offord-road, Islington, and Ranelagh Works, Pimlico—Improvements in operating upon metalliferous ores and other minerals, and upon slags and sweep, in order to facilitate the separation and recovery of the metals and other products; also in machinery or apparatus for effecting such improvements, which is in part applicable to other purposes.
128. A. Dalgety, Florence-road, Deptford—A new construction of rotatory engines or pumps.
129. J. Norton, Cork—Improvements in effecting communications between the different parts of railway trains.
130. T. Webb, Platt's Glass Works, Stourbridge—Improved apparatus applicable to the annealing of glass and the firing of pottery ware.
131. H. Guyon, Paris—Improvements in the manufacture of bread.
132. H. Brownentt, Liverpool—Treating scrap and waste iron, so as to render the same more readily available in the manufacture of iron.
133. F. Parkes, Sutton Coldfield, Warwick—Mode or method of fixing tools and implements in helves or handles.
134. N. Hunt, Massachusetts, U. S.—Improvements in machinery for sewing cloth or other material. (A communication from C. Hodgkins, Massachusetts.)
135. C. W. R. Rickard, Great Charlotte-street, Blackfriars-road—Improvements in cocks and taps.

*Dated January 20.*

136. H. Dircks, Moorgate-street—Improvements in safety-apparatus, applicable to certain boilers and stills.
137. H. B. Condy, Battersea—Improvements in the manufacture of sulphate of soda, sulphate of potash, and other sulphates, and in the manufacture and employment of muriatic acid.
138. E. Aitchison, Manor-street, Chelsea — Improvements in apparatus for fixing, removing, and plugging tubes of tubular steam-boilers.
139. A. E. L. Bellford, Castle-street, Holborn—Improvements in cutting out cloth and other fabrics and materials suitable for garments and furniture. (A communication.)
140. O. R. Chase, Boston, U. S.—Pulverising machinery.
141. J. J. Field, Charles-terrace, Islington — Improvements applicable to guns, cannon, or ordnance, rifles, and other similar implements of war or the chase, for more accurately aiming at the object to be struck by projectiles.
142. R. S. Smith and A. MacDougall, Manchester—Improvements in treating, deodorising, and disinfecting sewage and other offensive matter, which said improvements are also applicable to deodorising and disinfecting in general.
143. J. H. Johnson, Lincoln's-inn-fields—Improvements in the manufacture of stays or corsets. (A communication from A. G. Geresme, Paris.)

*Dated January 21.*

144. R. Roberts, Manchester—Improvements in machinery for cutting paper, pasteboard, leather, cloth, and other materials.
146. M. L. L. Beaudeloux, Paris—A candlestick working by machinery, so as to keep the candle always at the same height in a tube, with a shade of a peculiar construction, so as to augment greatly the quantity of light.
148. G. Grace and T. F. Jones, Birmingham—Improvements in boots and shoes, as also boot and shoe socks or inner soles, whereby the same are rendered waterproof.
149. J. Westerton, Earl's-court-road, Brompton—Improvement in the manufacture of night-light boxes or cases.
150. C. M. T. du Motay, Rue Fontaine St. George, Paris—Improvements in the manufacture of oil from rosin.
151. H. E. Falcke, Gateacre House, Liverpool—Improvements in preparing or manufacturing salt.
152. T. B. Venables, Burslem, Stafford—Improvements in the manufacture of earthenware.
153. P. Spence, Pendleton, near Manchester — Improvements in manufacturing the prussiates of potash and soda.
154. D. Warren, Exmouth—Improvements in raising, pumping, or forcing water.
155. C. J. Edwards, Great Sutton-street—Improvements in the manufacture of bands for driving machinery.

*Dated January 23.*

156. A. Shanks, Robert-street, Adelphi—Improvements in machinery for punching and shearing metals.
157. C. C. Armstrong and W. Pursall, Birmingham—New or improved percussion-cap.
158. W. Darling, Edinburgh—Improvements in sewing-machines. (A communication.)
160. T. Robinson, Farringdon-street—Improvements in apparatus for filtering volatile liquids.
161. M. A. Muir, Glasgow—Improvements in weaving.
162. J. Lockhart, jun., Paisley, Renfrew—Improvements in the manufacture of bobbins.
163. J. G. Taylor, Glasgow—Improvements in treating the fleeces or natural coverings of sheep and other animals, when on the animals.
164. J. G. Taylor, Glasgow—Improvements in lamps, and in substances to be burned therein.
165. H. Seebohm, Eshol, near Leeds—Improvements in combing wool, goats'-hair, alpaca, cotton, and other fibrous material.
166. J. Getty, Liverpool—Improvements in the manufacture of tubular bridges; part of which improvements is applicable also to the preparation of plates for covering iron ships, for constructing boilers, and for other analogous uses.
167. J. Westlake, Totnes, Devon—Pulverising, washing, separating, amalgamating, and otherwise treating ores, gossans, earths, and rocks, so as the better to obtain and extract therefrom the gold and other metals and minerals which may be contained therein.
168. A. E. L. Bellford, Castle-street, Holborn—Improvements in machinery for bending metal, and producing forms thereon by pressure. (A communication.)
169. J. M. J. L. Bouvet, Boulevart St. Martin, Paris—Improvements in kneading-machines.
171. R. A. Brooman, Fleet-street—Improvements in machinery for sawing stone and marble. (A communication.)
172. R. A. Brooman, Fleet-street—Improvements in extracting copper from the ore. (A communication.)
173. A. T. Wagner, Berlin—A psycograph or apparatus for indicating persons' thoughts by the agency of nervous electricity.

*Dated January 24.*

174. A. W. Sleigh, Weymouth-street, Portland-place—Creating a continual self-acting, self-sustaining new motive power, applicable to every purpose requiring speed, motion, and power, together or separately.
175. G. Williams, Cannon-street, St. George's-in-the-East—Improvements in the construction of waterclosets.
176. J. B. Monier, La Villette, Paris—A new chemical process for the production of sulphates of soda, potassa, and alumina, of nitrates of soda and potassa, of soap, and of hydrochloric, sulphuric, stearic, morgaric, and elaidic acids.
177. J. L. Schlossmaker, Paris—Improved support of lamps.
178. J. Ridgway, Cauldon-place, Stafford—Improvements in the method of generating and applying heat to kilns, ovens, and furnaces, for manufacturing purposes.
179. W. I. Ellis, Salford, Lancaster—Improvements in turntables to be employed on or in connection with railways.
180. W. Massey, Hemer-terrace, near Liverpool—Improvements in artificial teeth and gums.
181. J. Bapty, Leeds—Improvements in machinery for preparing to be spun wool and other fibrous substances when mixed with wool.
182. S. C. Lister, Manningham, Bradford—Improvements in combing wool, cotton, and other fibrous materials.
183. J. Bird, Oak Farm, near Dudley—Improvements in kilns for burning bricks and other articles.

*Dated January 25.*

184. J. A. Mingaud, St. Pons (Herault), France—Improvements in producing ornamental surfaces on velvet or other hairy cloths or fabrics.

185. E. B. Walmsley, Middle Mall, Hammersmith—Improvements in utensils, implements, and apparatus for the purposes of lighting, heating, and cooking.
186. W. E. Newton, Chancery-lane—Improvement in violins and other similar stringed musical instruments. (A communication.)
188. W. H. Thornthwaite, Newgate-street—Improvement in the manufacture of sulphuric acid.
189. R. A. Brooman, Fleet-street—New and improved fluid for illuminating purposes. (A communication.)
190. A. L. Reid, Glasgow — Improvements in printing textile fabrics and other surfaces.
191. J. Anderson, Auchnagie, Perth—Improvements in obtaining motive power.

*Dated January 26.*

192. T. Wicksteed, Leicester—Improvements in the manufacture of sewage-manure.
193. T. Wicksteed, Leicester—Improvements in the manufacture of sewage-manure.
194. T. Wicksteed, Leicester—Improvements in the manufacture of sewage-manure, and in apparatus for that purpose.
195. F. M. Blyth, Norwich—Improvements in the mode of heating water for steam-boilers.
196. C. Reeves, jun., Birmingham, and W. Wells, Sutton Coldfield, near Birmingham—Improvement or improvements in casting metals.
197. S. Smith, Hyson Green Works, near Nottingham—Improvements in valves or apparatus for regulating the passage and supply of fluids.
198. S. S. Stallard, York-street, Leicester—Improvements in the manufacture of knit fabrics.
199. G. Firmin, Bath—Improvements in anchors.

*Dated January 27.*

200. F. F. Rohart, Sotteville les Rouen, France—Improvements in the preparation of a certain substance for clarifying liquids.
201. P. M. Crane, Canonbury-villas, Islington—Improvement in the manufacture of iron.
202. A. C de Simencourt, Paris—Improvements in composing and distributing type.
203. W. Church and S. A. Goddard, Birmingham—Improvement or improvements in ordnance.
204. H. Tendall, Hoxton, and W. S. Trotter, London—Improvements in machinery and apparatus for crushing, washing, and amalgamating auriferous quartz and other ores.
205. T. Thurlby, Guildford-street East, Spafields—Improvements in the means of effecting instant communication between distant points of railway trains.
206. W. Palmer, Brighton—Improvements in the manufacture of materials for and in constructing houses and other buildings.
207. W. Partington, Bolton-le-Moors, Lancaster—Improved construction of safety-valve for steam-engines.
208. J. Atkinson, Richmond-grove—Improvements in thrashing machinery.

*Dated January 28.*

209. J. J. L. Fournier, Montpelier, France—Improved mode of obtaining alcohol.
210. J. Grist, New North-road, Islington—Improved break for railway and other carriages.
211. M. T. Raymond, Clement's-lane, Lombard-street—Improvements in apparatus for retarding and stopping trains of carriages on railways
212. J. L. Clark, Canonbury-villas, Islington—Improvements in apparatus for conveying letters or parcels between places by the pressure of air and vacuum.
213. W. Williams, Cheapside—A method of, and apparatus for heating the heaters of box-irons and other like purposes.
214. D. Chadwick, Salford, Lancaster, and G. Hanson, Manchester—Improvements in meters for measuring water or other liquids, and vapours or gas.
215. D. Bethune, Toronto, Canada West—Improvements in the construction of vessels propelled by steam or other motive power.
216. W. G. Taylor, Norfolk-terrace, Westbourne-grove—Improvements in certain parts of machines employed for preparing and spinning cotton, wool, hair, silk, flax, and other fibrous substances or materials.
217. W. Woolford, Bowling New Dye Works, Bradford—Improvements in pressing and watering moreens and other fabrics.
218. W. Redgrave and T. Redgrave, Bow-street, Covent-garden—New railway signal-lights, to be called "Redgrave's Patent Railway Signal-Light."

*Dated January 30.*

219. P. A. L. de Fontainemoreau, South-street, Finsbury—Improved means of preventing accidents on railways. (A communication.)
220. P. A. L. de Fontainemoreau, South-street, Finsbury—Certain arrangements for preventing accidents on railways. (A communication.)
221. H. J. Iliffe and N. Brough, Birmingham—Improvements in the manufacture of buttons, and in attaching them to articles of wearing apparel.
222. W. Phillips, Birmingham—Improvements in the manufacture of coffins.
223. W. Hodgson, Wakefield, York—Improvements in machinery for the manufacture of looped fabrics.
224. B. O. Stratford, Earl of Aldborough, Stratford-lodge, Wicklow—Improvements in aerial navigation.
225. J. R. Cooper, Birmingham—Improvements in preparing or constructing and dressing rolls for rolling gun-barrels, tubes, and bars.
226. R. Garrett, Leiston Works, Suffolk—Improvements in thrashing-machines.
227. J. Kershaw, Dublin—Improvements in steam-engines.
228. J. H. Johnson, Lincoln's-inn-fields—Improvements in the manufacture or production of gas, and in the application of the materials employed therein. (A communication from A. Koechlin, N. J. V. Duchatet, and J. A. A. de Perpigna.)
229. R. Chapman, Eaton, Norwich—Apparatus for regulating the feed to millstones.

*Dated January 31.*

230. T. Cox, Wolverhampton—Improvement or improvements in buttons, and in attaching the same to articles of dress.
231. A. M. Fatio and F. Verdeil, Paris—Improvements in preserving animal and vegetable substances.
232. E. W. K. Turner, Praed-street, Paddington—Treating gold and other ores.
233. T. Hollingsworth, Nottingham—Improvements in forming or applying tags to laces.
234. L. Young, Bow-lane, Cheapside, and E. Marten, Louisa-street, Stepney—Improvements in apparatus for regulating the pressure and supply of gas.
235. C. Erckmann, La Villette, near Paris—The manufacture of telegraphic wires.
236. I. Hazlehurst, Ulverstone, Lancaster—Improvements in the manufacture of iron by blast, and in the construction of furnaces and machinery for the same.
237. R. Oliver, R. Barlow, and J. Blundell, Manchester—Improvements in machinery or apparatus for embossing and cutting out patterns or devices for the ornamentation of textile fabrics or other materials or surfaces.
238. L. C. Koeffler, Rochdale, Lancaster—Improvements in machinery or apparatus for preparing, dressing, and finishing yarns or threads.
239. L. Koeffler, Rochdale, Lancaster—Improvements in the method or process of scouring, washing and oiling wool and other textile materials, for the purpose of spinning, and in the machinery or apparatus connected therewith.
240. W. Wright and G. Brown, Newcastle-upon-Tyne — Improvements in cupolas; which improvements are also applicable to smelting and other furnaces.
241. P. J. Meeus, Paris—Improvements in producing metallic surfaces.
242. W. Malam, Blackfriar's-road—Improvements in apparatus for the manufacture and holding of gas.
243. R. A. Brooman, Fleet-street—Improvements in the manufacture of steel. (A communication.)
244. P. Beudot, Boulevart St. Martin, Paris—Improvements in gas-burners.
245. J. Jackson, Broad-street, Golden-square, and G. M. Hantler, Sloane-street—Improvements in baths.

*Dated February 1.*

246. C. B. A. Chenot, Boulevart St. Martin, Paris—Improvements in accumulating, conducting, and treating gases of combustion, and also in generating and applying the same to metallurgic and other purposes.
247. H. Wickens, Tokenhouse-yard—Improvements in the mode of intercommunication in railway trains.
248. A. Motera, Paris—Improvements in apparatus for stopping locomotive engines, wagons, or other vehicles on railways.
249. J. Buchanan, Leamington Priors, Warwick—Improvements in propellers, and in applying them.
250. J. Burgum, Birmingham—New or improved self-acting damper for the furnaces of steam-boilers.
251. W. Guest, Lion-square, Nottingham—Improvements in machinery for making whips; parts of which improvements are also applicable to the manufacture of braids and wire-nets.
253. A. Robinson, Whitehall-place—Improvements in preparing compositions for coating iron and other ships' bottoms and other surfaces.
254. C. F. Le Page, Paris—Improvements in apparatus for lighting.
255. J. Jobson, Litchurch Works, near Derby, and R. Jobson, Holyhall Works, near Dudley—Improvements in the manufacture of moulds for casting metals.
256. A. Daniel, Moorfields, Wolverhampton—Improvements in locks, and in handles for the same.
257. J. Hargreaves and J. Fletcher, Facit, near Rochdale—Improvements in machinery for preparing to be spun cotton and other fibrous materials.
258. J. D. Morrison, Sunderland—Improvements in winches.
259. J. Beattie, Lawn-place, Lambeth—Improvements in furnaces, and in the treatment of steam.

*Dated February 2.*

260. T. Atkins, Oxford—Improvements in transmitting power and communicating motion to implements for agricultural and other purposes.
261. A. Mohler, Obernay (Bas Rhin), France—Improvements in apparatus for lubricating machinery.
263. C. E. Paris, Paris—Improvements in covering with metals certain metallic surfaces.
264. J. Stevens, Darlington Works, Southwark-bridge-road—Improvements in apparatus for giving railway-signals.
265. J. H. Glassford, Glasgow—Improvements in lithographic and zincographic printing.
266. F. H. Sykes, Cork-street, Piccadilly—Improved apparatus for supplying or feeding boilers with water, applicable to raising and forcing liquids for other purposes.

*Dated February 3.*

268. A. E. L. Bellford, Castle-street, Holborn—New system of apparatus, to be called "Atmospheric Post," for transmitting letters and messages, and applicable to railways, and as a speaking-trumpet. (A communication.)
270. R. B. Newhouse, Uckfield, Sussex—Improved apparatus for conducting off the gases of combustion from open fireplaces.
272. A. Lannes, Marquis of Montebello, Mareuil-sur-Ay, France—Improved propeller, applicable to the navigation of ships and other vessels.
274. E. Howard and D. P. Davis, Massachusetts, U. S.—Improvements in machinery for sewing cloth or other material. (A communication by S. H. Roper, Massachusetts.)

*Dated February 4.*

276. W. Gosling, Edward-street, Woolwich—An invention for the purpose of preventing collisions on railways, which he has designated "Gosling's Railway Danger Signal."
278. A. V. Newton, Chancery-lane—Improvements in springs applicable to railway carriages and other uses. (A communication.)
280. W. Little, Strand—Improvements in distilling or obtaining products from coals and bituminous substances.
282. E. Cole, Hemming's-row, Westminster—Improvement in the frames of travelling-bags.

*Dated February 6.*

284. D. Deyres, Bateman's-buildings, Soho-square — Improvements in drilling and boring.
288. T. and W. Hemsley, Melbourne, Derby—Improvements in the manufacture of looped fabrics.
290. A. Duncan, Glen House, Stirling—Improvements in bleaching.
292. P. Trumble, Huddersfield—Improvements in paperhangings.

*Dated February 7.*

294. J. Murdoch, Staple-inn, Holborn—Improved process for manufacturing paper. (A communication.)
296. E. Poitiers, Malden-terrace, Haverstock-hill—A new material for the manufacture of cordage, canvas, and linen, and generally as a substitute for hemp and flax.
298. W. J. Curtis, Birchin-lane—Improved railway-signal, especially adapted as a danger-signal.
300. A. F. D. Duvillier, Rue du Bouloi, Paris—New system of remontoirs, or apparatus for winding up watches without a key.
302. J. Taylor and I. Brown, Carlisle, and J. Brown, Oxford-street—Improvements in the charring of vegetable and animal substances.
304. A. V. Newton, Chancery-lane—Improved machinery for heckling flax and other fibrous materials. (A communication.)

*Dated February 8.*

306. E. T. Rees, Prospect-place, Swindon—Improvements in pressure slide-valves in steam-engines, to be called the "Anti-Pressure Valve."

## PATENTS APPLIED FOR WITH COMPLETE SPECIFICATION.

147. H. Watson, High-bridge, Newcastle-upon-Tyne—Improvements in waterclosets. —Jan. 21.
252. F. H. Wenham, Effra Vale Lodge, Brixton—Improvements in fire-arms.—Feb. 1.
286. R. J. Maryon, York-road, Lambeth—Improvements in the machinery for the improved construction of windlasses and other machines for which the same invention is applicable.—Feb. 6.
319. J. Taggart, Massachusetts, U. S.—Improved machine for excavating earth—Feb. 9.

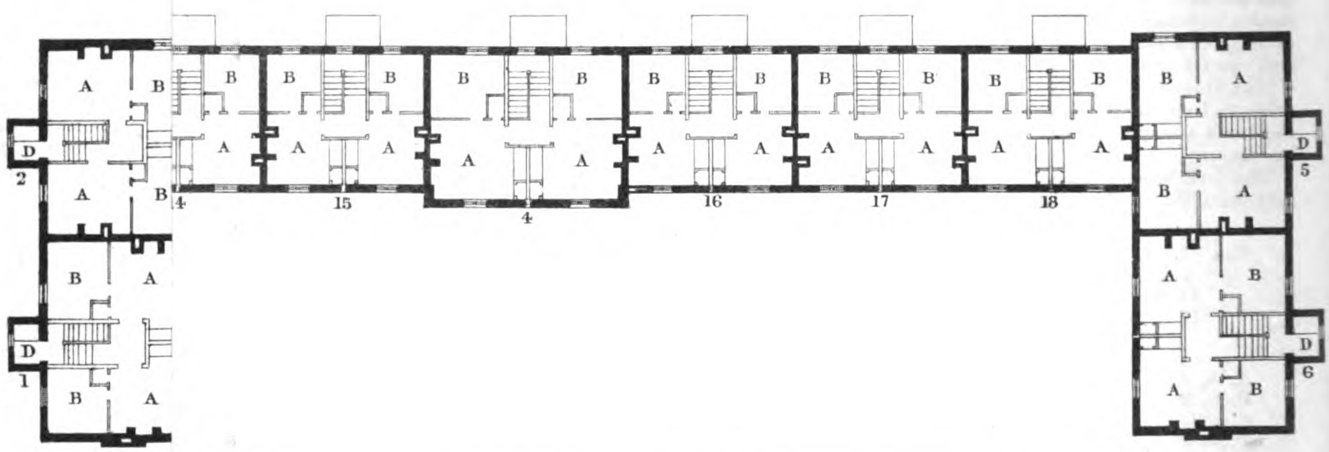
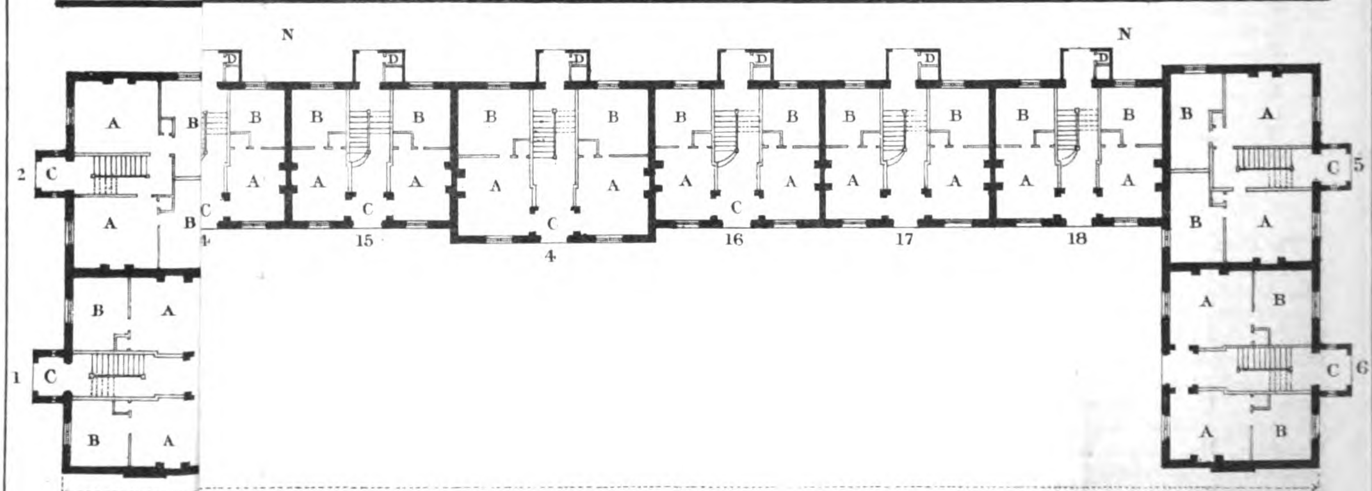
FTON PLACE, KENTISH TOWN.





## ST. PANCRAS ALMSHOUSES, KENTISH TOWN.

(*With an Engraving, Plate* XV.)

These Almshouses have been instituted by subscribers in the large and populous parish of St. Pancras, and are intended to receive those residents in the parish who from misfortune may, in their old age, have fallen into indigent circumstances. The inmates are elected by the whole body of the subscribers, and, to render them eligible, they must have paid poor-rates in the parish for not less than ten years, have borne a good character, never received parochial relief, and be upwards of sixty years of age. The centre building, with offices in the rear, and six of the houses, have already been erected, and are partly occupied. The committee are appealing to the sympathies of the benevolent to enable them to complete the remainder of the houses, and they intend holding a Fancy Sale in May or June next, for the benefit of the Institution, at the Colosseum, Regent's-park.

The Almshouses when completed will have a clear southern aspect of about 400 feet, and will form one side of a square to the north of the Governesses' Institution, and adjoining Grafton-road, Kentish-town. When completed, there will be eighteen houses, besides the centre building, which contains the board-room, secretary's-office, &c., as well as apartments for two married couples, who will be entrusted with the general superintendence of the whole. The eighteen houses consist of six for unmarried females, six for unmarried men, and six for married persons. Each house for the unmarried contains four persons, the apartments for whom are distinct and separate; each set of apartments is fitted up with living-room, separate place for bed, a properly-ventilated safe, coal closet, sink constantly supplied with water, as well as provision for taking away all refuse water. The houses for married persons each contain four couples, and except that an additional amount of room is provided, they are similar to the houses for the unmarried persons, and are fitted up in a like manner. In addition to this, there is at the back of the centre building a washhouse and laundry for the use of the whole of the inmates. There is also provided a bath-room for males, and one for females, to be supplied with hot and cold water.

The Houses externally have a picturesque and pleasing appearance, and are in the simple Old English style. The walls are of red brick and stone, relieved by diamond-work in darker-coloured bricks.

The builders are Messrs. Hopkins and Roberts, of Islington; and the architect, Mr. James K. Colling.

*The Conical Flour Mill.*—Since we noticed this valuable invention, it has been making rapid progress both at home and abroad. The Austrian patent has been sold for 30,000*l.* A large mill has been erected at Vienna, and is in full work. Another has been built for Lord Portman, at Bryanstone, Dorset, which grinds 8½ bushels per hour against an ordinary mill belonging to his lordship which grinds 2½ bushels, and the same power (water) does for both. The magistrates of Hampshire are erecting a mill in the county gaol at Winchester, and in Ireland Lord Talbot de Malahide, Mr. Dargan, and others take a lively interest in its adoption in that country. In France, Prince Murat has become the president of a committee to carry it out.

## THE ACROPOLIS OF ATHENS.*

The City of Athens was founded on an isolated rock in the midst of a plain. Originally this noble city, from which we derive all those arts and sciences which have illustrated the nations of Europe, was comprised within the natural and artificial fortifications which encircled the table land on the summit of the rock. The city did not for a considerable period exceed these limits. As the number of inhabitants increased, however, they built houses at the foot. The top of the hill, which the fortifications rendered a citadel, may be considered the more important portion of the city; and around the temple which was raised to Minerva, the patron of Athens, many other temples were successively erected. Statues of divinities and heroes, and inscriptions of every kind, were added. It was there, at the top of this impregnable rock that were celebrated the religious festivities of the people.

The rock on which the Acropolis reposes presents the appearance of a very irregular oval. On the north, east, and south it is too steep and high to be climbed, and it is only on the western side that a less abrupt descent gives access to the citadel. At the upper part of this declivity are the outer gates, the object of which had not been accurately determined until Mons. Beulé discovered a range of steps parallel to the front of the outer gates, and as wide as the principal body of the edifice. The destination, then, of the gates (Propylæa) has been ascertained,—after having mounted the immense stairs in question, this open portico formed the entrance to the Acropolis. Mons. Beulé attributes this grand and beautiful construction to Mnasicles, the builder of the Propylæa, and he is borne out apparently by the disposition and inclination of the ground compared with the site of the Propylæa. He considers, that although the plan (extremely original) of the gates is not in accordance with the traditional laws which were so religiously observed by the Greek architects, the details of the edifice, as pure as those of the Parthenon, prove that it was constructed during the most flourishing epoch of art.

Passing over the attacks and troubles to which it was previously exposed, Xerxes, after having ravaged the Peloponnesus, laid seige to Athens in the year 479 B.C., and the inhabitants having left the city with the exception of some old people who still remained, he set fire to all the edifices which covered the Acropolis. Mardonicus, master in his turn of Athens, succeeded in annihilating what Xerxes had been only able to leave in ruins. According to the testimony of Herodotus, he left neither a wall of the city nor a house standing; and even at the present day fragments of ancient temples are found, broken marble, blackened stones, coal, earthen and metal vases, all bearing witness to a devastation the traces of which twenty-four centuries have not been able to conceal.

There doubtless existed an ancient Parthenon, built by the tyrant Pisistratus, but of which there is no mention made in the ancient authors, so much had it been thrown in the shade by that which the architect Ictinus constructed during the government of Pericles.

The Acropolis of Athens, a spot considered sacred by the inhabitants, inspired even foreigners with such respect, that when it was taken by the conqueror Scylla, he stopped the pillage, and merely caused the town and citadel to be dismantled. Even when the rest of Greece was despoiled of its masterpieces of art, those of Athens were considered inviolable. Athens was not treated as a conquered city, but as the mother country of the conquerors;—Julius Cæsar forgave its fidelity to Pompey; Antony, its adhesion to the party of Brutus and Cassius; Augustus, the favours it had received from Antony. It was Nero who commenced the work of devastation. When he had depopulated Delphos and Olympus of their statues, he carried off the greater part of those which stood in the Acropolis of Athens. Before the close of the fourteenth century, the first Duke of Athens, Neri dei Acciajuoli, transformed the Propylæa into a palace, which he surrounded with fortifications, and of which he destroyed in all probability a considerable part, so as to change it into a princely habitation according to the ideas of the age.

Up to this period, the exterior of the edifice was in a good state of preservation, but the taking of Athens by Mahomet II., about 1456, and the effect of artillery already in use at this time, resulted in an almost complete destruction of the monuments of the Acro-

* Abridged from the French of Delécluse.

polis. Although the lords of Athens had previously erected numerous fortifications, it was necessary to strengthen them still further, in order to make the Propylæa, now the habitation of the Aga, and the only accessible point, secure from artillery which might be brought to bear against that structure. An immense bastion was therefore constructed in front, the approaches to the citadel were shut by a line of walls and gates, and the ancient towers and walls were buried 40 feet underground. The Parthenon became a mosque, the Erechtheion a harem, and, in their aversion to images, the Turks mutilated every piece of sculpture that came within their reach. In 1656, on the eve of a great festival the Turks wished to celebrate, the Aga Joussouf took it into his head to destroy the church of St. Dimitri, which is built in the plain at the foot of the Museion. With this object in view, he had three pieces of cannon planted, and ordered his soldiers to be ready on the following morning at break of day. This Joussouf lived in a great dome, constructed under the principal vestibule of the Propylæa, which was used at the time as a depôt of arms and powder-magazine. During the night a thunderbolt fell on this little arsenal, which exploded, and blew up the Aga and his whole family.

The invention of gunpowder has been fatal to the monuments of the Acropolis. Thirty-one years after the above event, the Venetians, who had just taken possession of the Morea, menaced Athens. The Turks, determined to make a vigorous defence, immediately set to work with the intention of fortifying still further the Acropolis, and constructing batteries, one of which has been elevated on the the ruins of the Temple of Victory, which indeed they ruined for the purpose. The Venetians, however, landed at the Piré, and the Count of Konigsmark, lieutenant of Morosini, planted his mortars on the hills which surround the western side of the Acropolis. The bombarding commenced on the 26th September 1687. The Parthenon, which commanded the platform on this side, and in which the Turks had shut up their families, was more particularly aimed at. The Turks had also placed in it all their most valuable effects and a large quantity of gunpowder. The bombs themselves would not have penetrated the solid roofing of the Parthenon, but sparks having got into the structure, the powder took fire, and the Parthenon blew up on the evening of the 28th September. Almost all the cella and its frieze, eight columns of the northern portico, and six of the southern portico with their entablatures, were overthrown,—the vast temple was cut, as it were, into two masses of ruins. The Turks, terror-stricken, surrendered the following day, and Morosini entered in triumph the Acropolis. By his orders the horses and car of Minerva, in such admirable preservation that the most indifferent traveller spoke of them with enthusiasm, were carried away; but the work was so badly conducted, that the whole group fell, and was shattered on the rock. The captains of Morisini followed the example of their chief, and fragments of the Parthenon, according to the testimony of Brönstedt, were carried even to Copenhagen.

Up to the end of the eighteenth century, the work of destruction may be considered as resulting from the exigencies of war, or the ignorance and apathy of the successive guardians of these precious remains. But when a taste for the works of antiquity began to spread throughout Europe, a new species of barbarism developed itself—a learned vandalism, which has taken from the principal monuments of Athens ornaments which had until then escaped destruction.

A piece of the frieze of the Parthenon—one only, and detached this long time, having belonged to the eastern side, entirely ruined a hundred years ago—was brought to France by the Comte Choiseul-Gouffier, on his return from an embassy to Constantinople. This served as a precedent to Lord Elgin in 1810 for carrying off more than 200 feet of the frieze of the Parthenon, and almost all the statues of the pediments. Besides, the metopes were torn from their grooves, the triglyphs and cornices were broken in pieces by the hammer, their fragments of architecture, capitals, entablatures, &c., were taken away. The Propylæa also furnished specimens; two sides of the frieze of the Temple of Victory without Wings did not escape; the Temple of Erechtheus was pillaged, and one of the statues which supported the portico of the Caryatides was carried off, at the risk of the whole portico falling to the ground.

These are the principal vicissitudes of the Acropolis of Athens during the two thousand two hundred and eighty-nine years which have elapsed from the destruction of this famous citadel by Xerxes to the carrying off the marbles by Lord Elgin. But not to omit any, it should be mentioned, that in the war of independence the Acropolis, where the Turks and Greeks alternately besieged one another, was still the scene of disasters, for at this period the cannon mutilated its marbles and overturned a part of the Erechtheion.

F. P. H.

## ON THE STRENGTH OF COMPOUND GIRDERS.

By Homersham Cox, M.A., Fellow of the Cambridge Philosophical Society, Barrister.

The recent publication of Mr. Fairbairn's interesting and valuable work, 'On the Application of Cast and Wrought Iron to Building Purposes,' affords a suitable occasion for reviewing some of the principles adopted in designing iron beams and girders of various forms. The diversities of opinion which exist respecting the relative merits of the modes in which iron is now most usually applied to constructive purposes, constitute a sufficient excuse for entering on the proposed inquiry.

The subject of the strength of simple beams, or those in which the whole of the material forms a single mass without joints or apertures, has been sedulously investigated both experimentally and mathematically: but the investigation of the strength of compound beams, consisting of several distinct parts connected by joints or otherwise, is comparatively incomplete. Such structures are now used to a great extent in modern engineering. My inquiries have led me to the conclusion that, notwithstanding the great importance of sound mechanical principles in forming such structures, some of the most common of them have been designed without sufficient knowledge of the strains to which they are subject.

### Trussed Cast-Iron Girders.

The first form of compound girder which I purpose to consider is the *Trussed Cast-Iron Girder*, represented in the accompanying diagram, copied from that given at page 32 of the work just mentioned. This girder is a single beam of the well-known form

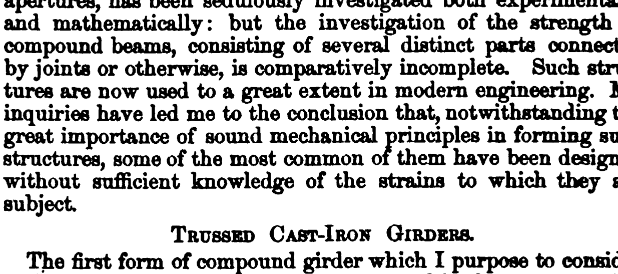

Fig. 1.

of section $a' b'$, modified by the addition on both sides of it of wrought-iron tie-rods A B, C B, connected to the upper part of the beam at its extremities, and meeting under it at B below the centre. Mr. Fairbairn is of opinion that in this truss-beam the two materials, wrought-iron and cast-iron, cannot be brought to act in perfect concert with each other, and that in order that the materials may be most economically disposed, the cast metal ought to be upon the point of rupture at the same time that the truss-rods are about to yield by extension. The difficulties of obtaining this perfect adjustment are two-fold—those arising from the different elasticity of the two metals, and those arising from their different expansibility by heat. These difficulties are well expressed by Mr. Fairbairn in the following laws, which he deduces from experiment.

1. Within the limits of 6 tons tensile strain per square inch for cast-iron, and $13\frac{1}{2}$ tons for wrought-iron, the tensile force applied to wrought-iron must be $2\frac{1}{4}$ times the tensile force applied to cast-iron in order to produce equal elongations.

2. For tensile forces below $7\frac{1}{2}$ tons per square inch the *set* of cast-iron is far greater than that of wrought-iron; but for tensile forces above 15 tons per square inch, the set of wrought-iron is much greater than the maximum set of cast-iron.

3. The elongation by 90 degrees of heat of a bar 10 feet long of wrought-iron is ·0067 of an inch more than the corresponding elongation ot wrought-iron: and from the last law Mr. Fairbairn infers that this difference of elongation is equivalent to a tensile force of $\frac{3}{4}$ths of a ton per square inch.

I shall occupy this paper with the consideration of the operation of the *first* of these laws as it affects trussed girders. The adjustment of truss-rods is investigated by Mr. Fairbairn as follows:—

"*First.* Let us consider the case, when the truss-rods have no strain upon them at the time the beam is unloaded. Suppose the beam to be loaded so as to produce a tensile strain upon the cast-iron equal to one-third its breaking-load, that is to say, let the force of elongation be $2\frac{1}{4}$ tons per square inch upon the cast metal; then, from Table III., we find that the strain upon the truss-rods will be about $5\frac{1}{4}$ tons per square inch, and that the set of the cast-iron, after these strains are taken off, will be 6 times that of the wrought-iron. Now, in this case, while the cast-iron is strained to one-third its breaking-weight, the wrought-iron is strained to only about one-fifth its ultimate strength; and, further, when the load is taken off, the cast-iron beam will remain much more elongated than the iron rods, which will, to a certain extent, destroy their original adjustment of tension, but this, in the present case, will not act unfavourably, for it will tend to give a certain amount of tension to the truss-rods.*

"Suppose the beam to be loaded so as to produce a tensile strain upon the cast-iron equal to $5\frac{1}{4}$ tons per square inch; then, in order to produce an equal elongation of the truss-rods, the strain upon them must be $2\frac{1}{4}$ times $5\frac{1}{4}$ tons, or $12\frac{1}{4}$ tons nearly. Here, while the cast-iron is strained to more than two-thirds its ultimate resistance, the wrought-iron is only strained to about one-half its ultimate resistance. One favourable circumstance connected with this load is, that the sets of the two metals are very nearly the same.

"Suppose the beam to be loaded so as to produce a tensile strain of 15 tons per square inch upon the truss-rods, then, by Table II, this will produce an elongation of $\frac{1}{470}$ part of the length of the rod; but, by Table IV., the ultimate elongation of cast-iron is $\frac{1}{550}$ part of its length; therefore the cast-iron would be ruptured by extension some time before the truss-rods could arrive at a strain of 15 tons per square inch, that is, before they could be strained to two-thirds their ultimate strength.

"This adjustment is defective: the truss-rods must obviously have a certain amount of tension before the load is laid on, in order to bring them into a higher condition of action, and to counteract the set of the cast metal.

"*Second.* Suppose the truss-rods to be screwed up so as to give them a tension of 8 tons per square inch, or one-third their breaking tension; and, for the sake of simplicity, let us suppose that the half-length of the beam is 10 feet. This high tension of the truss-rods, it should be observed, will produce a dangerous action upon the cast metal.

"Suppose the beam to be loaded so as to produce a tensile strain of $7\frac{1}{2}$ tons per square inch upon the cast metal. Now, by Table IV., this would give an elongation of ·22 inches; but the truss had an elongation of ·077 inches due to the strain of 8 tons when the beam was in a neutral condition; therefore the total elongation of the truss-rod will be ·22 + ·077, or ·297 inches; but from Table II., we find this elongation to correspond to about 16 tons per square inch tensile force upon the rods. Thus, it appears, that even with the dangerous tension of 8 tons per square inch on the truss-rods, we cannot produce a higher strain than 16 tons upon them at the moment when the cast-iron is about to rupture.

"Reasoning in this manner, it may be shown, that it is impossible to construct a truss-beam which shall task the high tensile resistance of wrought-iron without at the same time introducing a dangerous action upon the cast metal. We have shown, in Tables II. and IV., that for high proportional tensions, the rate of elongation of wrought-iron is from 10 to 26 times that of cast-iron; hence it is impossible to have the two metals acting in concert at tensions approaching their rupture."

It is stated that the length of each of the truss-rods is here considered to be one-half the length of the beam, and the conclusions are apparently arrived at on the assumption that *the truss is extended as much as the under side of the beam.* But I fear that the extension of the truss cannot be so simply computed even approximately. Each truss is placed diagonally, and symmetrically situated with respect to the upper and the under surfaces of the beam; that is, there is as much of the truss above as below the centre of the depth of the beam. Therefore, if we regarded the compression of the upper surface alone, or the extension of the lower surface alone, the argument would be just as strong for concluding that the truss is *compressed* as much as the upper surface, as for concluding that it is *extended* as much as the lower surface.

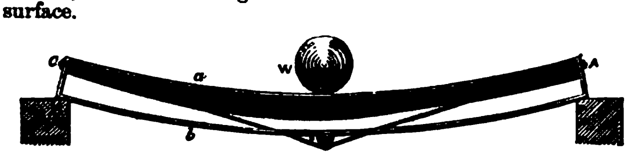

FIG. 2.

But, in truth, the effects at these two surfaces cannot be considered thus separately. The strain of the truss depends on the combined effects of the compression and extension at the two surfaces. *Four* causes may be here considered which materially affect the preceding computation of the strain of the truss. The *first* of these causes is the compression of the upper surfaces as just mentioned. The *second* of them is the deflection of the beam. If it be considered in its bent position as represented in the accompanying diagram, it is clear that on account of the curvature of the part $b$, the distance from B to C is less, *cæteris paribus*, than it would be if $b$ were straight.

The *third* of the causes in question is the varied tension of the underside of the beam. It appears to be assumed in the quotation that the under side of the beam is uniformly extended; but this is not so. This tension of the lower rib is greatest at its centre, and diminishes to nothing at its ends. Consequently, this flange is much less extended than is supposed in the preceding investigation.

There are three causes, then, either of which if it operated singly, would tend to make the tension of the truss even less than is here computed. Therefore, if these causes were not counteracted, not merely would the proposition of Mr. Fairbairn be established, but the insufficiency of strain of the truss would be even more than he has contended for. There is a *fourth* cause, however, which tends to counteract the three just mentioned; it is the inclination of the truss. This cause has more influence on the extension of the truss than any other.

The more inclined the truss is to the horizon the greater *cæteris paribus* is its extension produced by a given deflection of the beam. This may be shown as follows. In the diagram let BC represent the truss (of a given original length), in the one case little, in the other much inclined to the horizon. B and C are the two points of attachment to the beam, B being midway between the fulcra. AB is a vertical, and AC a horizontal, line. By deflection B and C will be both displaced. Let us suppose (as I shall presently show that we may) that the displacement of C is very small compared with that of B, and consider the only effect of deflection to be that of rendering B lower than it was before below $c$ by a distance B$b$. It is obvious that the more nearly the truss is horizontal, the less is the extension compared with B$b$. If the truss were originally actually horizontal, the extension would be ultimately nothing compared with B$b$; whereas if the truss were actually vertical, the extension would be equal to B$b$.

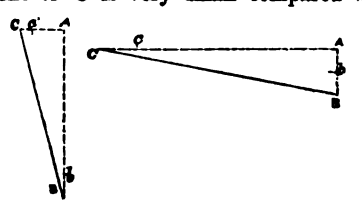

FIG. 3.

The inclination of the truss, then, is such a counteracting cause as has been above mentioned; if the effect of the horizontal displacement of C be small compared with that of the vertical displacement of B. That the former displacement is small will appear from this simple experiment. Holding a straight rod by one end, press the other horizontally against a wall. Then it will be found that a very small movement of the end held corresponds to a large deflection of the rod.

It would be extremely difficult to ascertain theoretically with exactness what the strain of the truss is, for the curvature of the truss does not follow the same laws as ordinary girders; the truss itself having a mechanical action which modifies the elastic curve. The following, however, is a method of approximating to the required result. Let A$c$ the original horizontal distance of the upper end of the truss to the left of the lower end $= a$; A$b$ the original vertical depth of the lower end of the truss below the upper end $= b$; the length of the truss $= l$; the increase of $a$ after deflection $= \text{C}c = h$; and the increase of $b$ after deflection $= b\text{B} = k$. Then $(bc)^2 = a^2 + b^2$; $(\text{BC})^2 = (a+h)^2 + (b+k)^2$.

$$\text{The extension} = \text{BC} - bc = \frac{ah}{l} + \frac{bk}{l},$$

neglecting powers of $h$ and $k$ higher than the first. But $h$, as has been shown, is usually very small. Therefore, when the truss is much inclined we may neglect the first term of the preceding expression. The extension therefore becomes simply equal to $\frac{bk}{l}$; or compute it by the rule of three, thus,

*length* of truss : *depth* of one end of it below the other
:: *deflection* of beam : *extension* of truss.

The inclination of the truss is not, however, generally so great that we can neglect the first term of the preceding expression

* "We have here considered the length of each truss-rod to be one-half the length of the beam. This supposition will obviously involve no appreciable amount of error."

When C is in the upper part of the beam, $h$ is negative, and the extension of the truss will be less than the foregoing computation by the rule of three would give it.

The conclusion that when the truss-rods have no strain on them originally, "the cast-iron would be ruptured by extension" before the truss-rods "could be strained to two-thirds their ultimate strength," is not supported by experiment. It appears from Mr. Fairbairn's first experiment (tabulated p. 47), that the girder "broke from one of the truss-rods yielding to tension;" but the extension must have been so small that this fracture was probably the result of accident.

Even though the truss-rod did not break simultaneously with the beam, it would by no means follow that the truss-rod was an improper or useless adjunct. It might still be the case that an increase of strength could be gained more economically by the proper use of the truss, than by adding to the mass of cast-iron —and this is, I think, shown by Mr. Fairbairn's experiments, noticed presently.

The real mechanical effect of the truss may be made most easily apparent by supposing its tension resolved into a horizontal and vertical component at one of its extremities. We may safely assume for the present that in the girder *not* trussed, the material is principally collected in the upper and lower flanges, and that the horizontal elastic forces of the part connecting them are small and nearly balance each other. Thus it is usual to consider that in a *simple* beam of the section $a'\ b'$, fig. 1, the total tension of the lower is equal to the total compressile force of the upper flange; the thickness of the intermediate vertical part being only just sufficient to develope the elastic forces of the flanges equally. But the tensile strength of cast-iron is so much less than its compressile strength, that the bottom flange $b'$ must be much larger than the top flange $a'$. If the bottom flange were of a material stronger to resist tension, its size in proportion to that of the top flange could be reduced. Now this reduction is precisely what is required by the introduction of the truss-rod. To understand its mechanical effect let us suppose its tension applied at B, fig. 1, to be resolved into a horizontal and a vertical component. Suppose, also, the beam divided in halves by a vertical section through B. What are now the horizontal external forces acting in that section upon the left-hand half ($BaCb$) of the beam? They are, a compressile force in $a$, a tensile force to the right in $b$, and the horizontal component of the tension of the *right-hand* truss (A B) acting to the right. This latter force concurs with and assists the tensile force of the lower flange to balance the compressile force of the upper flange. Therefore, as has been said, the lower flange needs not to be proportionally so strong as in the simple beam.

The same conclusion would be arrived at by considering the tension of the truss applied at C, to be resolved horizontally and vertically. The horizontal component acting along $a$ might be considered to be transferred to $c$, fig. 1, and there to oppose the compressile force, which therefore less tensile force of the lower flange would be required to balance.

Having now considered the horizontal effects of the tension of the truss, let us consider its vertical effects. I do not think their nature can be better designated than as *local disturbing forces*, which do not modify the relations among the forces external to the half-beam on which its equilibrium and strength depend. First these vertical components do not appear in the equations of equilibrium of the half-beam. To compute the strength of the right-hand half-beam B $a$ C $b$, fig. 1, we may take moments about a transverse horizontal axis through C. Then among the external forces must be reckoned the tension of the right-hand truss A B only. The horizontal component of this tension appears in the equation of equilibrium, but the vertical component passing through the supposed axis has no moment about it—that is, does not affect the strength of the beam. What is meant by characterising the vertical components of the tension of the truss-rods as "disturbing forces," is this: the ordinary theory of beams supposes the material composed of parallel layers, and regards only their longitudinal strains. Their strains in the direction of the depth of the beam are neglected, and for many purposes of approximation this simplification gives sufficiently correct results. But the vertical components of the tension of the truss-rod *may* add so much to the latter strains as to produce considerable strain of the beam vertically. In such case, the theory of parallel layers would no longer be even approximately correct. On the whole, it appears that the vertical part of the tension of the truss-rods is by no means advantageous. It seems therefore desirable to have those rods no more inclined to the vertical than is necessary; but it must not be forgotten that their obliquity tends, as has been explained, to subject them to the requisite strain by deflection. I concur therefore in the opinion of Mr. Fairbairn (p. 45), that it is inexpedient to unduly raise the points of attachment $a\ b$, but I have not been able to arrive at the conclusion stated by him, that the raising those points "increases the power of the truss-rods to rupture the upper flange of the beam." On the contrary, if I might venture to differ from so eminent an authority, I would submit that *cæteris paribus* the elevation of the points of attachment by increasing the inclination of the truss, diminishes the horizontal effect of its tension. That horizontal force, I have shown, is the only cause of an increased strain of the upper flange.

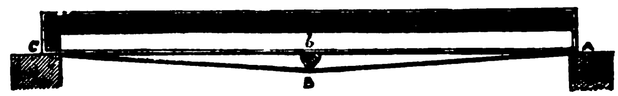

FIG. 4.

If the truss-rods were attached at the *under* side of the beam at A and C, fig. 4, the following result would follow. The points A C, being in the part of the beam which suffers *extension* by deflection, the requisite strain of the trusses would be greater by the displacement of A and B than if those points were in the part of the beam which suffers *compression*, because the strain of the trusses is diminished by the points of attachment to the beam approaching each other on its deflection. Their displacement is nearly horizontal. By varying the depth of $b$ B, the strain of the truss must be adjusted so as to insure its requisite tension. Probably for this purpose the inclination of the truss would have to be not very different from that in Mr. Fairbairn's experiments.

One most important point with respect to the use of truss-rods is, the form of section of the beams to which they are attached. A common, nearly universal, error is, to suppose that the form of section should be as in simple beams. But instead of the section being as at $a'\ b'$, fig. 1, with the largest flange downwards, it ought to be as at $d\ a'$, fig. 4, with the position of the section reversed, and the *largest flange uppermost*. The office of the tie-rods is to strengthen the lower side of a cast-iron beam, or to give it the strength which in a simple beam is obtained by an excess of material in the lower flange. The ratio of the areas $a'$ and $d$, fig. 4, would be difficult to compute, but the experiments show that in tie-rods of the strength usually employed, the area of $d$ ought to exceed that of $a'$. Indeed, this proportional excess may be increased *ad libitum* by increasing the strength of the truss-rods.

The following synopsis of the results of Mr. Fairbairn's experiments, which doubtless were carried out with the same skill with which they were evidently devised, fully establishes the foregoing conclusions. The following were the dimensions of the cast-iron beams of the sectional form $a'\ b'$, fig. 1, or $a'\ d$ fig. 4. The wrought-iron trusses, when used, were attached on both sides of the beam:—

| | |
|---|---|
| Length between the supports ... | 4 feet 6 inches. |
| Depth of beam ........................... | 4 inches. |
| Area of larger flange .................. | 1·05 square inch. |
| Area of smaller flange .................. | ·20 square inch. |

| Number of Experiment. | Section. | Breaking Weight in lbs. | Nature of Fracture. | Ultimate Deflection in Inches. |
|---|---|---|---|---|
| 1 | Small flange *downwards*, with truss of ½-inch diameter. | 5,502 | One truss broken by tension. | ·66 |
| 2 | Ditto, truss ¾-inch diameter. | 7,944 | Upper flange broken by compression. | ·988 |
| 3 | Ditto, ditto. | 8,854 | Ditto. | ·79 |
| 4 | Small flange *upwards*, *without* truss. | 5,830 | | 7·86 |
| 5 | Small flange *downwards*, *with* truss of ¾-inch diameter. | 12,316 | Lower flange broken by tension. | 1·06 |
| 6 | Small flange *downwards*, *without* truss. | 3,366 | | ·55 |

Let us first compare Experiments 4 and 5. In the former, we have the simple beam in its usual position; in the latter, the beam is reversed and trussed, and the strength is *more than doubled*. Mr. Fairbairn remarks, that the breaking weight in Experiment 5 would have been still greater if the upper flange had been of increased size. Comparing Experiments 1, 2, and 3, we observe, that where the truss is strong enough to resist fracture when the upper flange is broken by compression, there is a great gain of strength. Comparing 1, 2, 3, and 5, we find that the reversal of the position of the *trussed* beam greatly increased its strength. If we compare the ultimate deflections in Experiments 4 and 5, the advantage of the trussed beam properly placed appears still more strikingly, for it appears that its rigidity, measured by the ultimate deflection is between seven and eight times that of the common beam.

These experiments, then, seem to fairly lead to the conclusion, that most important advantages result from the use of the truss, and that the largest section of the beam ought to be uppermost.

Another striking view of strength of the trussed beams is, that they are much stronger than *wrought-iron tubular beams* containing the same quantity of material. In page 107 we have for the strength of the latter the following formula, which Mr. Fairbairn states that the experiments on them warrant—

$$W = \frac{60\,a\,d}{l},$$

where W is the breaking weight in tons, $a$ the area of the bottom flange, $d$ the depth of the beam, and $l$ the distance between the supports. To apply this formula to beams of similar dimension to those operated on in the preceding experiments, we must have $l = 54$ inches, $d = 4$ inches, and $a = 1{\cdot}05$ square inch, which is the dimension of the largest flange in the preceding experiments. It is to be observed, that in the tubular beams the area of the top flange is required to be much greater in proportion to that of the bottom flange than in the cast-iron beams; so that the quantity of metal required in the wrought-iron beams, in order to give the strength indicated by the formula, would be more than in these cast-iron beams. Applying the formula, however, we find $W = 60 \times 4 \times 1{\cdot}05 \div 54$ tons $= 4\frac{2}{3}$ tons $= 10{,}452$ lb.; whereas the strength of the trussed cast-iron beam, properly placed, was 12,316 lb. *Hence the cast-iron beam trussed appears stronger by more than* 15 *per cent. of its strength than the wrought-iron beam*; and this comparison is more favourable than it ought to be for the wrought-iron beam, for the material in it required for the computed strength has been under-estimated; and besides, the cast-iron beam appears, from Experiment 7, not to have been proportioned so as to have its maximum strength.

In an ensuing paper, I purpose to resume this subject, and to consider some of the properties of Trellis Girders, respecting which Mr. Fairbairn's experiments have elicited results as interesting and valuable as those above considered.

## THE COMMISSIONERS OF SEWERS AND THE GENERAL BOARD OF HEALTH.

Sir—Your readers are probably aware that the General Board of Health have succeeded in extending their usual system of obstruction to the operations of the Metropolitan Commission of Sewers. On the 27th February, the Commissioners received a communication from the Home Secretary, of which the following is a copy:—

"*Whitehall, February 18th.*

"Gentlemen—I am directed by Viscount Palmerston to transmit to you the inclosed copy of a letter from Mr. F. O. Ward, relative to the comparative advantages of the system of drainage adopted by the Commissioners of Sewers and the Board of Health, and I am to state, that in his Lordship's opinion, the system of drainage recommended by the Board of Health is that which ought to be adopted, as combining the greatest degree of efficiency with the greatest degree of economy.

"Henry Fitzroy."

This extraordinary missive left the Commissioners, as honourable men, no alternative but to resign their office as Commissioners, and not submit to have a most erroneous and most pernicious system of operation thrust down their throats by the indirect influence of a mere Pecksniff.

I have not been favoured with a copy of Mr. Ward's letter, which has so captivated the Home Secretary. There can be no doubt, however, but it has emanated from Mr. Chadwick, who is to all intents and purposes *the* Board of Health; aided, no doubt, by the more advanced of his apprentices, whom he now designates "Engineering Inspectors."

The Home Secretary must have relied principally upon his own engineering talents in arriving at the above conclusions; for without that make-weight there is only Mr. Chadwick, with some half-dozen apprentices in leading-strings, with the failure of his system at Croydon and several other places, to set against all the engineering talent of the kingdom, both civil and military, with numerous successful drainage operations on the most magnificent scale, as well as many minor successful works.

It may be laid down with something like axiomatic certainty, that there is no branch of engineering science which requires so much consideration as the efficient and permanent drainage of an extensive city—such, for example, as London; and it may also be asserted, that there is no branch of the profession in which the "hand-book system" ought more throughly to be deprecated than in the execution of extensive drainage works. Not only does every town differ from every other town with respect to drainage facilities, but every portion of a large town differs from every portion of the same town so essentially, as to make it absolutely necessary to consider and treat each portion on its own peculiar merits, and in reference to its own facilities.

There can never be a better criterion of quackery in any profession than that of propounding an universal mode of treatment for every possible variety of case, and under every variety of circumstance.

The Chadwickian system of *diminutive pipe-drains* meets every possible case of defective drainage under every variety of circumstance where drainage can be required, in the same manner and with as great success as Parr's Pills and Holloway's Ointment meet the varied cases of disease. Why not therefore dispense with the regular practitioners in both cases, and more especially in this age of boasted economy and unblushing effrontery?

The great peculiarity or leading principle of the Board of Health or Chadwickian system is, that the smaller the drain-pipe the more efficient the drainage. This leading feature of the system has been based upon erroneous formulæ, deduced from very limited and very imperfect experiments. These experiments were also, as a matter of course, made with pure water, but applied to sewage water of every possible degree of fluidity, and containing every variety of obstructing substance.

There are also very peculiar views held by the Board on the subjects of "combined back-drainage," "drainage-water supplies," "imperishable sewers," "distribution of sewer-water by pumping or otherwise, over adjacent lands," &c., and which views are repudiated by the most eminent and most practical men in the engineering profession.

It was certainly a bold stroke of Mr. Chadwick to attempt to foist his crude and ill-considered nostrum upon the Metropolitan Commission of Sewers; but having had such autocratic sway over the local boards in the provincial towns which have the misfortune to be placed under his sway, and being well aware that boldness and unscrupulous pretensions are essential to the success of an empereur—hence the *coup de main* upon the Commission.

It is scarcely possible to conceive of a case which more imperatively calls for a searching investigation by a select committee of the House of Commons than the entire working of the Health of Towns Act, and the manner in which it has been administered by the General and Local Boards, and it is to be hoped that some independent member will move for such a committee at an early period of the session.

C. E.

*** Subjoined is a copy of the letter from Mr. F. O. Ward to the Home Secretary, referred to by our correspondent, and made public subsequent to the receipt of his communication:

"17, *Stratford-place, Oxford-street, Feb.* 17*th.*

"My Lord,—The Commissioners of Sewers and the Board of Health are at issue as to the cheapest and best way of draining houses.

"The Board of Health advocate the drainage of each house block by tubular submain running behind the houses, and receiving the sewage of each by a short tubular branch. They recommend a large reduction of the sizes of drains hitherto employed for the single house drain; they recommend a 4-inch pipe for the submain receiving several of these; a 6, gradually expanding to 9·12, and so on up to 20, as the lengths of the submain and the number of branches received by it increase; such drains, they say, are self-scouring, the run of water through them is so concentrated that it keeps them clear of deposit; the branches being very short, and running backwards towards the drain behind, instead o forward beneath the houses towards a sewer in the street, have a quicker fall, and, in case of leakage, leak into the open air, not into the houses, while the cost is so much reduced by this method that blocks of labourers' houses may be thoroughly drained and fitted with sinks and soil-pans for an improvement-rate of less than 2*d*. per house per week.

"The Commissioners of Sewers, on the contrary, recommend large brick sewers under the street in front of the houses, beneath each of which they carry a long drain from back to front, strictly forbidding more than two houses being relieved by one pipe drain; a system which whether otherwise good or not, certainly entails an enormous increase of expense on the houseowners, and thereby redoubles the resistance on their part to sanitary improvement.

"The Commissioners of Sewers lay great stress on the independence secured by their system to each houseowner, whose premises are traversed by his own drain only, which he may take care of or neglect as he pleases, as its stoppage can only injure himself. They allege against the Board of Health plan, that it trespasses on private property, that any stoppage of the tubular submain exposes all the houses higher up to suffer, and renders it necessary for workmen to enter private back yards to search out and remedy the evil. They also deny the self-scouring property of the tubular submains, and refer in support of their view to several hundred cases of stoppages in tubular drains, collected in a report of Mr. Bazalgette.

"The Board of Health, on the other hand, declare the householders' pretended independence on this plan to be illusory, seeing that the big-street sewer is nine times in ten an elongated cesspool, where the sewage of each stagnates to the detriment of all, while the stoppage of a branch drain running beneath a house on the old plan often causes stench in the houses on either side. Against the inconvenience of an occasional invasion of the back-yards by workmen, they set the greater inconvenience of periodical invasions of the street and stoppage of the traffic, besides tearing up of kitchen floors to get at foul drains under the houses. In reply to Bazalgette's report, they bring forward examples by hundreds of pipe sewers working admirably year after year, and attribute such stoppages as have occurred to errors incidental to the first introduction of a new system—errors which, once known, may be avoided. Among these they cite the use at first starting of drain pipes which were too thin, so that they broke under the pressure of superincumbent earth, the uneven laying and careless jointing of pipes by the jobbing builders often employed (as in some parts of Croydon) on this work, the use of soil pans with ducts as large as the pipe drains to which they led, and, above all, the often scanty and intermittent supply of water to the system. They further point out that a population accustomed to open privies and cesspools, available as receptacles for solid refuse of every kind (refuse properly due to the ashpit), have to go through a transitional period of a few weeks, while they are learning that such practice leads to stoppage of the new circulating system, and must be abolished along with the old stagnant cesspols. They say that many of the tubular sewers put down as failures in Bazalgette's report, are at this moment working perfectly well, for which reason they take all his allegations with very great reserve. They point with some reason to Lambeth-square, New-cut, where the Commissioners have allowed 32 houses to be drained by four tubular dack drains, which act perfectly well, quite as well as 32 separate drains could act, though these would have cost eight times as much; and they ask, why this eightfold cost should be imposed upon London at large by the very same authority which sanctioned in this square the combined drainage, which is found to work well?

"The controversy is of immense importance, but I forbear further trespass to-day on your lordship's time."

"F. O. Ward."

## DRAINAGE AND WATER SUPPLY.*

In our numbers for February and March of last year, we published the cost of the private and public works of drainage and sewers in Rugby, Sandgate, Tottenham, St. Thomas's, Exeter, and Barnard Castle. We now give an abstract of the valuable report of Mr. Bazalgette to the Metropolitan Commissioners of Sewers, which from the great experience of that gentleman contains much that is of universal interest and conclusive upon many points connected with the theory and practice of effectual drainage and water supply.

Pursuant to instructions received from the Commission, Mr. Bazalgette proceeded to the five places named in our title, for the purpose of reporting upon the applicability of the systems of pipe drainage and water supply therein adopted, to the metropolis.

He states that the result of his inquiries and observations on the application of the tubular system of drainage in these five places affords no proof of its applicability to the metropolis, and no evidence of the cheapness and efficiency of the works at those five places, which should entitle the system to serious attention with reference to the works to be undertaken for drainage in London. In fact, the great difference of circumstances as affecting the drainage of a small country town and the metropolis, in respect of levels, weight of buildings, traffic and trade, quantities of drainage, and the distance it has to be conveyed, the cost of works, inconvenience of obstructions, depths of sewers, nature of soil, conditions of pavements, compensation for loss of trade, &c., payments to gas and water companies for protecting their mains, and various other sources of expense, scarcely leaves room for the comparison of the drainage and the cost of the two.

The conditions under which pipe sewers are and are not applicable, are—1. That, as a general rule, pipe sewers are not adapted to receive the surface drainage from those roads and streets upon which there is any considerable amount of traffic. If there be little or no traffic, there will be proportionately little refuse dropped upon them, and proportionately little detritus produced by wear and tear, to be washed by rains into the sewers; and if the surface be paved, there will be less road drift washed into the sewers than there would be from macadamised roads. 2. That pipe sewers are not fitted to receive both house and subsoil drainage. 3. That they require to have a considerable supply of water almost constantly passing through them. 4. That they require, under all circumstances, comparatively steep falls, and to be very carefully laid. 5. That they require to be sufficiently large to compensate for any slight settlement or irregularity in laying, and to admit of the passage of many of those innumerable substances which find their way into them, and which are now recorded "as having caused their obstruction and failure."

The places where all these requirements are obtainable, even in country towns and villages, are not very numerous; and the absence of some or all of them, in various instances, must considerably curtail the application, over any large area, of pipe sewers exclusively.

It is worthy of attention that a stoppage may exist in one part of a pipe whilst it is clear at a short distance further on; and that, in a porous soil, a stoppage in a pipe sewer may exist for a very long time without flooding the houses connected with the sewer, because the pressure of the sewage forces the clay out of the joints, which then become open, and the sewage oozes away through them into the soil. It is true that in such cases the houses escape being flooded, but it is only because the pipe sewer becomes a permeable elongated cesspool, attended with all the evils which have been so forcibly represented as attaching to the cesspool system.

In consideration of the number and variety of causes of stoppages in pipe sewers, a system so extremely liable to failure should be adopted with caution, and to a limited extent only. Thus, for instance, whilst an error in levels or a settlement in the ground to the extent of 3 inches would cause the choking up of half the area of a 6-inch pipe, it would only cause deposit to a quarter of the depth of a 12-inch pipe, and would be scarcely perceptible in the invert of a large brick sewer. Sewers are, moreover, required to carry off many solid substances, and if these are excluded by contracting the inlets to the drains, obstructions and floodings of the surface increase proportionately, and, to a similar extent, the sewers cease to remove the town refuse.

Economy has been urged in favour of the adoption of the tubular system in preference to the construction of large brick sewers. Upon this part of the question it is only necessary here to observe, that as an improved water supply is essential to keep a system of pipe sewers clear, the cost of the water supply must be considered in connection with that of the sewers; and, as pipe sewers do not provide for surface or subsoil drainage, together with house drainage, their cost must not be taken as the total cost of the entire drainage of a town. There must be added the cost both of constructing, and of maintaining, and repairing the surface and subsoil drains, without which the drainage of the town is manifestly incomplete.

### Rugby Drainage.

Rugby contains a population of about 8000, and about 1100 houses. The town rises with considerable inclination from the river Avon, which is the outfall for its drainage.

The town was originally provided with brick sewers, which are still in use, to carry off the surface and subsoil drainage; the house drainage having been generally conveyed into cesspools.

* 'Report upon the Drainage and Water Supply of Rugby, Sandgate, Tottenham, St. Thomas's, Exeter, and Barnard Castle.' By J. W. Bazalgette, Esq. Engineer to the Metropolitan Commission of Sewers. Published by Authority: 1854.

The completion of the public sewers may be considered, practically, the commencement of the drainage of the town.

The construction of private sewers and drains, and the laying on of water to the houses, are executed by the owners of the houses at their own cost, either voluntarily, or under compulsory powers enforced by the Local Board of Health as opportunity offers.

The private sewers and drains are composed of stoneware socket pipes, of London manufacture, the joints of which are formed in clay, it having been found that cement is liable to produce stoppages in the house drains by projecting and hardening inside the pipe.

The public sewers are laid at an average depth of about 8 feet. They vary from 6 to 22 inches in diameter. The private sewers and drains generally vary from 4 to 6 inches in diameter. The inclinations of the public sewers are upon the average remarkably favourable, being about 1 in 50 or 60. The best inclination is 1 in 19, and the worst 1 in 324. The inclinations for the private sewers and house drains are generally steeper, not less than 1 in 60.

The pipes have been laid down generally in the public thoroughfares; the road drainage is carried off mainly by the old brick sewers originally constructed in the town for that purpose. One of the branch sewers, which is laid at an inclination of 1 in 200, now receives as many as five gullies.

Wherever the road drainage is brought into sewers, it is certain that no description of gully or trap will suffice to prevent the road drift, whilst held in suspension in the water, from being carried into the sewer, afterwards accumulating in it, and ultimately becoming a source of inconvenience and expense.

The ventilation of the sewers has been effected where practicable by the connection of the rain-water pipes from the roofs with the sewers.

The water supply is obtained from the drainage of a gravel bed about a mile from the town. The present quantity supplied has, however, been found insufficient for the requirements of the town, and additional channels for collecting the water from a more extended area are about to be constructed. The water at present collected is conveyed by stoneware pipes, 7 inches in diameter, into a reservoir capable of containing about 200,000 gallons. An engine of 10-horse power is employed to raise it to a height of 110 feet, into an upper reservoir capable of holding 50,000 gallons; but a duplicate engine is still required, and will have to be provided to secure the certainty of the water supply at all times. The quantity of water now passed through the sewers is about 80,000 gallons per day.

The water is laid on upon the principle of constant supply; and the water pipes are laid at a depth of not less than 16 inches below the surface.

The cost of the water supply has been about 10,000*l*., exclusive of the extension now proposed, or the additional engine alluded to. That of the public sewers has been about 5000*l*. In these two sums are included the engineer's charges, 1090*l*., but they do not include the cost of the preliminary inquiry and report. The cost of the town survey, 814*l*., is not yet paid. The cost of the private works, including the laying on of water and destruction of the cesspools, has varied from 5*l*. to 50*l*. per house, according to the length of sewer and drain required to be constructed by the owner.

At an average of 8*l*. per house, the estimate would stand thus:

| | |
|---|---|
| Present water works | £10,000 |
| Public pipe sewers | 5000 |
| Private works | 8800 |
| Additional engine and extension of water works, say | 1200 |
| Total | £25,000 |

The cost of pumping is about 200*l*. per annum.

The cost of earthwork for laying the sewers, including the removal and relaying of the pavements, and all other incidental expenses, has been about 1*d*. per foot run for every foot in depth, or 10*d*. per foot lineal for a sewer laid 10 feet deep; which sum would not cover the cost of merely repairing the streets over such a work in London.

### Sandgate Drainage.

Sandgate is situated in a bay upon the sea coast, about a mile and a half west of Folkestone. It stands mainly upon a single line of road, running parallel with, and close to, the sea shore, at the foot of a range of hills, which rise precipitously from the sea, and prevent the extension of the houses excepting along the line of the shore. The beach, as well as the subsoil of the village, consists of shingle. The place contains at the present time about 330 houses, and a population of about 1400, which latter is considerably increased during the summer months by visitors for sea bathing, upon whom the village is mainly dependent for its support. From its position, resting upon a sea beach shingle, it required but little artificial drainage, all liquids percolating rapidly through the shingle into the sea. The present surface drainage has long existed in the shape of a few covered drains and open cuts, which admit of the rapid discharge of surface waters to the beach.

The private sewers and drains have been laid as much as possible in the public ways; and separate drainage for the houses has been adopted in preference to combined drainage, because it was found to be very difficult to get the owners of property to agree to carry out the latter, and the system of draining the houses separately was in general more satisfactory in the result. The sizes of the public sewers vary from 6 to 12 inches diameter, and their inclinations from 1 in 6 to 1 in 320. The surface drainage of the roads has not been admitted into the pipe sewers. The rain water from the roofs of houses is generally admitted as tending to cleanse the pipes. The pipes are of stoneware with sockets, from London, the joints of which are made of clay. The depth of the sewers averages from 5 to 6 feet below the surface. The public sewers consist chiefly of four lengths of pipes, forming one line, laid under the north side of the main street. These lengths severally are of 6 inches diameter at the upper end, and increase to 9 inches. They are arranged in two pairs; the lengths of each pair fall from opposite directions and meet at a certain point, whence they discharge through a common outlet, at right angles with them, into the sea. These lengths measure, respectively, 583, 320, 203, and 330 yards. The first portion of the outlet for the first two lengths is a 12-inch stoneware pipe, 73 yards in length: total, 1509 yards of stoneware pipe. The first two lengths discharge through a 12-inch pipe into a large egg-shaped brick reservoir sewer 7 ft. 6 in. by 5 feet, and 60 feet long. The reservoir sewer is below high-water, and stores the sewage for about three hours per day. It is furnished with a flap and iron discharge pipe to low-water. The other two lengths of main line discharge into a separate iron pipe laid at right angles to them, and across the beach to low-water.

The remainder of the public sewers consist of short branches falling with good inclinations into the above four lengths of main line. The general inclination of the main line varies from 1 in 240 to 1 in 320, with the exception of about 253 yards at the eastern end of the eastern length, the inclination of which varies from 1 in 15 to 1 in 25, and of about 118 yards more at an inclination of 1 in 120.

As a proof of the unsuccessful working of pipe sewers, after deducting 253 yards of the pipes, which have a fall of from 1 in 15 to 1 in 25, it appears, that out of the remaining aggregate lengths of main line, amounting to 1256 yards, 816 yards, or about two-thirds of the whole length, have already once failed and been relaid.

When 9-inch pipe sewers are laid, excepting in short lengths and with steep falls, so nice an amount of accuracy in the levels and workmanship is essential to secure efficiency, as to be scarcely attainable in practice; but even if this theoretic perfection should, in the first instance, be attained, the work is liable, afterwards, to be deranged by partial settlements and other unavoidable causes, any one of which is sufficient to produce the failure and inconvenience experienced at Sandgate.

The water supply is obtained by laying rubble stone collecting drains into the sand bed in the range of hills forming the northern boundary of the village, and thus collecting the drainage into two covered reservoirs. The western one is elevated 83 feet above Ordnance datum, and the eastern one 67 feet. Each of these reservoirs is capable of containing about 20,000 gallons.

The supply of water is upon what is termed the "constant supply" system; but there has been so much waste from leaving the taps open, that the surveyor has been obliged to turn off the water from the mains every night for some months past, to give a sufficient supply during the day time, so that, during the night, the houses, having no cisterns, are left entirely without water, instead of having a "constant supply." The drain pipes are laid upon one side of the main road, and the water-supply pipes on the other.

The average cost of the private works has been from 7*l*. to 8*l*.

per house; but, in some few instances, the cost of the drainage alone amounted to seven guineas per house. Taking the average at 7*l.* 10*s.* per house, these works when completed, will amount to 2475*l.* The public works cost,

| | |
|---|---|
| For water supply, about | £2266 |
| And for drainage works | 1000 |
| Total | £3266 |

This sum does not include the cost of the preliminary inquiry (170*l.*), nor the cost of the town survey, which has not yet been charged. But it includes the sum of 213*l.* paid for the previously existing water-supply pipes which are now used, and 100*l.* premium to the owner of the former water supply, and the engineer's charge of 314*l*, the clerk of works' charge of 90*l.*, and the legal expenses. So that the actual cost of these works to the place will amount to somewhat about 6000*l.*, including the survey and preliminary inquiry, but not including the surface or subsoil drainage. The estimate, therefore, will stand thus:—

| | |
|---|---|
| Water supply | £2226 |
| Public sewers | 1000 |
| Private works | 2475 |
| Preliminary inquiry | 170 |
| Survey, say | 89 |
| Total | £6000 |

The contractors' bill for relaying the pipes last year amounted to 77*l.* 13*s.*, being only about 7½*d.* per foot lineal of sewer relaid.

We shall complete the notice of this Report in our next number.

## HYDRAULIC PRESS.

— Dudgeon, *Patentee*, 1852.*

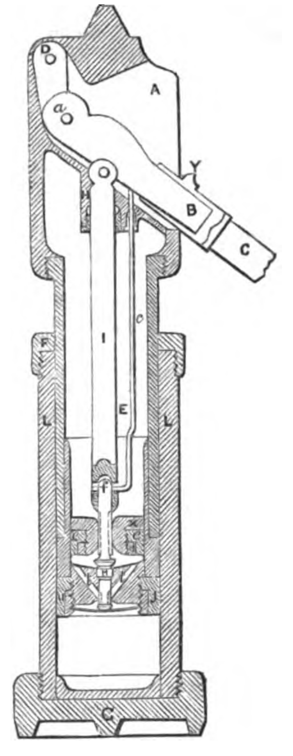
This ingenious and useful apparatus is becoming extensively introduced as a substitute for the old jack-screw. The advantages it possesses are, 1st, Its lightness, which makes it easy for one man to shoulder a press capable of raising ten tons. 2nd, The small power required to work it, every press being arranged so that one man can raise the weight for which the press is calculated. This advantage must be obvious, when we reflect that the friction of the old jack-screw, which is enormous, particularly when the oil has been gummed by cold or dirt, is replaced by the very trifling friction incident to the passage of the fluid in the press through the openings. 3rd, The ease with which heavy bodies may be lowered, which may be effected slowly or rapidly, as desired, by simply touching the relief valve with the working lever. 4th, The convenience of using it in confined situations, where it is difficult or impossible to turn the lever of the screw. To those who are accustomed to the use of the jack-screw, and who are therefore acquainted with its inconveniences, the advantages of this press will be evident.

The inventor has proposed to apply the same arrangement to pressing cotton and goods; and indeed he exhibited in the Crystal Palace, New York, a small press of the kind, which appeared to be very convenient, and certainly cheaper than any other form of press with which we are acquainted.

The press, or "jack," shown in the engraving presents a cylindrical appearance; it consists of an outer cylinder, or case, resting on the ground, and an inner cylinder, or ram, surmounted by a boss, in which the working lever is pivoted, and which is placed under the object to be lifted, of course moving up with it. The peculiarity of the arrangement is, that the *pump* is within the hydraulic press. The liquid used is oil, of good quality, which, however, ought occasionally to be renewed; and the ram is made hollow, in order to form a reservoir large enough to contain the oil when the jack is down.

The size of the cylinder (inside) varies from two to eight or more inches, according to the weight for which the press is designed; one of 3½ inches will readily lift 10 tons, and can be worked by one man with greater facility than two men could raise the same weight by a jack-screw.

The ram, with its head, contains just so much oil or other fluid as is requisite to fill the cylinder when the ram is all the way up; and when it is lowered, the fluid returns again to the original cavity upon the small valve *h*, being forced open by the lever. This lever is detached, and may be put in at pleasure; it is shown in the engraving upside down, and the press is in the act of lowering, so that the lever, by being pressed down, has forced open the small valve *h*, by the rod *e*, acting on the piston *f*. When the lever is raised, a small spring under the valve *h*, shuts



it, and arrests the descent of the ram. When the ram is to be raised, the lever is taken off, and put in right side up, or with the projection *y*, downwards; which brings up on the bottom of the slot in which the lever works, and limits its down stroke before it touches the rod *e*. The force pump barrel J, is fitted into the lower end of the ram, and its piston, consisting of top and bottom pieces *x* and *d*, with leather between, is connected by the rod I, to the lever B. The valves *f*, and *h*, have gutters or channels cut in their sides, along which the fluid can pass when the valves are down or open; the piston rod I, is kept in line by passing through the stuffing box H; and the short link D, to which the lever is attached, makes a species of parallel motion. The piston and ram and the cylinder bottom are kept tight by cup leathers, as used in hydraulic presses. The action of the pump will be readily seen by reference to the cut. When the ram and piston are both down, both valves are seated. On moving the piston up, the liquid above presses open the valve *f*, and flows into the cavity under the piston as it ascends. When the lever is again moved down, this same liquid shuts the valve *f*, and opens *h*, flowing beneath the ram, and raising it. This jack may be used either vertically or at any angle with the horizontal line. The head must, however, be slightly raised, to induce the fluid to pass the valves.

## DWELLING-HOUSE IN COBOURG.

(*With an Engraving, Plate* XVI.)

This house is intended for the occupation of a person engaged in business, and his family, and is arranged with all necessary conveniences. The arrangements for lighting are so managed as to give sufficient light in the interior of the building, where most of the living rooms and domestic offices are situated, and which are so managed that they can be made to communicate with each as the occupants may desire. The entrance to the cellars is under the main staircase.

The exterior of the building is made to break the lines of the masonry and windows by means of a tower which gives access to the garden, and likewise gives it the character of a villa residence. The decorations are of a modern character and of various styles, the blending of which, it is considered by the architect, is the proper mode of following the tendencies of the present day towards the creation of a new style, and calculated to produce a pleasing effect.

The masonry of the exterior walls is in rubble, with sandstone dressings. Brick courses are introduced for variety. The tower and windows are dressed with sandstone, and the window sills are of burnt clay. The roof is of brick.

The cost of the building was 13,000 thalers, or 2160*l.* It is erected from the designs of Hofbaumeister Scherzer.

* From the 'Journal of the Franklin Institute.'

ELEVATION OF GARDEN FRONT OF DWELLING HOUSE AT COBURG.

J. R. Jobbins.

## ON THE FRENCH AND OTHER METHODS OF CONSTRUCTING IRON FLOORS.

The discussion on the above subject, which had already occupied the attention of the three previous meetings of the Royal Institute of British Architects (see *Journal, ante* pp. 54, 90), was resumed on February 20th by Mr. C. C. Nelson, Hon. Sec., reading the following communication from Mr. H. J. Stevens, of Derby:—

"I beg to offer the following information as to the nature of the floors to which Mr. Garling alluded during the discussion at the Institute on the 6th February. Gypsum or plaster, from the quarries near Derby and parts of Nottinghamshire, is very extensively used for chamber flooring in this district, and its durability, when properly prepared and laid down, fully equals what Mr. Garling asserted. The coarsest description of gypsum is used, and after calcination is broken down with wooden flails. It is kept in a dry state, and when laid is mixed with water to the consistence of rough mortar, and spread over the wood joists on reeds or laths to a uniform thickness of 2 inches to 2½ inches. It hardens very rapidly, and the workmen use a long float of wood for levelling it, and on the second or third day it is polished off with boulder stones or trowels. It is desirable that the surface should not be broken by using the floors too soon after they are laid; it is also usual to give an increased hardness by a coat of linseed oil, and in Nottinghamshire the floors are painted, and look extremely well. Two sides of the room have wood fillets laid down, varying in thickness with the superficies of the floor, which being removed immediately after it is laid, allow for the expansion, which is not only very considerable, but continues for some time. Floors of this material are very strong, and are extremely well suited for cottages, being in this district much cheaper than inch white deal—*2s. 3d.* to *2s. 9d.* per superficial yard is the builder's price for laying them down, including reeds, laths for securing the reeds, and plaster. The under surfaces of the joists are edged, and sometimes planed, and the ceiling is formed by the plastering of the reeds between the floor timbers, for which an extra *3d.* per yard is sufficient. These floors are to a certain extent fireproof, and having a smooth surface are easily cleaned, and afford no harbour for vermin; on these accounts, as well as for their cheapness and durability, plaster floors, as they are called, are almost invariably adopted in the Midland Counties, where the carriage of the material does not operate as an objection. Mr. Garling is wrong as to the *finer quality* being laid over the coarser material. I believe what is herein stated will give you the detail of the process, and I have only further to observe, that it admits of being burnt over again, and it is considered desirable that a certain proportion of old plaster should be mixed with the new; when that is the case the floors are found to set harder. I have seen this coarse flooring plaster used externally as pane work in half-timbered construction, and believe it to have been two or three hundred years since it was worked into the building. I offer these observations for the information of the members of the Institute, as there does not appear to be a clear notion of the uses to which the gypsum of this neighbourhood has been applied for many centuries. It is not improbable that the material may be adopted for flooring in connection with a system of fireproof construction, and it might be desirable for some of our scientific members to examine and analyse its composition. I am disposed to disagree with Mr. Christopher as to the extra expense necessarily incurred by the adoption of Fox and Barrett's system of fireproof construction, but I have no doubt that Mr. Barrett will easily bring proofs that neither extra foundations nor hoop-iron bond are required; that the hoisting, &c. are included in his statement of *cost*, and that wood filleting for carpets cannot be necessary where a boarded surface is added."

Mr. T. H. Wyatt having before expressed a strong opinion in favour of Messrs. Fox and Barrett's system, was anxious that it should not be supposed that he had adopted it without mature consideration. He had heard with much surprise and pain the strong remarks of Mr. Christopher objecting to this system, for he could not but remember that his own attention had been first directed to the patent by a pamphlet of Mr. Christopher's published in 1848, which eulogised the system in a manner, compared with which, any praise which he (Mr. Wyatt) had given to it was as cold as possible. Certainly, his own experience, together with that of his friends, Mr. Salvin, Mr. Clarke, Mr. Rhode Hawkins, and others, who had used it largely, justified the opinions he had already expressed. He himself had never used it for roofs, neither had he used cement floors; and he was strongly of opinion that the failures which Mr. Christopher referred to had arisen from an injudicious application of the system rather than from any inherent defect. A principal objection raised by Mr. Christopher was the want of a good key for the ceilings; but having used the system successfully in four or five large buildings, especially in the Wiltshire Lunatic Asylum, where, from the constant vibration in the refractory cells and in the corridors, the ceilings were subjected to the severest test, he felt convinced that any failure elsewhere must have proceeded from bad workmanship, and in this opinion he was confirmed by the friends already mentioned. With respect to the time necessary for the drying of the concrete, he thought it rather desirable than otherwise that a check should be given to the rapidity with which buildings are now carried up; and in his own practice he had not found the difficulty to exist with a proper supply of air and provision of fireplaces, which did not exist in one of the buildings erected by Mr. Christopher. Mr. Christopher, in his pamphlet, had thus described the excellence of the ceilings at "Northwoods":—"The ceilings are finished, and appear as usual, but equalling the best, as they remain for fifteen years without a crack!" Mr. Christopher had objected to the solidity of the patent floors, as interfering with the supply of air to the fireplaces. He (Mr. Wyatt) thought it was much better to depend upon an artificial supply of air than upon that which came through the interstices of the floor bringing dust with it; and the objection, if any, applied equally to a good wooden floor, properly tongued and pugged. On the question of cost, Mr. Christopher had now given an opinion directly at variance with that expressed in his pamphlet, in pages 3 and 7 of which he stated that "Buildings may now be constructed fireproof without increasing the cost of erection; the above *grand desideratum* in the art of building is now no longer *theoretical*, but a fact supported by just such testimony as could be desired—viz., the existence of a building on a large scale erected throughout in the manner referred to, *which has not cost more* than if it had been constructed in the ordinary way. The roofs—at from one-half to one-third the cost of the usual roof.—*Economical*, rather less costly in first construction, and *much* less in use, from being *indestructible*." As he (Mr. Wyatt) had before mentioned, the adoption of Fox and Barrett's system in the Wilts Lunatic Asylum had not involved the expenditure of an additional shilling beyond the original estimates. He certainly could not suppose that any extra strength in the foundations was necessary in this system. The only difference in the weight sustained by them, as compared with a case where ordinary floors were used, would amount to four hundred weight on the square foot in a building of five stories; and no prudent architect would make foundations so weak that they could not sustain so small an extra weight as this, a tithe of the crushing weight. In his pamphlet, Mr. Christopher had expressed a very different opinion, and stated, that "the requisite strength is fully developed by combination and perfect union, giving equally sustained solidity to every part, while from the lightness of the floors and roofs, and their being quite level (without lateral thrusts), the inclosing walls need not be thicker than usual." For the same reason, he (Mr. Wyatt) did not conceive the use of an extra quantity of hoop-iron bonding at all necessary. In the case of the Thames Chambers referred to by Mr. Christopher, the nature of the locality might have suggested this precaution, which under ordinary circumstances was unnecessary. The objection raised as to the expense of cutting and trimming joists to suit openings and chimney-breasts, bore rather hardly upon the system, especially as the patentees took great pains to prepare their joists and girders accurately. Generally, Mr. Christopher had been very severe upon the estimates of Mr. Barrett. He (Mr. Wyatt) had not gone minutely into those estimates, but he had sent them to a surveyor in whom he could place confidence, who stated that they were perfectly honest, and applicable to the present time. It was not fair to compare this system with a wooden floor, as it should rather be compared with the French or some other kind of fireproof flooring, and if that were done, he believed the result would be in its favour. After a long discussion on the subject, the Institution of Civil Engineers had approved of the plan, the Inspectors of Prisons and the Official Referees had also treated it as a satisfactory and efficient fireproof construction; and he had himself found it to answer all his expectations. Whether this system or the French system should be considered preferable, one important point suggested itself in the present discussion, namely, that a very heavy responsibility would rest upon them and their successors as architects, if they should disregard the fact that there were systems known by which essentially fireproof construction could be attained with very little extra expense; and it was their duty therefore to test these systems as severely as possible, and to employ one of them whenever they had the opportunity of doing so. Some of the rooms in the Wiltshire Lunatic Asylum were 16 feet and 18 feet by 24 feet; the corridors being 150 feet by 12 feet. The rigidity of the floors was remarkable, and the only doubt which ever arose in his mind had been caused by the appearance of a dark line on the ceiling immediately under each joist. This he had thought proceeded from some chemical action, but it had been entirely removed by the second coat of lime whiting.

Mr. Papworth referred to the letter of Mr. Stevens of Derby, and inquired what amount of space in proportion to the whole superficies should be left around a plaster surface to allow of its expansion. His own experience suggested that 1½ inch on every side of a floor for every 10 superficial feet would not be too much.

Mr. Wyatt concurred in this opinion, and referred to a loft at the seat of Lord Cardigan in Northamptonshire, where the walls had bulged from the expansion of a plaster floor, although a space had been left originally to provide for this occurrence.

Mr. Inman (the Chairman) stated that floors of plaster, sometimes mixed with coal ashes, were in general use in large mansions in the vicinity of London about eighty or a hundred years ago. This was the case in some of the upper floors at Hampton Court Palace, where a layer of cockle-shells about 2 inches in thickness was also introduced in the floors, for the purpose of deadening sound.

Mr. Boulnois observed, that in his experience of Fox and Barrett's system he had never found the ceilings give way, though he had employed plaster of Paris to gauge them. From his remarks at a former meeting, it might have been supposed that he disapproved of this system, but on the contrary, he thought it an admirable system, and by far the best mode of fireproofing ever introduced. One great advantage which it possessed was that of economising height, which was a point of the greatest importance in London. With respect to Mr. Christopher's opinions as expressed in his pamphlet, and those which he had now put forth, it should be remembered that that gentleman had in the first instance been led to publish his opinions without having had any actual practical experience of the system. This experience he had since had, and, as the meeting knew, it had proved unfortunate to him, inasmuch as he had been subjected to an action at law and other difficulties. He (Mr. Boulnois) therefore contended, that it was the duty of the patentees to ascertain and remove all such difficulties and defects as Mr. Christopher had met with in his practice, and not to allow the task to devolve on the architect employing their system of flooring.

Mr. H. H. Burnell contended that the French system presented greater economy of space than the English, and that the latter was very defective in respect to its giving no key for the ceiling.

Mr. Wyatt said he had no doubt that Mr. Christopher had written his pamphlet, 'Notes of a Visit to Northwoods,' with the most perfect conscientiousness, but after expressing himself so very strongly in favour of the system there used, and leading others to adopt it, he of all persons should have dealt as leniently as possible with any defects to which it might be liable. For himself he had found that the system fully justified the praise which Mr. Christopher *originally* bestowed upon it.

Mr. Christopher reminded the members that at the commencement of his former remarks he had stated that he thought very highly of Messrs. Fox and Barrett's system. He had made minute inquiries of Dr. Fox, of his architect, and of the workmen at Northwoods, and was led to express his opinion very strongly in the pamphlet quoted by Mr. Wyatt; and he still thought that for all practical purposes this system, from its economy, was superior to any other for fireproof construction. He was therefore gratified to find, that Mr. Wyatt, after his extensive experience, did not think the warm approval which he (Mr. Christopher) had formerly expressed in any respect overcharged. On reading the remarks which he had made at the last meeting, he confessed they appeared rather strong, and he should be sorry if they were to injure the patentee. Still, however, after four or five years' experience, he had found imperfections in the system which had occasioned him much annoyance and loss, and he felt bound to caution his professional brethren on the subject. These, it was true, were comparatively *little* defects, and he did not wish to magnify them. He was not desirous to retract any of his former remarks, as he believed them to be strictly correct, with the exception of an obvious error of 1*l.* for fillets to a boarded floor in the estimate for a room 20 × 20 feet. Mr. Beck, in reply to an appeal from Mr. Barrett, had stated that he did not think it necessary to make any addition to "the footings of the walls" for this system; but what he (Mr. Christopher) considered necessary was to increase the "foundations," a distinction recognised in the Building Act and by other authorities. It was essential to be very careful with the foundations where this system was employed, especially if a rigid material like Portland cement were to be used for the floors. Hoop-iron bonding he considered necessary, as in the patent system there was no provision for a tie, and no substitute for the timber plates used in ordinary construction. Again, the play of the iron joists before the concrete was filled in was objectionable, and liable to loosen the green brickwork; and it had obliged him to take out the arches over openings and substitute stout iron lintels. He had not ventured to offer the remarks he had made in any case from the result of *one or two failures only*, and in all cases first-rate builders had been employed by him, and no expense or pains had been spared. On the subject of cost he had confined himself to *Mr. Barrett's estimates*, published in the Transactions, and the question was, are those correct, and not what the Wilts Asylum may have cost some years ago, when iron was at less than half its present price. With reference to the question of cost generally, he (Mr. Christopher) should not have entered upon the subject if Mr. Barrett had not endeavoured to show that his fireproof floors could *now* be constructed cheaper than ordinary floors of the best kind. Mr. Barrett had made a deduction of *one-half* the cost of the iron from his estimate for "excess of strength," and this deduction was one which he (Mr. Christopher) thought quite unwarranted, because if the strength of the floors were proportionably diminished they would not be safe.

Mr. Wyatt stated, that what Mr. Barrett said was, that he would not like to take the responsibility of the lightness of the French mode of construction, but that a great reduction in his standard of strength might safely be made.

Mr. Christopher repeated that Mr. Barrett's estimates were incorrect; that when he went into the matter with that gentleman they found it impossible to reduce the price to that of an ordinary timber floor, and that the additions made by him to Mr. Barrett's estimate for cutting and trimming joists, the use of the license, &c., were fair and moderate additions. Carefully detailed accounts had been kept of the recent buildings erected under his direction to test the result, and from these he had quoted, but Mr. Wyatt admitted he had not gone into the estimates. Another point that deserved consideration was, that many persons would desire a wooden floor upon the concrete foundation; in that case a considerable extra cost was incurred, and some of the advantages were lost, as the building was less fireproof, the floor afforded a harbour for vermin, and was liable to rot, besides which there was a loss of space. With respect to the roofing, it should be observed, that at Northwoods the concrete roofs were all finished with tarred paper and sand, which had been found successful. The Building Act however precluded the use of these materials in London, and therefore cement *alone* was used, which had failed, as before described. Now, although this question had been discussed chiefly with reference to *floors*, it appeared to him that the *roof* was the most important consideration with respect to fireproofing, as many buildings had been ignited through the roof from fires in adjacent buildings, and certainly if *floors* could be constructed on this principle at the same cost as ordinary floors, *roofs* could be constructed at less than half the ordinary cost.

Mr. Barrett wished first to offer a few remarks in reference to some observations made by Mr. Tite at a former meeting. That gentleman stated that the system of fireproof construction which Mr. Barrett had explained was very similar to one which he (Mr. Tite) had himself used twenty-eight years ago. There were however important differences both in the principle and the cost. In the plan referred to by Mr. Tite the stone landings were merely a modification of the iron girder and brick arch system; they were a dead weight upon the girders, and not an element of strength; while in his own plan the union and combination of the different materials produced a great increase of strength and rigidity, and at a small expense. In the one case these important qualities were derived from the *iron*—a costly material; and in the other from the *concrete*, a very inexpensive one. But the real question was, not whether any of these materials had been previously used in the construction of floors, it was rather whether they had been so arranged and combined as to produce a satisfactory floor of incombustible materials at a cost little, if at all exceeding, that of the ordinary timber construction; whether, in fact, it could be said before the introduction of this system (as it had been said by Mr. Wyatt) that a large and important public building had been constructed on a fireproof principle without incurring one shilling additional expense. Reckoning the cost of the 4-inch and 6-inch self-faced stone landings at prices furnished to him by a contractor, viz., 1*s*. 6*d*. and 2*s*. per foot, and assuming the iron to be no heavier than in his own case, the actual cost would be more than double that of his construction; thus—

*Dimensions of Room*, 12 × 12 *feet*.

| | | | |
|---|---|---|---|
| 144 ft.—4-in. landing—at 1*s*. 6*d*. | £10 | 16 | 0 |
| Iron work, as at page 92 | 3 | 15 | 8 |
| Facing surface and forming cement ceiling, 6*d*. ℔ ft. | 3 | 12 | 0 |
| Total | £18 | 3 | 8 |
| Instead of | 7 | 14 | 10 |
| Difference | £10 | 8 | 10 |

*Dimensions of Room*, 20 × 20 *feet*.

| | | | |
|---|---|---|---|
| 400 ft.—6-in. landing—at 2*s*. | £40 | 0 | 0 |
| Iron work, as at page 92 | 21 | 4 | 3 |
| Facing surface, &c. 6*d*. ℔ ft. | 10 | 0 | 0 |
| Total | £71 | 4 | 3 |
| Instead of | 32 | 4 | 3 |
| Difference | £39 | 0 | 0 |

He thought therefore there was sufficient reason for such a system never having come into general use. Mr. Tite had also referred to the decoration of ceilings, but he could not imagine any difficulty whatever to exist on this head, and if none was found in erecting a residence for the highest personage in the realm, there was little probability of its occurring elsewhere. Certainly, any kind of decoration that could be combined with the girder and arch system could, with at least equal facility, be applied to his construction: but upon this point any member present might satisfy himself by inspecting the new offices and station of the Brighton Railway Company at London-bridge, where the system was carried out on a very extensive scale, some of the bearings exceeding 35 feet, and where many of the ceilings were of a highly decorated character. Mr. Tite had also spoken of the possibility of the concrete yielding under the action of fire if it were formed with flints. This material was however never used for the purpose; the concrete being made of fine gravel or ballast, broken brick or tile, burnt earth, and lime. Upon this point he thought an important consideration had been overlooked, viz., the fact that in warehouses where large fires occurred, they were mainly owing to the circumstance that the timber floors themselves afforded both the fuel and ready supply of air to support and extend the fire, which would burn but slowly till it had consumed a portion of the floor, so as to obtain a supply of air. The case however was very different, if instead of a floor being of a highly inflammable nature, it was formed of a solid mass of incombustible materials 12 inches thick, by which the supply both of fuel and of air would be cut off. The fire, generating an atmosphere which will not support combustion, would under such circumstances probably burn itself out. Even supposing any intense degree of heat to be generated, before it could act injuriously on concrete it was probable that it would quite destroy a brick arch, either by disintegration or by the expansion of the arch, and the consequences which might result from the failure of a single arch in a building were fearfully exemplified in the fall of a cotton mill at Oldham some years ago, the replacing of one of the arches which had settled having led to the breaking of the iron beams from the lateral thrust of the adjoining arches, and the sudden and instantaneous destruction of the entire building—a calamity which could never possibly happen with his plan of construction. With regard to the objections raised by Mr. Christopher at the last meeting, there could be no question that Portland cement should never have been applied as a finished covering for roofs, but that gentleman had not stated that he had himself preferred it and introduced it. Indeed, he was the first to erect a roof upon the principle since the completion of the original building, the roofs of which he, "after careful inspection," greatly admired, and described in 1848 as being "marvellously simple and inexpensive while efficacious, being perfectly waterproof, and much more impervious to the variations of temperature than the usual roofs,—those built eight years since being perfect, and the ceilings under them without a stain." Mr. Christopher had adhered strictly to the construction of these roofs, except in that part which in his case had failed, viz., the finished covering, which he had formed of Portland cement instead of tarred paper and sand, the use of which was said to be prohibited by the Metropolitan Buildings Act. It had been intimated by that gentleman that the failure of the cement covering might have been occasioned by the expansion of the concrete; but the fact of its remaining sound for twelve months shows that it could not have arisen from that cause. Concrete does unquestionably expand *in setting*, but not afterwards. Mr. Christopher had moreover told him that the experience of a brother architect showed that when Portland cement was laid on brick arches there was the same uncertainty as to the result. It was however admitted, that metallic lava answered, and he might add, that asphalte, tiles in cement, and slates in cement, had also been applied with perfect success. As a finished surface for floors, Portland cement had answered perfectly in several instances, but it was a very uncertain material, and in those cases where the floors were not to be carpeted or covered, or where a slight superficial defect was of consequence, it would be better to use a cement of another description, such as Keene's, which had been substituted for Portland in a large building lately erected by Mr. Clarke—the Metropolitan Convalescent Asylum—at an additional cost of only 30*l*., and it certainly looked much better. With reference to the ceilings, and the alleged want of a good key having occasioned several falls, Mr. Barrett first observed, that if this really were a radical defect in the system, it admitted of a very simple remedy, for nothing could be easier than to attach the ordinary lath and plaster ceiling by means of light fillets placed parallel with the joists. So far however from the key being defective, he had been assured by practical men, plasterers, and foremen, that the key was a much better one than in the ordinary construction from the greater strength of the laths. He had communicated with several members of the profession who had used the system largely, upon this and other objections stated by Mr. Christopher; amongst them were Mr. Wyatt, who had had from 1400 to 1500 squares of flooring constructed; Mr. Rhode Hawkins, 530 squares; Mr. Brandon, 900 squares; Mr. Clarke, 400 squares; Mr. Salvin, 500 squares; Mr. Holland, 1200 squares; and Mr. Piper, 1400 squares;—in the aggregate several thousand squares; and it was remarkable, that out of so large a quantity no instance should have occurred of a ceiling falling. In Mr. Christopher's case, he believed it to have arisen from his having kept coke fires in the middle of the room, *upon the concrete, for several weeks in succession*, to dry the plastering of the walls, as the portion of ceiling which fell was directly under one of these fires.—The Report of a Committee of Magistrates who visited Northwoods to see the original building was to this effect: "Our attention was first directed to the very beautiful and perfect appearance of the ceilings of the rooms (after fourteen years duration), which are in fact a part of the fireproof floor; these ceilings, even after so long a period, presented a perfectly plane and level surface, and were quite free from cracks;" and Mr. Christopher's own report of this building was, "the ceilings are finished, and appear as usual, but equalling the best, as they remain for fifteen years without a crack!" Mr. Christopher had also stated, in reference to the ceilings of the building, the roof covering of which had failed, "the ceilings were everywhere entirely free from cracks, and decidedly more perfect than in ordinary buildings." In conclusion, Mr. Barrett begged permission to read the following letters from some of the gentlemen he had referred to.

1. *A communication from* Mr. JOSEPH CLARKE:

"I feel I ought to add my testimony to what I consider the full success of your patent, which I have adopted in several important buildings for some years past. I must say that I have not met with a single failure, and certainly on the points of objection which I hear have been raised:—1st. That the adoption of the system involves greater expense in foundations. These I have never considered it necessary to increase in the least; in fact, in one work I am now carrying out on your principle I even reduced the depth, and on a site of which I had a little apprehension.—From the confidence I have in the perfectly horizontal bond and tie given to the walls, I am satisfied that in the Oxford and the Gloucester and Bristol Training Institutions (both stone buildings) I derived much greater advantage than if I had adopted the common mode of timber floors.—2ndly. As regards a greater chance of smoky chimneys, I have been singularly fortunate in all the buildings thus constructed, and I can refer you to the Convalescent Hospital at Walton, where not a single chimney smokes out of nearly fifty, which have been in operation for months, even before the building was complete, that it might be ready for the patients.—As to the 3rd objection, that the ceilings are apt to fall, I have carefully examined many hundred squares executed on your principle, and I do not find the slightest tendency of the kind.—I am so fully convinced of the value of your invention, that I am prepared to recommend it, particularly since the adoption of wrought-iron, for every class of building."

2. *A communication from* Mr. Rhode Hawkins:

"There are three points on which you ask my opinion of the fireproof floors used at the new buildings at Guy's Hospital. 1st. With regard to the necessity of using more solid foundations in consequence of the increased weight of the floors. I have to say, that though your floors are heavy as compared with ordinary wood floors, yet as the weight of the floor is after all but a small portion of the whole weight which a foundation has to carry, I do not think that the extra weight should be considered for a moment. As to the necessity of additional ties to the walls, if the girders and joists are of sufficient strength, the weight will be conveyed directly on to the walls, and resolve itself into a mere crushing force, and ordinary brick walls are competent to carry five or ten times the weight which is generally put upon them.—With regard to the ceilings, I have only to say, that at Guy's Hospital I know of no ceiling having given way; the key seems to me to be a very strong one, and I see no reason to apprehend any accident of the sort. The ceilings have been finished nearly a year and a-half, and are perfectly good now. —With regard to the floors causing smoky chimneys, I have little to say, as I have not tried the plan in an ordinary dwellinghouse. At Guy's Hospital the smoke is carried in a long smoke tube into a lofty shaft where there is a considerable draught, and none of the chimneys smoke; but I must add, that I think that where it is necessary to supply air to the fireplaces, it should be done as a system, and not left to the chances of drawing the air through the floors, and with it a large quantity of dust and dirt."

3. *A communication from* Mr. R. W. Armstrong:

"In reply to your query, whether I deemed it necessary to go to extra expense with the foundations of the buildings in which I introduced your patent fireproof flooring, beyond that which I would have done had I used timber floors, I beg to say, the buildings in which I used your system of flooring being for factory purposes, I considered it expedient to provide foundations sufficient for any emergency, and therefore did not allow the fact of the floors being heavier than timber floors to influence me in any way. As to the broad question for buildings in general, much must depend on the number of floors and the proportion of bearing points to the void or area to be supported on those points, but I think few would venture to erect buildings with timber floors on foundations that would not be equal to the sustaining of the additional weight of floors constructed on your principle, as in my opinion it would be narrowing the point far beyond the limits of practical application. I have not in any instance found it necessary to introduce any additional 'ties' for the floors than that given by the joists."

4. *A communication from* Mr. Thomas Piper:

"The result of my experience with floors constructed on your principle is, that no additional foundations or ties are required beyond what would be requisite and necessary for good building on any principle. That the ceilings are not more liable to fall than ceilings on laths in the ordinary way—indeed, I cannot charge my memory with any instance of a ceiling falling in any of the works carried out on your plan. As to smoky chimneys, they are no novelty unhappily, and though the tendency of the greater accuracy of all building operations is unquestionably to limit the supply of air, and so retard the escape of smoke, I have noticed no difference between what occurs with your floors and a thoroughly good wood floor of the ordinary construction, pugged in the usual way."

5. *A communication from* Mr. Brandon:

"Has never had cause to increase the strength of foundations, or the walls, or ties in the walls. Has never known any defect whatever in the ceilings, except an occasional very minute crack, such as might be found in those of the ordinary construction, perhaps ten or twelve such in a building containing 800 squares, and has never known an instance of chimneys smoking."

Mr. Barrett continued — With regard to the time required for the floors to dry, it depended on the season, but they were always dry as soon as the walls and plastering made it safe or prudent to occupy the building; at some floors lately constructed at Windsor Castle, the rooms were occupied in six weeks from the receipt of the joists. The house in the Adelphi referred to by Mr. Christopher, was begun in April 1850, and though it was a large building containing nearly thirty rooms, and lying close to the river, it was occupied in March 1851, although there had been several delays. The peculiarities of the other building he referred to should have been stated: it was in a hollow, with lofty buildings at the back, two high flank walls, and a narrow mews in front; there was in fact no possibility of establishing a current of air through it, even if its construction had admitted; but the fact was, that out of forty-two rooms, only eighteen had fireplaces, and the twenty-four rooms which were without fireplaces were all so constructed that there could be no current of air through them, and twelve of them were lighted only from the staircase. These circumstances were quite sufficient to account for its taking a longer time than usual to dry. With respect to ventilation and artificial warming, it was quite true that facilities were afforded by the system, if those adopting it would avail themselves of them; but that they were more *necessary* than in the common method was not the fact; and as regarded loss of draught to fires by the floors not affording a supply of air, it struck him that this was rather an advantage than otherwise, as cold draughts to the feet and legs were always objectionable; indeed Mr. Christopher himself had been one of the first to point out this as an advantage of the system. Certainly this had never been complained of by any one else, and numerous inquiries had satisfied him that the complaint had no real existence. In speaking of Northwoods, Mr. Christopher had stated that "regarded simply as a residence, it was most comfortable." And so satisfied were the Metropolitan Association for Improving the Dwellings of the Working Classes with this system of construction, in one of their buildings containing 186 rooms, that the Secretary had written as follows:—

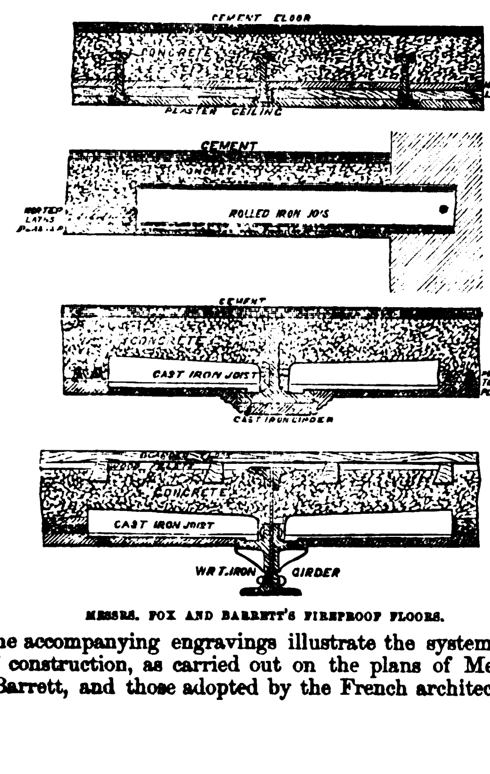
6. *A communication from* Mr. Gatliff, *Secretary Metropolitan Association for Improving the Dwellings of the Industrious Classes.*

"In reply to your inquiry as to the success of your fireproof flooring in the 186 rooms in which it was used by the above Association, I beg to say that an accident not having occurred to test its qualities in that particular, I cannot say more than that from the opinion I have formed, I should recommend its adoption in between 300 and 400 more rooms about to be constructed by this Association in Guy Street, in the Borough of Southwark, and more especially from its being *sound*-proof, which we find a great inconvenience from, in about the same number of rooms in the Old St. Pancras Road."

It was stated in the Ninth Report of the Directors of the above Association, that in the family dwellings above referred to, providing accommodation for sixty families, not a single death had occurred in the course of the preceding year, out of an average population of 300; a circumstance which may be presumed to indicate that the system is not without its advantages as regards the health and comfort of the occupants: and besides the circumstance of the building being fireproof, the Association has found that on certain other points this system of construction possesses advantages which are of much importance in buildings of this character, being "very instrumental in preventing the travelling of sound from floor to floor, of vermin, of offensive smells, and of the filtration of water in case of accident from the overflowing of cisterns or otherwise." These floors had a boarded finished surface. These facts he thought rather indicated that the system was advantageous as regarded the health of the occupants of the buildings, and this could not be said of smoky and ill-ventilated dwellings. The alleged necessity for better foundations and ties, was perhaps best met by the letters already quoted: they were not provided in the five-story building mentioned at the last meeting, nor at the large Hotel at Carlisle, lately erected by Mr. Salvin; and he referred particularly to these two works, because the plans of both were originally prepared for timber floors, and no alterations were made by the introduction of the fireproof system; nor could he find that they had been increased in any instance. In the original building at Northwoods, and many others, no ties whatever were provided. As to the License, although the charge was rather for the information supplied, yet it could easily be shown that it was soon repaid by the saving in the fire-insurance. This saving on the building in the Adelphi was 4*l.* 10*s.* per annum, repaying the charge in less than seven years, and after that time becoming an annual saving to that extent in perpetuity. The charge for cutting and trimming joists was certainly an error, as the castings were not adapted for trimming; the building had been altered during its progress, and some little expense might possibly have been incurred on that ground. The painting of the joists was by no means necessary. Upon the question of cost, Mr. Christopher had stated that the estimates were not to be depended on, and he had given a calculation of his own, making additions, to every one of which he, Mr. Barrett, altogether demurred, and for which he had shown there was no foundation, as they had not been incurred by any other architects. The figures he had originally given (*ante* p. 92), spoke for themselves, and showed the cost with the iron of the strength he usually employed, and also of that used in Paris. He did not however recommend a reduction to their standard, but had stated that some reduction might very safely be made, and he had actually had floors constructed with joists 25 per cent. less in strength than those which formed the basis of his calculations, and with perfectly satisfactory results. He had no doubt whatever that the joists he used were much in excess in point of strength, and he was confirmed in this view by the fact that those of extra strength described in Mr. Burnell's tables as employed at the Louvre (*ante* p. 95) were not so strong as those he had employed for ordinary dwelling-houses. Mr. Christopher's conclusions were therefore altogether erroneous as to the possibility of reducing the strength, and the cost of the iron work fixed Mr. Barrett had actually reckoned at 10*s.* per ton more than the price at which it had been lately undertaken. The cost of the roof, the cement covering of which had failed, was according to Mr. Christopher's own statements as follows:—"The roof with ceilings and cement surface had cost 74*l.*; while an ordinary slated roof with ceiling, would have cost 232*l.*; and a lead roof would have cost 300*l.*" If the cost of an additional covering of metallic lava (40*l.*) were added to the cost of the roof with a cement surface (74*l.*) the total cost would be 114*l.* against 232*l.*, showing a saving of 118*l.* or 3*l.* per square on the quantity of flooring in the building. Mr. Christopher had stated that the object of this discussion was to ascertain the truth, but this could only be done by the *whole* truth being stated, and that Mr. Barrett must contend had not been done in the several objections he had raised.

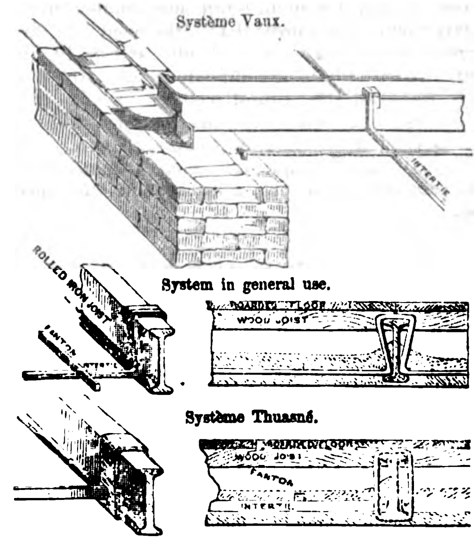
Mr. Scoles inquired whether concrete had been really found to be fireproof, and stated that a large mass which he had put into an ordinary fire had crumbled entirely in less than five minutes.

Mr. Barrett argued that this was not a conclusive test, indeed the plaster slabs mentioned by Mr. Wyatt at a previous meeting would have been destroyed under similar circumstances. It was in evidence that his concrete floors would be protected by the plaster ceiling, and where injury had arisen it was only by the long continued action of fires made for drying the plastering of the walls.



MESSRS. FOX AND BARRETT'S FIREPROOF FLOORS.

[The accompanying engravings illustrate the systems of fireproof construction, as carried out on the plans of Messrs. Fox and Barrett, and those adopted by the French architects, which have been fully described in the papers read by Mr. H. H. Burnell and Mr. Barrett, and in the subsequent somewhat lengthy discussion.]



FRENCH METHODS OF CONSTRUCTING IRON FLOORS.

Mr. Papworth observed that in his opinion no really fireproof floor or roof had yet been mentioned. An Obelisk erected in 1776 on Putney Heath, by order of the Corporation of London, commemorated the satisfaction felt by committees of that body with experiments made in 1776, described in a pamphlet, printed in 1785, and entitled "an account of the invention and use of fire-plates for the security of buildings and ships against fire." The author, Mr. David Hartley, was Member of Parliament for Hull. A reprint with additions by his nephew in 1834, stated that "resistance to every possible degree of fire, such as distillers' shops, or turpentine warehouses, may be accomplished by applying the fire-plates above and below the timbers with dry sand or rubbish between them: in experiments repeatedly tried with this double application, the room was filled from the floor to the ceiling with faggots and pitch and tar. As to common dwelling houses; when the single application of the fire-plates was used in the experimental house, where also air bricks were provided to the floors, the trials were continued from day to day to the same part of the ceiling and timbers of the house a great number of times after the plasterwork was burnt down and destroyed, but the timbers could never be set fire to, so as to burn of themselves, nor could the fire ever spread sideways; as long as the burning faggots were applied to the timbers, they were charred perhaps to the depth of an inch of their substance, but the fire-plates over them acted as an unconquerable extinguisher, preventing them from taking fire and burning of themselves." Rolled copper-plates are specified as well as those of painted iron; tinned or galvanised iron or zinc would be equally applicable. In 1774, the sum of 2500*l.* was voted to the inventor by the House of Commons, and in 1777, the patent was extended for thirty-one years from that time. The experiments he made however, showed that the only way to check a fire was to prevent the access of air; for flame would inevitably calcine such materials as concrete and plaster.

Mr. H. H. Burnell explained, that although violent and long continued heat would destroy the French floors, yet the earthenware pots would be a great impediment to the spread of any moderate fire.

Mr. Tarring said, that in the West of England where concrete or lime-ash floors were much used in common houses, the concrete failed or became rotten in the parts nearest to the fireplace, but when formed of lime mixed with sand and hair, it would last longer in that position than when composed of gravel. Plaster ceilings would resist fire, but cement would not, as that material soon yielded to heat. In old malt-houses in the West of England, with concrete floors 5 to 6 inches in thickness, he had seen the walls though built of stone 2 ft. 6 in. to 3 feet thick, bulged out three to four inches on each side by the expansion of the concrete.

Mr. INMAN (the Chairman) reminded the meeting of the different effect which fire would produce on timber and on metal, from the former being a nonconductor and the latter a conductor of heat. Such effect should be guarded against in a fireproof construction, so that the metal might not conduct the heat to the wood. Experience had shown that in the event of a fire breaking out, the grand object was to get it under within the first quarter of an hour, and to aid in accomplishing this, the Building Act had wisely restricted the cubical contents of each division to be separated by walls in warehouses and similar buildings.

At the suggestion of the Chairman, the vote of thanks was extended to all the Foreign and English gentleman who had furnished remarks upon the subject, and the meeting then adjourned.

NOTE.—Mr. Christopher thinks that the apparent difference in the testimony borne by Mr. Wyatt and by himself in reference to Fox and Barrett's patent may probably be explained by the fact that Mr. Christopher's experience has been almost wholly confined to London, while Mr. Wyatt's appears to have been restricted to the country. In London the frequently disturbed state of the soil and the height of the buildings require *extra foundations*, while the numerous windows, confined to the backs and fronts with small piers of separation, and many difficulties of construction, demand *extra iron* bonds. The long unpierced party walls, the contracted areas at the backs of the houses, and the want of sun in front, retard the drying, while the same causes, coupled with the smallness of the rooms in chambers and dwellings-houses, compared with the large dormitories and corridors in Asylums will, in some measure, explain why the loss of draught to the fires from the absence of hollow floors and partitions is so felt in these solid houses. Mr. Christopher thinks that none of these difficulties would occur at Northwoods, situated in the midst of a park, or to the buildings which Mr. Wyatt, Mr. Clark and others, have superintended in the country. Mr Christopher wishes to state that neither pains nor expense were spared to secure the most perfect execution of the buildings carried up under his superintendence in respect to materials and workmanship.

## PROGRESS OF MECHANICAL SCIENCE.*

WHILE the Mechanical Arts have progressed more rapidly during the present century than during any other, the development of the Science of Mechanics has been by no means co-extensive. The magnificent structures which the present generation have seen commenced and completed—the admirable works of modern engineering which have so largely increased the value of our island for all the economical purposes of life—the beautiful machinery and apparatus by which raw materials are converted, with almost magical transmutations, into delicate fabrics and products wrought with the most refined precision—all the greatest results of modern industry, have been created by mechanical contrivance and experiment, little aided, it must be confessed, by science.

In making this observation, we intend the word *science* to be taken in its true sense—*systematic knowledge.* The word is apt to be much abused. There is scarcely a speculative inventor or enthusiastic patentee who does not arrogate to himself the title of a scientific man. Unless newspaper reporters be fallible, there is never a vessel launched, never a screw propeller receives a fresh twist, never a new fire-escape rescues people from houses not on fire, never a fire-extinguisher subdues a prepared conflagration, but "scientific gentlemen" are present to witness the exploits. Let us not be supposed to underrate these essays. Doubtless, they are often useful and afford valuable suggestions, but it is by a misnomer only that they can be said to be scientific pursuits. The knowledge of experimental facts, however numerous, varied, and subtle, does not constitute science until it become systematic and exact. A man may be acquainted with all the forms of screw propellers which have been ever devised—he may know the measures of all their strange contortions—the names of their sanguine inventors, and, better still, the results of trials of them,—but without method, his knowledge is not science.

We have observed a test, nearly unfailing, which distinguishes merely accumulated knowledge from that methodised knowledge which constitutes science, properly so called. So long as the facts of any subject are undigested and its principles speculative, it is without a *nomenclature.* Vague expressions are applied to the different parts of the subject because the knowledge of it is vague. The so-called "principles" are little better than guesses, and if examined closely will be found to be clothed in a language so loose that they elude the grasp of true philosophy. We smile now at the old adage, "Nature abhors a vacuum;" but have we not similarly figurative adages seriously promulgated at this day respecting various branches of mechanical knowledge—as, for example, the laws of fluid motion? A maxim can have no claim to scientific accuracy so long as it retains the slightest trace of *metaphor.* In the adage just quoted, Nature is metaphorically represented as actuated by dislike. So again, Lagrange slipped in his celebrated proof of the Principle of Virtual Velocities, by representing gravity as an *endeavour.* Again, tomes of unnecessary discussion might have been spared if some old philosophers had not distinguished force into two kinds—living and dead—*vis viva* and *vis mortua*, as they were figuratively termed,—concerning which the controversy was not settled till the metaphor was abandoned. Many like instances are to be found in the early researches of every science. Alchemy and Astrology were full of them: when those pursuits were divested of the slough of metaphor, they became the noble sciences of Chemistry and Astronomy.

But it is not enough that the language of a science be free from figure—it must also be technical; that is, particular words must be devoted to single meanings. For this necessity there are two reasons,—first, in ordinary language inconvenience continually arises from one word having several meanings; and this ambiguity, which in conveying the simple thoughts of every-day life is merely inconvenient, would, in expressing the abstruse results of prolonged investigation, be absolutely fatal to accuracy. Secondly, the language of every-day life, for obvious reasons, frequently affords no means of expressing such results, and the deficiency has to be supplied by the invention of new words. From these considerations, then, it appears very manifest that a precise and methodic nomenclature is generally a test by which knowledge may be distinguished from science.

It is worth while to examine the reasons why mechanical science has made recently so slow progress as compared with the practice of mechanics. The reason cannot be that the tendency of our age is averse from exact philosophical investigation. On the contrary, in many other departments of science the progress of knowledge has never been so rapid as in the present century. The growth of the sciences of chemistry and geology has been almost exclusively confined to the last fifty or sixty years; and, during the same period, astronomy, physical optics, and pure mathematics have received some of their most important developments. But if we turn to the science of practical mechanics, we shall find in most of its branches numerous important problems the solution of which the practical engineer in vain demands of the theoretical philosopher. Who knows how to determine with certainty the proper form of a ship under different conditions of speed and loading? Who can determine completely the strength of an arch or suspension bridge subject to dynamical forces? Who the influence of the motion of steam on its pressure, and the consequent relation between the pressure in the boiler and cylinder of a steam-engine? Who the relation between the resistance to and the velocity of a railway train? Who the internal forces of friction in a deflected beam? Who the effect of a screw propeller of given form and dimensions, and rotating with given angular velocity?

These and many other questions, of which the answers would be most valuable and important additions to the knowledge of practical mechanics, remain for the present not merely unanswered but unanswerable. Take, for instance, the question just suggested respecting the forms of ships. We have not the slightest hesitation in asserting that in the present state of knowledge of the laws of fluid motion, the solution of such a problem, or even the simplest cases of it, is utterly and hopelessly impossible. Yet Nature effected the solution long ago in an infinity of ways. Fish, of divers forms innumerable, dart through the waters without noise or commotion, and direct their courses with an ease and rapidity—and the sea birds breast the waves with a stability and buoyancy—which human craft cannot rival. Nature then teaches us that our efforts fail because they are inadequate, not because they are directed to unattainable objects.

To ascertain why the desiderata of practical mechanics are yet unattained is obviously the first step towards devising new means for their attainment—or at least, towards estimating the probability of their attainment. Let us then see first what kind of advantage science has already afforded to the practical engineer and mechanic. Mechanical science consists of two distinct parts—experimental laws, and methods of applying them deductively. The experimental laws are inferred from a multitude of observed results by a process of induction which eliminates circumstances repugnant to the conditions assumed. For instance, the general

* 'A Treatise on Analytical Statics.' By I. TODHUNTER, M.A., Fellow and Assistant Tutor of St. John's College, Cambridge. Cambridge. 1853. Crown 8vo. pp. 318.
'The Steam Engine for Practical Men.' By JAMES HANN, A.I.C.E., and PLACIDO and JUSTO GENER. London: 1854. 8vo. pp. 240.

laws of equilibrium and motion are essentially founded on simple principles respecting action and reaction inferred from experiment, but not actually obtained from it, because nature presents no example of complete rigidity and complete equilibrium. These principles are so simple as to appear mere truisms, and yet so fertile that on them are based those magnificent systems of investigation—Statics and Dynamics. But the fertility of these principles, great as it is, is not unlimited, and moreover they are inferred, as we have said, by the abstraction of various extraneous circumstances. Consequently, the systems of Statics and Dynamics are limited two ways—first, they may require the abstraction of circumstances too important to be negligible; secondly, even with all the assistance which such abstraction affords, these systems may be insufficient for the solution of complicated problems.

Now, both these cases occur in practical mechanics. It is continually requisite, on the one hand, to consider molecular forces and displacements which Statics and Dynamics originally neglected; on the other hand, it is requisite to investigate the operation of forces of which the number alone affords an insuperable difficulty to their investigation, by the fundamental principles of mechanics. What course, then, is open for the remedy of the deficiencies in question? Clearly the extension of the science must depend on the establishing new experimental laws, or the improvement of the methods of applying them. The latter task belongs to the mathematician; it is the former which belongs to the experimental philosopher, and with which we are here chiefly concerned—for here, as we apprehend, is the great defect in our efforts to advance mechanical science.

Is there not, then, it will be asked, sufficient zeal for experimental research? There is doubtless much zeal, but it is not guided by adequate knowledge. Mechanical experiments are almost universally made to test directly the value of some invention, or to ascertain the powers of some machine, material, or structure—rarely to obtain inductive laws. The impatience of the experimenters is not satisfied except by *direct results*; the far more fruitful knowledge, for want of which mechanical science stands still, he despises as abstract, and not practical.

This explanation, if correct, is quite sufficient to account for the slow progress of mechanical science. The view we take of the question before us is this: that the very knowledge which is really wanted, experimenters almost universally neglect as valueless; and the reason why they neglect it is, because the use of it is indirect, and they have not the scientific knowledge which would enable them to perceive its use and value. As this matter is one of importance, let us endeavour to illustrate our meaning by reference to an example. The strength of a beam depends of course on its elastic forces, and these are of several kinds. There is the linear elasticity, resisting change of figure by longitudinal extension or compression; elasticity of rigidity, resisting change of figure by torsion or tangential displacement; cubical elasticity, which resists change of volume by increase or diminution of density. Now the knowledge of the relations of these elastic forces to each other, and to the displacements by which they are accompanied, is precisely the desideratum, at this time, for the completion of the science of the strength of materials. This knowledge, alas! is also precisely that which, in experiments upon the strength of materials, is most generally avoided. We have volumes full of details of *direct* experiments performed by bending or stretching rods till they break; and the information so gained is valued as practical because it is direct. But the more potent machinery of investigation, by seeking for laws first and applying them afterwards, is discarded because it operates indirectly. Were the experiments on extension or deflection of iron multiplied to ten times their present number, they would afford no aid for computing *the strains of torsion of the vertical sides of such a structure as the Menai tube.* At present, the absence of knowledge on that subject is almost complete.

The proverbial principle, that the shortest road is often the longest way about, is amply illustrated with respect to mechanical science in many other cases. For instance, the investigations of the effects of screw-propellers are as crude and undigested as they can be easily conceived to be. The proper course in this, as in other mechanical investigations, would be, that the experimenter and the theorist should *co-operate,*—each communicating the desiderata of his knowledge to the other. But this kind of co-operation is rarely attempted: consequently the experimenter pursues a course of experiment which from its very nature is *interminable,*—heaps together facts either altogether barren, or else fruitful of mischief only, because they suggest hazardous generalisations; while the theorist gives up in despair the solution of problems of immense practical importance, and wastes his strength on mere mathematical puzzles.

We cannot help thinking that the evils here insisted on as the true causes of the slow progress of the philosophy of engineering might be remedied in a great measure by the influence of the valuable Societies whose purpose it is to promote the advancement of mechanical art and science. It is difficult to imagine a more admirable field for the display of the utility of those Societies, than that which they would occupy by encouraging the pursuit of theoretical and experimental investigations by the method of the division of labour. There are many able mathematicians who would readily address themselves to the solution of questions respecting which every practical engineer feels the necessity for more knowledge, provided that the requisite experimental data were furnished. On the other hand, many engineers and mechanicians, who now exhaust their energy in most unproductive experimental investigations, would gladly address themselves to the task of furnishing such data were the value of them properly explained. At present, it is the practice of the Societies in question to encourage investigations having immediate and direct results. This course is the most attractive, but we doubt whether it be the most provident or effectual. It indicates a deference to the impatience of those who are unwilling to follow the devious paths by which scientific knowledge is most frequently obtained, or to the distrust of those who are ignorant of the enormous powers of mathematical investigation. By the powers of mathematics, difficulties have been overcome of which the vastness is not to be comprehended without long study, and results attained which had else been unimaginable,—the depths of the heavens measured; the myriads of whirling orbs which rush through space with far swifter than eagle's flight, marshalled in prescribed courses; the most complex motions and perturbation of the heavenly bodies investigated and predicted with unfailing accuracy; the marvellous phenomena of light explained by processes of extraordinary refinement.

The methods of investigation by which such magnificent results have been obtained have proceeded universally on those principles of co-operation and division of labour, here insisted upon as the most effective for the extension of mechanical science. Familiarity with the discoveries of Newton has not abated the astonishment at his marvellous powers of penetrating the secrets of nature. Yet even the intellectual powers of Newton would have been baffled by the difficulties in his path, unless way-marks had been previously placed in that path by the hands of the experimental philosopher. How many long years of unwearied toil did it cost Kepler to achieve for himself the glorious title of Newton's precursor! The laws of the movement of the planets about the sun, known as *Kepler's Laws,* were deduced by that indefatigable astronomer by observation alone, and often-repeated, often-disappointed, attempts to reduce his results to regular laws. In these discoveries he was aided by no mechanical principles: he contented himself with observing and systematising, without attempting to theorise. Nor was the full importance of his discoveries perceived until Newton applied them to determine the force which keeps each planet in its orbit, and demonstrated that the law of gravitation, which indicates the direction of each such force and the variation of its intensity, is the necessary consequence of Kepler's Laws. In like manner the path of the mathematical investigator of the phenomena of light was smoothed by a long course of antecedent experiments. Many of the mechanical problems of which the engineer now vainly desires the solution, difficult as they are, can hardly be considered so difficult as those optical and astronomical problems which have been successfully solved by the course of investigation just pointed out; and we cannot reasonably doubt that the same success would attend inquiries respecting practical mechanics, if the like method of systematic investigation were substituted for the immethodic and desultory inquiries by which, at present, mechanical investigations are almost universally characterised.

Beside the methods already pointed out for promoting the advance of mechanical science, there is another, to which our limits permit only a very brief allusion. The conclusions of mathematics are often far more exact than practice requires, and that very exactness necessitates the use of excessively complicated formulæ. In the present state of knowledge, science would, we submit, be often more usefully employed in determining *relative* than *absolute* results; that is, in *comparing* the efficacy of different modes of constructing, than in determining positive rules for calculating the powers of particular machines and the strength and stability of particular structures. Where, however, such calculations are required, it would be desirable that attention should be more frequently directed to ascertaining *superior and inferior limits*, within which the results must lie. We are justified by experience, and a knowledge of the imperfect state of mechanical science, in concluding, that what it apparently lost in precision by such a course of investigation, would be far more than compensated for by increased security of the accuracy of the conclusions so obtained.

It is time however to turn from these topics, important as they are, to the consideration of the works of which the titles are appended at the commencement of the present article. We have chosen these two works for notice here, because they are as excellent examples as could have been well selected of the efforts of the theoretical and the practical philosopher, to facilitate the acquisition of knowledge of their respective subjects. Mr. Todhunter's work is intended as a manual of the mathematical principles of statical science, and is characterised by that clearness of enunciation and precision of demonstration which constitute the real aids of the student of any exact science. Commencing with a perspicuous explanation of the fundamental principles of mechanics, he proceeds to discuss successively the laws of the composition and equilibrium of forces acting upon particles and upon rigid bodies, to investigate the analytical theorems respecting centres of gravity, the effects of simple machines, the laws of friction, the equilibrium of catenaries, the laws of attraction, and the principle of Virtual Velocities. To each chapter, by a useful arrangement, are appended numerous interesting examples for the self-examination of the student. The demonstration of the Parallelogram of Forces adopted by Mr. Todhunter is that of Duchayla, which proceeds on the assumption of the law of transmissibility of statical force in bodies at rest. The laws of the equilibrium of a *point* ought however, we apprehend, to be independent of all experimental results, and to be deducible solely from geometrical considerations and the definition of the measure of forces. Duchayla's proof is open to the objection that it imports an extraneous consideration—molecular action—into the demonstration of a principle which intrinsically has no dependence on molecular action. We perceive, also, that Lagrange's proof of the principle of Virtual Velocities is inserted. Now, it appears a bold assertion, but it is indubitably a correct one, that Lagrange's proof is essentially vicious. His statement (p. 308), "since the weight always tends to descend, if there were *any* displacement of the system which would allow it to descend, it would necessarily descend," is, we apprehend, simply untrue, for it neglects the case in which the weight is in its highest position —that of unstable equilibrium. It is true, that compared with any *indefinitely small* displacement of the system from that position, the displacement of the weight may be considered to be ultimately zero; but this is not what Lagrange asserts, nor has it ever been shown to be a consequence of his axiom respecting the tendency of the weight to descend.

It is sometimes supposed that the principle of Virtual Velocities has not been yet thoroughly proved. This we apprehend to be a mistake. The indistinctness in the ordinary proofs often arises from the geometrical and the mechanical parts of the principle not being kept distinctly separate. Nothing can be more clear and precise than the proof Mr. Todhunter gives: his separation of the mechanics from the geometry of this subject, and his treatment of these two branches of it are among the happiest of his efforts. We however venture to suggest, that a proof of the geometrical principle enunciated and assumed in Art. 252, would have added somewhat to the elucidation of the subject. One of the most satisfactory evidences of the advancement of education at Cambridge is the recent improvement of the University class-books. The perspicuous language, rigorous investigation, conscientious scrutiny of difficulties, and methodical treatment which characterise Mr. Todhunter's works, entitle him to a large share of the honour of that improvement.

The 'Treatise on the Steam-Engine for Practical Men,' by Messrs. Hann and Gener, proceeds on the somewhat novel method of applying rules first and demonstrating them afterwards. In the first part of the work rules are given for calculating the work done by steam; the velocity of the piston of a steam-engine; its resistances, duty, and rate of evaporation; the proper dimensions of the different parts of the "parallel motion," connecting-rod, fly-wheel, and the slide and eccentric levers; the mechanical effects of the safety-valve, crank, governor, indicator, paddle-wheels, screw-propellers, &c. The second part of the work contains the theoretical investigation of the rules explained in the first part. The authors condemn, as liable to occasion confusion, the method of giving the rules and the reasons for them together; yet the difficulty arising from this method seems to be merely typographical. We should be inclined to think, that if the rules were prefaced by the investigations from which they are deduced, the practitioner would be assisted in apprehending their import and estimating their value. This is however a mere matter of opinion, and not one of much importance. The rules are very distinct and clear, and well elucidated by numerical examples, so that for their comprehension little more is required than a knowledge of arithmetic. Carefully, however, as the rules are selected, it may be questioned whether in one or two instances they do not attempt more than the present state of mechanical science warrants. For instance, the enunciation of a rule for computing the centre of pressure on paddle-wheels in motion, seems a rather precipitate step, considering the doubts and difficulties in which the laws of fluid motion are involved. The rule depends on an investigation by Mr. Barlow, which is given at page 146, and is founded on "several experiments," from which he concludes that the resistance at any point of a paddle varies in slight immersions as the cube, and in deep immersions as the 2·5 power nearly of the distance from the "rolling circle." We cannot undertake to affirm that this generalisation is erroneous, but we should certainly, before assenting to it, require to know the number of the experiments and the circumstances of them.

It is very desirable, that in stating the bare results of a science for the use of those who are not supposed to be capable of examining for themselves the evidence on which they rest, the certain and the merely probable results should be carefully distinguished. Mr. Hann is too well versed in mechanical science to dispute the importance of such a distinction, and the care with which he has selected his rules betokens his knowledge of the numerous errors committed in existing treatises on the steam-engine. He has avoided the common fallacies which abound in such treatises respecting the relation of the evaporation of the boiler to the work performed by the piston, and gives a very lucid and satisfactory account of the real duty of steam-engines. The perspicuous statement of the thermal and mechanical properties of steam, and the numerous practical suggestions which are interspersed throughout the work, add much to its value and interest, and concur with its other merits to render it a very useful guide for the practical engineer. It is but fair to add, however, that Mr. Hann speaks in such flattering terms of this *Journal*, and certain scientific contributions to former volumes of it, that we may perhaps have fallen into an error which we wished particularly to avoid—that of returning compliments.

## SYMBOLISM IN ART.

Sir—In the review of my little work on Symbolism, in the last number of your *Journal*, it was said that, for a definition, "Mr. White appeals only to one of his co-sectarians, who is evidently regarded by him as an infallible authority," and that "the canonist appealed to has been pleased to define Symbolism as 'the having something in common with another by representative quality.'" Now this being the definition given by Johnson, I would venture to ask *in what way* I am to be considered as his "co-sectarian"? Not that there is anything to be ashamed of either in having one's name associated with that of the great etymologist, or in my having appealed to such an authority;—but, as very much of an argument depends upon the correctness of definitions, and your readers have been led to suppose that this one was taken (as best answering my purpose) from a prejudiced or "party" source, their minds ought, in justice both to them and myself, to be disabused of the idea. And as your Reviewer considers "the question of Symbolism in Art to be interesting to artists," he must be glad to see such an error, if inadvertently fallen into, corrected by an insertion of this letter in your next number.

39, *Great Marlborough-street*, *March* 7, 1854. William White.

## RAILROAD DRAWBRIDGE AND SWITCH SAFETY TELEGRAPH.

C. McRea, *Inventor*, Philadelphia, U. S.*

*The Committee on Science and the Arts, of the Franklin Institute (U. S.), to whom was referred for examination, a "Railroad Drawbridge and Switch Safety Telegraph," invented by* C. McRea, *of Philadelphia*, —Report:

That in this contrivance an electrical current is arranged so as to be closed when the drawbridge or switch is in proper position, and to be broken when this is not the case. The wire terminates in a rail carefully insulated from the rest of the track, and at such a distance from the bridge as to allow ample room for stopping the train of cars between them. The next rail to the one spoken of is also insulated from the track, and connected with one of the ground plates of the circuit. On the locomotive is placed an electro-magnet of the ordinary construction, whose keeper controls the works of an alarm, so that the bell, stopped while the keeper is not attracted by the magnet, is released and allowed to ring the moment that this attraction takes place. The wire of the coil terminates in metallic connection with the front and hinder axles of the locomotive. And it will be easily seen that when the locomotive reaches such a point that the fore wheels are on one of the insulated rails, and the hind wheels on the other, the electric circuit (provided the drawbridge is closed) is completed through the magnet, and the bell rings, indicating that it is safe to proceed; but if the drawbridge or switch is open, the bell will not ring, for the electric circuit is not closed, and the conductor is warned to stop or to proceed with caution.

The means proposed for obtaining this important end are simple, and not expensive, and the idea is certainly a very ingenious one; and it will be observed that the result of any failure in the apparatus is simply to excite the cautiousness of the conductor. This safety signal cannot be given unless every thing is in order. This constitutes, in the opinion of the Committee, the very great merit of the contrivance. In practice, the difficulties which suggest themselves, will be in perfectly insulating the rails, especially in low situations, and in very wet or icy weather; and, secondly, in arranging the extremities of the magnetic coil so that the current from the wire will pass through them. There can be little doubt that the grease on the well-oiled axle of a locomotive will prevent the passage of an electric current of such feeble intensity, and if it did not, it would pass through the pedestals and iron work of the engine to the other axle, and thus escape the magnetic circuit. But the avoidance of this objection will probably be easy; and the simplicity of the apparatus and importance of the result to be obtained, thereby recommend the invention to a practical trial.†

Mr. McRea has also proposed a modification of the apparatus for avoiding the collision of trains on a single-track road. At the turn-out at each extremity of the part of the track on which the trains may meet, the insulated rails are prepared as before, but at each point the line is provided with a "circuit changer," as shown in the accompanying engraving; the battery has a double circuit, each including one of these circuit changers. The ordinary position of the circuit changer is such that the current to which it belongs is interrupted. Now, the conductor of the train who first arrives at one end of the prepared track, shifts the circuit changer by a simple motion, and thus passes a current from the distant station through his magnet, and the ringing of the bell indicates that he may proceed in safety. In proceeding, he leaves the circuit changer in its new position, by which the circuit at the end is broken. If, now, while he is on the doubtful ground, the other train arrives, and the conductor shifts the changer at that end, he can get no circuit, and, consequently, his bell is silent; for it will be seen by the engraving that the current must come from the far station, and that has been thrown out by the first train in passing; he must therefore wait. As the trains pass off the ground they must stop to readjust the circuit changers in their first positions. It will be seen here again, that any failure of the apparatus, or negligence in its adjustment, can only produce delay, and that, provided the first conductor performs his duty, a collision is impossible. These changes may, it is manifest, be easily made by the locomotive itself, if that be deemed desirable.

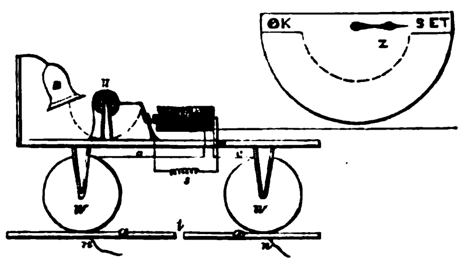
By order of the Committee,

*Philadelphia, October 15th*, 1853. W. Hamilton, *Actuary*.

### *Description by the Inventor.*

The mode of arrangement is, to extend a wire from a battery across the drawbridge, to a safe distance on each side, and there connect to an insulated rail in the track. When a train of cars approaches the bridge from either side, so that the wheels *w*, *w*, fig. 1, touch the track *a*, *a*, at opposite sides of the insulation *i*, if the draw is closed, a circuit will be completed; *n*, *n*, are the wires which extend from the battery and connect with the track; *c*, *c*, are wires which connect the circuit from the wheels to the electro-magnet *m*. When a circuit is formed, the armature *x*,

Fig. 1. Fig. 2.



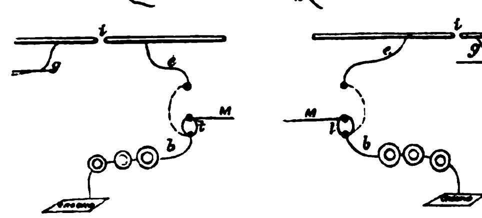


Fig. 3. Fig. 4.

will be so attracted as to release the hammer *y*, which will be acted upon by the spring *u*, so as to strike the bell B. The shaft to which the hammer is fastened carries with it the hand *z*, as seen upon the index in fig. 2, so that when the circuit is closed the hand will point to "O K." When the circuit is broken the armature will fall into its former position by aid of the spiral spring *s*, when the hand of the index is to be turned back to "*Set*," by which the instrument is adjusted for use. If the draw of the bridge be open when a train approaches it, the circuit will not be completed in consequence of the separation of the wire at the draw; therefore, the bell cannot ring, and the hand on the index will remain pointing to the word "*Set*." The same plan of galvanic connections, as also the same instrument, are applicable to the prevention of accidents at railroad switches; as by the displacing of a switch, the same effect may be produced upon the galvanic circuit as by the opening of a drawbridge. By means of a different plan of connections, the same apparatus may be used for the purpose of indicating to persons on board of one train as to whether an approaching train has passed a given point of the road or not. Figures 3 and 4 represent prepared places in the track, as seen in fig. 1; *g*, is the ground wire leading from the track on one side of the insulation *i*; *e*, is a wire which is attached to the track, opposite the ground wire, and which forms part of the main line; when the circuit changer *t*, is removed from the battery wire *b*, and placed so as to connect it with the wire M, which extends to the next turn-out.

On the arrival of a train at one of the prepared places, by shifting the circuit changer *t*, from the point where it connects with the battery wire *b*, so as to connect with the wire *e*, a current will be passed through the magnet upon the car from the battery at the distant station, causing the bell to ring, which indicates that they can proceed in safety. The circuit changer is to be left in its new position, so that when the approaching train arrives at the next turn-out, no circuit can be obtained, which indicates that said train must wait. As the trains pass off the ground, the circuit changers must be placed in the original position.

* From the 'Journal of the Franklin Institute.'

† As soon as these objections were proposed to the inventor, he suggested a mode of obviating both of them by terminating one end of the magnet coil on a rod projecting downwards from the cow-catcher, the other in a rod projecting similarly from the hinder frame of the engine, and setting the insulated rails in the middle of the track where they can easily be completely insulated. It would also be advisable that a signal should be given to the switch or bridge tender, to prevent the possibility of his opening the switch or bridge after the engine had passed the signal station, but before reaching the point of danger.

## ON ANCIENT AND MODERN METAL-WORKING AND ORNAMENTATION;

### WITH SOME ALLUSION TO THE ART OF NATURE-PRINTING.*

By W. C. Aitken.

[*Paper read at the Society of Arts, February 15th.*]

Before proceeding to the consideration of the more immediate purpose of the present paper, and directing your attention to the various specimens displayed before you, to which I will, as occasion requires, point for the more complete elucidation and illustration of the processes alluded to in my paper, may I crave your indulgence for a very brief space of time while I introduce for your consideration a few remarks on the subject of ornament on metal work generally. I am the more anxious to do this in order to place before you in its true light the necessity which exists for gratifying the demand now universally made for articles in and on which ornament is extensively introduced. That this demand has its origin in a desire for the beautiful, admits of but little doubt; that the faculty should be educated to desire what is correct is, I think, now very generally admitted; that it has not hitherto been so, must be laid rather to the charge of those in authority over us than to ourselves. An improved and improving taste is, however, observable; attributable, doubtless, to the increased and increasing circulation of works treating on ornament as applicable to the productions of the national industry, to the slowly but surely expanding, extending, and elevating influences of our schools of design; to the exhibitions of manufacturing art in the provinces; and last, but by no means least, to the great industrial display of 1851, which had its origin under the auspices of the Society within whose theatre I now have the honour to address you.

Admitting, then, the existence of a natural desire for ornament, which is to be found alike in a civilised and uncivilised state of society, it follows as a natural consequence that the demands of the former must keep pace with the possession of the means to procure it; and the character of the supply will, in turn, manifest the capabilities of the producer and his appreciation of the taste of his customers. Experience tells us, however, that, low as some may be disposed to consider the public taste, it indicates a growing feeling and tendency in the right direction. Those who have watched the avidity with which articles of an improved character have been laid hold of and purchased, will have no difficulty in detecting the change for the better which has come over even the spirit of common things. The gaily-painted plaster cast has given place to another, in which elegance of form is more apparent; the crudely formed and vulgarly coloured mantle-shelf ornament has in turn been superseded by the delicate and beautiful Parian statuette. We have now but few China services, so glaringly vulgar in their decorations as of old; coarsely executed wood-cuts, gaudily coloured, are but seldom now to be seen hung on the walls of the dwellings of the humbler classes. The japanned tea-tray wears a more sober livery; the room paper which, ten years ago, would have been looked upon as a marvel, would now be repudiated entirely; almost every article for household use, into which the element of ornament is introduced, demonstrates an improved and improving taste;—it ought, therefore, to be our duty to consider how this requirement may be made subservient to the cultivation and elevation of the public taste, by the substitution of superior ornament to that now in use; and this may be done to a great extent through the medium of mechanical reproduction with a larger infusion of the artist into the design to be reproduced than has hitherto been the case. That such is not quite an impossibility I trust to make apparent to you before the conclusion of this paper.

If in this direction much more has been attempted than has been accomplished, it is only an evidence to my mind that those who have attempted to do so have failed because the processes they employed were determined and limited in their applications and capabilities; and that they had selected examples or designs for imitation which the human hand, with its varied and multiform movements, aided by the intelligence of the human mind, could alone accomplish. In reference to this department of the subject, it may be suggested that it might be better to dispense with ornament altogether, or apply only that which is of an exceedingly high class, and adapted to the various objects which find their way into the houses of the titled and the wealthy. Admiring the labours of the artist-workman of the fourteenth, fifteenth, and sixteenth centuries, admitting the beauty of their handicraft, I well know that such ornament as they introduced, and which it is contended by many is the only legitimate kind, could only be produced by art-workmen like themselves, and, therefore, at a cost which would entirely exclude ornament altogether from what is used by the middle and operative classes, thereby effectually putting a stop to the expansion of the ideal faculty, and inducing a puritanical and non-artistic quakerism which could not fail, if adopted, to retard our progress in matters of taste.

It has become fashionable to decry certain kinds of ornamentation in which mechanism has taken the part of hand labour. The origin of this may, I think, be traced to the ever-to-be-lamented Pugin, who has been closely followed, like every other great man, by a train of disciples, the majority of whom, it is just possible, would scarce have detected for themselves what he has pointed out and made apparent. An examination of the treasures of art-workmanship, to be found in continental collections of antiquities—chiefly, however, in the first instance, of a sacred kind and for sacred purposes—disclosed to him the peculiarities which distinguished early and middle age workmanship, and demonstrated to his mind certain principles in ornament and in construction which have since become deservedly canons, which canons have, however, been applied somewhat indiscriminately by his followers. In doing so, they seem to have forgotten or altogether overlooked the premises upon which his conclusions were founded, and that they have no parallel in England in the present day. In the middle ages, what was decorated? Only the cathedrals, churches, the palaces of kings and princes, the halls of the guilds, and the dwellings of the wealthy merchants. In the possessors of these lay, or was concentrated, all the patronage and wealth of the various countries and states. They patronised Art in order to add to their magnificence and grandeur; to gain an additional prestige, and another claim to the admiration of the multitude. This, rather than a desire to patronise art for its own sake, to rival the glories of the ancient races, whose magnificence in matters pertaining to art, history and tradition had handed down to them, the desire to emulate such magnificence, was doubtless the leading and moving principle which animated them. The few attempted to do, in the middle ages, that which the many did in Ancient Greece; there, the most expensive material upon which to work, the greatest of artists then to be found to do the work, would alone satisfy the cravings of that naturally-constituted art-appreciating people, the whole of whom were animated with the like passion for art which distinguished their great leader, Pericles. We are told, as an illustration of this, that when the sculptor, Phidias, recommended marble as a cheaper material than ivory, for the great statue of Minerva, about to be erected in Athens, it was for the reason that it was more costly, that ivory was preferred by the unanimous voice of the assembly. In Greece, as in Italy, France, and Germany, at a later period, the passion for art doubtless served an excellent purpose; for, in discussing the merits of the last newly-erected building, inaugurated statue, or coming spectacle, the people forgot their feuds and woes, personal or political; and the tyranny of their rulers, lay or clerical. On the authority of Bulwer, we learn, that with the extraordinary development of art in Athens, the dwellings of the people were not in keeping—the houses of her private citizens were simple and unadorned—the streets were narrow and irregular, and, even centuries afterwards, a stranger entering the city could not have recognised her claims as the mistress of Grecian art. This statement is peculiar, but it is important as showing that, while the patricians enjoyed within their dwellings and private grounds all the gratifications arising from objects conceived and executed under the operation of the ideal faculties,—while for them Apelles, it may be, painted a Venus, and Praxiteles chiselled a marvellous statue; while some gold or silver smith, or carver in ivory, famed for his cunning workmanship, elaborated some costly jewel or cup, priceless beyond the value of the material in the yet higher value conferred on it by its art workmanship; while some Samian potter, celebrated for the exquisite taste displayed in the very simplicity of the contour of his vases, evolved from his wheel some masterpiece of his art; while all this and much more was being done for the few, we hear of nothing being done for the many. The same, undoubtedly, holds good at a later period, when Rome and Florence luxuriated in the hey-day of their prosperity, and art reigned supreme. It was to the few, still, that art more particu-

* From the 'Journal of the Society of Arts.'

larly spoke. No doubt can exist but that the people derived much pleasure and gratification from the magnificent buildings and other works of art with which their cities abounded. We know, however, that, so far as domestic comforts were concerned, the poorer classes were very deficient—their means were small. If comfort, then, was in abeyance, much of an ornamental kind could not be expected to be found in their dwellings. Ornament belonged only to the wealthy; it could only be had by being paid for at an expensive rate. Hand labour is in all civilised countries costly; at least such labour as, in connection with intellect and the perceptive faculties, gives existence to works of art, or the higher class of art manufactures. The people were content with what they saw publicly exhibited; they imagined it was their own, and in this idea they were gratified. Not so with England and Englishmen, existing under a government which is freedom itself, with an equalisation of wealth among the various classes to which the most prosperous nations of antiquity were strangers; with the great majority of the people in possession of comparative comfort, the desire for something more naturally manifests itself among them. It is unnecessary, in the presence of an audience like the one now addressed, to explain the great cost consequent upon high class artistic workmanship being employed, and the still greater difficulty which, under present circumstances, there would be, were the demand for hand ornamented work general, arising from the difficulty there is in finding workmen in sufficient numbers and in possession of a sufficient amount of average artistic manipulative skill. It is not with us as in those countries from whence were imported the works in precious stones, metals, ivory, and embroidery in costly materials, which so deservedly attracted so much attention in the Great Industrial Exhibition. The value of labour in these, as contrasted with that important element in England will not bear comparison. In those countries a vast population exists without any adequate means of employment. There is but little to be done, and there is consequently an excess of the means of doing it. Labour is therefore cheap, and it makes but little matter how much is expended; such labour in turn becomes simply a kind of luxurious idleness. With us it is different; we live in a country of improvement and progression: what is our goal to-day will, in all likelihood, be our starting-place to-morrow. Did we content ourselves, as was the case in time past, with making, it might be all very well, but we have arrived at a higher point in the social scale.

We now manufacture, and we manufacture for the world; and, with all the defects in our manufactures, the world is glad to get them, and in this it will take no denial. Our exports increase, though we may hear an occasional growl or two here and there from an art critic, or some one who lived in the days when a common and crude thing cost double the money it does now; while some *parvenu* turns up his nose at a pretty thing, rejects it because it is common, and because he says everybody has it, forgetting that "a thing of beauty is a joy for ever," and that in nature such things as are beautiful are most lavishly provided for the gratification of man. There is another class who content themselves with finding fault without the power to mend; they abuse manufacturers without being aware of the difficulties against which that important class have to contend; and they point to the time when workmen are said to have done things for the pure love of doing them; when locksmiths delighted to exercise the utmost resources of their art on the locks they made, forgetting that now a days it is not the external ornamentation but the internal workmanship which is the more important consideration; that we make locks which cannot be picked except by Hobbs, and, more than that, that they are made in ship loads, and that the locks made in England alone serve to lock two-thirds of the doors that are locked in the world. With every desire to believe the best things of the middle-age workmen, I am quite of opinion that much of what they did, and how they did it, was the result of ignorance and want of knowledge, arising out of the imperfect state of science in its application to industry. I cannot account for the round-about way in which they went about certain things upon any other principle; we may depend upon this, that had they been acquainted with many of the processes now in use, they would gladly have availed themselves of them. I do not believe that everything they did arose from their desire to do the work for the work's sake. In doing so, I think the admirers of mediævalism have attributed to a higher sentiment that which had its origin in a lower; and I think they have not failed to detect much in the labours of the men they admire, which the men themselves never anticipated or intended. Doubtless there were enthusiasts among them as there are among ourselves; but to assume for them a superior amount of sincerity, truth, and sacrifice over ourselves, is what I respectfully submit may, with perfect justice, be questioned. When two methods exist by which the same result can be accomplished, but the one is much more economical of time than the other, we are bound by the most solemn consideration to avail ourselves of it. To select the more tedious of the two is simply to practice and encourage industrious idleness. Art is assuredly very long, and life very short; if means can then be devised to copy, either by chemical or mechanical processes, and if the copy or reproduction comes at all near the original, is it not better to employ such means to reproduce, than expend precious life in imitating only? The life of a great artist workman increases in value as his works are reproduced, his fame is extended, and he largely adds to the amount of human happiness.

How very limited our knowledge of the genius and ability of Cellini must have remained but for the copies of his works, which the discovery of electro-metallurgy has enabled us to produce and disseminate. How imperfect an idea of the celebrated cup of the great Florentine artist the best plaster cast ever gave us, and how perfect in every minute detail is it rendered by the troughs of Elkington! What should we have known of the exquisite busts, statuettes, lamps, tripods, drinking cups, and vases, with the cunning workmanship thereon, or how far did our knowledge of these extend, notwithstanding their existence in the Naples museum, and of which but for the discovery of the art of the electrotype by Spencer, many of us must have remained ignorant? These are the results of a process enabling us to secure at greatly diminished cost, copies from works whose value is priceless, and all but inaccessible to the great bulk of the people; depend upon it those who value things only as they are rare (and there is reason to fear there are many of this class to be found), behave unjustly to their fellow-men in opposing such means to an end so important. They nip in the bud the expanding and growing taste of the people. Are we then to reject every thing of an ornamental kind which is not hand-made? Are we called upon to refuse the assistance which the group of appliances which follows will afford us? Thus Cheverton's process reduces the full-size statue to a mere statuette with an ease and certainty which the unaided eye and hand could never accomplish; or Collas's ingenious process, which produced upon paper the magnificent series of French medals known as the Napoleon series; or that of Bates, an Englishman and a Londoner, who invented the patent anaglyphtograph, improved upon the machine used by Collas, and produced thereby specimens of far greater excellence and size. Need I instance, as an illustration among others, the copies of basso-relievos issued by the Art Union of London. Jordan's wood-carving machine, with a little hand labour adding the grace touches, produces results which, though certainly not equal to the works of Gibbons, are not bad substitutes in their stead, and may be accepted cordially where economy is a requisite or where limited means accompanies a taste for ornament. Where uniformity of pattern or ornament is desired, this style of work may even be preferable to that produced by hand labour. In perforated woodwork, whatever the charm of hand labour, it cannot certainly surpass the mechanical saw-piercing of Prosser and Hadley. The mechanically formed tiles of Herbert Minton are, in durability and in beauty, equal to any encaustic tile fragment dug up from among the ruins of any cathedral chancel, while they fit together much better and are cheaper. The cylinder printed room-papers of to day all but rival, where simplicity, design, and uniformity of pattern prevails, the best hand-printed specimens. The tapestry of Crace, in tone, colour, and excellence, was never equalled or surpassed by any fabric produced in a loom of the most primitive construction, or even hand-made. My conviction is, that had the middle age weavers been in possession of the Jacquard loom, they certainly would not have rejected its assistance.

I do not desire to decry the labours of the really earnest men of old, who produced much of what is worthy of admiration and imitation, but I think they and their doings have been over-estimated, while our own have been correspondingly undervalued. There is probably nothing more amusing than the contradictions which the advocates of mediæval principles display and countenance in their practice as opposed to their theory, and in their adoption of certain most unconstitutional exceptions and practices. An apostle, who out-Herods Herod in literary devotion to the cause, expresses himself as follows:—"One thing we have in our power, the doing without machine ornament and cast-iron work, all stamped metals and artificial stones, and imitation woods and bronzes, over the invention of which we hear daily exultation—all the short, and cheap, and easy ways of doing that whose difficulty is its honour, are just so many ways or new obstacles in our already encumbered road." Will it be believed, that with all the detestation of die-work and mechanical repetition, the volume in which the above eloquent diatribe is contained is ornamented by one of the processes so bitterly condemned by the writer, viz., die-work.

To make my meaning clearly understood, while I express myself thus on hand ornamentation, I do so with the most earnest desire that where there are occasions and opportunities for those possessed alike of station, wealth, and taste, to employ the highest class of talent, they will not fail to do so, and that those who may be employed will not fail in their turn to desire to emulate the glories of the ancient art-workman; let us hope that that art, that true art, which transmutes everything it touches into a thing of almost priceless value, may be appreciated as it ought; that in time to come the value of an object produced from the precious metals will cease to be estimated only according to the weight of the material employed therein; that the head which plans, and the hand which executes, may be found united together; and that the remark which has been so judiciously applied by the Art Superintendent, in his report upon Design, and in reference to works of precious metal exhibited in the French Department of the Exhibition, may be equally said, a few years hence, of the works in precious metals produced in this country, viz. "that we have regarded the material, rich and costly as it is, merely as the vehicle of the art added to it." On the other hand, we must recollect that there are amongst us great numbers of the people, who, with a desire for ornament, are not in a position to expend great sums of money thereon, so far as regards the decoration of their dwellings, or on what may not improperly be called their household gods. In ornament in things produced by man for man's use, the same liberality which is so bounteously recognisable throughout creation should be observed. Rare plants which grow in hothouses and under glass cases, of right belong to those of high estate, but for those of low degree blooms every hedgerow flower; the daisy lifts its purple eye to heaven, and the buttercup gilds the mead: they indicate, that in the mental constitution of man there exists a feeling taking cognizance of the beautiful to be gratified. Articles in which ornament is introduced should therefore be provided for every rank and condition of man who may desire them. Permit me now, therefore, to direct your attention to a few of the processes by which the end desired may be accomplished. In doing so, I will in some instances contrast the ancient and modern methods of working metal, and, so far as my time will permit, point out their distinguishing peculiarities and characteristics.

The processes employed by the earlier workers in metal must necessarily have been of a very simple kind, and, in all probability, like many of the great discoveries made by man, casting itself was simply the result of accident. Tradition tells us that the discovery of the art of glass-making had its origin in a band of Phœnician mariners, who kindled a fire on the banks of the River Belus, and being unable to find stones on which to set their pots, used, instead, some masses of nitrum: these, being fused by heat, and uniting with the sand of the sea-shore, produced glass. Is it not in like manner exceedingly probable that the art of casting had its origin in an accidental observation that melted metal, in cooling, took the form of the irregularities of the surface on which it had run? Whether this was the earliest method adopted for copying, or producing works in metal, it is difficult to determine. The sacred volume, at a period of 4000 years before the Christian era, tells us of the existence of Tubal Cain, an instructor of every artificer in brass and iron. It is, however, silent as to the processes employed by him. At a somewhat later period, B.C. 1491, the distinction between two methods of working metals is clearly made out. Thus, the artificer who was employed in the formation of the metal-work for the Tabernacle in the Wilderness, according to the command of Moses, is stated as having, among other portions, "Cast the four rings of gold, to be attached to the four corners of the Ark," by which it might be carried or borne aloft, while he made the golden candlesticks of beaten work. No doubt can exist but that the idol which the Israelites desired Aaron to make was cast; and it is singular to remark with what minuteness the process of making it is described. He is represented as having fashioned it with a graving tool, after he had made it a molten calf, or cast it: he in fact pursued the same course as is still followed—after casting, he chased or worked upon it with a graver, to render the details more perfect. In the metal-work for the Temple, built B.C. 1000, the process of casting seems to have been that which was adopted by Hiram of Tyre, the artificer employed by Solomon to do the works in brass bronze. It may be remarked, that though the words *molten* and *cast* are frequently used in the description, that of *beaten* does not appear when brass is mentioned. The pillars are said to have been cast, and also their capitals. The knobs which encircled the molten sea were *cast* in two rows, the bases on which it rested and the wheels upon which it moved were all cast. Additional evidence may be adduced as to the method adopted in casting, in so far as the materials used to cast in were similar to our own, for we are told, "In the plain of Jordan did the King cast them, in the clay land between Succooth and Zarthan." The Egyptians were acquainted with the art of casting; the Assyrians were equally so, as the discoveries of Layard prove. The Greeks had arrived at a considerable degree of perfection in the art, and tradition tells us of a Colossus, of dimensions so vast that it bestrode the entrance to the Harbour of Rhodes; it was made of brass bronze; its height numbered nearly 160 feet; the thumb was so large that few men could span it, and it took 12 years to make. There is not a more interesting history in existence than that which tells us of the productions of the great Italian artists in the art of bronze casting; the doubts and difficulties which they laboured under while the work was in progress, expressed by themselves in quaint and curious language, and the enthusiastic expressions with which they heralded their own success, and announced the existence of a new statue or group into the world of art. Who that has ever read the biography of that eccentric genius Benvenuto Cellini, but must enter into the mingled feelings with which his mind was agitated on the results of a scheme which was to stamp his future life, and, if successful, throw confusion on his imagined enemies and detractors. I here allude to his description of the casting of his group of Perseus and Andromeda, abounding as it does with clever practical hints. To those interested in Metal Castings, let me recommend that particular passage to their careful perusal. The life of Ghiberti should also be studied, as it abounds in practical details, and is a noble illustration of devotion to art; the history of the celebrated Bronze Gates of the Baptistry at Florence, wrought with so much care, so marvellous in execution, so excellent in design, uniting together in one harmonious whole, contributions from all the department of nature, representing the most momentous events recorded in Bible History, and in a language equally understood by the most highly educated, or by the unlettered lazy Italian beggar who suns himself outside. So noble are these doors, that the greatest spirit who ever ruled in the realms of art is recorded to have said, "they are so beautiful that they might fittingly stand as the gates of Paradise." A great modern, but somewhat inconsistent art critic, has expressed himself in reference to them as follows:—The rock, the fountain, the flowing river, with its pebble bed, the sea, the clouds of heaven, the herb of the field, the fruit-tree bearing fruit, the creeping thing, the bird, the beast, the man, and the angel mingle their fair forms on the bronze of Ghiberti. Forty years were expended on these doors—forty years, however, which purchased an immortality, and supplied examples to which the most accomplished artist and the veriest tyro in art may repair to examine and receive instructions in composition, in the treatment of ornament, in mechanical execution, and other details, essentially necessary to be understood, in order to produce works for similar purposes. We pass over without allusion the works of Donatello, Verrocchio, John of Bologna, and of Michael Angelo, and remark that, of late years, a decided and recognised impulse has been given to the art of bronze casting. The Exhibition of 1851 showed that we are not wholly without the power of producing castings in bronze, which are something more than creditable; and when speaking of what has been done by ourselves, let us not forget the colossal Lion of Bavaria, cast in bronze by Millar, just as it left the mould wherein it was cast; and though *not* as a bronze casting, yet, *as a* casting, the Amazon of Kiss must not be overlooked. All these are so many evidences that the art of bronze casting is not lost, neither is it likely to be.

Of the method applied for the production of a bronze statue, we may now give a brief sketch. The model being decided upon, a pit is dug of sufficient depth, and a grating fixed at some distance from the bottom; upon this is raised a rude representation of the intended figure or group, proportionably less in size, and corresponding to the hollow of the interior; this is technically called a core; after this is sufficiently dried, sheets of modelling wax, corresponding to the thickness which the metal is intended to be, is spread upon it; on this the features, drapery, and other details to be represented, are reproduced by the artist with his modelling tools. Rods of bronze or of the same kind of metal of which the statue is to be cast, are driven through the wax, and project sufficiently to pass into the outer cover of the mould. These fuse with the molten metal, and are therefore not recognised in the finished statue. From the prominent parts rods of wax are projected, which rise upwards and are intended to allow the escape of air, the presence of which is attended with danger to the workmen, and is liable to endanger the perfection of the casting. Other rods of wax indicate the passages through which the metal is to be run. The external surface of the wax model is now coated with loam or powdered crucible, ground with water to the consistency of cream, and applied by a brush all over the wax; coat follows coat until it is ascertained that a sufficient thickness is arrived at, after which clay is heaped upon this, and the whole cased with bricks, bound together by means of iron rods; heat is then applied under the grate; the wax, which represents the thickness of the metal, melts and runs out; the heat which served to melt the wax, answers the purpose also of drying the mould and expelling the damp; when covered up the top of the mould is below the level of the furnace which contains the molten metal, and which when at such a temperature as to secure complete fluidity, is tapped or opened; and the liquid metal then runs through the various channels until the mould is filled. After being allowed to cool a sufficient time, the outer coating of the mould is destroyed, and the statue stands revealed. The runners are then cut off, the core removed, and the whole is chased or finished as may be desired. In some instances, portions are cast separately and joined together by burning. This process consists in allowing a stream of molten metal to operate upon the parts to be joined together, until fusion of the two takes place, when they will be found completely united.

For small castings in metal, such as statuettes or works of an ornamental character, sand is usually employed to cast in. As this material has the advantage of allowing an escape of air, and its cohesive properties are so great as to admit of considerable liberties being taken with it during the process of moulding, it is generally preferred. Simple cylindrical articles are easily moulded; and it is only when there are figures, foliage, and deep undercuttings introduced, that the operation is attended with difficulty. This difficulty consists in judging as to the number of cores to be employed. These the workman makes upon the pattern, removing them for the purpose of lifting the pattern out; the small pieces of sand or cores are then replaced, the mould dried, closed, and held together, in order to receive the melted metal. When very great delicacy of surface or texture is desired, the ordinary sand has its capacity improved for receiving the impression by dusting upon it a very fine loam, and thereafter powdered or ground wood charcoal, the consequence of which is that the most delicate line, mat, or chase, is imparted to the sand matrix, and is in turn communicated to the casting. Patterns for ordinary plain work, either round or square, are made in the turning lathe, or by planes and chisels. Ornamental patterns of figures or foliage are in general first modelled in wax, from which a cast in lead or tin is taken; this cast is trimmed up neatly, and from it a cast is taken in brass, which is carefully smoothed up and chased. This then becomes the permanent pattern from which any number may be cast. Care and attention in this department is of the utmost importance in the economy of time, and to the ultimate perfection of the work.

I have already incidentally alluded to the fact of works in metal being produced by the beaten process, a method of working, in all probability, adopted immediately upon the malleable and ductile properties of metals being recognised. Gold and silver appear to have been first treated in this manner, the ductility and malleability of each being very great. The frequent allusion made to overlaying with gold in the Sacred Volume, indicates that some means had been found out at a very early period, in addition to casting, by which these metals could be wrought into suitable form for the purpose, viz., rendered sufficiently thin; and we receive the additional information as to this from the minutely detailed instructions given as to how the candlesticks for the tabernacles should be made, viz., of beaten work of pure gold. The Assyrians understood the process of hammering. Among the relics dug up at Nineveh was found a bronze mask, beaten out by a hammer, and various other portions of articles. The Greeks covered large statues with plates of gold, probably reduced by hammering. At a later period the art was revived by different Italian artists, whose labours are now to be seen in the various Continental museums and collections. The advantages resulting from the beating, embossing, or *repousse* method of working metals is, the great amount of effect produced, in comparison to the value of the material used—the art bestowed upon the metal creating the value, and not the metal itself. Of this class of workmanship were several of the vases made for Francis the First by Cellini; some of these, two feet in height, were raised from a single flat disc of metal; careful hammering, annealing, and a judicious selection of tools, could alone have accomplished such a result. Recently the art has been revived with singular success by the French, and those who felt at all interested in the progress of art manufacture could not have failed to remark the truly magnificent shield by Vechte, exhibited by Hunt and Roskell, dedicated to the illustration of the genius of Shakspeare, Milton, and Newton. A work equally extraordinary was that of the vase, Etruscan in form, on which, in the most delicate and also with the boldest relief, was introduced the Battle of the Titans; this vase was also raised from thin sheets of metal. Another shield, with the Slaughter of the Innocents as the subject, and produced by the same process, was exhibited by Le Page, in the French Department of the Exhibition. Morel, however, exhibited by far the most extensive application of the process, in his Equestrian Group of Queen Elizabeth, the height of which was four feet two inches, and the length three feet. It was entirely formed of plates beaten out by the hammer, which when fitted together were thereafter held in their place by soldering. We may briefly glance at this process, which, in its simplest form, may be described as follows: a proper sheet or disc of metal having been selected, the artist sketches his design on the reverse side to that which is intended to be the finished work; he proceeds to raise the various projections by a series of punches, &c. When he has obtained the necessary convexities which he thinks will give sufficient relief to the subject and will look well, he fills the back of the work up with a mixture of pitch, rosin, and sand, and attaches it to his chasing block, or ball; he then works on the convex or right side with his chasing tools, with these adding the details of features, drapery, and foilage; any roughness is removed by means of rifflers, the work is then polished and thereafter burnished, gilt or parcel gilt. In this class of art the Italian gold and silversmiths of the 15th and 16th centuries were adepts. The art was revived in France in 1838, and has ever since been practised with success. In our own country, Pugin, in his efforts to revive and improve the character, taste, and style of ecclesiastical metal work, introduced anew the art of beating up, and by this process Messrs. Hardmans produced many of their most brilliant and successful works. In connection with this part of my subject I may remark, as to the difficulties which the late A. W. Pugin had to encounter, in his self-imposed task of church restoration, among others was that of finding workmen sufficiently acquainted with the old methods of manipulation. He says: "The whole restoration has been a series of experiments; everything had to be created from the employer to the artizan; such was the difficulty of procuring operatives that I was compelled, for the first altar lamp I ever produced to employ an old German, who made jelly moulds for pastrycooks, as the only person who understood beating up copper to the old forms."

Opposed, then, to the somewhat tedious and very expensive production of works in metal, by casting or hammering, we come to the modern art of electro-metallurgy, or the deposit system, which admits alike of the creation of new, and the reproduction of old works of art, at a cost which enables men of comparatively limited means to gratify their taste. Thus we find, in the Department of Practical Art, a magnificent rosewater dish, for a sideboard, the original cost of which, if made by hand, could not possibly be less than 100*l*., but which may be had for 6*l*. 6*s*. Also a more elaborate work, of the Rennaissance period, with bas-reliefs of the Prodigal Son introduced thereon, the original cost of which could not certainly be less than 200*l*., but which may be had for 12*l*. 12*s*. The most elaborate details may be copied by this process with the most minute accuracy, while the largest work for which a tank could be made to hold a solution, and a battery of power sufficient to generate a supply of the electric fluid, would not be beyond the limits of the art. Were it necessary, another Colossus of Rhodes could be produced by its agency. The truly excellent specimens of statuary which now occupy their place in the House of Lords, sufficiently demonstrate its fitness for producing statues or groups for monumental or commemorative purposes. In the formation of a statue by the deposit process, there is not that hurry and skurry—that mental anxiety—which occasions such sad havoc in the human brain and mind. The mould, produced from a carefully executed model, is rendered conducting, and then immersed in a solution of copper. The deposition of the metal goes on while we sleep, provided the fluid is generated in sufficient quantity, and the strength of the solution is kept up. There is no anxiety as to the congealment of metal consequent on the inattention of firemen, nor the chance of bursting a furnace from the expansion of the melted metal, or the thousand-and-one accidents which perplex the caster in bronze, but, it may be, add to his delight when the statue stands revealed. Mr. Potts of Birmingham, has recently applied the art to the production of emblematic groups or relievo panels to be used for sepulchral or monumental purposes; these he places upon various coloured slabs of artificial stone or marble, &c. The result is, as will be readily anticipated, a vast improvement for the better over the memorials of the skull and cross-bones school, which are not even tolerable with the addition of an hour-glass or two, a sickle, a scythe, and half a dozen bodiless cherubs into the bargain. A word or two as to the rationale of the process will not be out of place.

Electro-metallurgy may be described as a process in which a metal held in solution is deposited in a metallic form upon some metal to be coated, or form to be copied. In the last, the cast or mould has to be rendered conducting by being coated with a metallic substance, for which the metal held in solution has an affinity. Blacklead is the substance most commonly used, but nitrate of silver is employed for the purpose when more delicate or fragile moulds are used. The electricity was generated in the early period of the art by means of a galvanic battery in various forms. The loss of zinc and other metals was, however, great, and it was finally superseded (though at times still used) by the electro-magnetic machine. This is a comparatively economical method of generating the fluid, requiring little more cost in working, save the repairs of the machine, and the cost of the engine which sets it in motion. It was at one time held that composite metals could not be deposited; brass has, however, been successively thrown down, but the cost far exceeds any advantage gained by the deposit. Gutta-percha, sealing and other waxes, stearine, plaster of Paris, &c., have been employed in the composition of moulds for internal deposits, but a recent discovery has been made of an elastic mould, which may be fearlessly left in the deposit trough without injury, and which produces the most exquisite details and the most complicated undercuttings. The mould may be removed without injury, and used repeatedly. It had been previously customary to deposit copper on a prepared mould, thereafter to destroy the plaster, and deposit a precious metal (gold or silver) therein; and to remove the copper matrix by disintegration from its more precious internal lining,—when the object desired was exposed, accurately copied even in its minute details. Large works are frequently deposited in pieces, and thereafter fitted and held together by soldering.

Somewhat akin to the beaten work of the ancients and mediævalists is the production of articles, or portions thereof, by the comparatively modern process of stamping, at least in so far as the material out of which the articles are made is in sheets: by the modern process, however, the falling blow of the stamp-hammer takes the place of the hammer of the workman. The requisites for the successful prosecution of the process are a stamp formed of a heavy piece of iron, into which the force is fastened, traversing or sliding up and down two upright bars or rods. The hammer is raised by having a cord attached to it passed over a pulley. The die is held in its place at the bottom of the stamp by four screws or poppets. The die is sometimes made of cast-iron or steel. Steel laid upon iron is, however, the most serviceable, and therefore more generally selected. The die is cut from a model which has been previously made by the artist. The die-sinker has to cut in intaglio what is in relievo in the model, that is to say, he sinks into the steel what is in relief in the model; this is done by means of chisels of various shapes and sizes; gravers and rifflers, or small files are used to put the finish upon it; it is thereafter smoothed up by abrasion, or grinding with suitably-shaped hones, or pieces of wood, of various forms with emery powder upon them. One of the conditions to be observed by the modeller or die-sinker for stamped work is to avoid entirely everything like under-cutting, as the very nature of the operation of stamping is opposed to it; when introduced the metal will not leave the die. It is very probable that the artist may feel disappointed at the difference between his model, if he has introduced under-cutting and the work produced from the die; what he has to do is to select a style of ornament in low relief which accords with this mode of production, and model accordingly. As stamping is generally looked upon as a very simple process, it may not be out of place to glance at the *modus operandi*, in order to remove an impression which very generally prevails, that it is of so simple a character as to involve in the exercise no skill whatever. The production of a stamped article is not the result of one, but a succession of blows, and the amount of force should be regularly proportioned to the cohesive power of the metal. If too great a degree of convexity is desired to be produced at one blow the metal is fractured or torn; if less than necessary the number of blows is unnecessarily increased; it is in the true proportioning of these that the skill of the workman is shown. The operation proceeds as follows:—To the falling hammer what is called a "force" is attached; the die is placed on the bed of the stamp, and held there by four screws; a piece of flat sheet metal is then laid on the die, the hammer is elevated by pulling the cord, and when at the proper height it is allowed to fall; the result is that the convexity is given to the flat metal by the blow from behind. This, in the first instance, produces a very slight effect, the metal being but little raised; this is carried through a large number of pieces of metal, corresponding to the quantity of articles required; the force is then changed, that is to say, one of greater convexity is substituted, the previously stamped pieces of metal are annealed, and, after cooling, are subjected to the routine observed on the first operation. "Force" after "force" is substituted, each differing from the preceding one in the amount of convexity; annealing follows annealing in succession, until all the details marked on the surface of the die are observable. In the production of the object now before me as many as fifteen blows have been given, consequently fifteen different forces have been used, and fifteen times has the metal been annealed. In some instances I have known as many as thirty blows required, and an equal number of forces and annealings would be necessary to produce a single article. It is in the number sold that the repayment for dies is to be expected, as their cost is very great. Articles of a globular kind are made in parts, and are either soldered or checked together. Cornices are stamped in pieces, and joined by pinning on to the wood skeleton, or they are produced in lengths by what are technically called travelling dies—viz., dies which are formed as repeats of patterns, and the article stamped is removed, after the blow, the distance between the ornament forward, and so on until the entire length of the strip is finished.

Ornamentation by means of engraving, even of average ordinary quantity, is an expensive process, comparatively speaking, and there are difficulties frequently presenting themselves in the deficiency of engravers to be found to do the work. To obviate these objections and remove these difficulties various methods have been devised; among others, those of engine-turning and damasking. The sphere of operation of these two processes is, however, very limited. Engine-turning is generally understood to be produced by a lathe, describing a succession of concentric or intertwined circles or lines. The backs and dials of watches are frequently ornamented by this method, and will afford you an excellent illustration of the effect of the process. Damasking, not damascening (a process to which the present has no similarity), is now very generally applied to the ornamenting of small metal boxes to contain supplies of those now almost indispensable little requisites, lucifer matches. This style of ornamentation is somewhat similar in its operation to the medallion engraving of Bates, which I have already incidentally alluded to. The pattern to be copied is cut round a cylinder, which is fixed in the same plane and parallel with the tube to be ornamented. A point traverses the pattern, and another in connection with it, and which moves simultaneously, cuts a line corresponding to the depressed portion of the design, leaving the raised portion of the pattern blank. The cutting point is drawn the entire length of the object to be ornamented, but only really cuts on what has been described as the raised portion of the pattern. This being completed, the tube is moved a small space, by a mechanical arrangement in connection with the machine, aud the line again scratched or cut out, and so on until the entire circumference is ornamented. The colour of the original ground arises from the varnish lacquer or bronze applied previous to the operation of ornamenting being commenced.

Another simple style of ornamentation, devised for ornamenting the tubes of pencil-cases and other small cylindrical articles, is here shown, and is produced by a series of small wheels, round the circumference of which the pattern to be indented is cut. The operation is very simple, and the pattern is produced by drawing the reeded octagon or other shaped tube through the space left in the centre of and in contact with the rollers and wheels. These revolve, and the tube receives the impression from the cut pattern. A device on their external diameter, another variety of style, is produced by giving to a round tube a spiral motion; the consequence is, that the pattern is arranged running spirally up the tube. This kind of ornamenting is, however, exceedingly limited in its application.

Where large flat surfaces and plain mouldings are introduced in the plated trade, or that of the silversmith, for surface ornamentation, engraving is commonly called into requisition, and not unfrequently a cheaper substitute is that of chasing, which is much more quickly done, and consequently costs less. As engraving or chasing forms a very important item in the cost of an article, various means have been devised from time to time to take its place—among others, that of etching. The objection to this method, however, is the undeniable want of finish in the lines or surfaces operated upon by the acid, and their presenting a rough appearance as a necessary condition contingent upon the effect of the acid. The process is practised as follows:—From engraved plates or other surfaces, impressions on tissue paper are taken in varnish-ink; the surface of the metal to be ornamented is cleansed, so as to be quite free from grease; and the tissue paper with the design is then transferred to the surface of the metal, in the same manner as is employed in the pottery trade when a design is put upon the ware in its biscuit state. The impression is thus transferred to the metal, the tissue paper being removed by washing it off; a coating of gum is next applied to protect the surface which it is not desired to etch; a little turpentine applied to the transfer dissolves the varnish-ink of the impression, and leaves the lines exposed to the action of the acid to which the article is to be subjected. This being done, a copy of the original design will be found bitten in on the surface of the object which it is desired to ornament, the coating or protecting ground is thereafter removed, and the article finished by the ordinary method. When the lines of a design are desired to be left in relief, this is done by simply reversing the process—viz., protecting the impression by dusting it over with powdered resin or asphalte, and subjecting the article on which the transfer has been made to a degree of heat sufficient to produce fusion of the particles of the resin; etching then follows, and the portion previously sunk will be found in relief on a dead ground.

Permit me now to direct your attention to a process which has recently been introduced, with what success the specimens displayed before you will enable you to judge. The merit and chief recommendation of the invention is its very great simplicity, the ease, speed, and facility with which the effect of a reticulated surface, an elaborated, chased, or an elegant scroll or floriated design, apparently engraved, may be introduced on any object. The fact of a soft material imprinting upon a harder one an impress of its form has long been understood; its practical application to the production of ornamental designs upon metal is, however, but of very recent origin. Ornamentation has been produced by rolls upon which the designs have been cut in relief, or the reverse, as those on copper cylindrical calico printing-rollers. The cost of sinking such rolls in steel is necessarily very expensive; as a new one would be needed for every change of ornament, their accumulation would become a very heavy drawback on the capital of the manufacturer. By the present process the cost is much diminished, leaving ample room for the introduction from time to time of new and superior designs to meet the taste or requirements of the market. The practical application of the process is due to Mr. R. T. Sturges, of Birmingham, who, in connection with Mr. R. W. Winfield, of Birmingham, is a proprietor of the patent. The origin of the invention may be traced to the competitive spirit of trade, which operates with so much effect upon the manufacturing industry of our country, calling into action the inventive faculty to devise new and more economic methods of effecting certain results. The idea once originated, it is singular to trace its gradual development. In its early stage, it was imagined that the harder the material out of which the pattern or design was made the better for the purpose. Keeping this then-imagined requisite in view, the first ornament imprinted was made out of steel-wire formed into shape, and thereafter tempered; designs of a more complicated and minute character it was expected could be produced by using metallic lace or wire-web. I may here remark, that this idea gave the hint which resulted in the production of the wire-lace exhibited by Mr. Carey, of Nottingham, in your recent exhibition of patented inventions. This may be cited as a forcible illustration of the effect one invention may have in stimulating or introducing a new feature into a manufacture of an entirely different kind from that in which the want originated. I now exhibit to you the result produced from a piece of crochet-work in wire; it is remarkably indefinite and unsatisfactory, as the metallic wire cannot be drawn up tight into shape, owing to the elasticity of the wire out of which the design is made. The loops being loose, the consequence of the pressure to which the plates of metal are subjected, in order to receive the ornamental device, cause distortion or flattening, which completely destroys the arrangement of the threads or wires.

This led to the somewhat singular idea, that in all probability ordinary thread-lace could be used for the purpose of producing a device upon softer metals. I may here state, that the result of this experiment was just another illustration of the saying of Sir John Herschel, illustrative of the difference between theory and practice; thus no mere philosopher in his study could have predicted that so tender and fragile a fabric as ordinary thread-lace would have sustained a pressure of not less than ten tons, and come out from such a pressure comparatively uninjured, leaving its impress even on so soft a substance as Britannia metal; but how much greater is our wonder increased when we find the same result is produced on copper, and on the harder metal, formed by its alloy with zinc—namely, brass—the yet harder German silver, iron, or tin-plate, and more wonderful still on what we are led to believe is the most dense and hardest metal in ordinary use—viz., steel. I now exhibit to you the first experiment made with thread-lace, which is interesting, as demonstrating a very peculiar fact, and affords a very excellent illustration of a great philosophical truth—viz., the indestructibility of matter; it was found, as will be anticipated, that the more perfect and closely twisted the thread of which the lace is made the better and more definite is the impression. The transition from rags to paper is a natural one, and patterns or designs formed out of perforated paper were next tried. From its density, the almost complete cohesion of its fibres, and their close proximity to each other, it was found on experiment that designs formed thereof produced very satisfactory results, while in point of economy it is even superior. As a curious illustration of its capability of resisting pressure, I may state that I have myself passed through metal rolls, without injury, the same piece of perforated paper (ordinary writing-paper) in the ornamentation of tin-plates not less than ten times, after which it was not entirely useless, but it became hard and brittle, owing to the cohesion of the particles being destroyed by the compression it had undergone.

By far the most useful practical application of the invention was yet in store; and in economy of its reproductive powers, it bears a near relation to the multiplication of the duplicate steel plates from which the Bank of England notes are printed, and which are produced by pressure, in the first instance, from one original engraved plate, or to the production of the plates from which our ordinary penny postage-stamps are printed, the original of which, up to 1852, had been only once engraved. The reproduction in the two instances last mentioned is effected by means of steel rollers, the periphery of which, by pressure on the original plate, has received an impression of the engraving in relief, and which when hardened impresses upon the surface of a soft steel-plate, a fac-simile of the original. The plan adopted in the present instance, and applied to the ornamentation of metal, is somewhat similar:—A steel-plate very equal in thickness is selected, on which the design requisite for the ornamentation of the salver, tray, or other object, is engraved in the ordinary manner, but somewhat deeper, the point of the graver employed to cut the lines being ground more acute. The engraving must be carefully executed; erasures or scrapings out, or beatings up of the plate from behind, must be avoided, as where they occur they are detrimental to the appearance and uniformity of the work. The least departure from perfect flatness of surface or equality of thickness is fatal to the perfection of the impression. From this plate a matrix or impression is taken in German silver, steel, or other metal, by passing the plate to be used as the matrix, and the engraved plate or design to be copied from, through a pair of rolls, observing however that the pressure of the rolls is uniform all over the surface, or, in technical language, that the "pinch" is equal. If this has been the case, and if the pressure applied has been sufficient, the result will be, that upon the previously blank sheet of metal an impression, with elevated or projecting portions corresponding to the sunk lines in the engraved or chased original plate will follow. This impression is then used as the medium from which to obtain the ornamental blank thereafter to be made up. This is done, as in the former instance, by placing the sheet of metal to be ornamented with its face to the plate with the raised or projecting portions, and passing them through the rolls as before; the consequence is, that every line of the original design will be found impressed or indented into the previously plain sheet or blank of metal. The original steel-plate is thus used only for the preparation of reverses, one of which, however, may be used many times in succession, or in proportion to the hardness of the metal to be ornamented. The blanks, after being ornamented, may be stamped or spun up into shape; if of a globular or regular form of outline, if irregular, hexagon, octagon, or with bosses, the metal out of which the vessel or article is formed is ornamented in separate portions, which are thereafter bent, stamped, or raised into shape, fitted and soldered together. After trimming and dressing, the plating or silvering is effected by the electro-deposit process; burnishing follows, the tools employed being burnishers made of blood-stone. Females are principally engaged in this portion of the work. As the two last processes mentioned are very generally understood, it is unnecessary to do more than simply allude to them. It may not be out of place, before concluding the notice of this method of producing surface ornamentation, to remark, that the excellence—or the reverse—of the ornamentation bears a correct proportion to the original steel-plate, and just in so far as the design is a good one, and the engraver of the steel-plate has executed his part well, will the result be satisfactory, or in the inverse ratio; it is, in fact, just as faithful a copy upon a sheet of metal, as an engraving by Wass or Finden is upon paper. It affords a ready and cheap method of introducing good ornament in the place of unmeaning, ungraceful, inelegant, and badly-executed hand-chasing or engraving, which in general serve to deface what they are intended to adorn.

I now desire to direct your attention for a brief period to a subject which within the last few weeks has attracted some notice; and though somewhat out of place in a paper proposing to treat upon the working and ornamentation of metals, yet, in so far as the means employed to impress on metal certain indentations which are to be printed from, there is no difference whatever. I here refer to the art of natural printing, for which the Austrians have preferred a claim, taking to themselves an amount of credit to which, with all due deference to them, I think they are scarcely entitled, even had the invention been one of greater magnitude, and capable of a much more extended application than it really is; the process is simply that of producing on a piece of lead an impression from a natural object, such as a flower, a leaf, a feather, &c. This is done by means of rolls, as already shown. From the lead impression they take a copy by the deposit process, the lines of which are in relief; from this, again, they take another copy, which is printed from. The earliest application of the principle in which metal was used by the Austrians, in order to copy *lace*, appears to have taken place somewhere between May and October 1852; but Mr. Sturges had in August 1851 printed the two specimens of needlework and net now exhibited. It is very important to remark, that the English patent for the ornamentation of metals was sealed on the 24th January 1852, while the patterns of lace which directed the attention of Auer to the subject, was received by them at Vienna in May of the same year. The patent of Worrung does not appear to have been taken out until the 12th October 1852, three months after the English patent was specified, and when all the details of the process were explained at length in the then published specification. In the month of December 1852, I happened to be making some experiments on the process for ornamenting metals. I used various media, impressions of which I printed from; they are now before you. Reasoning from these, I at once saw that media of even a more fragile kind than had previously been used might be impressed on metal; I therefore experimented upon decayed leaves, feathers, &c., with the most perfect success, and as I think by your examination of the specimens exhibited you will readily admit. As my time is much taken up, the range of subjects has been somewhat limited from which I have procured impressions: but these have not been produced at third hand, as has been the practice of the Austrians, Messrs. Bradbury and Evans, and, until very recently, of Dr. Branson of Sheffield. In every instance save those in which I printed from transfers on stone, taken from my Britannia metal plates, I have printed from the plate indented by the object copied. The copying from the lead by deposition, using the lead impression as a matrix, and from the plate so copied with raised lines to copy another with sunk lines, which is that used to print from, can only result in losing many of the minute touches which constitute and form the chief recommendations of natural printing. ***In printing direct I therefore stood alone.*** Dr. Branson in the 'Journal of the Society of Arts,' has announced that a "step in advance had been made," by ***his*** discovering that Britannia metal was a better material than lead to take an impression, and it could be printed from. ***I made the discovery fourteen months ago,*** and acted upon it. If Dr. Branson had read the ***Athenæum*** of the 10th December last, he would have found I made no secret of the material used by me. In like manner, as to the application of the transfer to the lithographic stone; this I had also done some time before Dr. Branson's letter appeared. I must, however, hazard an opinion, that when lines of an exceedingly delicate kind occur, as in the down of a feather, the stone will not print a great number of impressions clear, but will be apt to block. Where the markings are clear and distinct in the object copied, the result will be more successful, though a want of solidity in the lines (a defect inherent to transfer lithography) may be anticipated.

In conclusion, it remains for me but to thank you for the attention with which you have listened to the paper just read. In treating the subject, a purpose has been kept in view—viz., to try to explain the principles involved in certain methods employed for the production of ornament, and this in order to guide the industrial designer to sure and certain results. To be successful, the processes involved in the production of articles of manufacture must be understood, and to this the earnest attention of all interested in the improvement of manufacture should be directed. The abstract teaching of design is comparatively valueless, and success will only be achieved when to the taste of the designer the skill of the workman is united. Without ignoring the higher walks of industrial art, that which addresses itself to the great body of the people should be specially cared for. In industrial art, as in poetry, we must have that which adapts itself to the various tastes and conditions of men. If we have Dantes, Miltons, and Shakspeares to pourtray the sublimity and grandeur of the unseen world, or express the deep, subtle, and nice distinctions which mark the mental constitution of man, we must also have Goldsmiths, Bloomfields, and Clares, who have a humbler walk, but who not the less address themselves and give delight to a more extended circle of admirers. If in painting we have Turners, Hiltons, Maclises, and Ettys, we must also have Creswicks, Redgraves, Mulreadys, Websters, and Friths. Taking nature for our guide, we find associated together structures the most complex and simple. Under the shadow of the rose blooms the lowly daisy; near the lordly oak the hawthorn blows. Let us, then, take care of that art which is intended to penetrate into the houses of the lowly. In doing this, we may be assured, that that which is intended to embrace a more exalted position will not be forgotten.

*Discussion.*—In reply to questions from different members, Mr. AITKEN stated, that from the Britannia metal plate then being printed from, on which leaves of trees were represented, he had already had upwards of 170 impressions taken. These leaves were dried; he had never attempted to transfer any in a pulpy state.

Mr. H. COLE (the Chairman) said—Of course the simpler the process the more valuable it was; and it therefore could not be denied that the nature printing of Mr. Aitken had great advantages over a system which had to pass through two or three processes to produce the same result. He apprehended there would be no chemical difficulty in printing in colours; it was purely a mechanical process. There appeared to be one point of difference between Mr. Aitken and Dr. Branson. The latter gentleman, he believed, had taken impressions of plants in their pulpy state. One of the dried leaves which Mr. Aitken had made use of he now held in his hand, and, although it was finer than the finest lace, it had not been injured by being pressed between copper plates.

Mr. Aitken believed that Dr. Branson originally used gutta-percha; and, after getting a deposit, it was transferred to metal. Where these things had to undergo two or three processes, the lines did not come out so smooth, fair, or well-defined, as when they were at once impressed on the metal. He should say that there would be a great difficulty in obtaining an impression of a leaf or flower in its soft or pulpy state, in consequence of the hardness of the metal and the pressure to which it was subjected. He then produced a coffee-pot of tinned iron, ornamented by this process, the medium being perforated paper. In reply to questions from Mr. Taylor, Mr. Aitken said he did not believe the impression would soon wear off in ordinary use; indeed, he had heated tinned plates so treated and wiped off the tin, and found the impression still deeply indented into the iron. He introduced this style of ornament in tin manufacture about two years since. In Sheffield he had seen large salvers chased for 8d. each, the work being done by boys who had received no instruction whatever in drawing. By the process of pressure the manufacturer, by paying a fair sum for an engraving in the first instance, might turn out a really elegant and artistic article at less cost than that now paid for the inferior workmanship.

Mr. H. Cole believed there could be no doubt on the point, that engraving might be almost constantly reproduced by pressure. The postage-stamp was a proof of that. There were 240 heads on a sheet of these stamps, and he was afraid to say how many millions of these sheets of stamps had been printed. Yet all had been produced from one head originally engraved upon steel, which had been repeated 240 times over on a sheet by the agency of rolling, and from that sheet impressions on plates had since been taken. The application of the principle and the proof of its costlessness might therefore be dated from the introduction of postage-stamps, though it had been previously applied to the plates from which bank-notes were printed, as a means of getting exact uniformity in a difficult and intricate pattern, and thereby render the detection of forgery comparatively easy. The cost of the postage-stamps to the country was so infinitesimal as scarcely to be worth consideration in comparison with the amount they produced.

## CABINET MAKING.*

Among the subsidiary trades connected with internal architecture, those of the cabinet-maker and upholsterer are the most important. Upon their co-operation it depends whether the design of the architect—if design there be—be carried out or marred, for it too often happens that these workmen are not dependent on the instructions of the architect. If architects were wise in their generation, they would when called in by private employers, or in the case of clubs, libraries, and the like structures, propose that they should superintend the furniture and fittings. Some architects, it is true, think this beneath them, —so Barry has not thought at the Westminster Palace or Reform Club; some are too indolent or too ignorant to charge themselves with such detail; some fear it will not repay them to undertake it. If a man has truly laboured to produce an artistic composition and effect, and if he is studious of his reputation, he will certainly not run the risk of having his labours frustrated by ignorant successors. Of course it will be said that employers or their ladies have their own notions, or as they call it, taste, as to furnishing; but we believe there are few cases where there would be any obstacle from such quarters if the architect took the trouble of entering into explanations on the subject. Those who have indulged their own taste are commonly very much annoyed when the consequences, in the shape of monstrous blunders, are pointed out to them; and the visitors to the cabinet of monstrosities at the Museum of Practical Art, have experienced such horror at seeing their favourite subjects in the *index expurgatorius* of that establishment, that they would willingly in the case of new experiments avail themselves of competent professional advice.

While there are such motives for the action of professional men, we believe there are some obstacles, for there are many not wanting in abilities or in knowledge of the higher branches of their art, who not having studied these matters of detail are incompetent for their treatment, and who, if intrusted with such a responsibility, offer such crude suggestions and tasteless designs, that their employers are not tempted again to incur the expense of demanding their services. Then again there are other members possessed of more taste, who make propositions so at variance with practical requirements and utility, for the mere purposes of display, that utilitarian householders refuse their concurrence. In this department utility is so essentially connected with art, that the two requirements are hardly to be dissevered, or if a preference be given, it must be to the former; and hence, to a well informed man, there is a particular gratification in the achievement of such results as may satisfy the eye and yet be found to minister usefully for the special purposes for which designed. Hence, on the other hand, a workman with less knowledge of art, but knowing better what is practically available, is often allowed full sway, to the detriment of what has already been done, and perhaps to the complete disfigurement of a well-balanced design, on which great expense has been incurred.

Why the labours of the architect should by any be held to end with the walls we cannot imagine, or why the upholsterer or cabinet-maker and their brother workmen should be let in to exercise independent functions, where they are naturally only ministers to the architect. Thus the architect designs the chimney, and the ironmonger is allowed to put in a stove utterly incongruous; the architect arranges his openings with due effect for the doors and windows, when the upholsterer comes and with curtains alters the effect of the windows, and puts in glasses which overbalance the arrangement of the doors or chimney piers. Then there is the paperhanger, who likewise operates on his own account, and who has a favourite contrivance in the arrangement of panels with borders, in virtue of which the doors, chimney, and windows come under such a form that it is made to appear as if the unfortunate architect had originally forgotten the means of access and lighting for the room, and that after the upholsterer had decorated it the architect had wilfully cut openings in his panels and ornaments for the requisite doors and windows. The gas-fitter sticks up a mediæval chandelier to match a Greek or Roman cornice; and the carpet planner declares war against the paperhanger, and lays down a totally opposed botanical or zoological illustration in an incompatible colour key. We have seen the ceiling, the papering, and the carpeting, each on independent and dissociative principles, with furniture and hangings, glasses, ironmongery, and gasfittings affording other incompatible members of the strange political community. The happy family in the cage at Trafalgar Square is nothing in comparison with some of the neighbouring mansions, where dissonant elements are congregated in far greater profusion and variety.

Upon what ground the upholsterer, the cabinet-maker, and the rest of the operators should be indulged in an independent career, it is difficult to understand, for unfortunately their artistic proficiency is neither attested by their education nor their works. We can very well understand an employer suggesting to an architect that he wishes an arrangement compatible with certain furniture already in his possession, or to accommodate some particular object; but it is not easy to see why the workman is to be allowed to carry on a virtual rebellion against the architect. The latter is the responsible artistic adviser, and the sooner he assumes this responsibility the better for all parties. The workman himself will profit by it, for his co-operation with the architect will train him in the combination of his works with a larger composition, insuring unity of design. The architect will benefit, because having an assurance that his ideas will receive due completion, and having before him the means of obtaining a better effect, he will be induced to study more carefully the means of obtaining interior effects. It need hardly be said that the employer and the public will obtain the full advantage from such co-operation.

If the architect finds it necessary to undertake such responsibility in his larger works, the same principle must urge him to a like charge in smaller works. Where this has been done very pleasing results have been achieved, and our exhibitions show some admirable interiors; but it has been well pointed out by "Candidus" and other writers in this *Journal*, that the variety of effects to be obtained by interior arrangements have been too little regarded. If the architect plans out certain rooms he commonly thinks he has done enough; he provides four walls, a

* 'The Cabinetmaker's Assistant: a series of Original Designs for Modern Furniture, with Descriptions and Details of Construction. Preceded by Practical Observations on the Materials and Manufacture of Cabinet-work, and Instructions in Drawing adapted to the Trade.' Blackie and Son, Glasgow and London. 1853.

ceiling, and a floor, and there his labours end: yet should he be fortunate enough to have the direction of a senate hall, of a club, or of a public library, he will not let a workman meddle with anything, but carefully prepares a design for every ornament and fitting. The recent arrangements as to churches have imposed a like care. Ecclesiological critics are exacting enough, and even to a chandelier or a free-seat there must be provided competent designs, preserving congruity of style and arrangement. The large class of works provided by the progress of church extension has given a valuable lesson in this respect, and has afforded good opportunities for training. What is wanted is to carry out the same system in domestic architecture, for what can be done for a palace or a club can be done as effectively for a villa, if not as sumptuously, and by the spread of sound principles would in time be provided for the cottage. The effect of a clubhouse arrangement, for instance, is very much enchanced by those judicious designs which have produced scenic interiors by the proper disposition of every detail.

The progress of the arts of design has been, there is reason to consider, materially impeded by the want of this salutary control on the part of the architect, for though certain conventional niches are sometimes provided, they are never filled with statuary, and panelling is not supplied with pictures, because the architect walks out with the plasterer, and the upholsterer prefers his own art to that of the sculptor and painter. The architect, on the contrary, prefers the co-operation of the two latter to that of the artistic workman, whose labours he adopts in subordination.

The work now before us takes up the subject in a proper spirit, and is calculated to produce a very beneficial effect on the trade to which it is addressed; and its greatest merit is, that it is a special work for a special trade, but none the less valuable to the architect, because it is a thoroughly practical work. The author writes for cabinet-makers, and he proceeds on the principle that it is much better to explain fully, and to be thought commonplace or trivial, than, by presuming too much on the previous knowledge of the reader, neglecting anything essential for information. For the workman, the course of practical geometry and mathematical drawing introduced will be very useful, because this is precisely what is essential for him to know, and precisely what is neglected. The author has not lost sight of the fact, that notwithstanding the progress we have of late years made, the majority of our workmen bestow far too little thought upon the articles they manufacture, whether as respects the materials of which they are constructed, the way in which they are made, the ends they are to serve, or the designs after which they are fashioned. Hence he observes, that many good plans are copied and re-copied by the unthinking many, without any intelligent appreciation, and, as a necessary consequence, the articles thus unintelligently copied have a constant tendency to degenerate in character in the hands of the copyist. He might even have added, that where an improvement is introduced it is rendered worthless, being wrongly applied.

It is well observed, that one of the leading causes of this state of things is doubtless the imperfect training given to apprentices, who when told what to do, are not properly shown how to do it, or the reason for doing it. He becomes a mere mechanical workman, even where a good one; and his reasoning faculties having been left dormant by his master, he seldom attains any particular eminence in his trade, and instead of an originator, becomes an inferior copyist. If, indeed, he should have the curiosity to inquire the why and wherefore, he is often thwarted by his master, it being a common practice in many branches of this trade to keep back instruction from the apprentices. In the metropolis, which is a great seat of the cabinet trades, employing many thousand hands, much is done by what are called chamber-masters, or in other places room-masters,—men working in a single room with an apprentice or two, or may be a journeyman, and jealous of the apprentice becoming a master and a competitor; for the amount of capital required for an outfit is so small, that in the special branches every apprentice looks forward to setting up as a master. This, which should be the element of good, is in many respects that of evil: the training of the apprentice is thwarted in the way we have stated, and the education of apprentice or master in design is neglected. The number of masters is, however, checked by various operations; for though in prosperous times and with high wages, many journeymen get the means to start as masters, yet their small capital becomes exhausted by their competition, by unfavourable bargains in wood, by long credit with the middlemen, and by bad debts. The existence of the chamber-masters in numbers favours the operations of a large number of middlemen, who keep the larger establishments, finish or put together the work, and supply the dealers, or themselves become dealers. Many of these work on the capital of the chamber-masters, from whom they receive long credits according to the extent of competition. These middlemen are in the habit of giving out designs in mass, which are reproduced by wholesale, and save the inferior chamber-masters from the necessity of designing. Some of the chamber-masters however, who are better instructed, submit their own designs to the middlemen, obtaining orders on the strength of the novelty or variety of such designs.

Another cause of the backward state of our workmen has been the want of schools of design, and of elementary instruction in drawing and modelling in the common schools, and this is a want which is being very slowly remedied. The author dwells on the advantages that the foreign workman has in the means of cultivating his taste, and he might have enforced this by the practical results, for although Australia has given a great impulse to our export trade, yet France, and more particularly Belgium, have a share in the export cabinet trade far beyond what their commercial position would naturally authorise them to obtain, and of course this is so much subtracted from the funds for the employment of our workmen, now devoted to the training of rivals. It is observed, with too great truth, that the workmen generally have not availed themselves to the extent they might have done of the means of instruction actually within their reach. Mechanics' institutes, schools of arts, &c., have during the last thirty years risen and multiplied in all our great towns, yet how small a portion of the young mechanics have taken advantage of them to acquire that knowledge of mathematics, natural philosophy, and kindred branches of study, that might through their means have been obtained. We regret, too, that the working classes have not derived all the advantage they might have done, and that the chief benefits have accrued to the more intelligent young men of the middle classes; but we believe that instruction has been much checked by the system of payment. It is the doctrine of the middle classes, that as money is the only thing to be valued, so education is only to be measured by a money price, and will not be valued unless it is paid for. This, however, is not the sentiment with the working classes, nor is it with the poorer students of the middle classes. In what are called the dark ages, a better spirit prevailed, and the poor scholar who had risen to wealth and dignity, remembering his early struggles, founded, for gratuitous instruction for the *pauperos et egentes*, those noble foundations now converted into sinecures for a few favoured churchmen and fellows. A very serious reflection on this great metropolis, notwithstanding the many benevolent and useful establishments we possess, is the paucity of institutions for gratuitous instruction. In attempting to compete successfully with our foreign rivals, we must have corresponding advantages, for the mere establishment of a few schools of design is not enough. We must have schools and institutions of the same character, and gratuitous admission. This we require on various grounds; among others, because the working classes, not being aware of the full value of instruction in design, need to be invited, and not repelled; and secondly, because many of the apprentices—hundreds and thousands, perhaps, in this metropolis — cannot afford to pay the moderate fees required for instruction, or must do so by the sacrifice of other objects. A little better acquaintance with the working classes would show at how hard a price is instruction obtained by the zealous learner. There are the fees for the school of design and the mechanics' institute, but the expense does not end there—there are books and materials. These expenses perhaps absorb those small savings meant as the reserve in sickness or dearth of employment. The working man, too, has his benefit society to pay, and has demands on his private charity, claims for a fellow workman in distress, for members of his family, and for trade purposes. Besides the money contribution, he must make a considerable self-sacrifice of time and disposition after a hard day's toil. The public benefit to be derived from the instruction of our workmen is perhaps greater than that of the individual, and at any rate it will answer public purposes to provide the moderate funds required.

A section of the work before us, which will be found very useful to cabinet-makers, is that on the selection of cabinet woods —a very difficult subject, one of great importance to the small master, and which is treated very minutely and very carefully. It is by no means uncommon for the cabinet-maker to pay a considerable sum for a log which turns out utterly worthless. The following remarks on Rosewood will illustrate this:—

"In selecting rosewood for purchase, it is of importance to attend to the size, soundness, colour, and figure, of the planks of which the various lots are composed. Planks of a small size, although bought at a lower price than larger wood, will be found less profitable to the cabinet-maker. For the manufacturer of picture frames, or of brushes, the narrow breadth is less objectionable; but in purchasing it as a material for furniture, the full-sized wood, although it cost more money, will be found the most economical. It is a matter of greater difficulty, in general, to secure *sound* wood, than to get it of a proper size; since, in importations of a fine quality, it is not uncommon to find the greater proportion of the planks, or half logs, scooped out on the heart side as if designed for pumps or canoes; and this may be the case to a considerable extent, even although it does not appear at the the ends of the wood. Pieces that are marked by sudden bends lengthways, are to be avoided as suspicious, where there is no opportunity to turn over and examine them. But the *colour* is of more importance than either size or soundness in rosewood. Much of it is to be found of a dull light brown colour, resembling nothing more than a dried peat; whereas in wood of good quality, the ground is of a clear sharp colour, varying in depth of shade from orange to dark red, having the graining or figure distinctly marked in black. In seeking to ascertain the colour, it is desirable to learn what it is near the heart; for often a thin rind of good coloured wood is found on the outside, enclosing a very inferior heart. The value, of course, is greatly increased when the wood is well coloured throughout. In seeking for wood of a fine figure, special attention is to be paid to the appearance of the annular rings, as seen in the ends of the planks. When the concentric circles of red and black are found regular, or only slightly irregular, much show or figure is not to be expected. But when, on the contrary, they are found in waving and tortuous lines, a good figure is certain to be found. Another indication of fine figure is the plank being marked by knobby protuberances, which, when pierced, are found of a light colour. These, when intersected by the straight line of the veneer saw, produce an abrupt dash of light, which contrasts very agreeably with the sober aspect of the general surface; and, therefore, planks having these knobs, and other indications of figure, should be carefully selected for veneers, while the plainer pieces are reserved for chair wood, couch-feet and scrolls, table-pillars and claws, and solid work generally. In cutting up veneer planks, regard must be had to the form of the concentric circles, in order to bring out the best figure which the plank is capable of exhibiting; and this object will be best secured by making the saw-draughts run as nearly as possible parallel to the circles.

"In drying rosewood, it is of importance to take care that it is neither exposed unsheltered to the rays of the sun, nor suddenly to artificial heat; for either will have the effect of producing cracks, which, even although they close, cannot be concealed in the finished work. To make good furniture of this wood it is especially necessary that it be gradually and thoroughly seasoned; otherwise it is sure to betray the neglect afterwards.

"Another peculiarity of rosewood is, that much of it is very porous, and that the pores are elongated on the surface, in a way that renders it difficult to produce a good solid body of polish on it. To remedy this, various plans have been tried. Size of various kinds has been employed to fill in the pores: but although well papered off, it furnishes a very harsh and ungenial surface to polish upon, and shrinks below the surface afterwards. Blackened bees'-wax has been rubbed in, and then cleaned off; but this has the effect of preventing the polish from getting properly riveted in the wood, and causes it, when the article is in use, to peel off on the least friction. The best remedy yet discovered, is, after the surface has been finished by the cabinet-maker, to rub it carefully in with plaster of Paris, coloured with rose-pink, which, after being *set*, is to be carefully papered off. This does not shrink like the size; and has the effect of preventing the oil used with the French polish from finding a hiding-place in the pores, whence it afterwards exudes on exposure to the air, and eats off the polish like rust on a metallic surface. The dull brown colour of a large portion of rosewood, has led to a variety of experiments to improve its appearance. Some have tried the dyeing of it with successive coatings of an infusion of logwood, but the effect is so unsatisfactory as not to repay the trouble. Others have used a strong solution of gum-dragon, or dragon's-blood, as it is commonly termed. This produces a very enlivening effect, in superinducing a rich purple hue on the dull brown of the wood; but it always presents the appearance of a thick coloured or painted medium being interposed between the spectator and the wood. We think it decidedly preferable to make use of a vegetable colouring, such as the extract of camwood, or other dyewood of the required tint; which, in solution with spirits of wine, produces the desired change on the colour of the wood, without suggesting the idea of its being painted."

The designs given for each description of furniture are very numerous, and very carefully described in the text. The work is a very useful one, and will we hope be successful.

## AUSTRALIAN AND COLONIAL RAILWAYS.

In consequence of the state of communication in Australia, South Africa, India, and our other possessions, I have submitted a plan, which has received the sanction of many of the home and colonial authorities, members of the legislature and capitalists, and which is now under consideration in Australia. The progress of Australia, it is felt, demands a large extent of railway communication. Such communication is there the more important, because the districts to be connected are far apart and the population scattered. In England a railway is considered necessary for a dense population,—in America for a thinly inhabited district, and as an instrument of colonisation and local improvement. Hence, no sooner does a Western State acquire the necessary organisation, than immediate steps are taken to form a railway system under circumstances far less favourable than those of Australia at the present moment. Nothing has indeed contributed more than these endeavours to the progress of the Western States, and the establishment of that vast population beyond the Mississippi; and there is nothing to prevent the like measures in Australia from being attended with equal success, the more particularly as there is no great inland navigation.

The want of railways has long been felt in Australia, and the cause has been ably advocated by her legislators, but hitherto no great undertaking has been effected. Through the liberality of the legislature of New South Wales, a short railway from Sydney to Goulburn is in progress under a liberal guarantee; the legislature of Victoria has made similar exertions for three other short railways, and South Australia has authorised two short lines. The main objects, however, remain to be accomplished, and of these the chief and first is a trunk line, connecting Sydney or Goulburn with Melbourne.

The length will be under 600 miles, and the cost per mile, if constructed upon the American system, will not exceed 5000*l*. a mile. It is believed that the necessary labour can be obtained at the same rates and in the same manner as in Canada and the United States. Chinese labour has been proposed, but there is some difference of opinion among the members of the legislature on this subject.

To establish such a trunk line the concurrence of several favourable circumstances is necessary,—the co-operation of capitalists, satisfactory financial arrangements, but, above all, the necessary legislative facilities. For an undertaking so large there are two modes in which the legislature can afford assistance. The one is by guarantee of interests or dividend, as done by the legislature of Canada, and as already carried into effect by the legislatures of New South Wales and Victoria. The other is by grants of land on the proposed line of route, a course sanctioned by Her Majesty's government in the American provinces, and successfully adopted in Illinois.

With regard to a guarantee, doubt is felt by members of the legislature of New South Wales whether it would be justifiable to enter into further guarantees burthening the finances of the province, the more particularly for such a length of railway as that of the trunk line in that province. With regard to a grant of land, most of the land on the proposed route is already appropriated within the province of Victoria. It appeared therefore most suitable that an application should be made for a guarantee to the province of Victoria, and for a grant of land to the province of New South Wales. For this latter purpose not only is the concurrence of the local legislature necessary, but likewise it is anticipated the authority of the imperial parliament to give the necessary power under the Land Sales Act.

With a view to promote the execution of such a plan, and to obtain the concurrence of the legislature and administrative authorities, a committee of co-operation was formed, in which the Australian interests are represented.

The appropriation of land, which it is to be hoped will be obtained on such a basis, would be one section or more on each alternate mile of railway. In Illinois six square miles per mile run is granted; for the trunk line of the American provinces ten square miles. The effect of such appropriation will be readily seen. It imposes no actual outlay on the provincial legislatures; and although it involves the free grant of a large tract of land, it is remunerative to the provinces, and in no way a diminution of their resources. The provinces, holding the waste lands within their bounds, are interested in every measure for their improvement; and it is almost needless to say, that of all means of improvement a railway is most efficient. By giving every second section to a railway company, the other sections on the line are necessarily enhanced in value to more than the amount alienated, besides the increased value given to all the neighbouring allotments. Thus the legislatures, like those of America, have every interest in making such grants and in promoting railway extension.

So far as capitalists and shareholders are concerned, such appropriation is most beneficial. On each mile of railway the minimum appropriation amounts to one mile square, or 640 acres. This taken at the upset price of 1*l.* per acre would be a considerable bonus on a possible outlay of 3000*l.* per mile, but the very construction of the railway immediately affects the value of the land. Taking the available land of the free grants at 600 acres per square mile, the following would be the value at the several rates stated below, and which would yield a minimum of 3000*l.* per mile run upon the one section only.

| Estimated Ultimate Value. | One Section per Mile Run. | Two Sections per Mile Run. | Five Sections per Mile Run. |
|---|---|---|---|
| £5 per acre | £3,000 | £6,000 | £15,000 |
| 10 ,, | 6,000 | 12,000 | 30,000 |
| 20 ,, | 12,000 | 24,000 | 60,000 |

Of course for South Africa these prices would be different; but still by this system the most effective basis would be offered for railway construction, giving extensive employment to our engineers and machinists.

To those of your readers who may be interested in the promotion of railways in the colonies, I shall be happy to give every information and to receive their co-operation.

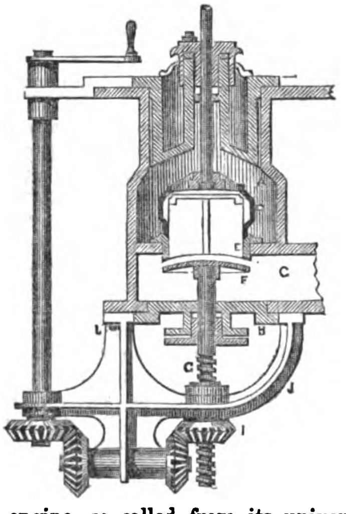
## SUPPLEMENTARY VALVE FOR CORNISH ENGINES.

— Birkinbine, *Patentee*, Philadelphia, U.S.*

The accompanying engraving shows a supplementary valve apparatus for Cornish engines, for which a patent was granted to Mr. Birkinbine in November last. The invention, though simple in itself, is likely to prove of considerable importance in connection with a class of steam-engines the merits of which have as yet been scarcely appreciated in this country, but which are now beginning to attract the attention of engineers, and will, without doubt, be eventually adopted in preference to all other hydraulic machinery for mining purposes, waterworks, &c.



The Cornish engine, so called from its universal adoption in the mining district of Cornwall, England, is single acting, the pressure of the steam acting on one side of the piston only, thereby raising the plunger and any requisite additional weights. The steam thus used in raising the plunger is afterwards admitted to the opposite side of the piston, and thus equalising the pressure on both sides, the weighted plunger descends and forces the water to the required height, completing one stroke of the engine. The steam contained in the cylinder is on the commencing of another lift of the plunger carried off through the exhaust-pipe to the condenser.

The several evolutions of the engine are effected by four valves; first, the regulator, through which is admitted the steam in the first instance, and whose movements are regulated by hand only; secondly, the steam-valve which admits steam to the cylinder; thirdly, the equilibrium-valve, by means of which the pressure on both sides of the piston is balanced; and, fourthly, the exhaust-valve through which the steam is carried off to the condenser. These valves are actuated by tappets on a plug-rod, which move simultaneously with the piston in conjunction with weighted levers, and the ingenious and well known cataract motion, the tappets serving to close, and the weighted levers (whose action is dependant on the cataract) to open the several valves. These are contained each in separate compartments of a chest or nozzle, communicating with each other and with the cylinder.

The required volume of steam is, in the first instance, admitted through the regulator-valve into the compartment occupied by the steam-valve, on the opening of which, by a weighted lever released by the cataract, the steam is admitted to the cylinder, thereby raising the plunger to the required height. In another compartment, which communicates with the passage through which the steam was admitted to the cylinder, is situated the equilibrium-valve, on the raising of which, the steam in the cylinder which has performed its duty of raising the plunger, passes into the space C, and thence through a pipe or passage to the opposite side of the piston, thus allowing the plunger to descend. The space C, communicates with the chamber of the exhaust-valve, as well as with the equilibrium passage; the exhaust-valve is, however, closed as long as the equilibrium-valve is open, and is not again brought into action until the engine is prepared to commence a new stroke. The accompanying sketch represents a sectional view of that portion of the valve-nozzle only which contains the equilibrium-valve, which will no doubt be sufficient, with the foregoing brief explanation, to render the apparatus familiar to our readers.

It may be here remarked that all the valves are of the double-beat description, so called from having two conical or beating surfaces instead of only one, as in the ordinary stalk-valve, and are in principle similar to those used in stationary and marine engines, and denominated balance-valves. D, is the equilibrium-valve contained in the compartment A, which communicates with the passage from the steam-valve to the cylinder. The seat of the valve D, is secured to the bottom of the compartment, and has a circular flange E, projecting through the opening. This projecting flange forms the seat for the supplementary-valve F, which is attached to the top of the screwed spindle G; the latter passes through a stuffing-box in the cover H, and screws into the hub of the bevel-wheel I, which runs loosely in the bracket J; this wheel is caused to revolve, and thus the supplementary-valve raised or lowered by the handle K, and shaft L, and the additional bevel-wheels.

The object of the invention is to arrest, more or less, as circumstances require, the passage of the steam through the equilibrium-valve from one side of the piston to the other, and, consequently, of regulating the descent of the plunger. The utility of the arrangement will be at once apparent: it obviates the necessity of adopting the old and tedious process of adding and removing heavy weights, while, in case of any breakage, or other accident occuring to the pumps in a mine, the damage likely to occur from sudden shocks is prevented by the facility of adjusting the valve to regulate the descent of the plungers.

It is in Cornish engines, when used for waterworks, however, where the utility of this invention may be brought into practice most advantageously, especially in those works where a stand-pipe is used to obtain the necessary head of water; in this case the fluctuation in the level of water is necessarily sudden, and of considerable extent, causing a similar variation of load on the engines, and rendering the machinery most unsafe and uncertain in its action. Should the head of water in the stand-pipe be low, the plunger would have a tendency to descend with a dangerous rapidity, which is checked in a moment by turning the handle K, so as to raise the supplementary-valve F, thereby arresting the steam on its passage from one side of the piston to the other, the plunger consequently descending with a safe and gradual motion. Should the head of water, on the contrary, be high, the valve F, is instantly withdrawn from the seat, and a free passage given to the steam, the head of water being in itself sufficient to ensure an easy descent of the plunger.

* From the 'Journal of the Franklin Institute.'

Although the apparatus is shown in the sketch as regulated by hand, it is proposed in some instances to allow the variations in the head of the head of water to be the means of adjustment, an application which might be made by a simple arrangement of machinery. It is Mr. Birkinbine's intention to apply his supplementary valve to the large engines he is now erecting for the West Philadelphia Water Works.

## RAILROAD SWITCH POINTER.

John Maston, *Inventor*, Saratoga, N.Y.*

The importance of a switch pointer which will show the engine driver at a glance, and without chance of mistake, whether the switch at any junction is in its proper position, is so great, that many forms of it have been invented, none of which have yet given perfect satisfaction, being either too clumsy, too complicated, or liable to be mistaken in their positions. The ordinary ball attached to the upper end of the long lever, indicates the position of the switch only by the inclination of the lever from or towards the line of rails; consequently, in dark and misty weather, the lever, which is generally thin and black, cannot be seen, and the position of the ball of itself indicates nothing. The vertical switch pointer, which shifts the rails by a crank at the lower end, and changes the vane at the top *across* the line of rails, or *parallel* with them, while it possesses great compactness and simplicity, has the defect, that when the switch is set for the main track, the *edge* of the vane is towards the engine driver, presenting the same appearance as if the vane were broken off altogether—an accident, by the way, which not unfrequently happens. On this switch also it is difficult to arrange lights for night signals.

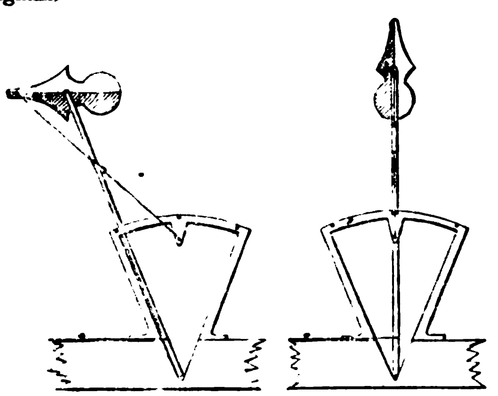


Fig. 1. Fig. 2.

The switch to be described, invented by Mr. John Maston, of the Repair Shops, Saratoga, N.Y., is intended to obviate these difficulties, and to indicate always unmistakeably for which line of rail the switch is set. The arrangement will be easily understood by reference to the annexed engraving. The dimensions are given for a particular case, and can be varied to suit circumstances. The long lever of the pointer moves about a pin through its lower end, and at a distance of 1 ft. 1 in. from this pin is jointed the horizontal bar which shifts the rails, which in this case switch through 4¾ inches. The entire length of the long lever from the bottom pin to the centre on which the vane is hung, is 6 ft. 6 in. The lever moves between the jaws of an arc 2 ft. 6 in. from the ground, in the upper edge of which notches are made, and a spring bolt on the lever retains it in its place when set for either track—a lock can very conveniently be applied to this bolt. The vane is of cast-iron, about 1 ft. 10 in. in length, and hung upon the upper end of the lever by a pin passing through it near its centre of gravity, the round end of the vane slightly preponderating. On a lug projecting downward from the arc, a rod is jointed at a distance of 2 ft. 9¾ in. vertically above the lower end of the lever; the other end of this rod, which is 4 ft. 8 in. long, being attached to a pin in the centre line of the vane, near the *point* 11½ inches from its point of suspension. This rod is forked where it crosses the lever, as represented in the drawing, embracing a pin in the lever, to make the reversing action more steady.

* From the 'Journal of the Franklin Institute.'

When the switch is set for the main track, the rod and lever, by their relative proportions, keep the vane in a vertical position, pointing directly upwards, as shown in fig. 2, showing the *whole flat side* of the vane to the engine driver, instead of the *edge*. Then, when the bars are shifted on to a siding, the lever moves over towards the siding, and the vane is turned by the action of the rod through a quarter of a revolution, pointing towards the track for which the switch is set, as in fig. 1.

It is obvious, that if the switch is for three tracks, when turned to the other side, the vane will point in the right direction for the third track. The vane is represented in the cut as painted half red, and half white, so as to be distinguished against any background. The proportions given, can of course be modified to suit particular cases. If the sinking of the lower end of the lever below the ground should be thought objectionable, it can be raised, and the switch rod bent down to the rails, or it may be made a lever of the first order, in which case the arrangement of the shifting rod must be altered.

Its advantages appear to be principally, great distinctness, the position of the vane being so decided as not to be possibly mistaken, and being not an arbitrary signal, but one easily understood, the vane actually pointing towards the track for which the switch is set. At night, different coloured lights being hung at the two extremities of the vane, their relative positions will indicate as well as the vane itself. In case the vane and its connections are out of order, so as not to indicate the change of track, the rod will prevent the lever from moving freely; and thus attract the attention of the switch tender. It is not composed of any complicated pieces, requiring expensive patterns or very exact forging, and is very easily repaired. Most of the ordinary lever pointers could be altered to this plan.

The switch pointer has had the great advantage of the test of experience. It is not merely a model, but has been in constant use about the stations at Saratoga and Ballston, and on the main line, where it gives more satisfaction than any switch hitherto used. An objection which may probably be urged against it, is, that the rods may be easily bent; but in practice this does not appear to be the case; at any rate, they being of wrought-iron, can be set upon an anvil in a few minutes, if they become bent.

## AMERICAN PATENT LAW REPORT.

*Report of the Examiners of American Patents for the year* 1852 (Part I., *Arts and Manufactures*. Washington. 1853.

[Second Notice.]

These reports, which are furnished annually to the Commissioners of Patents by the six Examiners of the Patent Office, although, from their brevity, they afford but an imperfect epitome of American patents, are nevertheless useful as an indication of the progress of the inventive genius of that country. Mr. H. B. Renwick impresses upon the American legislature the necessity and value of a succinct and clear digest of every patent, to be accompanied with carefully prepared drawings, when necessary, in a manner similar to the 'Brevets d' Invention,' published by the French Patent Office. He also at the same time reprobates as useless and superfluous, the project of publishing a systematic report of American inventions from the commencement of the present century up to the present day, and recommends that it should commence from the date of the present American Patent Law, thereby avoiding much that is crude and valueless.

Although no striking novelty of principle has appeared in these reports, yet much that is valuable and useful may be extracted from them. We have given a few of the chief inventions for which American patents have been granted. Under the class of Metallurgy, under the superintendence of Mr. H. B. Renwick, the first noticeable patent relates to a novel form of Reverberating Furnace, which is designed to dispense with the labour of stirring and balling materials exposed to the action of the fire in these furnaces. The grate, fire-chamber, ash-pit, and fire-bridge are constructed of brick in the usual manner. The body of the furnace, the roof, and working bottom are omitted, and their place is supplied by a cylinder of cast-iron lined with fire-brick, and caused to revolve upon metallic rollers by means of a cog-wheel or belt. This cylinder has an area about equal to that of the ordinary working chamber, and is provided with a door or man-hole. The materials, broken pig for instance, are introduced through the door, which is then closed; motion is now given to the horizontal cylinder, and each portion of its periphery in turn becomes the bottom, while the contents are rolled or turned over and over, and as continually agitated and exposed to the flame, which passes through the cylinder on its way to the chimney, as if acted upon by the ordinary rabble.—Another Furnace, having a similar object, has its bottom formed of a circular cast-iron table, covered with brick, and revolves on a vertical axis under the ordinary fire-brick roof of the reverberating furnace. Through the ordinary working door projects into the furnace and over the revolving bottom a rabble, connected at its outer end to a slide actuated by machinery, which imparts to it a reciprocating motion. This slide runs upon a guide, whose angle to the side of the furnace may be changed by the operator, and the rabble be thus forced to stir over every portion of the working bottom.

A useful invention relative to "Foundry apparatus," applicable to small castings, or pipes of less than 3 inches diameter, consists in an improved machine for tempering the sand, which is afterwards sifted and deposited in measured quantities in a flask; parting sand is then applied in the proper locality, and a pattern is forced into the flask. The machine then removes the pattern and returns the flask. The interior of the flask is shaped in such manner that there shall be the greatest depths or thicknesses of sand in the direction of the greatest compression, caused by forcing in the pattern, thus securing an equally hard face over the whole moulded surface. The same patent includes an improved core spindle, consisting of a long iron bar, of the sectional form of a cross, covered with wire from end to end, which thus takes the form of a helix. This spindle is coated with loam, and serves as the nucleus of a core more pervious to the air, and less apt to blow than those ordinarily employed.

An improved method of lifting the ordinary Trip Hammer, whereby any different degree of blow within the range of the lifting cams can be readily attained, consists in causing the cam, instead of acting directly upon a lifting leg, to act upon the end of a lever embracing the leg, and vibrating in a vertical plane. This lever is provided with a toggle catch, which grasps the leg firmly when the lever is raised, but has no hold thereon when the lever is falling. The point to which this lever shall fall is regulated by a wedge. The cams in their revolution strike it sooner or later according to the distance it has been permitted to drop, and the instant that the lever commences to rise it clasps and holds the leg, forcing the hammer up a distance proportioned to its own ascent only.

An invention for ensuring an equally sound and hard face on the entire surface of Anvils consists in forming the body of the anvil with a cavity extending from its bottom nearly to its face, allowing of the introduction of a stream of cold water to the centre of the mass, which is therefore cooled as rapidly as its exterior, and the soft spot in the centre of the steel face is prevented.

A machine for Threading Wood Screws has its centre somewhat like the fusee of a watch, but the grooves are in three sections, parallel to its axis, and deeply notched or serrated so as to form a series of cutters, counterparts of the thread of the screw to be cut. This cutter has a swift revolution on its axis, and its periphery revolves in contact with a blank, properly supported and presented to it; the blank revolves in the same direction as the cutter, with a slight motion in the direction of the axis of the cutter, and presses against the periphery of the same, so as first to mark, then to deepen, and finally to finish its thread. This machine renders the manufacture of small screws as profitable as those of the medium size.

A machine for forming Nuts acts in the following manner:—A heated iron bar, about the width and thickness of the intended nut, is advanced over a die-box of the exact shape of the periphery of the nut to be made. A die then descends, severs a blank from the bar, and forces it into the die-box. This die is bored out precisely to the same size as the aperture required in the nut, and as it carries the blank along forces it, still enclosed in the box, against a cylindrical punch, which punches out the hole, carries the disc it severs, and enters into the aperture in the die. This die, with the nut now punched out, and upon the punch in front of it, still advances until it brings the nut in contact with the face of another die, which, like itself, fills the die-box, and commences to move in the same direction as the first die is travelling, but with a less velocity. The nut is therefore submitted to powerful pressure between these two dies while still on the punch, and all cracks incident to the cutting or punching of it are thoroughly welded up, while the exterior of the nut is forced so strongly into the moulded faces of the dies, that, when discharged from the machine, it is nearly equal in smoothness to a nut that has been planed.

A machine has been patented for making the Thimbles used in the Rigging of Vessels. These thimbles are metallic rings, whose outsides are grooved, and whose insides are convex to the same extent that the exterior is concave. The machine consists of two shafts having a common axis, and so arranged as to revolve at the same time and in the same direction, and to be caused to approach or recede from each other. The contiguous ends of these shafts are provided with forming discs of the requisite shape to form the interior of the thimble. The discs, when brought together, exactly fill the finished thimble. A hammer, whose face is an exact counterpart of one quarter of the outside of the thimble, is so arranged as to strike repeated blows upon a piece of heated iron laid upon the discs, which, in course of revolution, present new surfaces of the iron to the action of the hammer, until it is bent into the circular form requisite. The shafts are then separated by a lever, and the finished thimble drops between them.

An ingenious automatic machine has been patented for performing, on a large scale, the well-known metallurgic operation of spinning up from a flat disc in a lathe, cups, platters, copper kettles, or brass batteries, &c., usually shaped by repeated blows of a small hand-hammer. A burnisher, provided, if necessary, with a friction roller, is forced, by means of screws and guides acting in curved slots, to travel in close contact with the exterior of a revolving cast-iron conical mandril. The flat disc of metal is clamped upon the apex of this conical former, revolves with it, and is gradually formed into shape by the action of the burnisher, Several mandrils, each more nearly approaching the form of the finished article, are employed to complete the operation of bringing the metal gradually, and without straining, into its new shape. An invention relating to the making of wrought-iron nails consists in arranging in the interior of a revolving ring, a radial series of gripers or pincers, each of which grasps firmly a blank. This ring revolves on its own axis, having an intermittent rotatory motion always in the same direction, and the gripers between each rest of the ring each revolve through a quadrant on their own axis. Inside the ring, and having axes coincident with it, are two rings carrying each a corresponding set of dies, one for each blank. These dies are arranged at different distances from the axes of their respective rings, the greatest difference being the length of a finished nail; and those attached to each ring are divided into two complete series, the one of narrow face being forgers, and the other much wider acting as finishers. The radial distance of these dies from their common centre is so graduated that each in succession acts upon a portion of the blank nearer to the point, the head thereof being held in a griper. When the griper ring is stationary these series of dies approach each other, each die giving a blow to the blank presented to it. The last griper in the series then drops a finished nail, and the first is provided with a new blank. On the movement of the griper wheel or ring, each griper makes a partial revolution on its axis, and, while doing so, advances the distance between two dies, and presents its blank, turned on its axis, to the secondary pair of dies, which again approach, as does the whole series, and act on the nail nearer its point than before. These motions are continually repeated until the nail is completely forged.

Under the class of Steam and Gas Engines, many practical and ingenious inventions have been patented, amongst which may be mentioned an improvement in Float-Gauges. In this arrangement, a vertical chamber or tube of large bore, is connected by branch pipes to both the steam and water spaces of the boiler, at some distance above and below the usual water level. This tube or chamber is closed at top, and is firmly cemented at bottom, below the lower branch connection, to a glass tube extending far below the water level and closed at its lower end. The upper tube has within it a float, from which descends an index-rod into the glass attachment. This index, owing to the absence of circulation in the glass tube, is always moving in water comparatively clear, cool, and unchanging in its temperature, and exercising no tendency to corrode or deposit upon the glass, or to fracture the same through sudden changes of temperature; the index, therefore, is always visible and less liable to disruption than the ordinary glass guage. Several varieties of syphon guages have been patented, for indicating the level of water and pressure of steam in the boiler at any point above the same; these prove eminently useful when applied to marine boilers, as the indicator may be located in the spar deck or hurricane deck, or pilot's house of steamships, thus giving the officers or engineers a check upon the firemen or stokers, without the necessity of visiting the fire-room.

An ingenious apparatus, capable of producing almost infinitely varied movements and stoppages of the Valves of Engines, is worthy of notice. Upon an ordinary eccentric, but outside the collar, in the direction of the length of the shaft, are cut cog-teeth. To the collar is fitted a hollow eccentric rod, carrying a small shaft, whose axis is parallel to the small shaft. The former shaft is free to revolve, and carries a main cog-wheel in gear with the teeth on the eccentric. This shaft also supports an eccentric provided with a collar, and a rod which passes through the hollow main eccentric rod, and carries the hook which takes in the pin of the rock shaft arm. The first eccentric imparts its usual motion to its rod, and by means of the cogs causes the secondary shaft to revolve, which actuates its own eccentric and rod. This latter rod, therefore, gives off a compound or duplex motion, dependent upon the varying throws of the two eccentrics and their relative position at any given time. A change in the relative diameters of the two cog-wheels will modify the differential or additional motion of the two eccentrics, as communicated to the secondary eccentric rod, causing it to move as if actuated by a cam of any desired form, at the same time avoiding jars and strains.

In an improved Vertical Engine, the pillars supporting the cylinder above the bed-plate are so shaped and arranged as to constitute the air pumps and condenser, thus effecting a saving of space and imparting additional firmness to the engine. In the same engine, the cut-off slide of one cylinder is actuated by a connection from the slide-valve cup of the other cylinder, the valve chests being arranged back to back. A supplementary sliding valve is also added in the side of the valve itself, by means of which the engine can be worked with full steam throughout the stroke, without altering the expansion gear.

In an ingenious arrangement of the Marine Steam Engine, the piston rod takes hold of a cross-head lying in the plane passing through the crank, from the four ends of which depend straps, attached to and moving up and down a ring surrounding the cylinder. The motion of this ring is governed by guides, and it has surrounding it a second ring, connected by two pivots, lying in a vertical plane passing through the shaft. To points ninety degrees from these pivots, on the outer ring, are attached the two ends of a forked connecting rod; the uppermost end of this rod forms the stril end, which receives the brass encircling the crank pin. This rod, as it rises and falls, oscillates with its ring upon the pivots, and at each oscillation passes into the split cross-head formerly named. This engine therefore occupies no more room than the ordinary oscillating engine, and dispenses with the trunnion, so objectionable in that description of engine.

In the department of Navigation a new system of Screw propulsion was patented by a French inventor, the object of which was partially to avoid the resistance offered by screw propellers, incapable of being hoisted out of water, to the progress of the vessel when under sail only. The wings of this propeller are arranged in pairs, and of equal width only with the dead wood of the vessel. The first pair, if there be six wings, is attached to a hollow shaft, the second pair is fastened to another hollow shaft concentric with and inside the first shaft, and the third pair is secured to a solid shaft inside the second shaft. The shafts are fitted with gearing and clamps, or their equivalents, to provide for alterations in their angular distance with respect to each other, or to clamp them in any specified relative position. This gearing is situated within the vessel, and by means of it the various blades are spread around the whole periphery of a circle, so that each acts in turn and in the same position as in an ordinary propeller. When the propeller is no longer to be used, and sail employed, the blades, by means of the gearing, are revolved so as to fold the one behind the other, like the leaves of a shut fan, and the whole set turned in a line with the dead wood, so as to offer little or no resistance to the progress of the vessel. The engine drives the whole of the shafts without altering their relative angular position, which is maintained by apparatus independent of the engine.

By a provision of the act of 1836, it is required that every applicant for a chemical patent in America shall deposit in the hands of the Examiner "specimens of the ingredients, and of the composition of matter, sufficient in quantity for the purpose of experiment;" these specimens it is the duty of the Examiner to test, and according to the result of his experiments the patent applied for is granted or refused. But by that fatality which occasionally attends the proceedings of most governments, whilst the American legislature passed the above measure, it provided no laboratory, or apparatus, or tests to experiment with, in consequence of which great inconvenience has been occasioned to the patent office and injustice to the inventor and the public, many patents having been granted that would have been refused, and others rejected that should have been granted. It is to be hoped that the petition of L. D. Gale, the Chemical Examiner, for the amendment of these anomalies, may meet with the sanction of Congress, and that this important section of patent routine may no longer be a source of annoyance and injustice.

The Report furnishes an abstract of each of the 48 Chemical patents, and much important information may be derived therefrom. The class of Agriculture includes no less than 27 patents for harvesters and 26 for seed planters, and embraces many highly ingenious and useful implements of agriculture. Under the class of Mathematical, Philosophical, and Optical instruments, 81 patents have been granted, embracing electrical apparatus, telegraphs, batteries, time-pieces, numbering machines, and pneumatic gauges, amongst which may be noticed:—A geometrical measuring instrument for finding the centres of wheels or circles, constructed upon the well-known principle, that if two tangents be extended until they intersect each other, a straight line bisecting the angle between them will pass through the centre of the circle. The instrument consists of two moveable arms united at one end, at right angles to each other, with a straight ruler attached to the meeting point of the two arms, and moveable upon a guide supported by the other extremities of the same. On marking the first diametrical line the instrument is placed at right angles to such line, and the centre of the circle readily determined.—A curious instrument is to be applied to omnibuses and other vehicles, whereby the weight of passengers is accurately registered, and those persons above the average weight are registered as liable to double fare.—A weighing machine, consisting of a platform, acting by means of a system of levers upon a vertical connecting rod, which operates by a rack and pinion upon a pendulum, the deflection of which from the perpendicular, indicated by a dial or index, determines the weight upon the platform. An extra platform rests upon knife edges at either side of the first, one edge of each lying upon the weighing platform, and the other edge touching the ground. These allow the carriage upon which the goods are placed to be gradually brought upon the weighing platform, therefore avoiding all jerking and inaccuracy of measurement of the pendulum. The pendulum registers the excess over a certain constant weight, and a second register, which counts the number of weighings, accounts for this constant weight, thus forming a very rapid weighing and self-registering machine.

Under the section of Stone and Clay Manufactures have been patented several machines; amongst the most important are —A Stone-dressing machine, in which the cutting chisel, instead of acting upon the stone by a blow, is actuated by a short crank or eccentric and connecting rod. The reciprocating motion of the chisel causes it to act upon the stone at the end of its stroke, and by the intense pressure it is capable of exerting at that point, chips it away, as fast as the stone, mounted upon a sliding carriage, is carried beneath by a gradual feed motion. A series of cutters, made to act alternately or in succession, is extended across the whole width of the stone.—In a Stone-drilling machine the drill-stock works between the grooved circumferences of two pairs of wheels, which, revolving in opposite directions, carry the drill-stock first one way, to give the blow, and then back again. The drill-stock is grasped or held by the two wheels of one pair only, a part of the circumference of the wheels of each pair being slightly reduced in such manner that while one pair is binding the drill-stock and giving it motion, the other pair serves only as a guide. The draw or binding part of the first pair, which gives the advance motion to the drill, is a trifle shorter than that of the second pair, in order to release the drill-stock just before the drill is ready to strike the stone. With this precaution the two pairs of wheels command both the blow of the drill and its progressive advance as the material is cut away. The turning of the drill is effected by placing the two wheels of the second pair a very little oblique to the direction of the drill-stock, thereby imparting to it a slight screw motion. These wheels are also made of smaller diameter than the first, to prevent any rapid return motion of the drill. In another of these machines, the drill-stock works through the hollow piston-rod of a small steam-engine, and is clamped thereto by an apparatus attached to the cross-head, which holds the drill-stock until just after the middle of the stroke, when, by the action of a fixed cam, it is unclamped, and proceeds with full velocity until it strikes the stone, before the piston-rod has completed its stroke. A spring reclamps the drill-stock, and it returns by the back stroke of the piston. The clamping apparatus causes the drill to rotate, and ensures its progressive advance to its work.

Under the section of Hydraulics and Pneumatics is patented a Turbine, the buckets of which are capable of adjustment for different heads of water, without changing the curvature of the buckets, by means of a sliding plate of the same width and curvature as the bucket; the moving of this plate outwards extends the curvature of the bucket, and diminishes the orifice of discharge.

Under the class of Civil Engineering and Architecture 38 patents have been granted, relating to railroads, hydraulic works, excavating and boring, bridges, &c.; but nothing particularly worthy of notice has been brought forward. 50 patents were granted for land conveyance, and 36 for mills of all descriptions.

The Report adverts to the impossibility and impolicy of the Examiners answering letters addressed to them, announcing discoveries, and requesting their opinion upon their novelty and utility. The examination necessary to decide these points would entail too much extra labour upon the Examiners, and any opinion or decision issued by them would undoubtedly commit the office in a way that would not be endured in any tribunal of law. Even a cursory opinion might embarrass the future consideration and disposal of the case, and should not be asked for any more than the views of a judge upon a question which he might be called upon to try. Persons requiring and interested in information respecting the practice and requirements &c. of the Patent Office of America, will find appended to these Reports a guide to the necessary routine.

## PADDLE-WHEELS.

AUGUSTE E. L. BELLFORD, *Patentee*, December 19, 1853.

(*With Engravings, Plate* XVII.)

THIS invention consists in arranging and combining the floats of paddle-wheels in such a manner that they form a continuous series of rhomb-shaped buckets all round the wheel. This method of arranging the floats prevents violent concussions when they strike the water, and holds the water upon which they act in an unbroken body, thereby rendering their action more effective than that of the ordinary floats.

Fig. 1, Plate XVII., is a front view of one of the improved paddle-wheels. The frame of the wheel, consisting of the bosses A, arms B, and rings C, is constructed in the usual manner, and strengthened by oblique stays *a*, *a*. The floats D, are made of sheet-iron, united together and to the arms by bolts or rivets, and arranged with their outer edges in lines running spirally round the wheel in opposite directions, at angles of about 75° to the axis; the intersection of these lines forming a number of rhomb-shaped buckets E, having their openings towards and from the centre of the wheel. The inner openings are contracted, and depart from the rhombic form, owing to the side angles being cut off and the figure made six-sided, thus giving the front angle such a form as to prevent back-lift in rising from the water. The number of buckets depends upon the width of the wheel; the one shown in the drawing includes three buckets. A number of triangular-shaped half-buckets will be unavoidably formed close inside the rings, but the wheel might be made of sufficient strength to dispense with the rings by uniting the floats and arms.

This wheel acts upon the water with a successive series of rhomb-shaped close buckets, of which the two front sides of the rhomb impart a propulsive effect, while the two back sides prevent the breaking up of the water upon which they act, and the consequent loss of their effect, and also from the front sides or propelling parts of succeeding buckets. The operation of this wheel is the same in whichever direction it turns, and as it is self-bracing it can be made of great strength.

*Claim*.—Arranging and combining the floats so as to form a series of buckets of rhombic or substantially similar form, as and for the purposes herein set forth.

## STEAM-BOILERS.

(*With Engravings, Plate* XVII.)

THIS invention has reference to the more perfect combustion of the gases generated by the ignition of the fuel; the attainment of a large extent of heating surface without subjecting any part to a very intense heat; the prevention of explosions produced by great diminution of the quantity of water; and the reduction of the necessary weight of metal and quantity of water in steam-boilers.

Fig. 2, Plate XVII., represents a vertical section through the centre of a boiler, constructed according to these improvements; and fig. 3, a horizontal section of the same, taken on the line X Y, of fig. 2. A, is the outer cylindrical shell of the boiler; and B, an inner cylinder, united to annular plates *a*, *b*, the space between them forming an outer water-jacket. C, is a cylinder or hollow frustum of a cone, united at its lower end to a cylinder D, open at bottom and terminating in a dome E, and at its upper end to the cylinder B, which also terminates in a dome F. The space between C and D, forms a second water-jacket, communicating with the outer water space through holes *c*, *c*, in the cylinder B, thereby maintaining the same level in both water-spaces, which are connected at bottom by a blow-off pipe *e*, and cleared out by one blow-off cock *f*. The outer shell A, rests upon a circular base G, containing the ash-pit and the fire-grate H. K, is a circular flue between the bottom of the outer water-space and the shelf I. J, J, are vertical tubes, connecting the flue K, with an upper flue L, formed by the dome M. Within the innermost cylinder D, are two vertical coils of tubing, N, N′, connected at their lower ends to the outer water-jacket, and terminating at top in two vertical pipes O, O′, reaching nearly to the top of the dome F, into which they open with their mouths turned downwards.

The water-heating surfaces of the boiler consist of the cylinders B, C, D, the dome F, and the coils N, N′; the gases, &c. rise, and are consumed in the cylinder D, and the space between the water-jackets. The products of combustion descend and pass off into the circular flue K, from whence they escape through the tubes J, J, to the flue L, and from thence to the chimney M′. The steam generated rises into the dome or chamber F, and passes off for use by any suitable contrivance at P. Steam is generated in and rises through the coils of pipe with such rapidity, that streams of water are constantly and forcibly driven through them into the steam-chamber so long as any water remains in the boiler; the water then descends to be again carried up, and thus a constant circulation of water is produced in every part of the boiler; and in the event of the water becoming low in the water-jackets, this circulation has the effect of keeping the heating-surfaces moist, obviating the danger of explosion, and preventing the plates from burning or any accumulation of impurities in the coils. The small quantity of water covering the heated surfaces becomes rapidly converted into steam, which passes by the pipe R, into the coil Q, in the space between outer and inner water-jackets, when it becomes surcharged with heat, and from whence it is conducted by the pipe S, to the engine. *d*, is a small pipe admitting a minute stream of water from the outer water-jacket into the pipe R, for the purpose of tempering the dryness of the steam. The form of the boiler is well adapted to withstand pressure without the aid of braces or stays.

*Claims*.—1. A boiler composed of an external water-jacket, with steam-chamber at the top, and with or without one or more inner water-jackets connected and in communication with the outer water-jacket, when either water-jacket is surrounded internally with one or more vertical coils of pipe, whose lower ends connect with one of the water-jackets, and whose upper ends discharge into the steam-chamber, substantially as set forth; 2. Drying the steam by passing it through a coil of pipe, within or between the water-jackets, substantially as set forth.

## MOULDING AND CASTING.

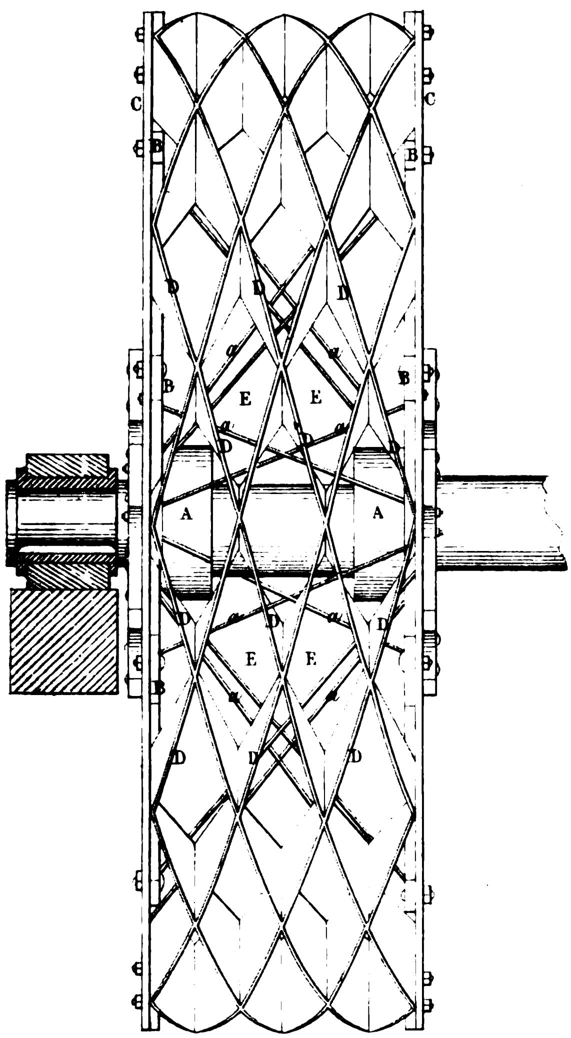
JULIAN BERNARD, *Patentee*, April 25, 1853.

(*With Engravings, Plate* XVII.)

THIS invention relates to a method of casting metals or moulding plastic materials of any kind; such casting or moulding being effected in a partial vacuum obtained by extracting the atmosphere from the moulds in which the metal or other materials are to be cast or moulded.

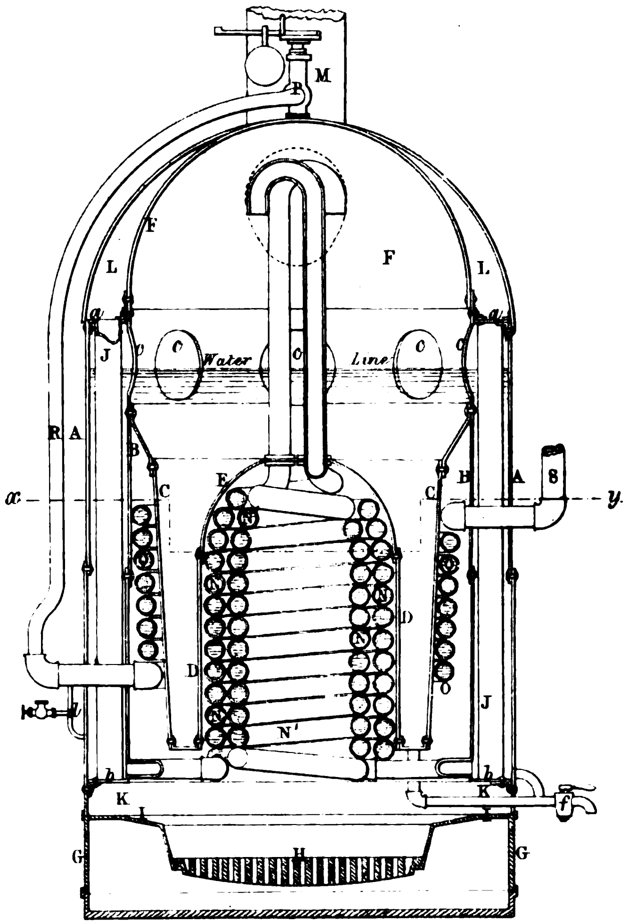
Improved Paddle Wheel.

Fig. 1.



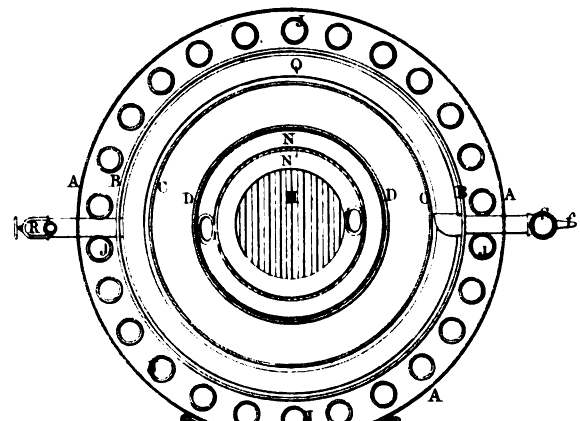
Improvements in Steam Boilers

Fig. 2.



Plan View

Fig. 3.



Improved Moulding Apparatus.

Fig 4

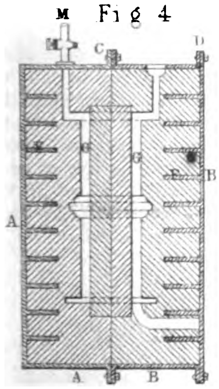


Fig. 5.

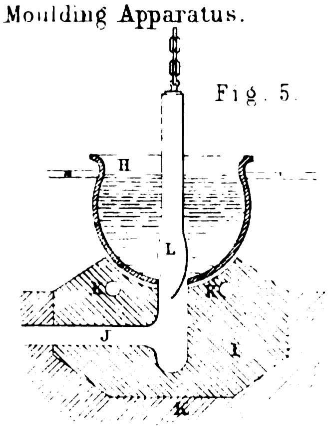

When metals are cast according to this process, the pot or crucible containing the metals has a hole in the bottom part plugged by a fire-brick or plug of any suitable material; the pot is placed over an air-tight channel communicating with the mould, which may be kept at any desired temperature by the application of steam or heated air, or cold water or air.

Fig. 4, Plate XVII., represents a vertical section of a moulding-box and mould for a steam-engine cylinder; and fig. 5, a section of the crucible or ladle of molten metal. A, B, are the moulding-boxes, joined together by flanges C. The box A, has its bottom cast on; the box B, is made in the ordinary manner, open throughout, but fitted with extra flanges at D, to receive the cover or plate E, which is bolted tightly up, to exclude as much as possible the external atmosphere from the interior of the mould G. The crucible or ladle H, containing the metal is supported on the fire-brick I, which is divided longitudinally down the centre of the channel or passage J. The ladle H, rests upon a bed of loam, which completely excludes the atmosphere from the channel J, and the interior of the mould. A plug of fire-clay L, is fitted into the aperture in the bottom of the ladle, and is there kept by the superincumbent pressure of the metal. A cock M, and flexible tubing connects the interior of the mould with an air-pump or other exhauster. When a sufficient vacuum is obtained, the cock M, is closed, and the plug L, in the ladle withdrawn; the metal is then forced into the mould by atmospheric pressure until it reaches the level of the cup N, which cup is closed before exhausting by a disc of metal or loam O. This disc is displaced by the rise of the metal in the mould, and indicates that a sufficient quantity has been run in, when the plug L, is immediately let down by a cord or chain, and the supply of metal consequently stopped. This system of casting produces a superior surface and sharpness of outline, the casting being perfectly free from air-bubbles or impurities. The moulding of plastic or soluble materials is effected in a similar manner to the method above described.

## MANUFACTURE OF IRON.

Henry Leachman, *Patentee*, April 6, 1853.

This invention consists in treating iron by means of a combination of the following materials, for the purpose of producing a more plastic and malleable iron than heretofore:—Common brick-dust or calcined clay, 120 lb.; common salt (pounded fine), 600 lb.; and black oxide of manganese, 280 lb. These materials are thoroughly intermingled and reduced to a powder, and added, in quantities varying from 4 lb. to 10 lb. weight, to the metal during the boiling process to which pig-iron is subjected. Metal of very poor quality requires 10 lb. weight of the powder to 420 lb. of metal.

## SELF-CLOSING VALVE FOR PREVENTING SMOKE.

Thomas Symes Prideaux, *Patentee*, December 27, 1853.

This invention consists of an apparatus to be applied to the fire-doors of furnaces, with the view of regulating the admission of air, in order to improve the combustion of the smoke, gases, &c., economise fuel, and at the same time to prevent the radiation of heat outwards. Fig. 1 of the annexed engravings is an elevation of the valve as fixed to a furnace-door; fig. 2, a sectional plan; and fig. 3, a section of the same. The front of the apparatus constituting the panel of the furnace-door, consists of a series of shutters *b*, moveable on axes *c*, so as to be capable of opening and shutting like Venetian blinds. Behind these moveable valves or shutters is a series of parallel plates *l*, fixed at a slight angle; a second series *m*, is then fixed at an opposite angle; and then a third and wider series of parallel plates *o*, which do not incline; *n*, and *p*, are air-spaces between each series. By means of the slight inclination in opposite directions given to the first and second series of plates *l*, *m*, the direct outward radiation of the heat from the fire is prevented although the air has free ingress, and the inclination, being at an angle to the axis of the line of draught, has the further effect of causing the current of air slightly to impinge upon the surface of the plates in its passage by which means the heat is more effectually extracted.

The shutters or valves are caused gradually to close in the following manner. Each shutter has attached to it an arm *d*, attached at its other end by a pin-joint to the bar *e*, to which motion is imparted by a rod *f*, connected at its lower end to the bar *e*, and at its upper end to the lever *g*, the gradual descent of which in any required time is effected by its being connected with a piston *i*, traversing a water-cylinder *h* (shown in section in fig. 4), which piston, by means of a valve, allows a free passage to the water from above to below, but resists its passage in the opposite direction. When the water is forced by the gravity of the lever, piston, and their appendages, from below to above through the narrow channel *j*, the size of which at the bottom is adjusted by the screw *k*, so as to regulate the time occupied by the passage of the water, the gradual descent of the piston and closure of the shutters is effected with the greatest nicety.

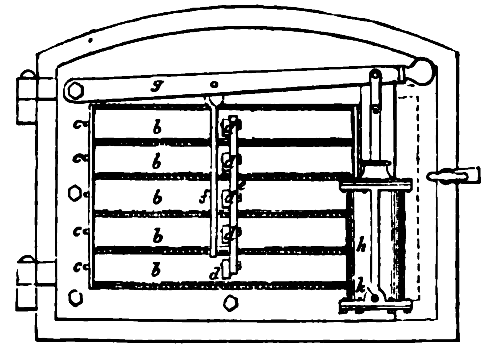

Fig. 1.

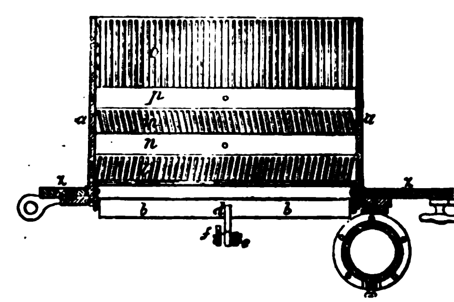

Fig. 2.

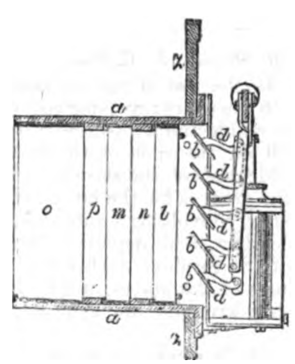

Fig. 3.

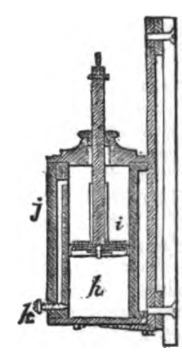

Fig. 4.

So perfectly does the above arrangement of plates, air-spaces, cylinder, &c., fulfil the desired object—viz., that of isolating the heat radiated against the inner surface of the fire-door, so as to confine it in the interior, and ensure the whole being transferred to the entering current of air during the periods in which the valve is open,—that after the valve had been closed ten minutes, and the innermost row had become red-hot, a thermometer with its bulb in contact with the face of the shutters indicated only 64 degrees. This valve may be seen applied to three furnaces at the Panopticon, Leicester-square.

## COATING IRON AND SHIPS' BOTTOMS.

HENRY BROWNING, *Patentee*, January 18, 1853.

THIS invention consists in combining the following ingredients, each in the proportion of one part by measure: white-lead, red-lead, and black-lead, together with one quarter part, by measure, of the sugar-of-lead. If the colour of the paint is required to be lead-colour the red-lead is omitted. These matters are ground with spirits of turpentine, to which is added gum-copal dissolved in turpentine (white copal varnish). A thin coating of this mixture is then applied to the iron or ship's bottom, the sugar-of-lead being reduced in quantity or left out in the subsequent coatings.

## RECENT AMERICAN PATENTS.

[Reported in the Journal of the Franklin Institute.]

*Daguerreotype Apparatus.* J. Brown.

The nature of this invention consists in the employment of an ornamental diaphragm, with a suitable opening placed in a suitable position in front of the person or subject to be represented, for the purpose of producing a portrait or picture, with an appropriate or tasteful ornamental border, either with or without the name of the person or subject and the name of the artist. The diaphragm may be, and will be mostly, used in conjunction with a background, such as is now sometimes, illustrative of the character of the person or subject represented.

*Claim.*—The employment of a diaphragm with a suitable opening, through which the person or subject is presented to the camera, when the said opening is surrounded by ornament or embellishment, for the purpose of producing a portrait or picture with an ornamental or embellished border.

*Dressing Staves.* J. D. Elliott.

The nature of this invention relates more particularly to the use of a transversely-inclined bed, upon which the staves are fed into the cutters, so as to adapt the machine to the dressing of thick or thin, tapering or wedge-shaped riven staves, with the grain of the wood, without separately adjusting the machine or assorting the staves.

*Claim.*—The combination of the transversely-inclined bed with the swivelled roller, for the purpose of adapting the machine to the dressing of riven staves with the grain of the wood, whether thick or thin, tapering, or inclined from edge to edge, without any separate adjustment for the various sizes.

*Finishing the Ends of Staves.* J. E. Warner.

This invention consists—1. In the use of circular-saws to cut the staves to equal lengths; 2. In the use of revolving cutter-heads, having in each three sets of moveable and adjustable cutters; the first set for forming the bevil on the ends of the staves; the second set for equalling the thickness of the staves at each end; and the third set for cutting the grooves for the heads; 3. In the use of a rotary bed, which, slowly revolving on its axis, carries the staves to the saws and cutters, and deposits them when finished on the opposite side of the machine. This bed is made to yield to the varying thickness of the staves, and by means of weights the staves, while being wrought, are kept steadily in contact with fixed stops.

*Claim.*—A feed-bed revolving in bearings which are capable of being moved by weights, springs, or other means, towards the beds or stops on which the back or outer side of the stave is supported, the extent of such movement depending upon the thickness of the staves operated on. Also, the combination of the feed-bed with the saws, cutters, fixed stops, and moveable frame, and what are substantially their equivalents.

*Chuck for Cutting Barrel-Heads.* F. Fruit.

The nature of this invention consists in holding the material of which the barrel-head is cut by means of a chuck, having a series of centres, placed in circular form, and concentric with the periphery of the chuck. Each centre is provided with a spiral spring, which enables the centres individually to give or yield, so that the different pieces forming the barrel-head may vary in the thickness, and still be firmly held by the chuck.

*Claim.*—The chuck, constructed as shown and described—viz., two circular discs, connected by studs and centres, placed between the studs, any proper number of studs and centres being used, the centres passing through both the front and back discs, and having collars upon them, each centre being provided with a spiral spring, which is placed between the collar and the inner side of the back disc, and by which springs each centre will yield or give, independently of the others, so that the different pieces forming the barrel-head may vary in thickness and still be properly adjusted and secured between the face-plate and chuck.

*Ventilators.* J. Leeds.

This invention consists in arranging a series of downwardly-inclined curved openings in the outer case or shell of the ventilator for taking in and directing downward into the building to be ventilated, a current or currents of pure air, and in connecting therewith a passage in the centre of the ventilator, through which the impure air may be drawn upward by an accumulated or increased draught over the top of said passage; also, in the manner of increasing the draught across the top of the ventilator to aid the upward current of air through the centre passage.

*Claim.*—The combination, in one case or shell, of the series of downwardly-inclined curved openings in the outer shell, for taking in and directing downward a column of pure air, with the centre pipe or opening crowned with two frustrums of cones, with their apices towards each other, for producing a counter-current, and carrying from the apartments to be ventilated the impure air, and increasing said ejecting current, the whole requiring but a single opening in the roof.

*Paddle-Wheels.* W. H. Muntz.

This mode of constructing the paddle-wheels consists—1. In making the supports of the buckets, a cut-water wheel, and two wheels of smaller diameter; 2. Of forming each bucket of a float and guard made to stand at an angle to each other; 3. Of making the guard to extend from the rim of the cut-water wheel to the other or smaller wheel, and so that the guard shall not only pass edgewise through the water, but endwise into the water, the float being made to project inwards from the guard, as stated. And in combination therewith, making the float narrowest at its outer end, or at the cut-water wheel, and gradually increasing in width towards its inner end.

## INSTITUTION OF CIVIL ENGINEERS.

*Feb.* 28.—JAMES SIMPSON, Esq., President, in the Chair

THE paper read was "*On the means of attaining to uniformity in European Measures, Weights, and Coins.*" By JAMES YATES, M.A., F.R.S.

Believing that the only way of attaining the object in view was by the adoption of the French system of measures, weights, and coins, and that such a step would be attended by great advantages in regard to exactness and convenience, as well as uniformity, the author first gave a brief account of the origin and principles of that system. The method of determination of the "mètre," as the standard of linear measure, and the representation of it by the bar of platinum, deposited in the National Archives at Paris, was narrated. A description was then given of the mode of deducing from that standard all other measures of length, of superficies, of solidity, and of capacity; also of the determination of the fundamental weight, called the "gramme," and the derivation therefrom of the "franc," containing five grammes of standard silver and forming the basis of the ascending and descending series of coins and monies. The advantages of the decimal divisions and multiples, and of the names applied systematically to all, were asserted, notwithstanding the partial recommendations of the octonal, and still more of the duodenal methods of computation.

Adverting to the successive obstructions and difficulties which the system had to encounter from political disturbances, as well as from popular prejudice and the previous habits of the French nation, the author mentioned its final establishment during the reign of Louis Philippe, and its gradual extension and steady progress subsequently to that period, both in France and in many other of the continental kingdoms. As practical examples, specimens were exhibited, showing some of the forms in which the French measures were now sold and applied to all the purposes of common life.

Considering the success which had attended this grand project of social improvement; the generous and enlightend spirit in which it was conceived; the difficulties which it had surmounted; the successive amendments which it had received, as the result of experience during the course of more than half a century; the exactness of its principles, and the beauty of its adjustments; and the almost universal approval accorded to it by the millions of persons who now employed it in their daily intercourse and occupations, it was considered manifestly impossible that it should ever be abandoned for any other system wherever it had once been adopted. If this were true, it followed that the French system must remain, whatever other systems might be discarded, and it might consequently become universal. It was therefore argued, that it would be wise to take advantage of the progress towards uniformity thus made, and to use all means for extending the influence of that system.

As the French had not hesitated to adopt British inventions when the advantages were made apparent, it was argued this country should be equally willing to adopt any amelioration, from whatever source it might be derived. No nation was better qualified than the French to introduce improvements in the theory and practice of metrology. If they had not already offered an admirable system to the world, all civilised nations would look to them as perhaps the most able to invent such a system, on account of their acknowledged attainments both in theoretical and mathematical science, and their dexterity in certain branches of mechanics. No narrow prejudice or national antipathy should prevent an international combination for the promotion of a scheme, fraught with advantage to the interests of commerce, of science, and of philantrophy.

In addition to the objections urged by theorists, there were others equally formidable, arising from habit and popular prejudice. These, it was contended, must be overcome by the combined efforts of the government and the people. The government had under its control infinitely the greatest amount of measuring and weighing, and counting of money, in the kingdom, and consequently had the greatest interest in introducing a system which would be attended, in addition to numerous and far greater benefits, with a saving of a very large amount (probably a quarter of a million annually) in the collection and management of the revenue. But the government could not possibly effect this great change, apart from the people; therefore the people should cooperate with, even if they did not commence the work, and it was a question whether it was not best that the change should begin at the bottom of the scale. The French system was so simple and beautiful that it could be taught, in a week, to the children of all schools for the poor, throughout the kingdom, and they would take a pleasure in diffusing the knowledge of it among their parents and elders. Decimal methods of computation, and the ability to use the French measures, weights, and coins, having been propagated among the poor, would necessarily be well known to the rich, and would thus soon become familiar and habitual among all classes of the people.

The objection made to the use of French terms, such as *Franc*, *Centime*, *Mètre*, &c., was refuted on various grounds. These terms were not in fact French, but rather Greek and Latin, and they were on that account at first to some extent repudiated by the French. On the other hand, Avoirdupois and Troy (*Troyes*) weight being French, the English were now only asked to exchange old and inconvenient French weights for new ones, which were better. But the introduction of numerous terms with other fashions and usages from France, and their constant recurrence, showed that this objection was much over-rated. Even if it were a valid objection in point of fact, it was one of little moment: for, if the terminology was objected to, the system might be taken without it. The Piedmontese, for example, used the French monetary system, although they called a "Franc" a "*Lira.*" As the Arabic numerals, which were used wherever computation by tens was practised, were the signs of numbers, which were called by different names in different countries, and yet were everywhere received in the same sense, so the same measures, weights, and coins, might be known in the various parts of the world under different denominations, and yet be perfectly understood and employed by common agreement throughout the earth.

The author exhibited a scheme of coinage, having the "franc" for its unit, the scale ascending to one hundred francs in the one direction, and descending to the one hundredth part of a franc, called a "centime" or "cent." (*pars centesima*) in the other direction. He maintained that the "franc," occupying a middle place between the highest and the lowest coin, and being of that value which was either on a par with the great majority of purchases and payments in this country, or certainly not at all below them, was well fitted to be taken as the middle term, and in this respect was preferable to the pound sterling, or even to the dollar. At the same time, nothing could be better adapted to secure facility, promptitude, and correctness, in keeping accounts, than the reckoning by francs and centimes. He thought it useful to have a gold coin of one hundred francs, and a centime (perhaps of brass, on account of its large dimensions), in order to exhibit both extremities of the series to the eye, and to make that series complete. He considered the rare occurrence of these smaller coins to be no objection, but the contrary; because it would show the middle term was fixed where it ought to be—at that point where coins were in most constant requisition for the purposes of trade and daily intercourse

Remarks were offered, showing the application of the subject to the employments of shopkeepers and retail traders, merchants and bankers, stock and share brokers, and more especially to railway companies; as also its almost indispensable necessity with a view to international postage.

In conclusion, it was suggested that all persons who were interested in this question, either on commercial grounds, from the love of science, or as the friends of peace and human progress, should use every means of co-operating with the government, and either by forming associations, or otherwise, endeavour in every possible manner to induce the mass of the people to become acquainted with the principles and advantages of the French system, and thus with all convenient speed to introduce the knowledge and the use of it, not only in Great Britian and Ireland, but in all the colonies and dependencies of the kingdom, and through the influence of example eventually to extend it to the United States of America, and other independent countries.

*March* 7.—The evening was devoted to the Discussion of the above paper. After describing the steps taken to induce the attention of the legislature to the subject, and reviewing succinctly the evidence of the different witnesses examined before the Select Committee on Decimal Coinage, and the report resulting from that inquiry, the advantages to be anticipated in all matters of money accounts were first dilated on, and then the translation of the present diversified weights and measures into one uniform and decimally-divided system was insisted on. It was urged, that great facilities would be introduced in keeping accounts and making calculations; that the pound sterling being adopted as the integer, the whole of the coins in present use might be retained, by only stamping their decimal value upon them, and thus keeping them in circulation until a new decimal coinage could be prepared. The proposed coins were shown to be sufficiently small for the purposes of the poor, for whom the quantities of merchandise would always be adapted to the purchaser's means; and the pound sterling remaining as the integer, was urged to be all that the large bankers and merchants could desire.

It was argued, that there were great objections against endeavouring to assimilate the coins of this country with those of other states inasmuch as it would be impracticable to get all countries to agree; despotic monarchs would still continue, as heretofore, to debase the value of the coinage to meet the exigencies of the moment, and even republican states had depreciated the value of their money; so that, if all coins were to-day universally of the same standard and value, there was nothing to prevent their being all wrong to-morrow. Therefore, all that could be done was to decimalise the currency of this country without reference to that of other countries, and it was then thought that eventually the same adjustment of weights and measures would follow. The work of General Sir C. W. Pasley was quoted, to show the inappropriateness of the mètre and its subdivisions for this country; it was urged, that even in France its use had only been enforced, during the Revolution, by the harshest means, and that even then the *systeme usuel* (feet and inches) had remained in force for nearly half a century, and in spite of decrees was even now scarcely abolished. The further propositions made by the General, for a decimal system based on the existing coins, weights, and measures, were carefully examined. Professor Airy's evidence before the Committee was dilated on, and it was endeavoured to be shown, that any attempt to assimilate English and foreign coinage must fail, if only from the force of public opinion and the passive resistance of those who had no interest in making any change.

It was a question of immense difficulty how to establish a natural basis for a standard; it had been, in almost all cases, found impossible to establish one correctly, and therefore an arbitrary standard had been preferred. The precautions taken for preserving correct types of the standards for England were detailed. The introduction of the decimal subdivision of the troy for the use of the Bank of England and the bullion dealers, was quoted as an example of what necessity would do naturally, and was used as an argument to urge civil engineers, architects, and builders, to introduce some uniform scale of decimal measures, to which money values would be brought to assimilate more easily on the decimal than on any other system. It was shown, that the government could only "enforce" a decimal division of the coins of the realm, but it might "permit" eventually such an arrangement of measures and weights, as would be found most convenient by merchants and traders for the purposes of commerce. The system of the franc, and the penny, was strenuously urged, as being the simplest and best adapted for the wants and habits of the labouring classes.

It was contended by others, that the proposition of the Committee on Decimal Coinage, for adopting the pound sterling as the integer and dividing it into 1000 mils was untenable; inasmuch as besides unsettling tolls and postage stamps, authorised by Act of Parliament, it would alter the prices of produce of all kinds, and only in a few cases supply equivalent rates; nor would it meet exchanges with France and other countries without dividing the cent. into most inconvenient fractions. It was therefore urged, that it would be more convenient to adopt a lower integer, proposing either a coin of the value of 25 pence = 100 farthings or cents.; or a coin of the value of 10 pence = 40 farthings or cents. The latter was considered to be more in harmony with the monies of France, Holland, America, and other countries, where the decimal system had been already adopted. The coin of $\frac{4}{10}$ths of a farthing would equal the centime of France. The exchange with other countries would be met within ⅛th of a cent., and manufacturers would have a denomination to suit the smallest variation in prices or profits, without using the extreme fractions now resorted to.

If it was admitted that the true arithmetical and scientific division of the integer was into 100 parts or cents., it was contended that no difficulty would be experienced in the practical introduction of the system into commerce, and into retail trade; that its adoption would lead to a more correct method of estimating profits and losses and of keeping books, and that it would facilitate calculation and the receipt and payment of duties, taxes, and monies of all kinds.

As early as the year 1832, Mr. Babbage had, in his 'Economy of Manufactures,' drawn attention to the decimal system, as being the best adapted for facilitating all mercantile calculations, and had suggested the conversion of the present currency into a decimal series.

It was stated, that at the period of the Great Exhibition in 1851, M. de Vinsac, Member of the Academy of Macon (France), was deputed by that Society, to endeavour to induce the adoption in this country of a system in weights, measures, and coins, somewhat analogous to, if not identical with, those of France. That period, however, was not favourable for the consideration of the subject, and M. de Vinsac had left with the Secretary of the Institution of Civil Engineers, certain documents from which should now be culled and translated all that might apply to the question, in order to their publication with Mr. Yates' paper.

*March* 14.—The Discussion on the above subject was resumed and continued throughout the evening, and not being concluded, was adjourned until the meeting of March 28th. The abstract of the Discussion on both evenings will be published in our next number.

*March* 21.—The first paper read was a *"Description of Martin's Improved Jacquard Machine."* By EDWARD LAFOREST.

After stating the very general application of Jacquard machines to all ornamental weaving, the Paper described the old machine, and the manner in which the patterns were produced, by means of bands of punched cards, acting on needles with loops or eyes, which regulated the figure. It showed also the great wear and tear to which these cards were subjected, indeed so much, that for the carpet trade they were often required to be made of sheet-iron.

In Martin's new Jacquard machine, the object had been to substitute for the heavy cards a sheet of prepared paper, punched with given apertures like the cards of the old machines, but instead of being a series of pieces 2½ inches wide, laced together, the punched paper formed a continuous band, only ¾-inch wide, thus so diminishing the bulk that the weight of the new band as compared with that of the old cards was in the proportion of 1 to 11. The method by which this desirable result had been attained was then explained to be chiefly by an arrangement which permitted the 400 spiral springs on the needles, used in the old machine, to be dispensed with, when as a consequence the force and wear and tear due to their resistance would be done away with, and fine and light wires could be made to do the work of strong and heavy ones. In order to render this clear, one of Martin's machines, with a part of an old machine, and bands of equal numbers of cards under each system were exhibited.

The next point demonstrated was, that like the bulk and weight, the cost of the cards under the new system would be greatly reduced. It was shown, that by a new system of punching machinery, the bands could be cut from a design, previously perforated, at the rate of 3000 cards per hour, and any number of duplicates could be produced with equal celerity; it was also stated, that by these means, when a pattern became fashionable, any number of looms might be set to work on it, in about as many days as it had previously required weeks under the old system. The price of the old cards was 6*s*. 9*d*. to 8*s*. 6*d*., and upwards, per 100, for new sets, and 5*s*. 6*d*. for recuts; whereas the new paper-bands would cost 1*s*. per 100, and 6*d*. per 100 for recuts. The comparison of cost of 3000 cards (an average band) would therefore stand thus:—

| | Cost. | Weight. | Length. |
|---|---|---|---|
| 3000 cards @ 6*s*. 9*d*. ℔ 100 | £10 2 6 ...... | 90 lb. ...... | 600 ft. |
| 3000 new bands @ 1*s*. ℔ 100 | 1 10 0 ...... | 8¾ lb. ...... | 63 ft. 9 in. |

In reference to durability, it was stated that a band had been in constant work for two years, although used on a heavy waistcoat-piece.

The second Paper read was *"An Account of the Deep-Sea Fishing Steamer 'Enterprise,' with Ruthven's Propeller,"* by D. K. CLARK, Assoc. Inst. C. E.

The vessel was described as having been built for the "Deep-Sea Fishing Association of Scotland," under the direction of the author, the consulting engineer to the Company, who had recommended the trial of Ruthven's propeller for fishing uses, in preference to the paddle or the screw, chiefly on account of there being nothing likely to interfere with the fishing nets; and also because the success of the previous trials of this means of propulsion, on board of boats 30 feet and 40 feet in length, when a speed of 7 miles per hour was attained, appeared to warrant its being tried on a larger scale.

The chief dimensions of the *Enterprise* were stated to be: length on deck, 95 feet; length at the water-line, 87 feet; breadth of beam, 16 feet; depth, 8 feet; draught to load water-line, 4 feet; burthen, 100 tons. The propelling power was derived from two pairs of horizontal oscillating cylinders, 12 inches diameter, and 24 inches stroke (with corresponding air pumps and condenser), working on a vertical crank-shaft. There was one cylindrical boiler, 6 feet diameter, and 5 feet long, with two through fire-tubes, 22 inches diameter, and 105 return flue tubes, 5 feet long, and 2 inches internal diameter. The propeller consisted of a fan-wheel, or centrifugal pump, 7 feet diameter, with curved blades, keyed on the lower end of the crank-shaft; it revolved horizontally in a water-tight wheel-chamber, into which the water from the sea flowed along a covered passage or water-chamber, through crescent-shaped openings in the bottom of the hull; and the water was expelled laterally, from the fan-wheel, in two continuous streams, by curved pipes with nozzles 10 inches diameter, through the sides of the hull. The nozzles worked in collars affixed to the sides, so that they could be pointed astern or ahead, as required for forward or backward motion, or vertically downwards when the vessel was to remain at rest. These changes were made rapidly and easily, as the nozzles alone were operated upon, whilst the engine continued to work at full speed. By setting the nozzles in opposite directions, one pointing ahead and the other astern, the vessel could be turned on the spot, swinging on her beam, without the aid of the rudder; the vessel could thus be steered by the nozzles, in case of the rudder being disabled. In fact, the manœuvring of the vessel was entirely in the hands of the persons on deck. The fan-wheel and water passages were entirely of wrought-iron, and all the parts were formed to avoid sudden enlargements or quick turnings, and the consequent absorption of power in the passages by friction and eddies. The motion of the vessel was very smooth, and all tremulousness was avoided by the uniform and continuous action of the propelling streams of water.

In a trial trip with the *Enterprise* on January 16th, from Granton to Kirkaldy and back, a distance of 10½ miles each way, the average speeds obtained were, 9·69 miles per hour going, and 9 miles per hour returning, giving a total average of 9·35 miles per hour, running against the tide for the greater part of the trip, and with a breeze ahead on the return trip. The engine made 50 revolutions per minute, and was calculated to have exerted 40 indicated horse-power, from the observed average pressure of 20 lb. in the boiler, with the valve-gear cutting off at one-sixth of the stroke. The consumption of fuel averaged 5 lb. of coal per estimated horse-power per hour. On another occasion, in a trial of her speed with one of the Granton and Burntisland ferry-boats, the *Enterprise* kept pace with the ferry-boat, at the regular speed of 12 miles per hour, the engine making 70 revolutions per minute.

In the estimate of the efficiency of this method of propulsion, with respect to the power applied at the fan-wheel shaft, three sources of loss were admitted: first, the friction of the water in passing through the fan-wheel and passages; second, the excess of the effluent velocity of the water at the nozzles, above the speed of the vessel; third, the elevation of the water-jet above the sea level. The first had been found, by careful experiment, with a small model, to amount to 16 per cent. of the power applied to the wheel-shaft; the second was estimated, from the known data, at 12 per cent.; and the third at 8 per cent.—making a total loss of 36 per cent., and leaving a useful balance of 64 per cent. of the power applied to the wheel-shaft.

Reference was made, for comparison, to the performances of Appold's pump, and of Barker's mill, as tested by Mr. W. M. Buchanan of Glasgow. After suitable allowances were made, corresponding to the loss at the nozzles, and the loss by elevation of water, the following percentages of useful effect were arrived at:—Ruthven, 64 per cent.; Appold, 57 per cent.; Barker, 67·8 per cent.; giving a mean of 63 per cent. of the power applied to the wheel-shaft. The friction of the engine was taken at 20 per cent. of the indicated power on the piston, leaving 80 per cent. delivered at the wheel-shaft. It therefore appeared, finally, that of the whole indicated power of the engine, as applied to work Ruthven's propeller, 50 per cent. was lost by friction and other causes, leaving a balance of 50 per cent. for useful work done. It was further argued, that by careful design, and good proportion of parts, so as to reduce the friction of the machine, the excess of velocity of the effluent water, and the elevation of the nozzle, 70 per cent. of the total indicated power of the engine might be utilised by Ruthven's propeller. The draught of the vessel during the trial was stated to be 3 ft. 2 in., and the immersed midship section 40·5 square feet. The united area of the nozzles being 1·09 square feet, the ratio of the area of propulsion to the immersed section was 1 to 37. To the load water-line, the immersed midship section was 55 square feet, and the ratio 1 to 50.

Many advantages of Ruthven's propeller for large vessels were pointed out and contended for. Several nozzles could be applied to one vessel, one acting for another in case of accident; whereas paddles and screws could not be so multiplied, and a number of engines and nozzle-propellers of moderate size, worked at high speeds, would it was contended be less weighty, more compact, and more manageable, for a large vessel, than the huge engines and appurtenances required on the present system.

## ART IN WASHINGTON.

The capital of this great nation is becoming something better than a mere hotbed of politics. Heretofore it has been exceedingly destitute of the attractions belonging to high art, but there are decided symptoms of a change for the better. First rate specimens in painting, sculpture, and architecture, are now appearing there.

Guire's and Corcoran's galleries are now open to the public Tuesdays and Fridays, presenting to the lovers of the beautiful many very clever original works, and respectable copies of renowned master-pieces. Corcoran's collection, in particular, is worthy of attention. The mansion is new, and presents a fair sample of the Romanesque style applied to domestic use. The picture gallery is appropriately arranged, with a concha recess opposite the entrance, wherein stands Powers' Greek Slave, well lighted from above. "Mercy's Dream," by Huntington, occupies a prominent place on one wall, and a pleasing variety of landscapes and other compositions hang opposite. Beneath the above are Cole's two magnificent pictures, exemplifying "The Spirit of the Middle Ages," and would be gems anywhere.

In the new square opposite the President's house, stands the equestrian statue of General Jackson in bronze, by Mills. The action, features, and general expression are bold, natural, and altogether admirable. It is a fitting exponent of the spirit which occasioned its creation, alike invincible at the council board and on the battle-field, ever courteous towards the gentle, and fearless before the strong.

The Washington Monument is constructing of white marble, in the form of a colossal obelisk, after the manner of that on Bunker Hill. But this one is to be surrounded by a circular temple, in the Egyptian style, a great incongruity, we think. But the shaft rising above ordinary objects, and seen at remote distances, will add much artistic expression to the metropolis. Let it proceed.

The Smithsonian Institute is nearly finished outside, and is occupied in part as originally designed. Taken as a whole, it is a striking object in the view, and is a valuable addition to our architectural wealth. It is composed on a reduced scale of nearly all the leading traits of the Norman style. A baron's castle forms one end, with corbelled chimney flues and clustered tops, canopied porch, arcaded terrace, machicolated parapets, and belltower; a Norman chapel at the other extreme, with triplet lights, rose windows, corbel-course cornices, apsis end, depressed entrance and groined roof; a Norman monastery between these, and connected with each by cloister arcades of the earlier and later types of the style, the transepts of the main body being formed by the two grand entrances at opposite sides. These are flanked by square and octagonal towers, each different from the rest in proportion, and all rather happily combined. Water tubes, buttresses, foliated openings, bay windows, niches, corbel-courses, embattled parapets, soaring turrets, and quaint finials, characterised by the bold and diversified mouldings of the twelfth century, give a new combination at each remove, and present a perpetual rest all around. The supreme tower, buttressed on the right of the front entrance, and surmounted by the octagonal lantern which rises so gracefully out of the cluster of turrets at its base, is a fine study, even to one familiar with Normandy in general, and the transepts of Rouen cathedral in particular. If the miserable stucco groining behind the beautiful stone fretwork in the arches at the base were displaced, that there might be harmony in the work as well as design, the architect's name would read better where it stands.

Romanised Corinthian and Ionic have been the modes in which national commissions have formerly been executed. The Patent Office was the first one started after the Doric manner; and had the material been as good as the Post Office, it would have been a vastly finer building. New wings are now building, of granite foundation and marble superstructure, and will add greatly to the attractions at Washington. The portion recently finished wares the air of calm majesty common to this order, when realised in proper substance under a master's hand. And such is Thomas W. Walker. It is well for American art that he has the supervision of the old as it is repaired, and of the new, as it is created for the use of our republic.

The grandest work of the age is the extension of the Capitol. This is in two portions, equidistant from the present edifice, and to be connected therewith through colonnaded corridors. Granite from the South and marble from the North, in immense quantities and of the most admirable texture, are in hand, already assuming shapes of substantial grandeur. The rusticated story is done, and the temple proper is begun. Marking the base of this is a sculptured stringcourse, going quite round. This ornament is indecorous, as would be a strip of calico bound about the trunk of a mighty oak. It is not the place for adornment; but there is no help for it in this instance, since the older portion immediately adjacent was so done for, and a return to classic purity at once would be too abrupt. Most of the openings of the old building are square-headed, and yet carry a cumbrous keystone over each. Why a horizontal member should be so cut through, and by a bevel that must more than annihilate all its strength—two halves of a lintel loaded by a central weight—is more than we can explain. No Greek ever saw such a solecism in art and such a blunder in construction. Mr. Walker happily mitigates the offence by inclosing his openings with a segmental arch, quite low, thereby giving the keystone something to do—the great lubber who has no business there, any how, but is too bold in his impertinence not to be immediately missed. The further the master gets above the realm of grovelling comparison, the more does he shake off incongruities and approximate perfection. According to the working drawings, the mouldings, entablatures, and pediments will round gently in their shadows or cut sharply in their lights, as when the first models augmented charms about the Acropolis. The truss, as a flanking feature to the head of the many openings, is often repeated in the parent structure, and everywhere, as is usual with artizans, looks like a thing stuck on, and just ready to slide down. But the continuator of the great design proposes, while he retains all the conventional elements of the truss, so to blend it with the integral jamb as to render it constructive as well as decorative, in a manner palpable to the critical eye and grateful to tastes refined. But the most magnificent external feature will be the eastern colonnades. There has been little pure Corinthian art since the Choragic monument of Lysicrates. Perhaps the only pure specimen on a large scale in our country, or for two thousand years before, is the Girard College. In that Mr. Walker adhered to the order as transmitted by Stuart, but re-cast all the proportions, in order to regain the same perfect symmetry on a scale vastly greater than Greece ever knew. But in the present undertaking, the architect trusting yet more to independent genius, will excel that masterly monument, by keeping closer to nature in the florated details. He has made a special study of the acanthus, and we may confidently expect from him capitals which from necking to abacus, through all the volutes, will seem to wave with flexile beauty in mid-air. The edges of the leaves are not to assume the astute and serrated aspect of carpenter's foliage, but the infinite ease and variety which signalise the handiwork of the great Creator. In the foliations of the interior apartments, we understand the architect designs to incorporate all the leading characteristics of the graceful and grand vegetation peculiar to our national domain. His facility at original composition and elegant execution is well indicated in the new library, which was projected while the ruins were yet smoking, and is now completed, ready for congressional use, and an honour to the land.

The new Senate Chamber, however, will doubtless constitute the chief glory, as is fitting, of the Capitol. The approaches, unlike the present, will be spacious, luminous, and direct. The forum itself will be worthy of that great deliberative and executive body. Immediately in the rear, and contiguous to the diameter of the more public amphitheatre, will be a spacious rectangular hall, the floor, walls, ceiling, all of purest marble, relieved by the richest paintings, and adorned by the noblest sculpture American genius, inspired by American patriotism, can produce. Should the works already projected be consummated under the auspices of such inventive genius as is at present employed, and with the facilities so abundantly at our control, then may Washington present to intelligent foreigners, art, as well as statesmen, second to none in the world.

The new group by Greenough has just been opened on the pedestal opposite Persico's Columbus; and the last panel in the Rotundo will soon receive Powell's De Soto. Perhaps he is the youngest citizen who ever received a national commission, and who would say that his work is inferior to the oldest? The circle of art thus finishes with "the little Westerner" in its first cycle. Hereafter, from remoter regions of our political union, yet to embrace even more than "the great West," the grandest productions will appear in all the realms of literature, science, and artistic excellence.—*American Paper.*

## ROYAL INSTITUTE OF BRITISH ARCHITECTS.

*March* 6.—EARL DE GREY, President, in the Chair.

The Medals and the Premium in Books awarded during the Session were presented by the President as follows:—

The Royal Gold Medal of the Institute—Philip Hardwick, R.A.

A Silver Medal of the Institute—Mr. Edward L. Tarbuck, for his Essay—"An Historical Sketch of the past development of Architecture, considered as a fine art, with an examination into the principles of modern practice, and the present state of the profession."

A Medal of Merit (with an honourable addition thereto)—Mr. C. F. Hayward, for his Essay "On the Pre-Gothic Age in Germany, or the Romanesque development of the Rhine and Central Europe."

Medals of Merit—Mr. J. G. Elgood, for his Essay "On Architecture, its Past, Present and Future;"—and Mr. T. A. Britton, for his "Essay on Timber and Deals, with some remarks on Seasoning and Dry-rot."

A Prize in Books—Mr. F. T. Gomperts, for his "Design for a Metropolitan Railway Station."

The PRESIDENT having congratulated the several candidates who had obtained the Silver Medals and Prizes, said, the next prize is that which the munificence and kindness of our Sovereign authorise me to distribute.—Mr. Hardwick, you will, I am sure, from what you know of me, feel that no part of the duty which devolves upon me from my position in this chair, is more grateful to me than that of being the means, as the interpreter of the feelings and wishes of your professional brethren, of offering you the mark of their respect and admiration which I am now authorised to present to you. You know me well enough to feel that what I say is not a mere compliment. It is not for me, in speaking to a man like yourself, and in such a society as the present, to enumerate the various claims you have on our admiration and approbation. It is not for me, however fond I may be of architecture, and anxious to encourage it,—to set up my opinion; but I think I may honestly appeal to everybody when I say that the prize now in my hand is given to a man who has great talent of invention, and the power of accomplishing many different objects in many different ways. I am one of the Goldsmiths' Company, and therefore have enjoyed many festive meetings in their magnificent hall. I also am occasionally obliged to travel by the railroad; and the young gentleman who has just now received a prize for his suggestions on that subject, has an excellent specimen before him of a man who can form a grand railway station. Again, when we remember by whom the most ornamental and important part of one of the great legal institutions of this country, Lincoln's Inn, was constructed and decorated,—when we recollect that for one of the largest systems of Docks in this country, we are indebted to my friend, and to his energy and capability in satisfying the wishes and wants of a great mercantile people,—I do not believe it is necessary for me to say that he affords an exemplification of what the mind of man can do, devoted to the purposes which his country calls upon him to fulfil; and when his brethren around him pay a tribute to his merits, I think it is indeed well deserved. It is therefore a source of the greatest gratification to me that it has fallen to my lot to be the means on the present occasion. If you were not present I might perhaps say more. I have alluded to the professional and public character of Mr. Hardwick; I might say a great deal more with regard to private circumstances. I might allude to the integrity of his character,—the confidence which has been placed in him by all classes,—the reference to him in cases of arbitration and similar matters. Omitting these, however, I am satisfied, that all who hear me agree with me that the prize which I have now the pleasure of giving, is fully deserved.

Mr. HARDWICK replied,—I believe it is now my pleasing task to thank your Lordship, and you, gentlemen, for having this year selected me to receive this Royal Medal, a selection that may be considered a very proud distinction for the member who receives it. I must, in the first instance, almost before I thank his Lordship for the kind expressions he has used towards me, express on the part of the Institute, our gratitude to our Sovereign for the interest her Majesty has been pleased to show in the Institute by this mark of her Royal favour. Let me also for one moment advert to her Royal Consort, Prince Albert. I believe that through the extreme devotion and attention he has paid to the advancement of art in this country, there is no period that we can look back upon when art was so greatly encouraged as it is in this present moment; and I think, without using too flattering expressions, we may date that encouragement from the time when His Royal Highness first came to this country. Let me now for one moment advert to the expressions with reference to myself which have fallen from His Lordship. They are to me much too flattering. I cannot take the credit to myself of deserving the very kind manner in which His Lordship has brought me to your notice; but this I may say, that having had the honour of enjoying his personal and corteous kindness many years, however great the gratification I feel for this honour, that gratification is very much increased by the mode in which it has been conferred. Gentlemen, however high the reputation of an architect may be in public estimation, I hold that it is equally important that an architect should feel himself placed highly in the estimation of his professional brethren; and it is that very circumstance which increases the gratification of this honour; for Her Majesty with great kindness has allowed the members of the Institute of British Architects to determine among themselves the selection of the member who is to receive it; and I cannot imagine, after a long professional career, a prouder position than that in which I am this night placed. Gentlemen, I feel that another point which affords considerable gratification to the architect of Great Britian who receives this medal is, that it is well known to him that it is not confined to architects of this country; but that Her Majesty has most wisely considered that excellence in art is peculiar to no soil, and that therefore this honour may be participated in by every part of the civilised world. But, my Lord and Gentlemen, I cannot but feel that I owe in some degree the position in which I am now placed to the loss which architecture has just sustained by the death of one of her most distinguished professors; and France must deplore in particular that architect, who, I am sure, would have had this medal, and would most justly have deserved it. With consummate talent he had surmounted the great difficulty of uniting the Louvre and the Tuileries. After having matured and perfected that scheme with the approbation of the Sovereign and the universal consent of the country, he was charged with the completion of that vast work in which so many architects of great celebrity had preceded him. But alas! in the zenith of his high career, M. Visconti was arrested by the hand of death; and it should be a warning to us all, whenever a large work is entrusted to us, not to be too confident that life may be spared to us to witness its completion.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated October* 17, 1858.

2389. W. Roy, sen., Cross-Athurlie, Renfrew—Improvements in the preparation or thickening of colouring matters for printing

*Dated October* 21.

2434. C. N. Michel and A. Lecomte, Paris—Improvements in windows

*Dated January* 3, 1854.

17. J. Bernard, Regent-street—Improvements in the manufacture of boots and shoes; part of such improvements being applicable to the manufacture of garments

*Dated January* 7.

40. J. Ross, Keighley, York—Improvements in making compounds of chocolate, cocoa, and other ingredients for breakfast and occasional beverages

*Dated January* 21.

145. M. L. L. Beaudeloux, Paris—A self-acting cradle, with improved mattrass.

*Dated January* 23.

159. J. Rowlands, Ladywood-lane, Birmingham — Improved fastening to be used instead of buttons, buckles, clasps, snaps, hook and eyes, and other similar fastenings.

170. P. A. Lecomte de Fontainemoreau, Finsbury—Improvements in the preparation and combination of fatty and resinous bodies, and vegetable and other wax, for the manufacture of candles, also in the preparation of a wick to be used for the same. (A communication)

*Dated February* 2.

262. H. Watson, High-bridge, Newcastle-on-Tyne — Improvements in the working of brass and copper into forms, and planishing them

*Dated February* 3.

267. P. A. Lecomte de Fontainemoreau, Finsbury—Improvements in the construction of buildings. (A communication)

269. C. H. Collette, Lincoln's-inn-fields—Improved method of reducing ores. (A communication)

271. J. Rogerson, S. Rogerson, and J. Rogerson, jun., Manchester—Improvements in machinery or apparatus for embossing, cutting, and perforating textile fabrics

273. W. Longmaid, and J. Longmaid, Beaumont-square—Improvements in the manufacture of vegetable charcoal

275. P. J. Meeus, Paris—Improvements in the manufacture of threads from or with gutta-percha, and in ornamenting the same

*Dated February* 4.

277. G. Mills, Glasgow—Improvements in the construction of steam-vessels, and in steering the same

279. J. Boydell, Anchor Iron Works, Smethwick, near Birmingham—Improvement in the beds of reverberatory furnaces used for puddling iron

281. R. S. Newall, Gateshead, Durham—Improvements in the setting up of ships' rigging

*Dated February* 6.

283. T. Sullivan, Foot's Cray, Kent—Improvements in rollers and moulds used in making paper

285. B. W. Firth, Oldham, Lancaster—Improvements in the method of stopping railway trains, of working breaks on railway and other carriages, and of communicating signals from one part of a railway train to another

287. A. L. N. Comte Vander Meere, Paris—The manufacture of artificial whalebone, or a substance capable of being employed as a substitute for whalebone and tortoise-shell. (A communication)

289. J. B. Graham, Glasgow—Improvements in the production of printing surfaces

291. W. Neilson, Glasgow—Improvements in blowing-engines

*Dated February* 7.

293. J. W. Moseley, Heathfields, Stafford—Improved method of uniting glass and argillaceous cylinders and tubes for conducting water and other fluids

295. J. Elce, Manchester—Improvements in machinery for spinning cotton and other fibrous materials

297. H. Olding, Lambeth—Improvements in stoves and fireplaces

299. A. E. L. Bellford, Castle-street, Holborn—Improvements in the manufacture of artificial stone. (A communication)

301. A. Pope, Edgeware-road — Improvements in machinery for crushing, grinding, amalgamating, and washing quartz or matters containing gold.

303. A. V. Newton, Chancery-lane—Improvements in bleaching textile fabrics. (A communication from J. Lea and A. Roth, Philadelphia, U. S.)

305. B. U. Bianchi, Paris—Improvements in preventing accidents on railways

*Dated February* 8.

307. G. W. Knocker, Bushy Ruff, Kent—New method for producing rotatory motive power by means of water

*Dated February* 9.

308. J. Perry, Leeds—Improved drilling-machine
309. J. Ramsbottom, Longsight, near Manchester — Improved hoist for raising and lowering railway rolling stock and other articles
310. J. Dalton, Hollingworth, Chester—Improvements in the construction of bowls or cylinders employed in printing and other processes; and which improvements may also be adapted to other mechanical appliances
311. H. Moorhouse, Denton, Lancaster—Improvements in part of the machinery or apparatus used in preparing cotton, wool, or other fibrous materials to be spun
312. P. A. Lecomte de Fontainemoreau, Finsbury—Improvements in fire-arms. (A communication)
313. F. Vouillon, Princes-street, Hanover-square—New process of protecting the silvering of looking-glasses. (A communication)
314. J. Samuel, Great George-street, Westminster, and A. W. Mackinnon, New Palace-yard, Westminster—Improvements in drying flax, straw, and other fibrous substances
315. G. Tournay, Newington-causeway—Improvements in obtaining motive power
316. E. Boileau, Holford-place, Clerkenwell—Improvements in producing raised printing surfaces
317. F. M. Lyte, Florian Torquay, Devon—Improvements in apparatus for ascertaining the depth of water
318. P. J. Meeus, Paris—Improved apparatuses for planting grain and seeds, depositing manure, and for performing operations connected therewith. (A communication)

*Dated February* 10.

320. D. Brown, Smethwick, Stafford, and J. Brown, West Bromwich, Stafford—Improvement or improvements in the construction and manufacture of axles for railway and other carriages
321. W. Duck and W. Wilson, London-road, Southwark—An internal gas-heating apparatus
323. S. Hunt and T. Morris, Long Eaton, Derby—Improvements in covering the roofs of buildings with slates, tiles, or other material
324. T. Allcock, Ratcliff-on-Trent, Nottingham—Improvements in machinery for cutting straw and other vegetable substances
325. B. H. Hine and J. A. Mundella, Nottingham, and L. Barton, Hyson-green, Nottingham—Improvements in the manufacture of knitted fabrics
326. J. Young, Glasgow—Improvements in gas-making
327. J. Rives, Hotel Motay, Rue Motay, Paris—Improvements in railways and railway-carriages
328. H. Warner, J. Haywood, and W. Cross, Loughborough—Improvements in knitting machinery
329. J. Johnson, Manchester—Improvements in apparatus to be used for the preservation of life at sea
330. H. Bridges, Bridgewater, Somerset—Improvements in buffers for railway carriages and wagons
331. J. Mitchell, Dyke Head, Lanark—Improvements in forcing or distributing liquids
332. W. Whiteley, Lockwood, near Huddersfield—Improvements in machinery or apparatus for tentering or stretching woollen and other fabrics
333. J. H. Johnson, Lincoln's-inn-fields—Improvements in the manufacture of metallic pens. (A communication)

*Dated February* 11.

334. A. J. B. L. Marcescheau, Paris—Improvements in locomotive engines. (Partly a communication from C. Baron de Berchtold, Vienna)
335. P. Buchan, Peterhead—Improvements in apparatus for measuring and indicating the distances traversed by carriages
336. G. Bird, Glasgow—Improvements in the sub-structures or foundations of buildings
337. J. Jennings, jun., Lorton, Cumberland—Improvements in breaks for railway and other carriages.
338. J. Getty, Liverpool—Improved mode of plating iron vessels
339. J. Rogers, West 21st-street, New York—The preparation of asphaltum, coal tar, resin, resin-oil, naptha, and turpentines, for the manufacture of lamp-black
340. J. F. D. de Bussac, Upper Charlotte-street, Fitzroy-square—Improvements in paving and covering places

*Dated February* 13.

341. G. Ayres, City-road—Improved clip or file, for holding papers or other articles
342. W. Brown, Albany-road, Old Kent-road—Improvements in printing machinery
343. T. Edwards, Broad-street, Birmingham—New or improved fastening for articles of dress
344. A. Chalmers, Dundee—Improvements in mangles
345. D. Campbell, and J. Barlow, Accrington, Lancaster—Improvements in looms
346. E. Clegg and E. Leach, Rochdale—Improvements in slubbing, spinning, drawing, twisting, doubling, and winding wool, cotton, silk, flax, and other fibrous substances
347. J. Cox, Wenlock-road—Improvements in knives for cutting paper and other materials
348. S. R. Brown, Glasgow—Improvements in printing textile fabrics, and other surfaces
349. W. Macnab, Greenock, Renfrew—Improvements in steam-engines
350. J. Greenwood, Irwell Springs, Lancaster—Improvements in dyeing textile materials or fabrics
351. J. B. Smith and E. Smith, Regent-street—Improvements in bonnets
352. A. V. Newton, Chancery-lane—Improved mode of protecting iron from oxidation. (A communication)

*Dated February* 14.

353. T. Bury, W. Glover, J. W. Speed, and J. Hardman, Salford, Lancaster—Improvements in machinery or apparatus for stretching, drying, and finishing yarn and woven fabrics composed of cotton, wool, silk, or other fibrous materials
354. W. Sealing, Old Basford, Nottingham—Improvements in machinery for cutting and ornamenting skeins to be used in the manufacture of baskets and other wicker-work
355. L. Faure, Paris—Improvements in the process for manufacturing iodine
356. C. A. Holm, Cecil-street, Strand—Improvements in propelling
357. T. Irving, Mould Green, near Huddersfield—Improvements in obtaining a metallic and lustry appearance to fabrics and yarns
358. S. Perkes, Walbrook—Improvements in valve-cocks. (A communication)
359. A. Jonson, Mitcham, Surrey—Improvements in preparing barley and grits or groats
360. G. Wilson, Sheffield—Improvement in axle-boxes
361. P. O'Connor, Wavertree, near Liverpool—Improved lever-hinge for suspending and closing doors and gates

*Dated February* 15.

362. J. Hossell, Regent-road, Salford—Improvements in machinery or apparatus for washing, scouring, and squeezing leather, or other similar substances
363. J. Potter, Manchester—Improvement or improvements in machinery for preparing, spinning, and twisting cotton or other fibrous substances; applicable also to machinery for winding threads or yarns of the same
364. W. Asbury, Birmingham—Improvement or improvements in forks for agricultural and other purposes
365. B. H. Hine, A. J. Mundella, and W. Onion, Nottingham—Improvements in machinery for the manufacture of textile and looped fabrics
366. O. Barrett, Wimpole-street—Improvement in the construction of tobacco-pipes
367. T. Jennings, Brown-street, Cork—Improvements in stoppers for bottles
368. J. Wren, Tottenham-court-road—Improved construction of folding-chair bedstead
369. G. F. Wilson, Belmont, Vauxhall—Improvements in preparing an oil, and in the manufacture of candles and night-lights

*Dated February* 16.

370. F. Preston, Manchester—Improvements in flyers for machinery for preparing flax, and certain other fibrous materials
371. C. F. Varley, Charles-street, Somer's-town—New arrangement or apparatus for transmitting electric telegraph signals
372. J. Bush, Derby—Improvements in locks and lock-furniture
373. J. Greenwood, Irwell Springs, Lancaster, and R. Smith, Bacup—Improvements in sizeing, stiffening, and finishing textile materials or fabrics
374. T. Summerfield, Birmingham—The manufacture of chromatic glass and glass-faced bricks, which said bricks are applicable to face-work or fronts of buildings, basements, pilasters, string-courses, door and window heads, medallions, cornices in part or whole, or other purposes where a superior finish and durability are required; a part of which is also applicable to bricks made wholly of clay
375. J. D. M. Stirling, Larches, near Birmingham—Improvements in the manufacture of steel
376. J. Pritchard, Portsea, Hants—Improvements in the construction of screw-propellers, and machinery for driving the same
377. G. F. Wilson, Belmont, Vauxhall—Improvement in the manufacture of lubricating matters

*Dated February* 17.

378. T. Fawcett, jun., Lisburne, Ireland—Improvements in weaving linen or other fabrics to produce plaits or folds therein
379. T. T. Macneill, Mount Pleasant, Ireland—Improvements in drying flax, straw, and other organic substances
380. A. Ford, Lowndes-street, Belgrave-square — Improvements in manufacturing varnish
381. H. Ross, Nottingham—Improvements in machinery for the manufacture of textile and looped fabrics
382. W. Wright, Wolverhampton—Improvements in ornamenting walls and other similar surfaces
383. G. Smith, jun., Belfast—Improved machinery for retarding and stopping railway carriages
384. G. Wethered, Maidenhead, Berks—Improvements in machinery or apparatus for shaking straw
385. J. Hinchcliffe, jun., Dam Side, York—Improvements in metallic pistons for tightening or adjusting the packing of the same, and also improvements in the construction of such pistons. (A communication)
386. R. Holt, Shaw, Lancaster—Improvements in machinery or apparatus for manufacturing bricks and tiles
387. E. Rowland and J. Rowland, Wakefield-street, Manchester—Improvements in cleaning the tubular flues of steam-boilers
388. M. Poole, Avenue-road, Regent's-park—Improvement in boiler-furnaces and other furnaces. (A communication)

*Dated February* 18.

389. P. G. Harris, Buckingham-street, Adelphi—Improvements in locomotive engines. (A communication)
390. W. Morrison, Bowling, Dumbarton—Improvements in railway-wheels
391. J. C. Nesbit, Chemical and Agricultural College, Lower Kennington-lane—Improvements in the manufacture of manure
392. B. W. Wells, Windmill-lane, Camberwell—Improvements in printing floor and other cloths
393. E. Loysel, Rue de Gretry, Paris — Improvements in apparatus for obtaining infusions or extracts from various substances
394. B. Britten, Annerley, Surrey—Improvements in crushing, pulverising, and washing mineral earths or ores, and amalgamating the gold and silver contained therein; which said improvements are also applicable to crushing and pulverising other substances

*Dated February* 20.

395. J. R. Hill, Princes-street, Lambeth—Improvements in machinery for pulverising metallic ores, or other similarly hard substances
396. N. Riggenbach, Basle, Switzerland—Apparatus for preventing incrustation in steam-boilers.
397. W. H. Barlow, Derby—Improvements in securing and connecting the rails of railways
398. J. Aspinall, King William-street—Improvement in machinery employed in the manufacture of sugar
400. T. Gray, St. Clement's-lane, Strand—Improvements in the manufacture of pulp from wood
401. J. Chisholm, Holloway—Improvements in the purification of gas
402. J. Beall, Effingham-place, Herts — Improvements in apparatus for suspending looking-glasses in frames
403. H. Hilliard, Glasgow—Improvements in apparatus for cleaning and sharpening table cutlery
404. T. Towers, Salford, Lancaster—Improvements in marking-boards used in connection with billiard and bagatelle tables, for registering and indicating the number of games played
405. W. Milner, Liverpool—Improvements in locks for safes; which said improvements are applicable to locks in general
407. J. Urie, Glasgow—Improvements in photographic pictures

*Dated February* 21.

408. J. Ramsbottom, Longsight, Manchester—Improvements in welding
409. F. Osbourn, Aldersgate-street—Improvements applicable to the cutting out of garments
410. H. King, Gilbert-street, Oxford-street—Improved mode of signalising between the guard and driver of a railway train
411. J. Gedge, Wellington-street South—Improvements in the construction or adaptation of certain fittings for gas. (A communication)
412. V. Pernollet, Broad-street, Golden-square—Improvements in machinery or apparatus for sorting or separating wheat and other grain from different kinds of grain, and for separating or removing extraneous matters from wheat and other grain
413. S. T. Jones, Union-court, Old Broad-street—Improvements to reduce and wash minerals to extract metal therefrom, especially gold
414. R. Walker, Glasgow—Improvements in signalling by voltaic electricity, for the purpose of increasing the safety of railways
415. J. Boydell, Gloucester-crescent, Regent's-park—Improvement in the manufacture of hurdles and gates
416. E. Gessner, Ane, Saxony—Improvements in gig-mills
417. J. Smith, Glasgow—Improvements in ornamental weaving
418. J. H. Johnson, Lincoln's-inn-fields — Improvements in machinery for making matches. (A communication from E. Zulser, New York)
419. A. Dixon, Smethwick, Stafford—Improvements in railway axle-boxes and bearing-springs
420. A. Dixon, Smethwick, Stafford—Improvements in timber scaffolding or stageing
421. A. B. Baron Von Rathen, Wells-street—Improvements in omnibuses, for the purpose of adapting them to be drawn by one horse, and to be attended by one man only

422. W. Gossage, Widnes, Lancaster—Improvements in the manufacture of certain alkaline carbonates, and in the useful application of such carbonates
423. W. C. T. Schaeffer, Stanhope-terrace, Hyde-park-gardens—Improved mode of recovering the fatty matters contained in waste waters of woollen mills

*Dated February* 22.

424. W. E. Newton, Chancery-lane—Improvements in fire-arms and in projectiles. (A communication)
425. J. Morison, Paisley, Renfrew—Improvements in celestial and terrestrial globes
426. E. Taylor, Kinghorn, Fife—Improvements in gill-heckles or combs for treating fibrous materials
427. D. Assanti, Upper Berkeley-street—Means of rendering porous substances waterproof
428. E. Massey, Tysoe-street, Clerkenwell—Improvements in ships' logs, known as "Massey's Patent Ships' Logs"
429. S. Colt, Spring-gardens—Improved machinery for rifling fire-arms. (Partly a communication)
430. J. de Wolfe Spurr, Kenyon-terrace, Birkenhead—Improvements in distilling coals and bituminous and resinous substances and products thereof
431. J. Boydell, Gloucester-crescent, Regent's-park—Improvements in applying apparatus to carriages to facilitate the draft

*Dated February* 23.

432. T. Settle and P. Cooper, Bolton-le-Moors, Lancaster—Improvements in machinery or apparatus for preparing, slubbing, and roving cotton and other fibrous materials
433. A. Oppenheimer, Manchester—Improvements in the manufacture of mohair velvet or mohair plush
434. T. Robinson, St. Helen's, Lancaster—Improvements in machinery or apparatus for raising and lowering goods
435. J. Barling, High-street, Maidstone—Improvements in treating the hop-bine, and rendering it applicable to the manufacture of paper and other articles
437. T. D. Pruday, Rupert-street, Haymarket—Improved apparatus for cooling liquids and edible substances
438. W. Hunt, Lea Brook Chemical Works, near Wednesbury—Improvements applicable to the utilising of ammonia given off in certain manufacturing processes
439. H. Stoy, St. John's-road, Battersea—Stopping of engines and carriages on railways, and also vehicles of every description on the common roads
440. E. Foard, Nicholas-street, New North-road—Improvements in furnaces

*Dated February* 25.

441. P. Fairbairn, Leeds—Improvements in machinery for winding slivers of flax, tow, or other vegetable fibrous materials into laps or balls
442. W. Ryder and J. Ryder, Bolton-le-Moors, Lancaster—Improved composition applicable to coating metals
443. E. Kingsbury, Knightsbridge—Improvements in apparatus for indicating the rise or fall of water or other liquids in ships' holds, tidal harbours, or other vessels or places
444. S. L. Hardy, Dublin—Improved apparatus for applying chloroform vapour or other similar vapour in certain cases
446. C. Cowper, Southampton-buildings—Improvements in furnaces. (A communication from L. Laureau, Paris)
447. C. Cowper, Southampton-buildings—Improvements in the manufacture of potash and soda. (A communication from L. Laureau, Paris)
448. J. Banfield, Birmingham—Improvements in apparatus for communicating (while riding) with the drivers or guards of public or private vehicles
451. C. J. Fisher, Temple—Improved means of detecting forged or counterfeit bank-notes, bills of exchange, cheques, or other documents, labels, or trade-marks
452. E. H. Bentall, Heybridge, Essex—Improvements in ploughs or implements for cultivating land
453. E. Power and T. Knowles, Birmingham—Improvements in watches, spring-clocks, and time-pieces
454. T. Forsyth, Wolverton, Buckingham—Improvements in furnaces
455. A. E. L. Bellford, Castle-street, Holborn—Improvements in machinery for dressing stone. (A communication)
457. A. E. L. Bellford, Castle-street, Holborn—Improvements in engines for generating power by means of the expansive force derived from heated air and gases, or by means of the expansive force of liquid carbonic acid and other expansible liquids. (A communication)
458. J. Barker, J. Andrew, and W. Hayes, Salford, Lancaster — Improvements in cleansing sheep's wool, mohair, and other animal fibrous substances
459. C. W. Siemens, Adelphi Chambers—Improvements in electric telegraphs. (Partly a communication)
461. G. Collier, Halifax, York—Improvements in twisting fringes of shawl and other fabrics
462. J. Keenan, Paris—Improvements in forming blocks or surfaces for printing. (A communication)
463. C. F. Bekaert, Rue de la Victoire, Paris—Improvements in linseed-oil for painting, called "Oxigenated Oil." (A communication)
464. C. Lamport, Workington—Improvements in machinery used in shipbuilding
465. J. Boydell, Gloucester-crescent, Regent's-park—Improvements in the manufacture of hurdles and fences
466. J. Elder, Glasgow—Improvements in marine steam engines
467. A. Plantin, Thayer-street, Manchester-square—Improvements in the arrangement and combination of apparatus for stopping and retarding railway trains and carriages
468. W. E. Staite, Manchester—Improvements in the treatment and preparation of madder and munjeet for dyeing and printing
469. F. Westbrook, Kensington—Improvements in apparatus for facilitating the cleaning of windows

*Dated February* 27.

471. P. Fougerat, Bordeaux, France—Improvements in paddle-wheels of steam-vessels
472. J. D. M. Stirling, Larches, near Birmingham—Improvements in the manufacture of tubes and cylinders of steel
473. C. de Bussy, Mornington-road, Regent's-park—Improvements in machinery or apparatus for the amalgamation of gold ores
474. J. H. Johnson, Lincoln's-inn-fields—Improvements in harrows. (A communication)
476. J. Morrell, Bradford, York—Stopping the tap of any vessel containing oil, treacle, or any other liquid, as soon as the quantity required of such oil, treacle, or other liquid has been taken therefrom, such quantity being ascertained by weight

*Dated February* 28.

477. L. A. Pallegoix and A. L. Bellange, Paris—Improvements in treating wheat and other grain
479. F. S. Thomas, Cornhill—New rifle carriage
480. E. Marsden and J. Marsden, Liverpool—Improvements in pumps
481. A. E. L. Bellford, Castle-street, Holborn—Improvements in the means of admitting the steam or other motive-power agent to and exhausting it from the cylinders of oscillating engines. (A communication)
482. J. H. Rebe, Bayswater—Improvements in machinery or apparatus for mixing, washing, crushing, bruising, reducing, or comminuting various substances
484. C. Mather, Salford Iron Works, Manchester—Improvements in valves for reducing the pressure of steam
485. A. L. Mallet, Rue de la Pepinère, Paris—Improvements in apparatus to destroy the effects of shocks
486. W. Patten. Old Fish-street—Improvements in valves and apparatus for supplying water
487. J. Medwin, Blackfriars-road—Improvement in water-gauges for steam-boilers
488. E. C. Shepard, Trafalgar-square—Improvements in decomposing water by electric currents. (A communication)
489. J. T. Way, Holles-street, and J. M. Paine, Farnham—Improvement in the manufacture of gas, and also of a charred product
490. T. J. Johnson, Booth-street, Spitalfields—Improvements in apparatus for roasting malt
491. J. S. Holbeche, Sutton Coldfield, Warwick—Improvements in the construction of invalid bedsteads; which said improvements are also applicable for couches, chairs, and reclining seats or beds for invalid carriages
492. J. H. Johnson, Lincoln's-inn-fields — Improved apparatus for facilitating the acquirement of the art of reading. (A communication from N. Chéron and F. N. Tallempin, Paris)

*Dated March* 1.

493. H. Gilbert, Suffolk-street, Pall-Mall—Improvements in connecting and supporting artificial teeth
494. J. T. Cortin, New Compton-street, Soho-square—Soleing shoes and boots with leather combined with gutta-percha and wood, sewed with metallic wire
495. W. Ehrhardt, Birmingham—Improvements in the construction of ordnance and fire-arms, and in loading the same
496. C. Hargrove, Birmingham—Improvement or improvements in steam-boiler and other furnaces
497. W. J. Curtis, Birchin-lane—Improved levigating machine
498. T. H. Ewbank, South-square, Gray's-inn—Improvements in the manufacture of terry or looped fabrics, and in machinery for producing the same
501. J. Sibley and T. Sibley, Ashton-under-Lyne, Lancaster—Improvements in machinery or apparatus for cutting discs or circles out of plates or sheets of metal or other substances
502. W. and J. Clibran, Manchester—Improvements in apparatus for regulating or governing the supply or pressure of gas as it is conducted from the main to the burners
503. M. N. Illakowicz, Maddox-street—Improvements in picture-frames
505. J. S. Holland, Woolwich, Kent—Improvements in locks
506. T. Metcalfe, High-street, Camden-town—Improvements in the manufacture of portable and folding bedsteads, chairs, seats, tables, and cots

*Dated March* 2.

507. J. Parry, jun., Liverpool—Improvements in mills or machinery for grinding or cutting bones, wood, or other like substances. (A communication)
508. R. V. Houssart, Dunstan-street, Kingsland-road, and R. Houston, Skinner-street, Snow-hill—Improvements in vessels to contain fluids
509. H. Ellis and J. Ellis, Salford, Lancaster—Improvements in machinery or apparatus for stretching and finishing woven fabrics
510. A. Barclay, Kilmarnock, Ayr—Improvements in lubricating shafts and revolving metallic surfaces
511. A. Barclay, Kilmarnock, Ayr—Improvements in arranging and working mining engines and machinery
512. J. Currie, Glasgow—Improvements in the treatment and grinding of grain, and the products thereof
513. T. Dawson, King's Arm's-yard—Improvements in umbrellas and parasols
514. J. Taun, Minerva-terrace, Hackney-road—Improvements in the construction of locks

*Dated March* 3.

516. T. Yates and R. Yates, Bury, Lancaster—Improvements in looms
518. L. Tindall, Scarborough, York—Improvements in churns
520. G. Spill, Old Farm House, Stepney—Improvements in the application of waterproof hat-bands to the manufacture of hats.
521. W. E. Newton, Chancery-lane—Improved machinery for measuring and folding cloth and other fabrics, or manufactured materials. (A communication)
522. C. Bloomer, West Bromwich, Stafford—Improvements in spikes and bolts
523. J. Bour, Mauritius—Improvements in evaporating saccharine liquids
524. W. Vaughan, Stockport, Chester, and J. Scattergood, Heaton Norris, Lancaster—Improvements in machinery, apparatus, or implements for weaving

*Dated March* 4.

526. C. Nightingale, Wardour-street, Soho—Improvements in the mode of curling horsehair and other materials
528. R. Madeley, Birmingham—Improvement or improvements in the joints and framing of metallic and other bedsteads, chairs, sofas, couches, and such other articles as are or may be used for sitting, lying, and reclining upon
530. H. D. Mertens, Margate, Kent—Improvements in working steam-engine valves. (A communication)
532. J. K. Stuart, Glasgow—Improvements in hats and other coverings for the head

*Dated March* 6.

534. J. Warhurst, Hollingworth, Chester—Improvements in steam-boilers
538. T. H. de Nivelles, Foley-place—Apparatus for separating metallic from earthy and other substances, and for classifying metallic substances according to their specific gravities
540. P. A. de St. Simon Sicard, Paris—Improvements in purifying sea and other water
542. B. Brokenshar, St. Austell, Cornwall—Improved amalgamator

*Dated March* 7.

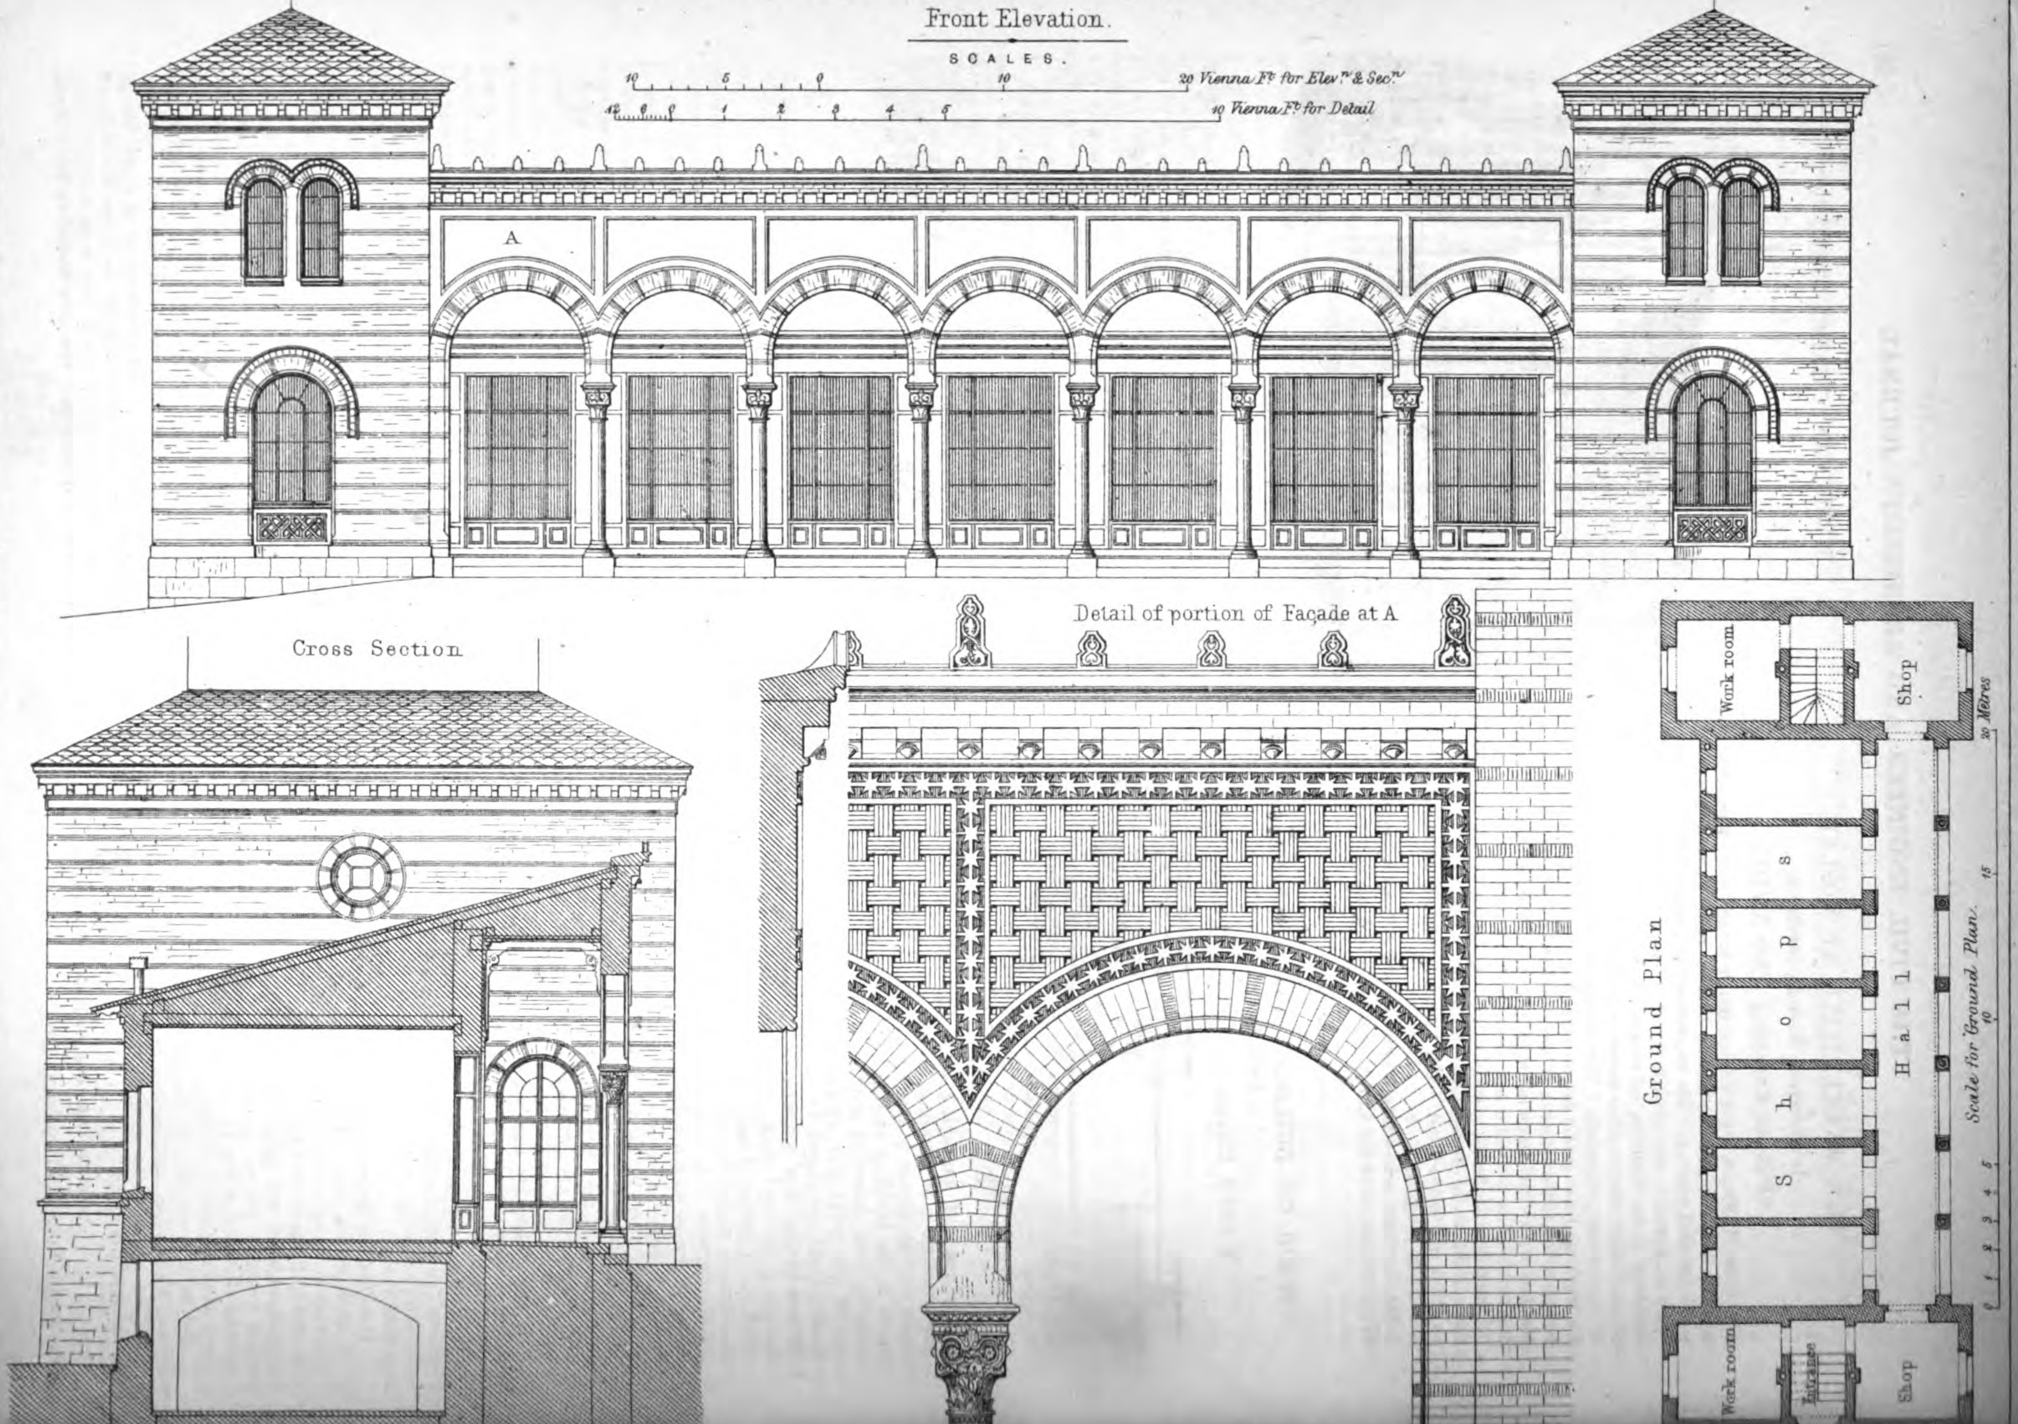
544. W. Clay, Liverpool—Improved mode of manufacturing axles, shafting, and other like solid articles which present a round figure in cross section
546. G. Chant, Stoke-sub-Hamdon, Somerset—Fan-parasol, or sun-shade

---

PATENTS APPLIED FOR WITH COMPLETE SPECIFICATION.

460. F. W. A. de Fabeck, Norfolk-street, Strand—Construction of bridges, viaducts, lintels, beams, girders, and other horizontal structures and supports.—Feb. 25
504. T. Truscott and T. P. Baker, Naval Engineers' Club, Portsea, Hants—Improved arrangement of steam-engines adapted to screw propulsion.—March 1
515. W. Brown, Glasgow—Improved mode of obtaining voltaic products from bituminous coal and other bituminous substances.—March 3
519. J. Nicholson, Dublin—Improvements in and applicable to certain descriptions of close kitchen-ranges.—March 3
571. S. Trotman, Portman-square—Improved alarum night-clock or time-indicator.—March 9
585. G. Appolt, Sulzbach, Prussia, and C. Appolt, Metz, France—Improvement in the manufacture of coke.—March 10

MARKET HOUSE AT VŒSLAU NEAR VIENNA.



## THE MARKET-HALL AT VOSLAU.

L. Forster, Vienna, *Architect.*

(*With an Engraving, Plate* XVIII.)

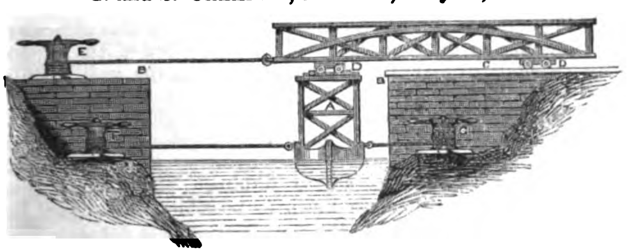
Count M. Fries, a gentleman much attached to the arts, has erected a small market-hall at Voslau, near Vienna, a watering place for that capital. He intrusted the design and execution to Herr L. Forster, the architect, of Vienna. The object of this building is to combine, by means of the pillared hall, the wants of the traders during the summer months with the requirements of the bathing visitants. The basement serves as a store-cellar for fruit, and the levels are so arranged that a union is effected between the place or area of the market-hall and the large space planted with fruit trees belonging to the garden of the Count's mansion. The pavilions are occupied as dwellings.

The columns, bases, cornices, and acroteria are of sandstone, and all the walls of well-burnt yellow tiles, among which rows of red tiles are introduced. The ornaments are from the clay-ware factory at Wagram.

Mr. L. Forster has lately constructed a new bridge over the Wien stream, near the Carinthian Gate at Vienna.

## MODE OF BUILDING AND TRANSPORTING BRIDGES.*

T. and S. Champion, *Patentees*, May 22, 1853.



The annexed engraving is a side view or elevation of an improved mode of building bridges on the land, and conveying them to their places over streams. The principal feature in this mode is, the building of the bridge on the land, at about the level with its intended position, on a prepared roadway C, on one of the previously prepared abutments B, B, on which the trucks D, D, are placed for the land part of the transportation. Which having been accomplished, a vessel or vessels of sufficient buoyancy for the burden to be imposed, having upon it a frame work A, of proper height, is floated by the stream either under the already projecting end of the bridge, or against the abutment, for the purpose of having the bridge rolled upon it. The vessel being provided with a valve to receive, and a pump to discharge water, it may be ballasted therewith, and its buoyancy regulated as desired; after which, all things being in readiness, by means of the capstans F, G, with the ropes attached, the vessel and bridge upon it may be speedily and safely drawn over its place, and lowered to its proper position, by letting water into the vessel, or by jack-screws or other process.

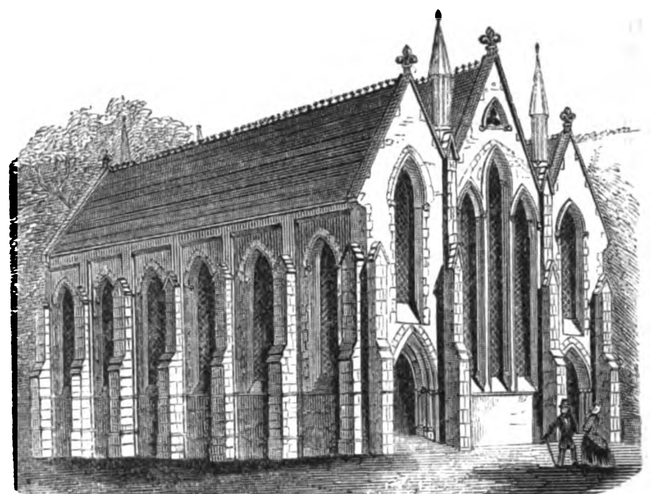
It is claimed for this mode, that a great saving is effected thereby, over the old mode of timber supports from the bed of the stream, even where such supports are practicable, but where the streams are deep, the currents rapid, and the bridge high above the water, such supports are always dangerous, liable to be carried away with freshets, and in some cases positively impracticable.

It is further claimed that the advantages are equally in favour of this mode, over that adopted in placing the celebrated Britannia Tubular Bridge over the Menai Straits, as it is nearly if not quite as convenient and safe to build the bridge at once at the right as at any other height, while it is much easier and safer to move the whole affair on a level, or inclined properly prepared road and flotilla, than to raise the whole weight by any process perpendicularly to its place.

By this mode all the danger incident to working over the water, all the cost and danger of raising such heavy structures from the water, is avoided, by means as simple and safe as they are beautifully effective.

* From the 'Journal of the Franklin Institute.'

## WESLEYAN CHAPEL, TORQUAY.



The annexed woodcut represents a perspective view of a Wesleyan chapel, recently erected at Torquay, of which Mr. E. Appleton was the architect, and Messrs Harvey and Henley the builders. It is capable of holding five hundred persons on the ground (there being no galleries). The internal dimensions are 66 feet by 41 feet. The roofs are open, with arched principals to the nave, supported upon bosses. Each pair of rafters in the aisle roofs intersect one another in the manner of struts. The fittings are of deal, stained and varnished; the pews have trefoil bench-ends. The pulpit is octagonal, buttressed and approached by a double staircase. The communion railing is formed of ornamental scrolled wrought-iron, as also the pulpit stair-rails. An organ of suitable design, by Dickes of Exeter, has been since added. The building is divided by two arcades of six bays, and stands at a considerable elevation above the road, upon a sudden incline under the cliff. Though simple in design, it is highly creditable to the architectural taste of Mr. Appleton.

## EXTENSION OF THE UNITED STATES CAPITOL, WASHINGTON.

The prosecution of the works at the Washington Capitol having been transferred, by order of the President, from the Department of the Interior to the War Department, the Hon. Jefferson Davis, Secretary-at-War, deputed Capt. M. C. Meigs, of the Corps of Engineers, to the special charge and direction of the works, which, under his supervision, have progressed in a manner highly creditable, alike to the liberality of the American legislature and the reputation of those to whom they have been intrusted. On examination of the reports from various officials employed in the erection of this structure, it is particularly observable that proper provisions for the effectual warming and ventilation, as well as the best means for ensuring an equal dissemination of the voice of speakers, have been made during the progress of the works; and not, as is too often the case in our own country, left until after the completion of the building, when alterations are objectionable, not only from their inconvenience and expense, but from the apparatus, &c. involved in these matters being so frequently unsightly and out of all character with the architectural design of the structure wherein they are placed.

The lamentable effects of the want of this foresight in the proper authorities are painfully conspicuous in most of the halls and public buildings hitherto erected; but we trust that the day has arrived when as much scientific investigation and skill will be bestowed upon these all-important particulars as upon the more captivating study of the peculiar style and architectural detail of our churches and national erections. The results of the experiments and observations of Capt. Meigs, in connection with the interior arrangements of the Washington Capitol, will be found to contain much that is exceedingly valuable and universally applicable. We give therefore his "Notes on Acoustics and Ventilation with reference to the New Halls of Congress."

These Notes were submitted to the consideration of Messrs. A. D. Bache, LL.D., and J. Henry, LL.D., who fully corroborated the principles laid down by Capt. Meigs, and approved of their judicious application. The above gentlemen visited many of the most important buildings in Philadelphia, New York, and Boston, for the purpose of examining them in reference to their acoustic qualities, which examination completely established the accuracy of the observations of Capt. Meigs.

---

*Notes on Acoustics and Ventilation, with reference to the new Halls of Congress, by Capt.* M. C. Meigs, *United States Corps of Engineers, May* 1853.

Experience shows that the human voice, under favourable circumstances, is capable of filling a larger space than was ever probably inclosed within the walls of a single room. Herschel, in his admirable treatise on sound, gives a few instances which are instructive. Lieut. Foster, on Parry's third Arctic expedition, found that he could converse with a man across the harbour of Port Bowen, a distance of 6696 feet, or about one and a-quarter mile. Dr. Young records, that at Gibraltar the human voice has been heard at a distance of ten miles. I have myself, on the shore of Lake Champlain, at evening, heard the echo of the voice returned from the opposite shore, at a distance of nearly two miles, the sound having travelled between three and four miles before it returned to the ear. If sound be prevented from spreading, and losing itself in the air, either by a pipe or an extensive flat surface, as a wall or still water, it may be conveyed to a great distance. Biot heard a flute clearly through a tube of cast-iron (the water-pipes of Paris) 3120 feet long. The lowest whisper was distinctly heard. In fact, the only way not to be heard was not to speak at all. Standing on the platform used by the painters in the new Congressional Library, Professor Henry and myself conversed in a low tone, hearing distinctly from one end of the room to the other. The room is 99 feet long. The platform is about 7½ feet below the deeply-moulded iron ceiling. Professor Reid states, in describing his lecture and practical class-rooms, which together occupied a space of about 80 feet square, that in every part, both of the lecture-room and of the practical class-room, whether crowded or empty, the slightest whisper or the loudest noise was heard distinctly, without offensive reverberation, or the necessity of any exertion of the voice beyond that used in conversation.

The favourable circumstances seem to be a perfectly tranquil and uniformly dense atmosphere, absence of all extraneous sounds, absence of echoes and reverberation, vicinity of reflecting surfaces, and perhaps in some measure the presence of substances which conduct sound well. A pure atmosphere being favourable to the speaker's health and strength, will give him greater power of voice and more endurance; thus indirectly improving the hearing by strengthening the source of sound, and also by enabling the hearer to give his attention for a longer period unfatigued. The analogy between sound and light in regard to their progress, reflection, and refraction, seems well established. By employing reflectors of proper forms, sound emanating from one point can be collected to a focus at another. When the reflector is a plane surface, the angle of reflection is equal to the angle of incidence. Experiments under water show, that in passing from a denser to a rarer medium, there is an angle of total reflection. The speed of its transmission varies with the elasticity and density of the medium; like light, it is confused by passing through air unequally rarified by heat. It is more difficult to trace the progress of sound than of light. Sound is invisible during its passage, and cannot be traced as light is, by illuminating the motes in its path; nor is the ear as accurate in estimating the direction from which it receives sound, as the eye is in determining the direction of the source of the light which falls upon it. But finding a strong analogy to light in those cases where it can be followed, we may reasonably, within proper limits, infer it in others. The effect of echoes in a small room is generally unnoticed; the echo returns so quickly that the ear receives it as coincident with the original sound, to which it in that case merely adds strength, perhaps prolonging it very slightly. If the room be larger, and the echoing wall so distant that the interval is sensible, the echo makes confusion. If on a calm day we advance towards a wall, producing at each step some sound, we will find a point at which the echo ceases to be distinguishable from the original sound. The distance from the wall or the corresponding interval of time, has been called by Professor Henry the limit of perceptibility. This limit will vary with the nature of the sound; if the sound be sharp and distinct, as that produced by striking some hard substance, we shall find the limit of perceptibility less than for the more prolonged sound produced by the voice. The limit will probably vary also with the acuteness of the ear; some persons being probably able to separate sounds undistinguishable to others. The general limit is probably about 30 or 35 feet. It should be ascertained exactly, and in constructing a room for public speaking the height of the ceiling should not exceed this limit. The sound will then be strengthened to the speaker himself by the echo. The interval between the original and reflected sounds will be shorter for all his hearers than for himself, as twice the path of the voice and echo for the speaker is considerably longer than the difference between the paths of the direct and reflected sounds of one of the auditors. The direct echo from the ceiling then becomes an advantage, by strengthening without confusing the sound. But echo acts in still another way by being repeated between opposite surfaces. The effect is like the multiplication of the image of a candle between two opposite and parallel mirrors. I have noticed it in the long, unfinished room of the Smithsonian, where the sound produced by clapping the hands is repeated so as to resemble a laugh—ha! ha! ha! In this case the distance between the end walls is such as to separate the successive echoes; but when the walls are nearer, the sound becomes contiguous, and is the ringing sound often produced in speaking in empty rooms, and called reverberation. This might trouble us between the ceiling and floor of our room; but a thick carpet absorbing sound and not reflecting it will remove this difficulty. The great size of the room needed for the meeting of the House of Representatives makes it impossible to bring the walls within the limit of perceptibility. Professor Reid proposed in the Houses of Parliament to make the ceiling high in the centre, declining towards the sides, with floors and galleries rising from the centre towards the walls, thus reducing the height and surface of the walls, so as to diminish the quantity of sound reflected from them as much as possible. All regard for architectural beauty forbids the adoption of this construction, which seems to have been modelled upon an empty tortoise-shell. Breaking the walls into deep panels has also been proposed. But when we recur to the limit of perceptibility, we shall perceive that a panel or recess must be over 30 feet deep to separate the echoes from the bottom of the recess and from the face of the wall. The surfaces of mountains covered with trees and rocks return echoes. No wall of an inhabited apartment can be made rougher than these natural reflectors. A simpler and more effectual method of controlling the echoes from the walls will be to cover them with drapery absorbent of sound. The echoes from the ceiling are thus turned to account, and those from the floor and walls guarded against; but the echoes from small objects and surfaces may still be troublesome unless provided for. The trunks of trees in the edge of a forest return together a distinct echo. The beams under the flooring of the Menai Suspension Bridge are instanced by Herschel as giving a curious echo; and even such small objects as the vertical iron rods composing the fence on Pennsylvania Avenue, in front of the President's house, will be found to return a singular whistling echo to the sound made by striking a smart blow upon the pavement on a still night. To guard against this, it will be sufficient to cushion the chairs and cover the desks with some material which will not reflect sound. This may seem, and may possibly be, an unnecessary precaution; but I wish to leave no possible cause of confusion unnoticed, and to point out what I consider the means to obtain, for the first time, a room perfect in its acoustic arrangements.

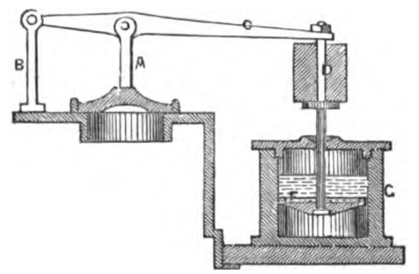
Having thus disposed of the question of echoes and reverberations, the next essentials to perfect and distinct hearing are a tranquil atmosphere and the absence of extraneous sounds. I consider them together, as we shall find that the precautions essential to obtain the one will also secure the other. Windows, in cold weather, separating the warm air within from the cold air without, serve as refrigerators, cooling the air in contact with the glass. The air, thus rendered heavier, immediately falls, and a descending sheet of cold air is produced, which, on reaching the floor spreads over it in a cold stratum, and to persons of sensitive nerves or feeble health causes great inconvenience, being felt as a draught upon the feet and legs. And many an unfortunate page has been blamed for leaving open a door, when the draught really has been caused by this air cooled by the closed glass of an adjacent window. The circulation thus produced of air of different densities is unfavourable to distinctness of hearing. As the ascending hot air along a stove-pipe or heated wall causes irregular refraction of light, and produces a tremulous appearance in all objects viewed through it, so sound, irregularly refracted, becomes less clear and distinct. If we exclude external windows, and light the room only from the roof, we get rid of this fruitful source of discomfort and indistinctness; at the same time, we obtain a pleasanter light, ample for all useful purposes, as is proved by its adoption in all the best constructed picture-galleries. We also exclude the sounds of the exterior, which, saturating the air as it were, distract the attention, and even overpower the voice we wish to hear, as the diffused light of day causes the stars to disappear. Open windows for hearing will be worse than closed ones; they not only let irregular, disturbing currents of air in, but they let the voice out—acting like black spaces in the wall of a room, which do not return the light which falls upon them. The common mode of warming and ventilating public rooms is fatal to perfection of hearing. One or several columns of intensely-heated air are introduced through holes in the floor. Being much warmer than the air of the apartment, they immediately rise to the ceiling. If the exit-apertures for foul air are above, this fresh and heated air alone escapes, having done nothing for the apartment except to cause whirls and currents, such as we see in a column of smoke passing from a chimney on a calm day. The irregular refraction of sound through these currents of unequal density tends greatly to produce confusion. If the exits for foul air are below, the hot air accumulates at the top of the room, and gradually displacing the cooler air, forces it out through these passages. Professor Reid relates that he has found the air near the ceiling of a room at the boiling temperature, while those on the floor were complaining of cold. Here we have strata of different densities and unequal refractive power, and hence confusion of sound. As the warm air must ascend to the top of the room, I propose to let it do so in a large trunk outside of the apartment—pass into a space above the ceiling, and thence by numerous holes find its way, as through a sieve, into the room. By a steam-driven fan, or other mechanical means, we can pump air, in any desired quantity, into any spot to which we choose to direct it. I would drive all the air required for the supply of the room through a maze of hot-water pipes, raising the whole of it to the temperature desired—60° or 80°, as the case might be. If the room be 30 feet in height, and it be desired to change all the air in it every fifteen minutes, enough air should be pumped in above to cause a general descent of the whole body of air in the room at the rate of 2 feet a minute. This would be an imperceptible current. The exit should be made by numerous holes in the floor, perhaps through the carpet, or the risers of the platform on which are the members' chairs. Three important advantages would thus be gained: the avoidance of all eddies, a nearly homogeneous and tranquil atmosphere, and the immediate removal downwards of any dust from the carpet, which would thus be prevented from rising, to be inhaled into the lungs. To prevent the disturbance and contamination of the atmosphere, by the gas-lights, I would place them above the glass of the sky-lights—the space between those in the ceiling and those in the roof being separated from the chamber into which the fresh air should be admitted. In summer, the same apparatus which sends in warm air in winter would supply a constant breeze, and if the temperature of the external air was too high, it might be cooled by jets of water from pipes in the air-passages, or even by melting ice.

To recapitulate, then, I propose to place the ceiling at such a height as to be within the limit of perceptibility, and thus strengthen the voice; to destroy reverberation between the ceiling and the floor, by a thick carpet on the latter; to prevent echoes from the walls, by drapery; from the chairs and desks by cushioning or covering them; to keep out extraneous sounds, by making the room an interior apartment lighted only from above; to secure a tranquil atmosphere, uniform in its density and refraction of sound, by excluding all currents of hot or cold air; to secure a constant supply of pure air at the temperature desired for the room, by mechanical means introducing the air through all parts of the ceiling, and taking it out through all parts of the floor—thus also to remove dust; to prevent all interference with ventilation by the lights at night, by placing them outside the room above the sky-lights.

## SAFETY-VALVES.

H. Waterman, U.S., *Patentee*, November 15, 1853.

The object of this invention is to attain as near as possible a constant and uniform pressure upon the valve; and in order to prevent the vibrations of the weight and lever. A and B, are standards supporting the valve lever C, to the outer end of which is applied a weighted-rod D, connected to a valve F, freely moving in a cylinder G, filled with a fluid to nearly its top. By this means the piston can move no faster than the fluid is made to pass by the piston, and thereby to check sudden vibrations.



*Claim.*—The piston F, attached to the weighted end of the valve-lever within the cylinder G, and immersed in the liquid in the cylinder, combined and operating in the manner and for the purposes herein described.

## REVIEWS.

*Practical Remarks on the Warming, Ventilation, and Humidity of Rooms.* By Francis Lloyd. London: Cox, King-street, Covent-garden. 1854.

This exceedingly clear and common-sense pamphlet should be attentively perused by all classes of society, containing as it does so many practical remedies, within the reach of all, for most of the evils attendant on bad ventilation and imperfect warming of dwellinghouses of all descriptions. Dependent as we are upon the purity and proper degree of humidity of the atmosphere we inhale, it is remarkable that the knowledge of the right means of attaining these essentials is possessed by so few. Until we have purified, and precautions are taken to get rid of the noxious exhalations from, our dwellinghouses, the external atmosphere can never be other than foul. Numberless works are published, and patents secured every year, in connection with ventilation, heating, and improving our sanitary condition; yet the propositions and remedies contained in them are either too complex and expensive, or based upon fallacious principles, or they are crude and impracticable, and but half meet the requirements of the case. In the little work of Mr. Lloyd, the subject is treated in a very explicit and practical manner; the contrivances suggested have been submitted to the test of experiment; they are cheap, simple, and founded in strict accordance with scientific laws.

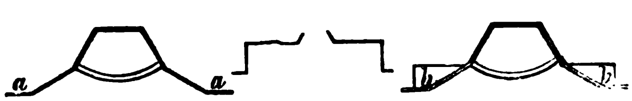


Fig. 1. Fig. 2.

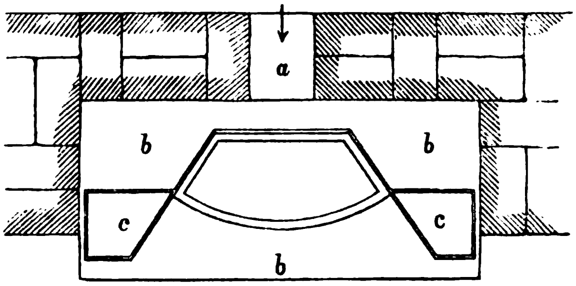
The imperfections of most of the systems of warming are so generally admitted, that we shall refrain from alluding to them here, and pass at once to a simple arrangement for warming proposed and tried by Mr. Lloyd in an old and indifferently built house. The existing stove was removed, and the one shown in plan in fig. 1, substituted, to the cheeks and back of the face *a*, *a*, of which were riveted two strips of sheet-iron, bent so as to fit the stove, as seen in fig. 2, and forming two side chambers or flues *b*, *b*; these flues were connected at top with a horizontal rectangular chamber, having a longitudinal opening towards the apartment, immediately under the mantelpiece. The lower ends of the flue *b*, *b*, were passed into a chamber formed beneath the hearth-plate, which communicated, by means of zinc tube, with the external atmosphere. A passage-way of 36 inches area was thus obtained beneath, around, and above the front part of the stove, providing ingress for pure air from the garden, and egress from the upper part of the stove into the room.

The air passing through this passage-way attained, and was maintained at, by a comfortable fire, a temperature of 80°. The highest temperature was found to be 95°, whilst the lowest on cold days, with only a small fire, was 70°. "The mean temperature of the room at the level of respiration was 61°, while the uniformity was so perfect, that thermometers hanging on three sides of the room rarely exhibited a greater difference than one degree, although two of the sides were external walls." This description of stove is better illustrated in figs. 3 and 4, the

Fig. 3.



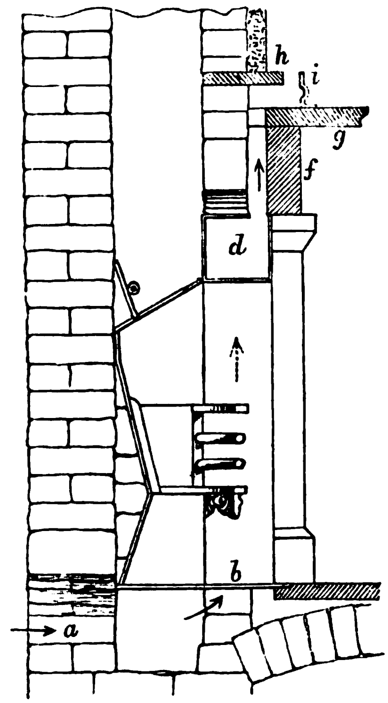


Fig. 4.

former of which is a horizontal section and the latter a vertical section of the tubular stove in its complete form. *a*, is the flue for conducting the external air to the underside of the hearth-plate *b*; *c*, *c*, are openings in the hearth-plate *b*, communicating with two upright tubes of a corresponding form, which conduct the air entering at *a*, upward to the horizontal tube *d*, above which tube is an opening or passage, the orifice of which is immediately above the mantel-shelf *g*; *f*, is the upper mantel, which stands forward 1½ inch from the chimney-breast *e*; *h*, is a thin slab of marble built into the chimney-breast, for the purpose of supporting a chimney-glass, and diverting the current of air from flowing directly up the chimney-breast; *i*, is a strip of metal (or marble), which may be moved more or less towards the slab *h*, either to diminish or stop the supply of warm air to the apartment, or a thin strip of metal may be made to act as a throttle-valve between *i*, and *h*. The arrows in the engraving fig. 5 indicate the path of circulation of the air in a room fitted with the tubular stove. Mr. Lloyd states, and we have every reason to believe that he is correct, that the advantageous results obtained by this construction are—"First, the prevention of a smoky chimney; for as provision is made for the regular inflow of air to the room, the outflow of smoke may be deemed tolerably certain, as an open window or door almost invariably secures that end. Secondly, the equal distribution of warmth, and freedom from draughts; for whilst in an ordinary stove, heat is obtained by radiation only, in this there is also a copious supply

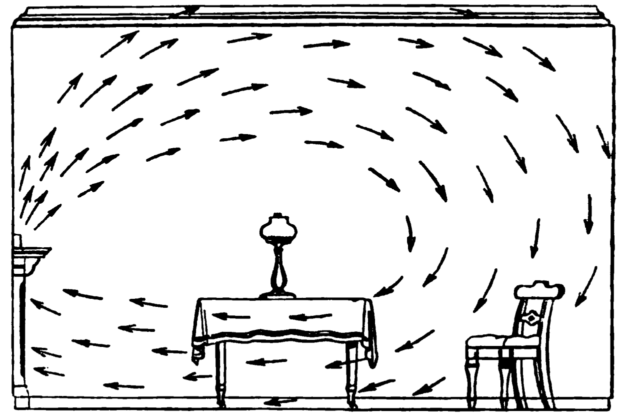

Fig. 5.

derived from the warmed air dispersed insensibly over the room. The intense heat to which the hearth, cheeks, and jambs of an ordinary stove are raised, produces through the fire a very rapid draught, which carries up the chimney a large proportion of the heat which should be diffused; but by converting the hearth-plate and jambs into air-tubes, a considerable portion of the heat given out by the fire is absorbed, and the intensity of the draught is diminished, without hindrance to a steady and continuous current up the chimney. Thirdly, complete ventilation, unaccompanied by any sensible current. There being a continuous flow of air, of a temperature exceeding that of the room, distributed over the upper part, while there is a continuous drawing off of air at the lower part by means of the fire, it follows that there will be a regular current in the upper half of the room from, and in the lower half to, the fireplace." This steady circulation of air is found to absorb and neutralise all those obnoxious draughts and currents that usually stream in from the defective construction of windows and doors, and which are increased in proportion as the apartment attains a higher temperature. As Mr. Lloyd admits, the principle on which the tubular stove is constructed is not new; but all former apparatus of this description has been costly, and objectionable from their drawing their supply of air from the apartment to be warmed, thereby not only detracting from the healthy condition of the atmosphere, but also increasing the number and strength of the draughts from the present uncertain and objectionable sources of supply for the combustion of the fire. The novelty of Mr. Lloyd's stove consists in the supply of air to be heated being derived from the external atmosphere, and also its being carried through passages in front of the fire-grate instead of at the back, thereby preventing the possibility of the air being over-heated, and admitting of regulation of its temperature. "The tubular stove warms a room partly by direct radiation and partly by communicating heat to the air which passes beneath the hearth and through the tubes, which are warmed by the radiated heat of the fire; and considering that the smallest increment of heat, say only one degree, will cause air to ascend, the tubular stove thus becomes in effect a manageable, economical, and powerful pump. A bright metallic screen placed before the fire will prevent direct radiation, and by reflecting the heat to the grate will increase the pumping power of the fire. By forming the screen so as to make it interpose between the tubes formed in the hearth, the sides, and the fire, the supply of radiant heat to the air-passages may be cut off."

Mr. Lloyd proposes to provide churches, theatres, concert-rooms, and places of public resort with hollow columns, perforated or open at top, and communicating with the basement of the building or the external atmosphere. These columns might be somewhat similar in construction to a twisted Saxon column (fig. 6), and made to play like fountains in a way that would diffuse a pure atmosphere without causing any inconvenience. Supposing the area of such rooms to be measured out into squares of 100 feet area (adequate to the accommodation of about thirty persons), and to every such sub-area there be provided one of these columns of any convenient height. The air fouled by thirty persons in an hour being not more than 120 cubic feet, the bore of this fountain, to supply it at the rate of 10 feet per second (the rate of a gentle, pleasant wind), will not exceed the area of 12 square inches, or a tube 4 inches in internal diameter. These columns may be made to support the gas or other lights (as shown in fig. 7); and in order to disperse the air in all directions equally, may be fitted with an ornamental perforated cone, gradually diminishing from the full diameter of the pillar to that necessary for the supply of a gas-burner above. This would involve an addition to the diameter of the column sufficient to admit a supply of pure air for the lights, which, if of gas, would consume about fifteen times as much air as gas; so that fifteen times the capacity of the gas-pipe, added to the above 12 square inches, will give the internal diameter of the whole pillar.

Fig. 6.

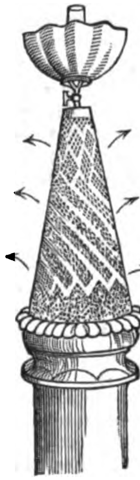

Fig. 7.

These air-fountains, in connection with a proper provision for drawing off the vitiated air, and applied at the proper points of the building, would be a great improvement upon the present absurd system of providing an escape for air at the top of apartments without means of supply, but allowing the air to find its way as it best can through chinks or ill-made or open doors and windows, to the great danger and annoyance of the occupants.

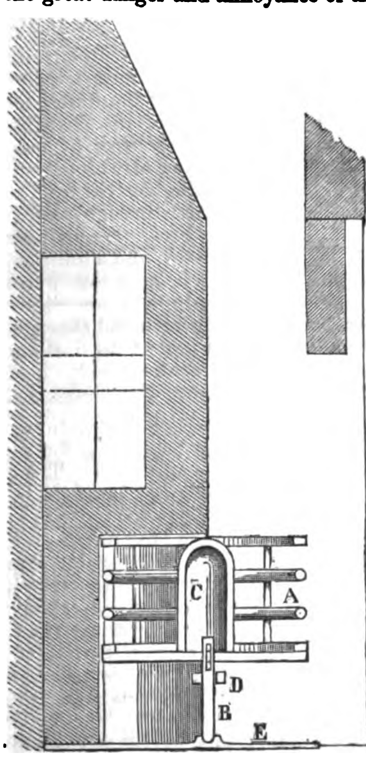

Fig. 8.

Mr. Lloyd also proposes a simple contrivance for the consumption of smoke in domestic fires, which, from his own experience, he states to be convenient and economical. Fig. 8 represents a vertical section of this apparatus. A, is a circular fire-grate, consisting of four circles of bars, separated by pins, and fastened to an iron cross; B, the vertical spindle, to which the grate is firmly secured by means of keys above and below the cross; C, is a hollow cylinder of iron or fire-clay, with a hemispherical top having a slit in it. This cylinder rests on the cross, and is open at its lower end. D, is an iron bar, with a coupling to embrace the spindle immediately below the fire-grate A; E, is an iron hearth-plate, having a hollow boss to receive the end of the spindle B. The brickwork was built with a semicircular recess, to receive one-half of the circular grate, above which was placed a Welsh lump, about half-an-inch from the top, thus completely inclosing the half of the grate. The fire being lighted and got well up in the whole circle of the grate, fresh coals are put on the half projecting from the brickwork, and the grate is turned half round on its axis B. A clear, bright fire is then apparent in front, while the gases and smoke from the fresh coals at the back make their way forward to the edge of the Welsh lump, where they are subjected to the heat of the clear front fire, whilst the stream of air passing up the hollow cylinder C, escapes by the slit, commingles with the smoke, gases, &c., and ensures their almost perfect combustion. A clear fire with a semicircular face, well adapted to the radiation of heat, is thus always presented to the room.

This description of fireplace may be modified so as to combine the warming and ventilating effects of the stoves before described, as well as to retain its own peculiar advantages, and thereby prevent any heat from being absorbed by the brickwork immediately around the circular fire-grate.

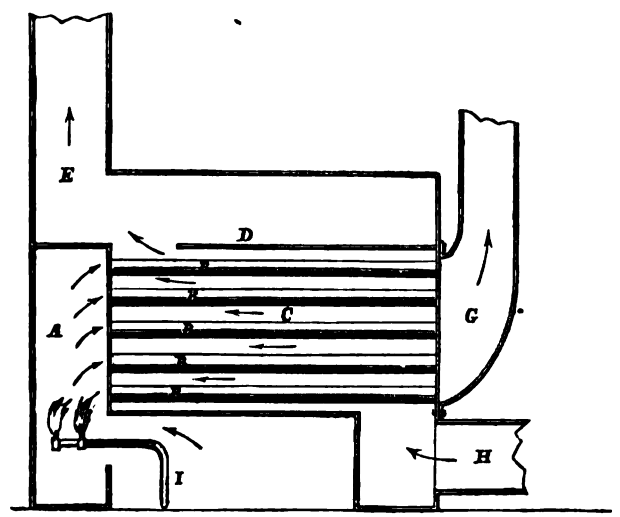

Fig. 9.

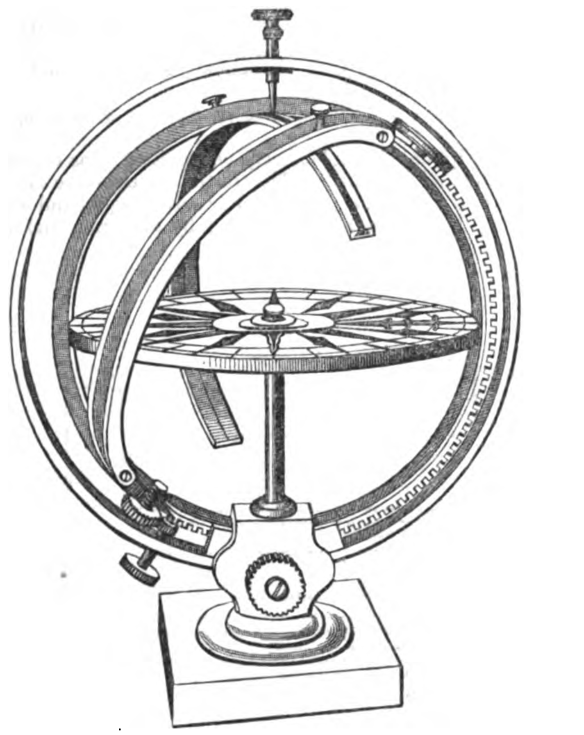
Fig. 9 shows an arrangement for a gas-stove, having for its object the prevention of any loss of heat given out by the combustion of the gas, with the exception of what little is carried off by the noxious vapours up the chimney; but this escape is found to produce considerable ventilating effect. A, is the gas-box, and B, a series of horizontal pipes or smoke tubes, each 20 inches long and $\frac{3}{4}$-inch diameter, affording a heating surface of 1020 square inches; C, is the air-chamber attached to the gas-box A, and through which the smoke-tubes pass; G, is the chimney-tube connected with the chamber C; H, is a tube for conducting external air to the chamber C; D, is a sliding-plate of metal resting on the smoke-tubes B; E, is a tube attached to the air-chamber over the gas-box, to assist the ascent of air through C; F, is the gas-pipe and burners.

Supposing the gas to be burning and the tube H, open, it is evident, that while the gas is flowing from left to right, a supply of fresh air will flow from right to left, and effectually take up the heat radiated by the tube B, while the air from the apartment supplies the burners through the opening at which the gas-pipe is placed. In order to diminish the quantity of heat taken up by the fresh air, the plate D, may be moved to the left, in which case the air will pass directly upwards, and over the plate D, instead of sweeping the whole length of the pipes B. The same arrangement on a larger scale would be economical for the combustion of coal, compared with the ordinary open fire-grate, a large proportion of the heat of which passes off up the chimney.

The observations of Mr. Lloyd respecting the humidity of the essential atmosphere of dwellings, are especially worthy of perusal. The sanitary condition of the air by which we are surrounded has hitherto received but little general attention, notwithstanding its great importance, especially in rooms or buildings heated by close stoves, hot-air stoves, steam, or hot-water pipes. In these cases, small fountains or open vessels of water or steam-jets might be very beneficially employed. In conclusion, we may remark, that all the apparatus suggested by Mr. Lloyd have stood the test of experiment, and been found to answer admirably the purposes intended. They are therefore entitled to more consideration than the untried theories of most of the ventilating savans of the day.

## THE GREAT CIRCLE COURSE INDICATOR.

Lieutenant E. D. Ashe, R.N. *Inventor.**



Lieutenant Ashe, of the Royal Navy, the talented director of the observatory at Quebec, previous to leaving this country in the autumn of 1850 for Quebec, devised a simple useful instrument for the purpose of finding the Great Circle course and distance between places for the use of navigators. It was at the time when Great Circle sailing was regaining attention; and lectures were given here and there on a subject which was soon found to be scarcely worth while to lecture on. But Lieut. Ashe made no essay on this ground, and, starting for his destination, left his views on the subject to be carried out while he proceeded to his business at Quebec. The 'Nautical Magazine,' as the general receptacle of any inventions likely to become useful to seamen, is the fittest place for its description; and we have, therefore, prepared the following account of it for our readers, under the name given to it by its inventor as "The Great Circle Course Indicator."

The meridian circle inside the large outer one is supported by a brass socket attached to the stand of the instrument at the nadir. The outer circle carries the zenith point, which is raised or depressed by a screw at pleasure. This meridian circle is also moveable by a screw in the brass socket which carries it, so that by altering its place in the socket the poles may be elevated or depressed as required. The anterior or elevated portion of this meridian circle consists of two semicircles moveable at the poles, marked east and west, these being similar to each other and graduated in degrees and minutes, are readily adjusted and fixed at any angle by a clamp screw. Another screw moves these semicircles in azimuth, and they are then fixed at the required angle by the clamp screw.

A moveable arc traverses these moveable meridians in any direction and, continuing to the horizon, indicates the course to be steered by compass at the point on the compass card intersected by it. This moveable arc, called the course indicator, is fitted with two brass pointers (intended to represent the ship), so as to slide easily in a groove on this arc and to show the places of departure and arrival; and this arc is adjusted as follows:

The moveable meridians are opened to an angle equal to the difference of longitude between the place of departure and arrival, measured by the moveable arc being brought to the equator of both, and are fixed at that angle by the clamp screw. The moveable arc is then released, and when the place of arrival is west of the departure the zero on this arc is clamped at the latitude of the place of the departure on the eastern meridian. The arc is then brought to coincide with the latitude of the place of arrival on the western meridian. The zero of this arc or the point of departure on the eastern meridian being then brought under the zenith point, the intercepted arc then represents the distance to be sailed over, and the intersection of the same arc on the compass card beneath it gives the course to be steered, and the distance is read off on that portion of the arc C, that is intercepted between the two meridians.

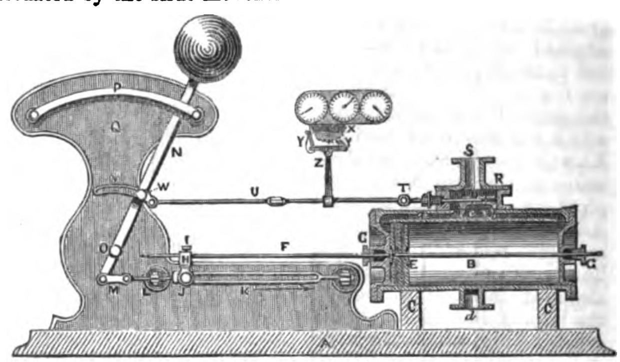
It may be as well to remark that the north and south points of this card being fixed so as to coincide with the outer meridian circle the course thus read off is the true course, to be corrected for variation and local attraction before adopting it with the binnacle compass.

* From the 'Nautical Magazine and Naval Chronicle.'

## CYLINDER WATER-METER.

J. Hartin, *Patentee*, May, 1853.

This meter, which is an American invention, consists of a simple arrangement of a cylinder and piston, fitted with slide-valves, for the ingress and exit of the water to be measured; the cylinder, which is the actual measuring vessel, being filled at each stroke of the piston, after which the slide-valve is reversed, when the water escapes, and a fresh supply is admitted on the opposite side of the piston. This action therefore keeps a reciprocating movement of the piston, and the registration of the measured fluid is effected by a counter attached to the valve-spindle, and actuated by the slide movement.



The annexed engraving is a sectional elevation of the meter complete. At A, is a wooden or base-plate, for supporting the cylinder and working parts of the apparatus. The cylinder B, is carried by the two vertical supporting brackets C, and is fitted by a slide-valve D, and piston E, screwed on to the piston-rod F. This rod passes through a stuffing-box G, in each end of the measuring cylinder, and has a short adjustable arm H, screwed to it near its outer extremity by a pinching screw I. The lower end of this arm is fitted with a stud-pin J, which works in the longitudinal slotted-rod K. This rod slides in the fixed bearings L, which are bolted to the main vertical portion of the framing. The outer extremity of the slotted rod is connected by a short link M, with the lower end of the vertical weighted tumbling lever N, working on a fixed centre O. The upper end of this lever is guided in its movements by the segmental guide-plates P, which are carried by a pillar Q, bolted to the main framing. The slide D, is contained in the chamber R, which is furnished with an inlet-pipe S, and the spindle of the slide is jointed at T, to one end of the adjustable connecting-rod U. The opposite end of this rod is jointed to the segmentally-slotted plate V, in which works a stud-pin W, fitted into the lever. The slot on this segmental plate is rather shorter than the traverse of the pin in the lever, so that, when the lever is caused to oscillate or vibrate, a certain amount of traverse is given to the slide D. The movement of the lever N, is effected by the stud-pin J, in the slotted rod K, the slot in this rod being shorter than the stroke of the piston; and consequently, when the pin arrives at the end of the slot, the further traverse of the piston slides the rod K, in its bearings, and thereby turns the lever N, on its fixed centre O. The registration is effected by the ratchet-wheel X, actuated at every stroke of the slide by the pawls Y, fitted to the T-lever Z, which is secured to the connecting-rod of the valve-spindle.

In measuring fluids by this meter, the fluid to be measured enters by the inlet-pipe S, into the chamber R, whence it passes along the open part *a*, into the corresponding end of the cylinder B. The pressure of the fluid forces the piston to the opposite end of the cylinder, thereby causing the pin J, to traverse along the slotted rod K, and move it in the direction of the arrow. This movement of the rod reverses the lever N, which effects the movement of the slide D, by means of the stud-pin W, and slotted link V. By this means, the port *b*, is opened suddenly, and the fluid is allowed to enter the oposite end of the cylinder, thereby forcing the piston back again, and consequently expelling the fluid which was contained above the piston; this fluid escapes by the egress port *c*, which is now in communication with the inlet thoroughfare *a*. A hollow zone or belt is cast round the cylinder, and forms the outlet for the fluid which pours into the source-pipe through the branch-pipe *d*, cast in one piece with the cylinder. By fitting a moveable false bottom or end to the cylinder, so as to be capable of adjustment by an external screw or other movement, the capacity of the cylinder may be regulated to the greatest nicety, by simply screwing or setting in or out the internal false bottom.

## THE FOUNTAINS OF CONSTANTINOPLE.*

*(Concluded from page 85.)*

As the Turkish capital lies at the feet of such an extensive mountain range as that of the Hæmus, there is no other city in Europe which can be compared with it in the rich and abundant supply of pure and healthful water. In this respect, the great meadow of Pacha Dshaïri is now to be alluded to. It is situated one hour's distance from Ejub, and in perforating the soil to the depth of only a few feet, abundant springs of water are found. The mountains of Karamatli, distant six miles from the gate of Adrianople, furnish also great quantities of water, which has been conducted in various directions. The heights of Kalkali, east of St. Stephano, likewise abound with springs. The water of the two latter localities passes in two parallel stone pipes over the Aqueduct of Chavass Kiöi. In the vicinity of the Adrianople gate is a valley towards Ponte Piccolo, whose springs have also been collected. The springs of the two hills on which lie the villages of Nifez and Aïpa, near the slope of the sea, have also been gathered up and led to the metropolis. The springs on the hills of Baluki have been similarly made use of, and show the great impulse which the laws of Mahomet and their injunction of cleanliness and copious ablutions, have given to the engineering works of the Turkish capital; and thus the arrangements for supplying that city and its suburbs with water may be reckoned amongst the most complete and interesting of any of the towns of the modern world. From a very accurate computation deduced from especial tables, it appears that the fifteen separate springs or systems of watercourses used for the numerous aqueducts and other works of Constantinople, yield a daily supply of 249 lulchs, equivalent to 12,267,532 kilogrammes; and computing the population at 600,000, the daily supply for each person amounts to 20·44 kilogrammes, or about 5 gallons.

Equally surprising is the number of fountains, which are to be met with not only at every mosque, but in every part of the city, and amounting altogether to about five hundred. The founding of a well is one of the most esteemed acts of Moslem religious charity; and if the means of one individual are insufficient to erect such a monument, several persons combine their funds and erect a little pavilion, where dervishes distribute fresh water to the believers at all hours of the day. It is upon these structures that Turkish architects and artists employ their whole talent and ingenuity. The railings are most skilfully made, and the columns have long inscriptions concerning the piety and morals of the passers-by, and reminding men of the benefactions they receive from the dews of heaven and the sources of the earth.

The richness of ornamentation and the elegance of design of some of these buildings are surprising, in which qualities, however, the fountain of Sultan Achmet III. surpasses all others. It stands in the square of the Seraglio, in the ancient Augusterca, and comprises a reservoir, a fountain, and a pavilion. Its ornaments are splendid in the extreme, and, like the other fountains of Constantinople, it consists of a huge mass of masonry. A corridor runs throughout the whole interior of the building, and leads to the towers situated at the corners, which serve for the distribution of the water. The water gushes from the mouths of several cranes, placed symmetrically at each façade. Inscriptions, apothegms in gilt letters, cartouches, arabesques, executed with much splendour upon marble and lapis-lazuli, give to the building, covered thus from top to bottom, a splendid appearance, which is not impaired by a critical and minute examination. A special inscription, composed by Sultan Achmet himself, records the founding of the structure.

The small fountain which stands near Sta. Sophia, appears to be of the same epoch as that of the Seraglio, although it is without any inscription. The ornaments present all the Arabic character of the monuments of Asia Minor,—a style preserved up to the reign of Sultan Osman III., who employed Italian artists, and even sent students to Italy to cultivate the fine arts. At that period, however (1680-1720), Italian architecture had already lost its purer character, and the taste for puerile and trifling ornamentation was extended thence all over Europe, Turkey not excepted. If we, however, examine the ornaments of Arabic structures, we find that the right line and the circle form the basis of all combination. No other nation has ever pushed geometrical combination so far, for obtaining forms for architectural ornamentation. The necessity imposed upon the Mahomedans, of abstaining from all representation of men and animals, has made their art pursue a path to which other nations were not confined. But although they might have found on the Byzantine buildings of Constantinople, a number of objects bearing on the principles and practice of ancient architecture, yet they never once imitated the ornaments of the Greeks, although they took their patterns from Byzantine buildings in a structural point of view. The large Turkish mosques, albeit some of them are almost servile imitations of Sta. Sophia, still exhibit ornaments in accordance with the principles of the buildings of Brussa, Siwas, or Korieh in Asia Minor.

If we draw geometrical plans from all these combinations, the particular complications of the circular arches of doors and niches of the mosques vanish, and we find that a very small number of fundamental forms and polyhedrons is sufficient for the construction of the most complex vaults of arches. A very general ornament of the monuments of Constantinople is that composed of portions of a pyramid between two inclined planes, and is formed of right lines and planes, and seems somewhat an imitation of a similar device of the ancients; still, it is not to be met with on the monuments of either Spain or Egypt. This ornament, changed into a variety of forms, is the governing principle of the capitals of the Turkish order, as prevailing in Constantinople and Asia Minor. These forms, apparently so bizarre, can always be reduced, as well in the ground plan as in elevation, to geometric forms of great simplicity. The elegant form of this ornament arises from a certain number of circles of different diameter. Flowers, as ornaments of these interlacements, are constantly to be met with, and many of fantastic shape are often commingled with the forms of real flowers, as the tulip, pink, and bindweed.

The cypress is an ornament much used on Turkish fountains and tombs, and is associated with the religious and mystic conceptions of the Eastern nations. The cypress, even in the earliest ages, was considered as a symbol of the mind, as its obelisk-like shape, rising towards the sky, was regarded as an image of that divine flame which animates humanity. It is to be met with on the oldest monuments of Persepolis and Bisutun, as also on the miniature paintings of Persian MSS. The cypress is, moreover, the constituent of all the ornaments on Indian tissues, which in Europe are erroneously considered and termed *palms*. These

* Abridged from the 'Allgemeine Bauzeitung.'

so-called palms of Indian cachmeres are, in fact, only diversely coloured cypresses, which, however, always exhibit the pyramidal form. The fountain of Sta. Sophia affords some samples of this ornament,—at first the straight and perpendicular tree, then the same tree with a somewhat bent crown, and again this tree of the graves with its branches intertwined with flowers and garlands. As soon as the oriental painters had seized the idea of enlivening the dark green of the cypress by the addition of flowers, they soon invented those designs which we admire on their tissues, and which have not been changed for many centuries.

Although the richest marbles have been used in the construction of the public buildings at Constantinople, still the prevalent taste of the Oriental nations for vivid colours was not satisfied by this variety of tint, and the sculptures of the monuments of that city are likewise painted and gilded. It is to be regretted that the custom, and even the art of painting and gilding stone in a permanent manner, seems to be lost in the East, and at the present moment the Turkish artists are satisfied to gild marble like they do wood. Some still follow the old method of soaking the stone carving in a hot solution of alum, then employ the colour, and afterwards lay on a varnish of mastic from the Island of Chios. It is further to be observed, that the Turks are very attentive in choosing for their fountains the most picturesque spots, as exemplified by that of Sultan Selim on the Bosphorus, which commands views of the Castles of the Dardanelles and the surrounding charming scenery.

## THE NEW THEATRE AT AIX-LA-CHAPELLE.*

HOF-BAURATH CREMER, *Architect.*

(*With Engravings, Plate* XIX.)

IT is a remarkable observation, that those buildings of larger structure which are destined not so much for common use and practical purposes, as for the more ethic aims of social life, have considerably fallen off, compared with what they were some few years ago. Architectural activity has *not* decreased; on the contrary, it has become more extensive—the sense for artistic forms has been successively developed and increased; but the scope and aim of the building art has changed, and with this other demands have arisen, and other modes and kinds of construction have become necessary, out of which (as has always been the case) a *new style* of architecture will ultimately take its rise.

The Theatre of Aix-la-Chapelle was built in the years 1823-24; but as little has been published as to this class of buildings, and as an important enlargement has recently been made to it, the following details will perhaps be interesting. Aix-la-Chapelle, renowned for its mineral baths, possessed but recently a small, badly-constructed theatre, being, moreover, inadequate to the increased population of the city. Thus arose the plan carried out by the architect, and subsequently enlarged, as remains to be stated. The simple motives for adopting this style and detail of construction will be best understood from the following particulars.

Fig. 1, a ground plan of the lower story.—1, pronaos; 2, vestibule; 3, money and check takers; 4, second vestibule; 5, staircases to the orchestra and its accessory rooms; 6, dwelling of the restaurateurs; 7, kitchen, communicating by a staircase with an area kitchen; 8, refreshment saloon; 9, passage to the ground-floor boxes; 10, staircases to the different boxes and to the gallery; 11, entrance; 12, spaces for storing the properties; 13, entrances to the pit; 14, entrance to the reserved seats; 15, ground-floor boxes; 16, reserved seats; 17, pit; 18, orchestra; 19, vaulted spaces providing the hypocausts for warming the interior; 20, staircases to the boxes of the proscenium and the roof; 21, lateral portals, which are opened at the end of the performance; 22, scenery; 23, staircases to the wardrobes and the galleries for the machinery; 24, vestibule for the scenery; 25, dwellings of the steward; 26, greenroom; 27, stairs leading to the wardrobes; 28, waterclosets; 29, a brook, which passes in proximity to the theatre.

Fig. 2, the ground plan of the second story and galleries.—1, passage; 2, galleries; 3, boxes of the actors; 4, staircase to the roof; 5, landing place; 6, sleeping-room of the restaurateurs; 7, an orchestra for music and dancing; 8, galleries of the stage machinery; 9, suspended wings; 10, landing-place; 11, wardrobes; 12, staircase to the roof.

Of these spaces, the audience of a full house will contain, in the pit, 243 persons; in reserved seats, 107; in the ground-floor boxes, 100; in the first tier of boxes, 160; second tier, 170; gallery, 400: total 1180 persons.

The main walls of the building were made of bricks. The base, the open stairs, and the pronaos, with the exception of the capitals and bases of the columns, which are made of marble of Namur, are of the limestone from the quarries near Eupen. The sculptures of the main pediment were made of the marble stone from St. Petersburgh, near Martrich. The foundation occasioned much expense and trouble, as a plate of oak had to be previously laid down.

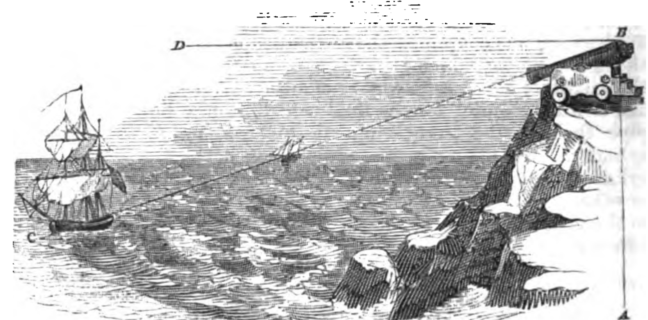
## MEASUREMENT OF INACCESSIBLE DISTANCES BY INSPECTION.

By ALEXANDER ALCOCK.*



I am induced to forward you the following plan, which I proposed to be followed in large fortifications, some twenty-five years ago for determining with little more than inspection, the distances of objects on the horizontal plane, from any fortified position on an eminence. The principles upon which my plan was adopted are of course found in geometry and trigonometry, I only allude to their adaptation to the construction of tables, necessary to be calculated and kept in each battery for inspection.

Let B, be the position of a gun on an eminence, whose height B A, above the level of the sea is known; C, the position of a ship or other object on the horizontal plane; suppose B D to be drawn parallel to A C. Lay the gun by the line of metal for the object at C, and with a quadrant determine the angle of depression D B C, which will be the measure of B C A, the alternate angle. Now in the right-angle triangle A B C, we have three quantities given to find all the rest. Then as the sine of A C B, is to A B, so is radius to B C, the inaccessible distance. Thus we obtain a common formula, namely, the height of the piece above the horizontal plane divided by the sine of the angle of depression will in all cases give the distance of the inaccessible object from the gun.

Being quartered in the garison of Gibraltar for some years, where batteries are to be found at various elevations from the horizontal plane to the rock mortar, which is about 1296 feet above the sea, I proposed to calculate and construct tables for every battery on the foregoing data, as follows:—

Take a card in the form of a rectangle, and on the top horizontal line place all the angles within the capabilities of the piece, and on the left hand vertical side, place the several heights of the batteries, then draw cross lines, and under each angle and opposite each height, insert at the intersection the calculated ranges. Thus when you lay the gun for an object, and find the angle of depression, all that is necessary to do is to look down the column under the angle found, and opposite the corresponding height of the battery already known, and the distance will be found in yards.

## THE COMMISSIONERS OF SEWERS AND THE GENERAL BOARD OF HEALTH.

Sir—In the former article on the above subject, forwarded by me, which appeared at page 125 of your last month's Number, "impermeable," in the last paragraph but two, has been printed "imperishable;" thus giving to the sewers of the Board of Health a character which it is to be feared they will never merit, even in the lowest acceptation of the term;—and in the last paragraph but one, "empiric" has been printed "empereur."

As you have now favoured your scientific readers with a copy of Mr. Ward's letter to the Home Secretary, every one is much surprised that so miserable a production could have been entertained at all, much less acted upon, by so able a diplomatist as his lordship of the Home Office. It is, however, not given to poor humanity to be perfect in all branches,—it is one thing to be expert at diplomacy, and another thing to be quite at home in sewers and cesspools.

The general opinion is that, in keeping with the fashion of the times, there is some secret correspondence or secret influence between the high contracting parties, as the few contradictory and inconclusive remarks contained in Mr. Ward's letter appear to all reflecting men to be utterly insufficient to base an important decision upon; and especially as that decision conveyed a direct censure, if not an insult, to the Metropolitan Commissioners of Sewers, who are acting under a specific statute, and giving their services gratuitously.

Mr. Ward's letter is exclusively confined to the subject of house drainage—not by any means the most important or the most difficult portion of the general system; and it may be fairly questioned, whether the reasons, as stated in Mr. Ward's letter, which influence the Metropolitan Commissioners of Sewers in their practice of house drainage, are not more substantial than the reasons which are given in favour of the mode adopted by the Board of Health, notwithstanding the evident one-sidedness of the entire document.

If Mr. Ward be at all qualified to act as umpire in these matters, he must be aware that there are, in the average of all towns, quite as many, if not a greater number, of front areas and front kitchens to drain to the rear under the house on the Board of Health system of back drainage, as there are back area drainage to be brought to the front under the house on the system usually practised by the Metropolitan Commissioners. He must also be aware, that there are numerous cases of sunk stories where there are no back areas in which to place the "tubular sub-main" of which he speaks, and in which case the sub-main must be dug some 8 or 10 feet into the ground of the back-gardens, to the manifest destruction of private property, and the great annoyance of the inhabitants. But it is absurd to discuss the subject on the supposition of a uniform practice in every variety of circumstance; each case must be treated on its own peculiar merits, after a careful examination on the ground. This mode of proceeding, it is true, will require the exercise of talent and skill; and the only plausible reason that can be given for the adoption of the *stereotyped process* is the want of talent in the parties carrying out drainage operations upon this absurd system. Nor could men of talent be found who would submit to be trammelled by an absurd uniformity of practice, where the circumstances are constantly changing.

It is somewhat singular, that the advocate of the Board of Health could not find an example in the drainage operations of that Board to hold up as an example to the Commissioners, but is driven to the necessity of quoting the Commissioners against themselves. The Commissioners, Mr. Ward states, "have allowed thirty-two houses to be drained by four tubular back drains, which act perfectly well, quite as well as thirty-two separate drains could act, though these would have cost eight times as much; and they [the Board of Health] ask why this eight-fold cost should be imposed upon London at large by the very same authority which sanctioned in this [Lambeth] square the combined drainage, which is found to work well?"

It would be difficult to find a greater number of fallacies in so few words in the loosest possible statements which are brought before the public for the purposes of puffing and deception. This statement supposes that the "four tubular back drains" are each equal in length to the extent of the thirty-two houses,—that the thirty-two separate drains from the houses into the street-drain (which is considered the invariable practice of the Commissioners), would each be as long as each of the four back drains. No account is taken of the short junction drains from the houses to the four back drains, otherwise it is probable that the front drainage into an existing street sewer, or one necessary to be formed, would be the cheaper mode of the two. It also supposes, that the Commissioners invariably drain only one house by one drain, although in a former part of the letter it is stated that the Commissioners forbid "more than two houses being relieved by one pipe-drain."

In arriving at a conclusion, however, Mr. Ward does not consider it necessary to recollect his premises, even when he has any, which is but seldom. Thirty-two drains (which should be sixteen) are divided by four, without any reference to *length, capacity*, or *expense*, and, presto! out comes an "eight-fold cost," which this sapient writer fears will be "imposed upon London at large;" as if London at large could be drained advantageously in the same manner as the thirty-two houses in question.

It is to be hoped for the honour of the professions, that Mr. Ward is neither an engineer nor an architect, nor even one of the more advanced pupils of the Board of Health; and it is quite clear that his epistle should not be disturbed in its progress to oblivion, had it not been treated as a document of considerable importance by the Home Secretary,—and from the nature of our institutions, the Home Secretary for the time being possesses the power of doing much good or much evil, accordingly as he takes the advice of wise men or of fools.

Considering the failure of the great water scheme, and the great interment scheme proposed by the Board of Health, or more properly by Mr. Chadwick, and the impediments which these foolish projects have thrown into the way of legitimate undertakings; considering, also, the slow progress made in the drainage operations of the towns under the Board of Health, and the many instances of failure in the executed works, it would be difficult at the present moment to point to a case which more loudly calls for a searching investigation by a committee of the House of Commons, or by a scientific commission, than the working of the whole operations of the Board of Health.

C. E.

## DRAINAGE OF THE METROPOLIS.

Report *to the Metropolitan Commissioners of Sewers upon the Sewage Interception and Main Drainage of the Districts North of the Thames.*

Gentlemen—In pursuance of the resolution of your General Committee of the 24th May last, followed by an order of Court on the 2nd June, associating us for the purpose of remodelling the scheme of the late Mr. Forster for the main drainage of London, so as to accord with the views of the Consulting Engineers of the Commission, we have now the honour of laying before you the conclusions at which we have arrived, with reference to the districts north of the Thames, reserving for a future Report the remaining portion of the main southern drainage, which is not embraced in the Reports of your engineers presented in October last.

The sewers recommended in those Reports, forming portions of the entire scheme for the main drainage of London, are designed to serve the double purpose of drainage and interception; for they will not only drain the districts through which they pass, but also intercept the sewage of those districts from its more direct course towards the Thames, turning it eastward until it can be discharged into that river at a more convenient spot lower down. Of the additional sewers proposed in the present Report, some, in like manner, possess that double character, whilst others are simply "intercepting sewers," adding nothing to the drainage of the districts they pass through, but merely giving a direction to the flow of the sewage which they will receive from the drainage sewers.

The scheme proposed by Mr. Forster in January 1851, for the drainage of the districts north of the Thames, comprehended generally the interception from that river of the sewage of most of these districts. It also contemplated some provision for future increase of population on an area of about thirty-nine or forty square miles. But it provided neither main outlet lines for such districts as needed them, nor the means of interception for any district beyond the area named; these being subjects, as shown by his Report and plan, intended to be dealt with by him at a future period.

After careful consideration of the necessities of various districts, for many of which the main outlet lines are deficient in capacity or are entirely wanting, and bearing in mind the rapid increase of the population over the very large area not included in Mr. Forster's plan, it appeared to us essential, that in completing our scheme, all these more extended requirements should be held in one general view, and should be arranged, as far as practicable, in connection with the plan of interception of sewage from the Thames. This course we have adopted; and accordingly we have extended our scheme over an area of about fifty-nine square miles, instead of confining it to the forty square miles which Mr. Forster's plan embraced. Moreover, we propose to render the scheme adequate to the requirements of a population exceeding the present number by upwards of one-half. Although therefore our estimate may at first sight appear more costly than that of Mr. Forster, it is not so in reality; inasmuch as it is more comprehensive, embracing objects for which his scheme, as propounded in 1851, did not make provision, but which must have been provided for eventually, with a corresponding addition to his estimate.

The area included in our present design comprises about fifty-nine square miles, which we have subdivided into four districts, to be dealt with according to their varied requirements, so as to secure for each of them the particular objects sought to be accomplished.

These approximate areas are as follows:—1. Northern high-level area, 14; 2. Middle-level area, 16; 3. Low-level area, 11·1; 4. Western division, 18: total, 59·1 square miles. The lengths, sizes, and inclinations of the proposed sewers, hereinafter described, are, for the sake of brevity and convenience of reference, given in a tabulated form in the summary.

### I.—Northern High-Level Area.

This district, comprising about 8913 acres, or 14 square miles, is bounded on the north by a water-shed line, about Hackney, Homerton, Clapton, Stamford-hill, Highgate, and Hampstead; on the south, by the Regent's-park, Camden-town, Holloway, Dalston, and the Victoria-park; on the east, by the River Lea at Stratford; and on the west by the Edgeware-road at Kilburn.

The district has a natural valley line, defined by the Hackney-brook open sewer, which runs from west to east through a great portion of its length. The surface falls from the northern edge with considerable inclination, and from the southern portion with a gentle inclination towards this valley line.

At the present time this area is suburban in character. Its population is limited, but rapidly increasing. It is in immediate want, for the general extension of the district sewers, of main outfall lines, which therefore require designing, with reference to future as well as present necessities.

The wants of this district, as regards both arterial drainage and interception. have been provided for by the plan of Mr. Bazalgette, described in his report of the 1st October 1853, for the details of which we beg to refer to the Report itself.*

### II.—Middle-Level Area.

This district, comprising about 10,260 acres, or about sixteen square miles, is bounded on the north by the southern margin of the high-level drainage area, Willsden-green and Harlesden-green; on the south by Bethnal-green, Old-street-road, Lincoln's-inn-fields, Piccadilly, Hyde-park, Oxford-street, Notting-hill, Wormwood-scrubs, and Acton; on the west, by Hanger-hill, near Ealing; and on the east by the River Lea, at Old Ford, near Stratford.

Of this area the largest portion is closely populated; and probably its population has nearly reached its maximum density. Its western portion is suburban in character, but is rapidly being covered in every direction with human dwellings. Its levels are such as will enable the sewage to be conveyed by gravitation to the level of Trinity high water, beyond the eastern extremity of the metropolis. With one exception,† its middle and eastern portions are provided with main outfall lines, which will be found sufficient when the intercepting lines of sewers are built. Its western extremity on the contrary, is in want of adequate main outfalls. We propose for this area a main line of sewers, which shall serve for the drainage of the district itself, as well as form part of the general scheme of interception.

The sewer will commence at Acton, thence proceed in an easterly direction, and pass under the North and South Western Junction Railway, by the side of the Great Western Railway, and under the West London Railway, near which it will intercept the Counters' Creek sewer; it will then proceed into the Uxbridge road at Notting-hill, and continuing along that road to Gloucester-road, will join the Ranelagh sewer. Between Acton and the Gloucester-road, it will fulfil all the duties of a district sewer, receiving both collateral sewers and house drains, and carrying off all the flood waters, which latter will at this point be discharged into the Ranelagh sewer. Eastward of the Ranelagh, it will become solely an intercepting sewer, and will proceed by the way of Oxford-street, intercepting the King's Scholars' Pond sewer at Duke-street, Grosvenor-square. At the Regent-circus it will join with the Regent-street sewer, thence it will continue along Oxford-street, New Oxford-street, Hart-street, King's-road, Liquorpond-street, and Back-hill, where it will intercept the Fleet. It will then proceed along Ray-street, across Clerkenwell-green, and St. John's-square to Wilderness-row, thence by the way of Old-street-road and New-inn-yard to High-street, Shoreditch, along Church-street, Bethnal-green-road, and Green-street to the Regent's Canal (beneath which it will pass), along Old Ford-lane, and beneath the East Indian Dock Railway, near Sir George Duckett's Canal, at which point a junction will be effected with the northern high-level sewer, with which it will be carried over the River Lea, near Old Ford, at such an elevation as to enable it to be continued eastward to Barking Creek, and at that point to discharge into the Thames at high water.

Upon its course it receives two branches, projected with the view of intercepting as much sewage as possible, for delivery by gravitation at high water. The first branch commences at Curzon-street, Piccadilly, and proceeds by the way of Leicester-square, Chandos-street, Covent-garden, and Lincoln's-inn-fields, and joins the main branch at King's-road, Gray's-inn-lane. The second branch commences at Commercial-street, Whitechapel, and proceeds by Old Montague-street, Buck's-row, Devonshire-street West, beneath the Eastern Counties Railway, and along West-street, to a junction with the main line at Green-street.

### III.—Low-Level Area.

This district comprises about 7100 acres, or 11·1 square miles. It is bounded on the north by the lower margin of the middle level area; on the south, by the River Thames; on the east, by the River Lea; and on the west, by Kensington-gardens, Brompton, and Chelsea Hospital. Its levels are such, that a large portion of it cannot be drained by gravitation, except at low water; the aid of pumping is therefore absolutely essential, in order both to drain it effectually and intercept its sewage from the Thames.

Like the central portion of the middle-level district, the largest portion of the low-level area is densely populated, and little or no increase in population can be anticipated; the quantity of sewage to be provided for may therefore be determined with tolerable accuracy. With one exception, about Bromley and Bow Common, this district is sufficiently provided with main outfall lines, some of which however require alteration and repair.

The line proposed for the interception of the sewage of this district, commences by a junction with the Ranelagh sewer at Grosvenor-row, Queen's-road, Chelsea. It passes along Queen-street and Belgrave-place, to a junction with the Victoria-street sewer, at the western end of the latter, near to which it intercepts the King's Scholars' Pond sewer. The Victoria-street sewer then becomes an integral portion of the main line as far as Parliament-street, at the northern end of which the sewer leaves the Victoria-street sewer (which will now discharge the office of a flood outlet) and is continued by Whitehall to Charing-cross, where it receives the contents of the Regent-street and Northumberland-street sewers, and then proceeds by the Strand, intercepting the Essex-street sewer at the west end of Essex-street. It then passes along Fleet-street to New Bridge-street, where it intercepts the Fleet. It then crosses New Bridge-street, passes along Crescent-place under houses to Shoemaker-row, along Great and Little Carter lanes, Cannon-street West, and Cannon-street to King William-street, where it intercepts the London-bridge sewer; thence it proceeds through Eastcheap, Great and Little Tower streets, and Tower-hill, to the Minories, there intercepting the Irongate sewer; thence by Royal Mint-street, Cable-street, Back-road,

* Mr. Bazalgette's Report, referred to above, was given in the *Journal* for November 1853, p. 401.

† Allusion is here made to the want of an outfall sewer, for flood-waters only, running due south from Bethnal-green to the Thames. Such a sewer would serve also the purpose of a district drainage sewer. The latter, indeed, would be its principal character.

Brook-street, and under the London and Blackwall Railway, near Stepney Station, to and along the Commercial-road, and under the Regent's Canal, to the Limehouse Toll-bar, at which point, turning northwards into Devon's-lane, under the East and West India Dock Railway, and along the Three Mills-lane, it passes under the River Lea, near Three Mills-bridge, to a pumping-station on the eastern side of that river, near Abbey Mills-lane. Here the sewage will be lifted to the high-level sewers by pumping.

The height of the high-level above the low-level sewer being about 35 feet, we consider that engines of about 1700-horse power should be provided for this purpose.

Near to the Stepney Railway Station at Brook-street, this sewer will have a flood outlet into the River Thames, at such a level as will enable the whole of its contents to be discharged at low water, if required upon emergencies.

There are two branches connected with this line. The first commences by a junction with the King's Scholars' Pond Sewer at Besborough-street, Vauxhall, and passes along Millbank and Abingdon street, to a junction with the main line at Parliament-street.

The second branch commences at Ferry-street, in the Isle of Dogs, and passes along the East Ferry-road, Preston New-road, Bow-lane, Catherine-street, and under the Limehouse-cut, to a junction with the main line at Brickfield-lane.

The whole of the foregoing lines converge to the same point on the eastern side of the River Lea; the two high-level sewers having crossed over, and the lower sewer under that river. The sewage of the lower sewer having been lifted to the upper level, the sewage of all three will proceed by three parallel lines in a nearly direct course to the Thames, at the outlet of the River Roding, or Barking Creek, where a reservoir will have to be provided, and means adopted for discharging the accumulated sewage at and near the time of high water.

The reservoir will be about a mile and a-half in length, and about 70 feet wide, forming, in fact, the last mile and a-half of the outlet sewer, enlarged to a capacity sufficient for storing about 7,000,000 cubic feet, or double the average quantity of sewage, which, with an improved water supply, would be produced by the prospective population during the eight hours in which the reservoir outlet would be closed. We assume, that it will be considered necessary to cover this reservoir, and we have designed it with that view, in order to which it has been reduced to the smallest size compatible with effecting the proposed object.

We have considered it better to allow a portion of the rainfall which will be delivered by these sewers to flow into the river on certain occasions,* at all times of tide, rather than to increase the size of the reservoir to such an extent that the enormous expense of the work would probably prevent its being covered.

### IV.—Western District.

The area designated as the Western District comprises about 11,500 acres, or eighteen square miles. It is bounded on the north by the western end of the middle-level intercepting sewer before described; on the south, by the River Thames; on the east by the western limits of the low-level area; and on the west, by Hanwell and Brentford. The general levels of the surface are low, much of it being but slightly above high-water mark, and the remainder rising gradually to its northern margin, at which line it ranges between 50 and 60 feet above Trinity datum.

Nearly the whole of the area may at present be termed suburban in character; there being however, various localities, as Fulham, Brentford, Hammersmith, &c., which are closely built over and populated. As in the other suburban districts, the population is rapidly increasing upon it, and outfall lines of sewer are immediately required for present necessities, as well as for the subsequent extension of the district sewers.

This district extends between six and seven miles west of Chelsea Hospital, the most eastern portion of it being about ten miles from the River Lea. To effect the interception from the Thames of its sewage, by means analagous to those proposed for the general area of the metropolis, would involve, (1) the lifting of the sewage into the main low-level sewer before described, at a point near Chelsea; (2) the conveying of it through the metropolis by that line of sewer (which would have to be correspondingly increased in size through its entire length); and (3) the lifting of it a second time near the River Lea from the great depth to which it would by that time have fallen, to the same level as the higher and gravitating sewers.

The objections to such a course, independently of its immense cost would be considerable, and are such as have induced us to recommend for the Western District the adoption of a system based upon principles entirely different from those which are proposed for the other portions of the metropolis.

Whatever difference of opinion may exist as to the commercial value of sewage water, and the cost of its conversion into dry manure, we believe that experiments already made tend to demonstrate the practicability, not only of abstracting from the water all that is noxious or deleterious, but also of effecting this inoffensively, by works properly constructed.

The cost, though considerable, of establishing and maintaining the works for thus purifying the sewage water of the entire district, and then discharging it into the Thames within the limits of the district itself, would, we are satisfied, after a careful comparison of the probable expense, both original and annual, of the two processes respectively, be less than that of carrying the sewage to Barking Creek. Upon the score therefore of economy alone, even if no other reason existed, we would recommend the former in preference to the latter process, irrespectively of any chance of profits from the manufacture and sale of the manure. It may fairly, however, be anticipated, that means will be shortly developed for effecting the purification of the sewage waters without annual cost to the Commission, and that at a future day this may be made a source of revenue to the ratepayers. The matter has been referred by your honourable Commission to, and is now under the consideration of, a gentleman eminently qualified by his knowledge and experience to pronounce an opinion upon the subject.

In accordance with the views above set forth, our plans for the interception and main drainage of the Western District are designed. The system we propose comprehends two large outfall lines of sewers for the drainage of their respective areas, each with a subsidiary branch, and all converging to a point, at which sewage manure works are proposed to be established, on the banks of the Thames, at the mouth of the Kensington Canal. The main lines will receive the whole of the sewage and drainage of the sub-districts through which they pass, and serve as intercepting lines for conveying the sewage of the entire Western District to the purifying works.

The first of these lines is the Acton line, with a branch from Chelsea; the second, the Brentford line, with a branch from Fulham.

### I.—Acton Line.

This line commences near Acton, in the Uxbridge-road along which it passes to a junction with the Counters' Creek sewer at Royal-crescent. From that point it is proposed to reconstruct the Counters' Creek sewer, enlarging and deepening it, and to continue it as a new and independent outfall into the Thames, near the Kensington Canal.

#### *Chelsea Branch.*

The Chelsea Branch commences at Smith-street, and passes along the King's-road, Cheyne-walk, and Lindley-row to a junction with the Acton Line at Gunter's-grove, King's-road.

### II.—Brentford Line.

The Brentford line commences at the River Brent, near the bridge, and proceeds along the High-street of the town, the Brentford-road, and Turnham-green, where it affords an outfall for the Chiswick drainage; then along King-street, Hammersmith, to a point near Brook-green, where, turning southward through private grounds into the North End-road, it passes on to Walham-green; thence it proceeds along the Fulham-road, down Sand's End-lane, and across Marsh-land to the Thames, on the south side of the Kensington Canal. This line of sewer is provided with auxiliary flood outlets at Brentford and Stamford-brook.

#### *Fulham Branch.*

The Fulham Branch of the Brentford-line commences at Fulham-bridge, and passes along Bridge-street, Church-street, and King's-road, to Parson's-green, and thence to a junction with the Brentford-line at Sand's End-lane.

The outlets for the main lines of the Western Division are at such levels as to admit the discharge of flood waters at half tide. The lift, therefore, required for the sewage water will be only that necessary for raising it into the depositing reservoirs; and

* These occasions are times of heavy rain, not exceeding perhaps twenty-four days in the year.

the subsequent discharge of the purified water can then be effected at any level of tide. The inverts of these sewers are about 18 feet below Trinity high-water mark, and we consider that engines of about 900 horse-power should be provided.

A junction will be effected between the two main lines by a short length of sewer, to convey the sewage to the purifying works.

The marsh lands on the banks of the Thames, near the mouth of, and on the southern side of, the Kensington Canal, appear peculiarly eligible for the establishment of Sewage Manure Works. The land itself is of inferior value, and there are but few habitations in its vicinity; while its proximity to the Thames, to the Canal, and to the West London Railway, would afford great facilities both for bringing materials for the process of deodorisation, purification, &c., and for the economical transit to the markets of the manure when manufactured.

The scheme here proposed for the main drainage of the Western Division is the best which, under present circumstances, it is in our power to offer. But when the result of the inquiry now pending respecting the practicability of effectually dealing with the contents of sewers in the Metropolis shall be ascertained, some considerable modification of this portion of the main drainage scheme may possibly become advisable.

### Estimate.

Our estimate for the whole of the foregoing works upon the northern side of the Thames is as follows:—

| | |
|---|---|
| Northern high level gravitating sewer and branches as given in Report of Mr. Bazalgette . . . | £271,290 |
| Middle level gravitating sewer and branches, including land . . . . . . . . . | 238,000 |
| Main low level line and branches, including land . | 162,400 |
| Extension of high level, middle level, and low level sewers to Barking, including reservoirs, tidal gates, purchase of land, &c. . . . . . . . | 453,500 |
| Pumping engines, pumps, engine houses, &c. . . | 130,000 |
| Western Division, including Acton Line and branch, Brentford Line and branch, land, &c. . . . . | 123,000 |
| Total . . | £1,378,190 |

In our Report upon the scheme of the great London Drainage Company (May 1853), we drew attention to those conditions and requirements which should aid in determining the capacities of sewers having for their object the interception of the sewage from the Thames. We expressed an opinion that they should be adapted not only to the present, but to the future wants of a rapidly increasing population, and that they should be calculated to carry off during a period of six hours one half of the daily sewage discharged.

An examination of the recent Census Tables leads us to the conclusion that, from the manner in which the lines of streets and buildings are now laid out in the suburbs, from the roads being wider, and from there being in most cases yards, gardens, or squares attached to the houses, the average density of the population of those districts, when at its maximum, will not exceed 30,000 inhabitants per square mile. Our calculations of the increase of sewage to be delivered in future years are framed upon this assumption, and in anticipation of an improved water supply equal to five cubic feet per head per diem.

To render complete the interception from the Thames of the London sewage, some provision should be made for carrying off a certain amount of additional flow from the sewers during rains. The washings and scourings from the streets, houses, and sewers, during the first hours of rain, being extremely filthy, we consider that if provision be made for carrying off a depth of 0·25 inches of rain, falling equally in 24 hours, or 0·0104 inches per hour, without making deduction for loss by absorption or evaporation, and in addition to the maximum flow of sewage already calculated upon, the object will be sufficiently realised.

The above conclusions will afford sufficient explanation of the data upon which the sizes of our intercepting sewers are calculated.

The northern high level gravitating sewer, reported upon recently by Mr. Bazalgette, being intended for an intercepting sewer, and at the same time as a main drainage outfall capable of performing all the functions of such a sewer for the district through which it passes, has been calculated to carry off all the sewage as well as all the rain, including storm waters, likely to pass into it from the area drained by it.

The middle level gravitating sewer, and the low level sewer, are calculated to carry off the maximum flow of sewage likely to accrue from the present or prospective population upon the areas draining into them, as well as a rainfall running off equal to a depth of 0·0104 inches per hour. But they will not carry off extraordinary storm waters, with the exception of the western portion of the middle level sewer, which will, as we have before stated, discharge the flood waters received by it into the Ranelagh sewer.

The whole of the sewers designed for the Western Division being intended, in conjunction with the flood outlets, to act as district as well as intercepting sewers, are calculated to carry off the prospective maximum flow of sewage as well as all the rainfall, including storm waters, which they will have to receive.

The sewers from the River Lea to Barking are intended to convey the maximum flow of prospective sewage, and a rainfall running off equal to a depth of 0·0104 inches per hour, over the whole area drained by the northern, middle level, and low level sewers.

In those cases where the main lines are not calculated to receive storm waters, the latter will be carried off either by existing, or by new flood outlets.

In determining the route of the sewers, we have almost entirely kept to the lines of public thoroughfares, and where it has been impracticable to avoid deviating from them, we have selected, as far as possible, such routes as will involve the least outlay for compensation to the owners of property.

With respect to the line of low level sewer, it is desirable that it should be constructed as near the Thames as practicable, both to avoid the public inconvenience, which to some extent must ensue during the construction of the sewer along streets of crowded traffic, and to intercept the sewage at points close to the existing sewer outlets: indeed, had it not been for the much greater cost and engineering difficulties involved, the reasons here stated would have induced us to recommend that the portion of the low level sewer, between Hungerford and London Bridge, should be constructed on the very margin of the Thames, instead of being carried, as we actually propose, along the line of the Strand, &c. If, however, the long contemplated embankment of the Thames between Westminster and London Bridges, which again occupies public attention, should be carried out, much of the cost and difficulty of a river line of sewer would be obviated, and the intercepting sewer might be most advantageously constructed in conjunction with the embankment between Hungerford and London Bridges.

It has been with us an object, as far as practicable, to assign to the whole of the sewers such rates of inclination as would, with their other conditions, insure an uniform velocity of flow through them, sufficient to make them self-cleansing. But the importance of intercepting and delivering by gravitation at high water as much sewage as possible at Barking, so as to perfect above that point the interception from the river of the sewage, has necessitated the reduction of the gradients of the sewers to the minimum, and has, with other considerations of equal importance, necessitated, in some exceptional cases, the reduction of the inclinations below those which we would otherwise wish. But the sewers are, in all such instances, arranged so as to admit of their being cleansed by flushing from existing and available heads of water.

The aim of a system of interception is to discharge the sewage of the metropolis into the river, at such a point, and at such level of the tide, as will prevent its return with the flood tide to the inhabited parts of the town.

The experiments made by the late Mr. F. Forster show, that in order to effect this object, it is necessary to discharge at as remote a point as Barking Creek, and at about high water. We would here observe, that the delivery of the sewage at high water into the river at any point, is equivalent to its discharge at low water at a point twelve miles lower down the river; therefore the construction of twelve miles of sewers is saved by discharging the sewage at high, instead of at low water.

We have already adverted to the question of effectually purifying sewage water without creating a nuisance at the spot where the works are carried on; and we may express a hope, that the time is not far distant, when the manufacture of sewage manure may become a remunerative undertaking. Should this anticipation be realised, then a new consideration, and one seriously affecting the scheme now proposed, immediately arises; namely, whether it would not then be advisable, on the score of economy, to modify considerably the designs here presented for the middle and low level sewers, and to abandon the chief portion of the line between the Lea and Barking Creek, and to establish at suitable spots works for the purification of the sewage water, and for the manufacture of solid manure.

On the other hand, delay is objectionable. Independently of interception, the main drainage of London should be no longer postponed. And assuming that the system of interception must be carried out, so rapidly are the suburban becoming urban districts, that the difficulty and expense consequent upon executing such a work yearly increases: indeed, since 1851, when Mr. F. Forster prepared his scheme, considerable portions of private grounds through which his sewers were intended to pass, and which were then unbuilt upon, are now closely covered with houses and buildings.

In conclusion, we beg to express our belief that the plan we now have the honour of submitting to you will be found to fulfil, as far as practicable, the manifold and various requirements of the large area and population dealt with. But the necessity of considering the question in relation to the existing as well as to the future population; to the wants of districts already densely inhabited, as well as of those which are at present suburban; to the relief required to be provided by new outlet lines of sewers, in addition to those now in existence; to tidal levels; to the existing mass of sewers; to the navigation of tidal channels; and to the fixed and varied levels of railways and roads; together with the present uncertain value of sewage water,—renders difficult the production of a scheme which shall perfectly answer its purpose in all respects, and be economical in first cost, as well as in the charges for maintenance. In preparing this scheme, we have pleasure in acknowledging the information and assistance we have received from the various officers of the Commission throughout our investigations.

J. W. Bazalgette,

Report *of* Sir William Cubitt *on the Report of* Messrs. Bazalgette *and* Haywood, *on the Lines of Arterial Intercepting Drains on the North side of the River Thames.*

Gentlemen—It now becomes my duty once more to report to you on the Report of the Engineers of the Metropolitan and City Sewers Commissioners respectively; and in the performance of this duty, I have to lament the absence from England of Robert Stephenson, Esq., my colleague in this matter, whose world-wide reputation as a civil engineer, could I but have been favoured with his co-operation in drawing up this Report, would have added much weight to the opinions I have ventured to express.

The Report now under consideration comprises the whole system of the main arterial and intercepting drains on the north side of the Thames, extending from Brentford on the west to Barking Creek on the east,—a distance, in a direct line, of sixteen miles or thereabouts. For the greater portion of this distance, the sewage of the Metropolis on that side the Thames is proposed to be diverted from or rendered innoxious in that river at all times, when not more than one quarter of an inch of rain falls upon the entire district (comprising about 378,000 acres) in 24 hours. When more than that depth falls, which may be on an average 24 days in the year, the dilution of the sewage will be so great, and the scouring effect upon the sewers so useful, that the quantity passing off into the river by the overflow or escape valves will not sensibly or injuriously affect its purity. It would be quite impossible by any known means at *all* times to divert *all* the sewage and surface dirt of the Metropolis from the Thames —a near approximation only can be made to that object.

The districts of the Metropolitan Sewers Commissioners already reported upon, and the cost estimated by Mr. Bazalgette, the Commissioners' Engineer (which Reports were afterwards examined and reported upon by Mr. Stephenson and myself, as Consulting Engineers), were, first: the Northern or Hackney Brook District; the cost of a high-level intercepting sewer for which was estimated by Mr. Bazalgette at 271,290*l*. The plans and details were much approved by Mr. Stephenson and myself, at an amended estimate of 300,000*l*, Secondly: the Surrey and Kent Districts, from Battersea Fields, near the River Wandle, to the Ravensbourne River or Deptford Creek. This comprised, first, a high-level intercepting arterial drain to take off all the rainfall north of the watershed between the Rivers Wandle and Ravensbourne, and to deliver the same into the Thames at Deptford Creek above high-water level, and thus preserve all the southern margin of the river from Battersea to Deptford from being flooded by storm waters; and, secondly, a low level intercepting arterial drain between the high-level drain and the river, to take off both the rain water and the sewage from the insulated strip of land above mentioned. The contents of this would either have to be pumped up, deodorised, and delivered into Deptford Creek, or to be conveyed by an extensive drain or tunnel passing through or near to Greenwich and Woolwich, and receiving the sewage of that district, into Plumstead Marshes, where it would be delivered into the river (either by pumping or alternative reservoirs) opposite to the mouth of Barking Creek—the outlet of all the high and low level intercepting drains on the north of the Thames (with the exception of the Western District, the produce of which it is proposed to deodorise and pass into the Thames at or near the junction of the Kensington Canal therewith; divested of its impurities in the first instance, and taking the chance of obtaining any return by the manufacture of sewage manure).

Reverting again to the Reports of Messrs. Bazalgette and Haywood on the interception or deodorising drainage north of the Thames, I can most unhesitatingly state—after a very careful examination of the reports and plans, and the elaborate set of sections and details which they have produced, together with the estimates founded thereon—that the whole are worthy of every attention, as regards the capacities and inclinations of the various intercepting drains in relation to the quantities of water they have to carry and discharge.

Nevertheless, as works of this kind, from a variety of circumstances which can form no items in an estimate, are seldom or never completed within even the most elaborate calculations that an Engineer is justified in making, I feel bound to state that, although I fully agree with and highly approve the estimate of quantities and probable costs given in the Reports now under consideration, I do not think, even if the funds were at once obtainable, that the whole would or could be carried into effect for the sums stated by the Engineers; and no blame would attach to them on that account; for there is so much disagreement between the fairest estimates and the ultimate cost of public works of this peculiar nature—so many unforeseen items arise—so many inconceivable claims for damages and compensation are preferred, both by public and private individuals, that it is totally impossible for the Engineer of an immense undertaking of this kind to know and clearly foresee all these contingencies and claims; and, could he do so, it would neither be prudent nor, perhaps, even proper to state them, in cases where advantage might be so easily taken both by the public and by contractors, to assist them in making out their claims and estimates.

I have made the above remarks in order to account for the fact that, although I agree with and approve of the mode of carrying into effect the principle (that of interception) upon which the greater portion of these plans are founded (without giving any opinion upon the principle itself), and although I agree with the estimates of the Engineers as being most fair estimates for carrying into effect the works set forth in the Report, plans, and sections, yet I feel it my duty to state distinctly that, in my judgment, the complete establishment of this system of arterial intercepting drains, with all accessories, would not be accomplished for the amounts stated in the various Reports of the Engineers to the Commissioners of Sewers, fair and unassailable though they be.

I shall, therefore, instead of drawing up a longer Report of details upon the various levels, drains, &c., described in Messrs. Bazalgette and Haywood's Report of January 21st, 1854, advise all persons interested in the measure to read that Report, and study the tables and estimates thereto appended, which will well repay the perusal; and shall add an estimate of my own, as to the probable *actual* cost of the works therein described, and also of those proposed for the south side of the Thames, including the extension to the Thames in Plumstead Marshes, of which I have already spoken. This will therefore be my estimate of the total cost of a complete system of Arterial Intercepting Drains for the *whole* Metropolitan district.

*Estimate.*

As to the north of Thames intercepting system, and conveyance down to Barking Creek, instead of a total cost of 1,378,190*l.* as estimated, I am of opinion, for reasons before alluded to in this Report, that the probable cost would be .................. £1,750,000

And as regards the south side of the Thames, say—

| | | |
|---|---|---|
| For the former estimate of Mr. Stephenson and myself, terminating the drainage in Deptford Creek.................................. | £750,000 | |
| Extension of ditto through Greenwich and Woolwich, to an outlet in Plumstead Marshes ........... | 500,000 | 1,250,000 |
| Making a total of ..................... | | £3,000,000 |

to complete the arterial and intercepting drainage of the entire districts north and south of the Thames.

In conclusion, it must be borne in mind, that of the above estimated expenditure of 3,000,000*l.*, the most important and essential parts are in the order in which they should be executed. First, the high-level catch-water intercepting drain on the north of the Thames, which will deliver at all times, the small quantity of sewage and the large and uncertain quantity of storm-water which is produced on an area of 12 square miles, or 7680 acres, between the rivers Wandle and Ravensbourne and the watershed line south, the whole of which would pass into the Thames at all times, at or below high water level, thus relieving from sudden floods of storm-water the whole of Southwark, the waterside premises from Vauxhall Bridge to Deptford, and various portions of Lambeth, Battersea, &c., at the same time rendering it quite possible to drain, by artificial means, the whole of the above-named districts between the high level intercepting drain and the Thames, containing other twelve square miles, which at present cannot be efficiently drained, as almost the entire district lies below the equinoctial tide level, and a great portion of it, the basements of the houses in particular, below even low water level. They are, therefore, subject to be flooded by every high tide or heavy downfall of rain; and when both these casualties occur at the same time, the consequences are lamentable and very destructive, both of human life and property. Second, the work which would meet these difficulties, and might in great measure be carried on concurrently with No. 1, the high level intercepting drain described above, is the low level drain or sewer extending from Battersea Fields to the Ravensbourne, under which it would pass into a pumping station. This, with its branch, would intersect and communicate with all the existing sewers, the present mouths of which in very heavy rains, would serve as safety valves to discharge the storm-waters before they could accumulate and flood the houses of the inhabitants, and engender diseases as at present. But to effect all this, the present outfalls of the sewers would have to be improved and turned into escape valves, shutting out the tides, and the very high tides to be dammed out by raising either the quays or the land a short distance inside the quays.

The above operations are, in my humble opinion, those which require the first attention; and they present this peculiarity, that, to the extent above specified, they must be looked at as a whole, and carried on simultaneously, for no real good can be obtained by attempting to carry them out piecemeal. The portion below, which I have called the Extension Drainage through Greenwich and Woolwich, might stand over for a time; and before entering upon the drainage of the Surrey and Kent districts, down to the Ravensbourne, the way must be seen to the attainment of the 750,000*l.* necessary to its completion, exclusive of any current expenses for local and house drainage. In fact, the great difficulty in my mind relates to the raising of the funds for the execution of the works, which latter might be completed in about two or three years, if set about in earnest, and the quicker they could be carried on the less they would cost.

Pending the decision as to the extension drainage through Greenwich and Woolwich to the Plumstead Marshes, the work of next greatest importance, and one which is within itself and unconnected with others, is the north high level drainage, or the Hackney Brook Sewer, estimated at 300,000*l.*; all the other works on the north of the Thames might then follow in the order stated in the Report of Messrs. Bazalgette and Haywood, of the 21st ultimo.

In making this Report, I have strictly followed what I took to be my instructions, viz., to report upon the Reports of Mr. Bazalgette, and of Messrs. Bazalgette and Haywood, on the construction of Intercepting Sewers, which would divert the sewage of the Metropolis as much as possible from entering the Thames, till it was so far below London that the returning tide would not bring it back again, and this the system proposed by them would certainly accomplish; but to divest the Thames altogether of sewage would be literally impossible, although, no doubt, much may be done to divert the greater portion of it from the river, and to permit none to enter except in a very diluted state. The cost, as stated above, would most probably be 3,000,000*l.* sterling.

6, *Gt. George-street, Westminster,* WILLIAM CUBITT.
*January 25th* 1854.

## ON SMOKE CONSUMPTION.

By C. Guthrie, Birmingham.

All the schemes which have hitherto appeared for purifying the atmosphere of towns seem directed exclusively against smoke production; and although undoubtedly smoke does much mischief to property, health, and beauty, and therefore it would be a great advantage if we could consume it, both as regards economy of fuel and the condition of the atmosphere,—nevertheless, we could not thus attain all that is essential to a pure atmosphere. The gases which are produced by burning coal are not only very injurious to many substances exposed to them, but are even poisonous to all animal life; and it is in vain we procure wholesome food for the stomach, if at the same time the food of the lungs is poisoned. There appears to be nothing which can cause town to be more unhealthy than country but the difference in the purity of the atmosphere: although one great cause of this is imperfect ventilation, still no ventilation can be perfect till we have a source from which we may draw an unlimited supply of pure air. It is desirable, then, on the score of economy, that all the smoke should be consumed; but it is essential that the products of the burnt coal should be altogether removed from our atmosphere.

There appears to be no other way of doing this but by causing these products to ascend very high shafts. This then is the way proposed—the products from each fire passing down flues into mains in the street, and thence into the shaft. The following calculations show that a shaft 600 feet high, and 27 ft. 6 in. clear diameter, with all necessary mains and branch mains, would be sufficient to carry off the smoke from a district extending over four square miles, at a cost of 13*s.* 4*d.* per flue. As 3,600,000 tons of coal are brought to London every year, we may presume that 3,000,000 tons are actually consumed there, which is nearly in the proportion of 500,000 tons for every four square miles. But the shaft must be sufficiently large to carry off the smoke from the coal when at its greatest rate of consumption—say 1,000,000 tons per annum. Now 1,000,000 tons of coal when burnt produce about 12,810,000 tons of gases, for 100 lb. of coal contain about 86 lb. carbon, 5 lb. hydrogen, 5 lb. oxygen, and 4 lb. of ash; and when it is entirely burnt in air, $ON_2$, we get $CO_2$ and $HO$. The atomic weights of these substances are

$$C = 6; \quad H = 1; \quad O = 8; \quad N = 14.$$

Suppose 2 lb. of the oxygen of the coal unite with 2 lb. of the carbon, and the rest of the oxygen with the ash. Then we have 84 lb. of C, which will unite with $14 \times 2 \times 8 = 224$ lb. O, giving 308 lb. $CO_2$, and liberating $14 \times 2 \times 2 \times 14 = 784$ lb. N; altogether $84 + 224 + 784 = 1092$ lb. of gases.

The 5 lb. H will unite with 40 lb. O, producing 45 lb. $HO$, and will liberate 140 lb. N; altogether 185 lb. of gases. Therefore, 100 lb. of coal produce $4 + 1092 + 185 = 1287$ lb., and 1,000,000 tons produce 12,810,000 tons of gases.

We should also have to provide for a quantity of air which would escape into the flues, but this should be reduced as much as possible. The mouths of the flues not in use should therefore be closed; and if each house were taxed according to the quantity of gases passing from it, this might be ensured. Also the mouths of the flues should be placed as near to the fires as convenient.

Suppose then the greatest rate would be $2 \times 12{,}810{,}000$ tons per annum. The specific gravity of $CO_2$ is 1·527, of $HO$ ·624, of N ·972; and for 312 lb. $CO_2$ in the shaft, we have $784 + 140 = 924$ lb. N, 45 lb. $HO$, and $312 + 924 + 45 = 1281$ lb. of air. Therefore the specific gravity of the mixed gases in the shaft

$$= \frac{312 \times 1{\cdot}527 + 924 \times {\cdot}972 + 45 \times {\cdot}624 + 1281}{2 \times 1281} = 1{\cdot}048.$$

One cubic foot of air at 32° weighs about 570 grains. Therefore one cubic foot of the mixed gases at 32° would weigh 597 gr. Suppose that the temperature of the air in the shaft is 80° above that of the external air, which is at 32°. Then since gases at 32° expand $\frac{1}{580}$ of their volume for every degree of temperature, a cubic foot of the mixed gases would weigh $\frac{597 \times 580}{580 + 80} = 524$ gr., and therefore would ascend in air at 32° with a force equal to $570 - 524 = 46$ grains, or $\frac{46}{570}$ of gravity.

This force would produce a velocity of 45 feet per second, for

$$v^2 = 2fs,$$

where $v$ is the velocity sought, $f$ the force producing it, and $s$ the space passed over = about 575 feet. Therefore $v = 55$ feet. But say that the velocity would be 45 feet per second on account of friction. Then the sectional area of the shaft in feet would be equal to

$$\frac{\textit{No. of grs. to be discharged per year}}{\textit{No. of grs. discharged by 1 ft. of shaft}} = \frac{25{,}620{,}000 \times 20 \times 112 \times 16 \times 24 \times 20}{45 \times 60 \times 60 \times 24 \times 365 \times 524} = 593 \text{ ft.}$$

and its diameter 27 ft. 6 in. Each district should be hexagonal in form, and have six main flues, 11 ft. 3 in. diameter, lying in the direction of its shortest diameters. An ordinary house flue would have to be about 1 inch diameter.

To ascertain the cost, suppose that every street main is equal in sectional area to the sum of the sectional areas of the whole of its branches, and that the thickness of the material forming them bears a fixed proportion in all cases to their diameters. It is necessary to find the mean length of the distances of the fires from the shaft in one-sixth of the hexagon, measuring down the centre line and at right angles.

Let $a$ be half the length of the diameter of the area; then

$$\frac{3a \times 2a}{\sqrt{3}} = 4 \text{ miles.} \qquad a = 5670 \text{ feet.}$$

Then we have

$$\text{Mean length} = \frac{\int_a^0 \frac{2x}{\sqrt{3}} \left(x + \frac{x}{2\sqrt{3}}\right)}{\frac{a^2}{\sqrt{3}}} = 4384 \text{ ft.} = 1461 \text{ yds.}$$

The excavation necessary for one yard of the main, 11 ft. 3 in. diameter, would be about 27 yards. Suppose the excavation bears the same relative proportion to all the other mains, then the excavation for all six mains will be $6 \times 27 \times 1461 = 236682$ yards.

Suppose the flues are formed of brickwork, 18 inches thick, then the brickwork in 6 mains $= \frac{6 \times 40 \times 4384}{272} \times \frac{4}{3} = 5157$ rods.

The brickwork in the shaft (620 feet high, 50 feet internal diameter, $7\frac{1}{2}$ bricks thick at bottom, 30 feet internal diameter, and $2\frac{1}{2}$ bricks thick at top) will be $= \frac{5}{3} \times \frac{(176 + 100) \times 620}{272} = 1050$ rods reduced.

The digging for shaft, 63 feet diameter and 21 feet deep, equals $346 \times 7 = 2422$ yards.

The site for the shaft would cost, say, 5500*l.*

Suppose there are 250,000 1-inch house flues, average 8 yards long, = 2,000,000 yards.—So that altogether we have:

| | | | |
|---|---|---|---|
| | 236,682 yds. digging—one-third filling-in and two-thirds carting | @ 2*s.* | £23668 |
| | 5157 rods of brickwork in main flues in street, and labour | @ 10*l.* | 51570 |
| Shaft | 1050 rods brickwork, and hoisting | @ 10*l.* | 10500 |
| | 2422 yds. digging and carting | @ 2*s.* | 242 |
| | Cost of land for site of shaft | say | 5500 |
| | 2,000,000 yds. of inch piping for house-flues and laying in walls | @ 6*d.* | 50000 |
| | 250,000 valves, meters, &c. | @ 2*s.* | 25000 |
| | | Total | £166480 |

Or nearly 13*s.* 4*d.* per flue.

If, instead of having one shaft to every four miles, we had one to every square mile, the cost of the mains and digging for them would be reduced $\sqrt{\frac{1}{4}} = \frac{1}{2}$ per square mile; but the cost of the shaft, with necessary land, &c., would be increased four-fold.

To find what would be the extent of area best adapted to each shaft, we have:

| | |
|---|---|
| Cost per square mile of mains and digging, in the above example | £18809 |
| Ditto ditto of shaft, site, &c. | 4068 |

Let $x$ be the area required, taking four square miles as unity, and $u$ the cost per mile; then

$$u = 18809\sqrt{x} + \frac{4060}{x}$$

$$\frac{du}{dx} = \frac{9404}{\sqrt{x}} - \frac{4060}{x^2} = 0, \text{ when } x \text{ is so taken that } u \text{ is a minimum;}$$

$$\therefore x^3 = \frac{4060^2}{9404^2} = \frac{100}{536}. \qquad x = {\cdot}57 \text{ nearly.}$$

That is, the area ought to be about 2·28 square miles in extent, and the saving per mile would then be

$$22877 - 18809\sqrt{\cdot 57} - \frac{4060}{\cdot 57} = 1527l.$$

The cost per flue would thus be 12*s.* 10*d.*; but this saving would not perhaps compensate for the unsightly appearance of so many shafts.

There would be several advantages in this system besides the purity of the atmosphere, as, for instance—Possessing the power of regulating the draught to any desirable extent, a smoke consuming arrangement might be adapted to ordinary house fires, without materially altering their appearance, and at a trifling cost, thereby effecting a great saving of fuel or heat. The flues might be used as heating pipes before leaving the house, but not so as to reduce the temperature of the shafts too much. There would be a saving in construction and space, as no chimney stacks or breasts would be required, the inch flues being built in the ordinary thickness of the walls. In old buildings the flues are generally arranged in stacks, so that in most cases the new inch flues would be brought down inside them without disturbing much brickwork. The flues would sometimes want clearing; this might be done by firing them, the draught being sufficient to carry off any ash which would result.

## TAPER AND PARALLEL SUSPENSION BRIDGES.

SIR—After seeing the taper principle on which the Balloch and Lochy Bridges are constructed, I took an interest in promoting its adoption in the Aberchalder and in the Ness Island Bridges, which are just finished; and feeling persuaded that an explanation of the principle would not be uninteresting to the readers of your *Journal*, I venture to send it to you for insertion. But before entering upon it, I beg to premise it with a well-authenticated fact, "that it is only by comparison that we can obtain the intrinsic value of things." In attempting it therefore, and in order to bring it home to every one's comprehension, I must put it in juxtaposition with the effects and results of the suspended weight in a bridge on the parallel principle, to those in a bridge on the taper principle, of the same breadth of roadway, span, and deflection, and both having two main chains of the same sectional area and strength at their four respective points of suspension. In the first place, let the deflection of both bridges be $\frac{1}{15}$ of their span, and the suspended weight of the parallel bridge between the points of suspension be 600 tons—*i.e.*, 200 tons the chains and 400 tons the roadway. Then, these being its governing laws, consequently on the chains at the centre the deflection and weight would engender 2250 tons of tension and 562·5 tons at each point of suspension. In operation, truthfully, it is half of the whole weight suspended on the centre of the chains, which is multiplied by half the deflection, and the product is the tension then resulting from these causes. Example: $300 \times 7\cdot5 = 2250 \div 4 = 562\cdot5$. But the usual mode is to multiply the whole suspended weight by one-fourth of the deflection, which produces the same results. Example: $600 \times 3\cdot75 = 2250$ tons.

The roadway in the parallel bridge is only a dead load upon the chains, proportionally producing the same results upon them as their own weight, and therefore I computed the result from the weight of the chains and platform in one sum; but that it might be more clearly understood, I will compute it in the ordinary way separately. Example: 1, weight of chains in tons $200 \times 3\cdot75 = 750$ tons of tension; 2, weight of roadway in tons $400 \times 3\cdot75 = 1500$ tons of tension; and these products are the 2250 tons of tension in the chains at the centre of the bridge, and the 562·5 at each point of suspension resulting from the suspended weight. The results are the same upon the back mooring chains to resist the effects of the suspended weight.

Now, in respect to the taper principle, on the contrary; first, in consequence of each section of the main chains being tapered from its base or main points of suspension to 0 at the centre of the bridge, they would be but half the weight of the parallel main chains, or 100 tons, and this multiplied by one-sixth of the deflection, namely 2·5, the product would be 250 tons of tension resulting from their whole weight, or 62·5 tons at each point of suspension. Example: $100 \times 2\cdot5 = 250 \div 4 = 62\cdot5$. Therefore the economy of iron in the main chains between the points of suspension would be 100 tons, and 100 tons in the back chains, and the reduction of tension at the main points of suspension would be 500 tons, which would be an increase of strength to that extent. But independently of these advantages, the taper principle transfers the horizontal force from the chains to the horizontal line, which effects the same proportional economy of material in the roadway as the taper does in the chains; and besides, it makes the roadway as essential an element of sustentation as that of the chains and the piers, and it secures a rigidity to the bridge that cannot be attained by any other means. The roadway therefore in this instance would be but 200 tons, or twice the weight of the chains, which is the same comparative weight as it is in the parallel bridge. Hence, 200 tons multiplied by 3·75 equals 750 tons of tension resulting from the whole suspended weight of the roadway, and this added to the tension produced by the weight of the chains will be 1000 tons, or 250 at each point of suspension, resulting from the suspended weight.

Here, then, in the parallel bridge, at the main points of suspension, there is 2250 tons of tension resulting from only half the suspended weight, and only 1000 tons in the taper bridge, resulting from the whole suspended weight, which is 1250 tons less in the taper bridge, and consequently this is an increase of strength to that extent; and 1250 divided by 3·75 equals 360 of dead load in tons that the taper bridge would sustain on transit before its chains would be exposed to the same tension as those of the parallel bridge by its weight alone.

Moreover, there are still two other considerable items of difference in these bridges at their main points of suspension, which, for the sake of simplicity, have not yet been alluded to in these definitions:—1. In the parallel bridge there has been but half of the suspended weight taken into account; the other half, or about 300 tons, is direct additional tension at the main points of suspension over and above what has been stated, and consequently this is additional weakness or reduction of strength to that extent. 2. On the contrary, in the taper bridge the diagonals at the piers, in every instance, should sustain one-fourth of the roadway, which is a great object of additional strength that has not been brought into account. Therefore, in round numbers, it may be safely stated, that in this instance the taper bridge for traffic purposes would be more than 500 tons stronger than the parallel bridge. And further, it may be stated that at the centre of the taper bridge there is neither weight nor tension on the chains, because they are connected only through the medium of the horizontal line; therefore both weight and tension become evanescent at this point, and from it as the chains progressively increase in section, and therefore in strength, to their points of suspension, the weight, and consequent tension, increase in the same proportion progressively upon the main chains, and the effect of transit loads operate upon them in the same way.

The superiority of the taper principle, as shown in this instance, is more and more immense as the magnitude of bridges is increased, and proportionally less in smaller bridges, because it springs from three great causes:—First, *from the reduction of half the suspended weight in every instance;* secondly, *from the centre of gravity in the taper chain being one-sixth of its length nearer the point of suspension than it is in the parallel chain;* and thirdly, *from the transfer of the horizontal force from the chains to the horizontal line, which thereby transmutes one of its most destructive elements into one of the strongest supports in a bridge.*

The horizontal force in the chains at the centre of the parallel bridge (2250 tons) is that strain or tension which naturally arises in the formation and maintenance of the bridge, and the effect of it is always directly as the deflection, and inversely as the span existing upon the centre of the curve; that is, half of the suspended weight multiplied by half the deflection. But in the taper bridge this force is sustained by the roadway, and therefore it may be truly said, that whilst the parallel chains have to sustain themselves, the roadway, and load too in the weakest of all positions, the roadway of the taper bridge, in combination, sustains the chains, itself, and the load too in that position. And this is the great mechanical difference in the two principles.

In respect to the economy of material in the roadway, which in principle is neither more nor less than a long beam, and the fundamental law of which is, that when the beam is tied at both ends it will sustain twice the weight it will bear when both the ends are loose. Therefore the same rule holds good in bridges; and as the roadway of the bridge is only hanging neutrally upon the chains, whilst in the taper bridge it is full of equidistant horizontal ties from end to end, and as active as the chains, one-half of the material is fully its own weight stronger in consequence.

*Bath, March 24th* 1854. A LOVER OF MECHANICS.

## DRAINAGE AND WATER SUPPLY.*

*(Concluded from page 128.)*

### Tottenham Drainage.

The general surface of the ground at Tottenham has a gentle fall towards the valley of the River Lea. The subsoil of the northern portion of the town is gravel, and of the southern portion London clay. Its surface and subsoil drainage was provided for by brick sewers, which have been many years constructed, and which are still maintained for this purpose. The house drainage was conveyed into cesspools with overflows into the adjoining sewers or ditches.

In May 1849, Mr. W. Ranger, one of the Inspectors of the General Board of Health, made his Report to that Board upon Tottenham, and a rated district was formed, containing 2000 houses and a population of 11,000 persons, with a Local Board of Health. The plans of their engineer, Mr. J. Pilbrow, for the water supply and house drainage of the town were submitted for the approval of the General Board on October 1st, 1850, and received its sanction on the 22nd August 1851.

Here, as elsewhere, the new sewers are divided into two classes,—public sewers executed at the public cost, and private sewers (including also house drains) executed at private cost.

The public works of a portion of the district were completed about September 1852. The private works or house drainage commenced about that time, and the number of houses connected with the sewers was, in February last, about 400; in August last, about 1100; and at the present time, 1800; so that, in point of fact, Tottenham does not afford a longer experience of the working of this system of sewerage than the other places which I have lately visited.

The works, with a few exceptions, have been executed as originally designed by Mr. Pilbrow; and the only alteration of importance which he was required to make by the General Board of Health was, the reduction in diameter of his outlet sewer from 21 to 18 inches; but as the drainage of the district is rapidly extending, there are good grounds for believing that the outlet will have to be taken up, and a brick sewer of larger dimensions substituted for it.

The main sewers are laid generally under the footpaths of the public thoroughfares, and vary from 7½ inches to 18 inches in diameter; but Mr. Pilbrow would not again use pipe sewers larger than 15 inches in diameter, and those only under peculiar circumstances; beyond that size he prefers brick sewers, upon the score of both economy and efficiency.

The inclinations of some of the main lines are flat; for instance, commencing with the outfall and going upwards they are as follows:—

| Diameter of Pipe. | Rate of Fall. |
|---|---|
| 18 inches | 1 in 1062 to 1 in 659 |
| 15 inches | 1 in 635 |
| 12 inches | 1 in 635 |
| 9 inches | 1 in 340 |

The greatest depth below the surface at which these sewers are laid is 13 feet, and the average depth is about 7 to 8 feet.

The pipes are circular stoneware socket pipes, formed with a bell mouth, so as to prevent the shoulder of one pipe projecting beyond the adjoining pipe, in case of any settlement of the ground; and this appears to me a decided improvement on the usual form. The joints are made with Portland cement, and Mr. Pilbrow attaches great importance to this mode of jointing, because Portland cement, taking a long time to set, to some extent adapts itself to any settlement of the pipes which may happen while the ground is soft.

Flushing-shafts have been constructed at the heads of the branch sewers, which are flushed out every two or three months; and there are four man-holes or shafts constructed for the purpose of inspecting the pipes; but they show the condition of the pipes only at those particular points at which they are fixed, and are no indication of their condition at any other points.

Provision for the ventilation of the sewers has been made by connecting the stack pipes of the houses with the sewers, or by carrying up a shaft in the centre of a garden-wall unknown to the owner, or where the sewer crosses a field, carrying up pipes by the side of trees; indeed, when sewers are constructed in districts not closely peopled, many opportunities of obtaining ventilation present themselves which are not to be found in a crowded city.

The surface drainage has not been admitted into the sewers, and Mr. Pilbrow expresses a very decided opinion, that if it were admitted they would very soon become entirely choked up.

The outfall is at present into the Mosell, and thence into the River Lea, the water of which is supplied below this point by the East London Waterworks Company to the London consumers, upon whom a great evil is thus inflicted. The Local Board are alive to this point, have purchased land for the construction of sewage works, and are now in treaty with a contractor for undertaking, free of cost to the Board, the purification of the sewage, of which he is to have the free use for twenty-one years. The process of precipitation proposed to be adopted is known as Higgs' process, now used at Cardiff jail. If the agreement renders compulsory, under penalties, the purification of the sewage at all times, and this obligation be strictly enforced, the result promises to be satisfactory.

Back combined drainage has been generally adopted for the private sewers and house drains. The latter vary in diameter from 4 to 6 inches, and their average inclination is about 1 in 50 or 60. In some cases the 6-inch pipes have been laid down for a length of 600 or 700 feet at an inclination of 1 in 200; but I am informed that no stoppages or breakages have yet taken place.

The cost of the private works is said to average about 8*l.* per house; but they have in some instances amounted to 60*l.* or 70*l.*

The water is obtained from two bore holes, one of 12-inch bore sunk 100 feet into the chalk, and one of 10-inch bore sunk through the gravel to the surface of the chalk. The water from these flows into a subterranean reservoir, whence it is raised by two 6-horse engines to a reservoir 100 feet above the town, capable of containing 100,000 gallons, or barely one day's supply. A further quantity of water, about equal in amount, gains admittance into the sewers from springs in the gravel; so that, on the average, about 200,000 gallons of water are passed daily through the sewers. The supply pipes to the houses vary from 1 inch to ¾-inch, and the water is laid on upon the system of constant supply; but Mr. Pilbrow's arrangements in this respect, as in many other details, are superior to those in any of the other towns included in this Report, and it is only due to him to state, that they exclusively originate with himself.

Mr. Pilbrow has invented what he terms a "Preventor," consisting of a stone or gutta-percha ball, which, when a tap is opened, is forced up with the rising stream of water, and stops the orifice after about a pail-full of water has passed through it; and the ball will not then admit of any more water passing until the tap has been turned back and the ball allowed again to fall to the bottom of the chamber. This simple apparatus prevents the great waste of water which is complained of in other places where the constant supply system has been adopted; and the quantity and force of the flush of water here used are vastly superior to what I have witnessed elsewhere, and tend materially to mitigate the evils attendant upon too extensive an application of small pipes.

| | |
|---|---|
| The cost of public works, irrespective of extensions, which will hereafter become necessary, and irrespective also of the preliminary inquiry, survey, &c., have amounted to ... | £10,000 |
| The private works, taken at an average of 8*l.* per house, would amount to ........ | 16,000 |
| Total ........ | £26,000 |

The public works at Tottenham were executed at very low prices; they could not now be done for the same money; but they could always be done at a very much less cost there than in the streets of London.

The following give a fair average of the contract prices at which these works were executed, the greater portion of the sewers being laid under the footpaths. When laid under roads they cost rather more, and when in fields rather less.

Pipes laid in footpaths and courtyards, every expense included, except the cost of the pipes:—

| Diameter of Pipe. | 6 ft. Depth. s. d. | 8 ft. Depth. s. d. | 10 ft. Depth. s. d. |
|---|---|---|---|
| 6 inches | 0 8¼ | 0 11 | 1 0 |
| 9 inches | 0 9¼ | 1 2¼ | 1 3½ |
| 12 inches | 0 11¼ | 1 3¼ | 1 7¼ |

The rateable value of the property in this district is about

* 'Report upon the Drainage and Water Supply of Rugby, Sandgate, Tottenham, St. Thomas's, Exeter, and Barnard Castle.' By J. W. Bazalgette, Esq. Engineer to the Metropolitan Commission of Sewers. Published by Authority: 1854.

25,000*l*. A special rate of 4½*d*. is raised to pay off the principal and interest for the public works, and a general district rate of 2*d*. to pay salaries. No provision is at present made for repairs to these sewers, inasmuch as the contractor is bound to execute all repairs for the next five years. The general district rate was formerly 5*d*., in order to cover the payment for the survey and preliminary expenses. The water-rate appears to be about 3½*d*. in the pound, varying slightly with different houses.

### St. Thomas, Exeter, Drainage.

The rated district of St. Thomas is situated on the banks of the river Exe, opposite to the city of Exeter. The greater part of it is rural. The town portion consists (1), of the town of St. Thomas, forming the south-western suburb of Exeter, and containing 598 houses; and (2), of the village or hamlet of Exwick, containing 80 houses, about a mile to the north of St. Thomas, on the banks of the Exe. Exwick is drained into that river above Exeter. The population of the whole district is about 6000. The subsoil, to the depth at which the sewers are laid, is clean river gravel and shingle, showing, from their appearance, that the lower parts of the district were at one period washed by tidal waters. The surface of the ground at St. Thomas, near the river is low and flat, whilst that of Exwick has a rapid fall towards the river.

Before the new works were contemplated, the surface drainage was provided for by means of some old brick sewers and cesspools, into which the water was allowed to flow, from considerable distances, over the pathways, and along the surface of the streets. These old sewers and cesspools still exist; and in addition thereto, thirty-one new gullies have been connected with the new sewers, but the rain water is still allowed to run from the roofs of the houses over the footways and along the street gutters, and in this respect the surface drainage is still very defective.

The gravel upon which the houses are built is in itself a natural drain, and mere holes or pits in the ground would convey the liquid refuse of the town into the gravel, whence it would filter without artificial means down to the level of the river Exe.

The preliminary Report upon St. Thomas was made to the General Board of Health, by Mr. G. T. Clarke, one of their Inspectors, in April 1849.

The public sewers of St. Thomas were designed by and executed under Messrs. Dymond and Sons, and they were completed in August 1851. They consist of stoneware socket pipes of London manufacture, varying in diameter from 4 to 18 inches, and in inclination from 1 in 22 to 1 in 1000. Their average depth below the surface is only 5 feet, and they are laid in a gravel soil. The main lines are constructed generally either along the roads or across fields.

The 18-inch and 15-inch pipes, comprising the outlet sewers of the suburb of St. Thomas (which are laid at the flattest inclinations), are almost entirely outside the town; and they are flushed frequently from three places constructed for that purpose. Usually they have a considerable stream of water passing through them. With respect to the main body of the sewers in the town itself, which are of smaller dimensions, no means exist of either examining or flushing any of them. And as they have not been inspected since they were laid down, the present condition of the sewers in the town itself must be unknown, because (for the reasons more fully given in the Report upon the sewers at Sandgate) when stoppages occur in pipes laid in sand or gravel, the soil receives and discharges the sewage which the pipes cannot convey away, and so the stoppage is not discovered until some accidental circumstance draws attention to it.

The main outfall sewer consists of an 18-inch pipe, which is carried across the fields by the side of the South Devon Railway, for a distance of about a quarter of a mile; it then enters and passes through a brick chamber, and discharges into a large shallow pond of filth, constituting a wide-spreading open cesspool at the foot of the railway embankment. The overflow from this pond is into an adjoining stream of water, running by the side of the railway. The pond here described exposes a large evaporating surface of the most disgusting kind, and some means should be immediately taken for its purification or removal. The brick chamber through which the sewage passes is divided into two or three small settling reservoirs, which were no doubt intended to receive the sewage. A man comes down occasionally to try various means of saving the manure, and two or three small heaps were pointed out as having been collected by him, but none of these have as yet been used upon the land, although the sum of 20*l*. per annum is paid for the use of the town sewage. It would thus appear that the works for manure operations, constructed at this point at a cost (including the land) of 700*l*., have not, up to the present time, been of any practical utility.

There are from twenty to thirty of the houses in the suburb of St. Thomas which are not connected with the above system of sewers, but have separate lines of pipes with outfalls direct into the River Exe, opposite to Exeter.

The public sewers of the hamlet of Exwick vary from 4 to 9 inches in diameter, and their inclination from 1 to 7 to 1 in 100. There are two separate 9-inch outfall pipes, which discharge into a mill-stream, and thence into the River Exe, about a mile above Exeter.

No provision has been made as a general rule, either in St. Thomas's or in Exwick, for the ventilation of the pipe sewers; as an exception to this observation, in two or three instances the waterspouts from the roofs of the houses have been connected with the upper ends of the pipe sewers, for the purpose of ventilating the latter.

It is stated that none of the pipes have broken since they were laid down; but a general examination of the sewers, or longer experience, is requisite to elicit the fact.

The house drainage may be considered to have commenced in August 1851; and in March last there were in St. Thomas's and Exwick together, 402 houses drained into the sewers; in September last, 580; and at the present time 640. But this statement requires closer examination.

To a large extent there is but one watercloset for two or three houses. In particular, one block of 21 houses was pointed out which have only seven waterclosets amongst them; so that here, in point of fact, No. 1 is drained, and has water and a watercloset; whilst Nos. 2 and 3 are undrained, but the inmates are allowed to avail themselves of the drainage provided for No. 1. Now, the Report of Messrs. Dymond would lead to the supposition that Nos. 1, 2, and 3 have all been drained; whilst, in fact, the cost of the drainage of the one house has been divided amongst the three, to give the average cost of draining each house.

Mr. Bazalgette estimates that there is, upon the average, about one watercloset to two houses throughout the district. If, then, from 678—the total number of houses in the district—are deducted 80 which belong to the hamlet of Exwick, and are drained by distinct sewers, 38 not yet drained, and 25 which drain by separate outfalls into the river, and assume that the remaining 535 have waterclosets at the rate of one to every two houses, and if it is to be understood that a single connected system of sewers is spoken of, we should have 267 instead of 640 waterclosets now draining through the main system of pipes into the open cesspool near the railway; 243 instead of 580 so draining in September last; and 168 instead of 402 in March last. The remainder discharge by separate sewers into the River Exe, or the houses are yet undrained. Thus, upon consideration, it appears that St. Thomas's does not afford the experience as to amount of drainage by pipe sewers, which, from the statements respecting it, it would seem to do.

The private sewers and house drains vary in diameter from 4 to 9 inches; the former size is used for a single house. The average inclination is from 1 in 25 to 1 in 30.

Combined and back drainage has been generally adopted. When the owners of houses were willing to combine in the execution of the minor branches through their property, and at their own cost, they constructed such branches as private works; but when they were unwilling to do so, or objected to their property being intersected by their neighbours' drains, the Local Board, out of the public funds, carried up the branch sewers to the last house in the line, so that there was a strong inducement to all parties not to agree to construct combined works at their own individual cost, but to oblige the Local Board to carry those works out at the cost of the public. There are said to have been about a dozen stoppages discovered in the house drains, from the introduction of improper substances, such as flannel, rags, straw, &c.

The actual cost of the work, as given in the letter of Messrs. Dymond to Lord Palmerston, exclusive of any of these charges, is set down at 2371*l*. The average cost of the private works is stated to be 4*l*. 2*s*. 6*d*. per house; but it must be borne in mind that this sum does not represent the actual cost of the drainage works for each house actually drained. If the averages assumed above, of one watercloset to two houses, be correct, the cost of private works for draining each house would be 8*l.* 5*s.*, exclusive of supervision. Therefore, assuming in the first place, the present defective provision of one watercloset to two houses to be completed and continued—

| | |
|---|---|
| The cost for private works would be .................. | £2796 |
| The cost for public sewers .............................. | 2371 |
| Total ............... ........... | £5167 |

And in the absence of more definite information, and reasoning from analogy, as in the case of the other towns, the cost of surveys, supervision, &c., would increase the above amount to from 6000*l.* to 7000*l.* If, on the other hand, a watercloset were provided and water laid on to every house—

| | |
|---|---|
| The private works would amount to .................. | £5593 |
| Public sewers.................................................. | 2371 |
| Total ...................... | £7964 |

And the surveys and supervisions, &c., would make the total cost somewhere between 9000*l.* and 10,000*l.* These estimates are exclusive of the public works for the supply of water, and for the removal of rain water from the surface of the footways, or for any improvement of the outfall. The prices at which the works were executed were as follows:—

Excavation and laying pipes, filling-in, strutting, shoring, carting away superfluous earth, including all expenses, excepting the cost of the pipes—

| | | | | | Per foot lineal. |
|---|---|---|---|---|---|
| 6-inch pipes, average depth being 3 to 4 ft. | | | | ......... | 5*d.* |
| 9-inch | ,, | ,, | ,, ditto. | ......... | 5*d.* |
| 12-inch | ,, | ,, | ,, 5 ft. | ......... | 8*d.* |
| 15-inch | ,, | ,, | ,, ditto | ......... | 9*d.* |
| 18-inch | ,, | ,, | ,, ditto | ......... | 11*d.* |

An additional price of 2*d.* per foot lineal was paid for removing and relaying pitching; 4*d.* per foot lineal for macadamised roads; and 6*d.* per foot lineal for pavements. Most of the footpaths are made with round-stone pitching, and there is but little pavement in the place.

The rateable value of the houses in St. Thomas's is about 5000*l.*, the rateable value of the whole district being about 11,000*l.* A special district rate of 7*d.* in the pound per annum upon houses, and 1¾*d.* upon land, is raised for the repayment of the money borrowed. A general district rate of 10*d.* in the pound is raised to cover supervision, repairs, &c.; or, in its stead, a highway rate of 4*d.*, together with a general district rate of 6*d.* The water rate amounts to 10*d.* in the pound, and 1½*d.* in the pound for public purposes.

The Exeter Waterworks Company provide St. Thomas's with water upon the system of constant supply. It is obtained from the River Pynes, a branch of the Exe and Culm, about four miles above Exeter. The reservoir is 170 feet above St Thomas's, and the Company are now extending their works. The Superintendent, under Mr. Simpson, Engineer of the Company, states, that "the supply of water from the Exeter Works to the district of St. Thomas, as near as it can be ascertained, usually exceeds an average of 120 gallons per house per diem. "In dry weather the gutters are washed occasionally by allowing the water to run from the waterworks' plug for about fifteen minutes each time. The pipe drains do not at present extend to the whole of the district, but there is a great waste of water, which no doubt tends materially to cleanse them. The pipe drains have not been down a sufficient length of time to ascertain any practical result as to stoppages or otherwise which ought to be relied on."

Mr. Bazalgette's visit to St. Thomas's was made on the 1st of February 1854. He considers the arrangements for its drainage still far from being perfect and complete; and that they do not afford sufficient experience of the success or failure of such an application of pipe drainage.

### Barnard Castle Drainage.

Barnard Castle is a small, quiet country town, containing about 4600 inhabitants and 700 houses. It is situated upon the side of a hill, having a precipitous fall towards the banks of the River Tees.

The town drainage is divided into two separate and distinct systems of sewers:—1, those sewers originally provided to carry off the road and surface drainage; 2, another system of sewers recently provided under the General Board of Health, to carry off the house drainage. The latter are again subdivided into public and private sewers. Of the entire number of sewers and drains for house drainage laid down upon the Engineer's plan, extending, in the aggregate, to a length of about eight miles, four and a-half miles, or thereabouts, in length, are marked as public sewers; whilst the remaining three and a-half miles, constituting the private sewers and drains, either have been or will be executed out of the private funds of the individuals required to construct them.

The public sewers and the main lines for the supply of water were designed and executed under the direction of Mr. Ranger, the Inspector of the General Board of Health, who had, in November 1848, made the preliminary inquiry into the sanitary state of the town and its drainage, and who was afterwards appointed the Engineer to the Local Board; and they were constructed under the immediate supervision of his assistant, Mr. A. Morgan. These public works were completed in April 1852. From that date, the drainage of the town may, with but few exceptions, be considered to have commenced; because, until the house drainage was conveyed into the sewers, the latter remained inoperative, and only came into action in proportion as the private works progressed. Towards and since the completion of the public sewers, the Local Board, as far as practicable, have from time to time required the owners of the houses, at their own cost, to destroy their cesspools, put up waterclosets, lay on water, and construct drains and private sewers from their houses to the public sewers. But inasmuch as these proceedings have in many cases given rise to much opposition, the Local Board have found it necessary to proceed slowly, and with much caution and forbearance. About rather more than one-half of the houses have up to the present time been connected with the public sewers.

The road and surface drainage continues to be carried off by the previously existing brick drains; and only house drainage and the rain from the roofs is allowed to be conveyed into the pipe sewers. The pipe sewers and drains vary in size from 4 to 15 inches in diameter. The following table gives the length and sizes of the public sewers:—

| Diameter of Pipes in Inches. | 15 | 12 | 10 | 9 | 8 | 6 | 4 |
|---|---|---|---|---|---|---|---|
| Length in Feet ... | 500 ... | 800 ... | 645 ... | 635 ... | 2366 ... | 14,417 ... | 5104 |
| Total ................. 24,467 | | | | | | | |

The natural levels of the surface have afforded such favourable inclinations as can be obtained in but very few other towns in this country. They range from 1 in 5 to 1 in 200, the average or ruling gradient being about 1 in 30.

The pipes used have socket joints, and they are mainly of fireclay from the neighbourhood of Manchester and Leeds, but some few are stoneware, from London. The joints are formed with cement, great care being taken to make them water-tight. No provision has been made for the ventilation of the sewers or drains. The sewers have been laid at the backs of the houses or under the side channels of the streets, at an average depth of from 8 to 10 feet below the surface, and they are subjected to little or no traffic over them.

There have been but three or four stoppages in the pipes. Indeed, considering the extraordinary falls above named, the small amount of drainage received, and the facility that exists of passing, at any time, a rapid stream of water through the sewers and drains, it would, with moderate-sized pipes, be surprising were it otherwise. The stoppages alluded to are stated to have been occasioned by imperfectly-formed junctions or other avoidable causes. In one instance however, viz., a 6-inch branch pipe laid near Thorngate, at an inclination of 1 in 200, and receiving the drainage from eight waterclosets, stoppages occurred, requiring a considerable length of pipe to be broken up; and the surveyor has reason to believe that deposit is again accumulating in it, and that in order to make it efficient, it will have to be detached from the main line, and reconstructed with a discharge into the River Tees, at a nearer point, so as to obtain a better fall. Another cause of stoppage, occurring in a private drain, arose from the joints not having been made water-tight, so that the water escaped through them into the soil, leaving the deposit to accumulate and cause a stoppage in the drain.

The surveyor is of opinion, derived from experience, that the successful working of pipe sewers is essentially dependent upon perfect workmanship and water-tight joints, with an abundant supply of water, and the exclusion of surface drainage coming from the roads.

The supply of water for the town is obtained from Stoney Keld Springs, distant about six miles; it is conveyed thence, by gravitation, through 9-inch stoneware pipes, for a distance of four miles, to a reservoir about 100 feet above the level of the centre portion of the town, and capable of holding about 20,000 gallons; but this reservoir is too small for the wants of the town, and will shortly have to be enlarged. The supply pipe from the reservoir into the town is an iron pipe, 7 inches in diameter. The system of constant supply is here adopted; but some inconvenience has been felt from the waste occasioned by careless persons and children leaving the taps open, by which, upon one or two occasions, the reservoir was emptied in the course of the night. The fire-plugs are opened, and the water allowed to flow through the sewers for about a quarter of an hour once a week, in order to cleanse them.

At the time when Mr. Bazalgette inspected these works, he found many of the waterclosets and water-pipes frozen up and inoperative; arising in several instances from the owners having laid the drains and pipes too near the surface, in order to save the expense of excavation. Some of the householders have excavated the ground for themselves, only 9 or 10 inches deep, and employed a bricklayer only to lay the pipes, doing the rest themselves. The works in this case will have to be reconstructed. The cost of the private works was stated to have amounted to about 5*l.* per house on the average, which, upon 700 houses, would amount in the whole to about 3500*l.*; but in many instances there is but one watercloset to three or four houses. This sum does not therefore represent the actual cost of draining each house, but it gives the cost of these works reduced, by being divided amongst a larger number of houses.

The cost of the works termed "public works" was, for water supply 4000*l.*, and for public sewers 2000*l.*; those sums include the engineer's professional charge of 397*l.*, and all other charges for supervision, but they are exclusive of the cost of the survey (which is not yet paid), and the preliminary inquiry of and reports by Mr. Ranger. Taking into account these additional items, the cost of the house drainage and water supply of this town will, when completed, amount to a sum of, probably, 10,000*l.*; but this, it must be borne in mind, is irrespective of the cost of the sewers for surface and subsoil drainage, and of the proposed enlargement of the reservoirs. The estimate would stand thus:—

| | |
|---|---|
| Waterworks | £4000 |
| Public Sewers | 2000 |
| Private Works (upon reduced estimate by being divided amongst a larger number of houses) | 3500 |
| Survey and preliminary inquiry, &c., say | 500 |
| Total | £10,000 |

The rateable value of the property included in the district rated to the works here described is about 6000*l.*, and a rate of 1*s.* 6*d.* in the pound per annum is charged upon the whole of the property in respect of the public works, in addition to a charge of 2*d.* in the pound per annum for private water supply to all consumers. The charges for supervision, maintenance, and repairs, of the double system of pipe and surface drainage sewers, are paid for out of a rate called the "General District Rate," amounting to 4*d.* in the pound.

As the local circumstances under which drainage works are constructed vary so considerably, it would be perfectly idle to institute a comparison, either as to cost or in any other respect, between the drainage of two distinct places, without a full consideration of the circumstances applicable to each. And this observation applies with peculiar force where an attempt is made to compare the drainage of a great city like London with that of a small town or village in a distant province or in a rural district. The nature of the soil and surface; the nature and quality of the roads; the amount of traffic over them; the weight and proximity of the buildings; the existence or non-existence of cellars under the houses and streets; the rate of wages; and a variety of other circumstances, must not only govern the kind of structure best adapted to the locality, but will also have a material influence upon its cost and the difficulty of its execution. One very heavy item in London, which has scarcely a parallel in a small country town, consists in the cost of strutting, shoring, lighting, fencing, and watching, and taking those other necessary precautions against accidents and danger to buildings and the inhabitants, as well as to passengers in the streets, which are indispensable in a large and crowded city with enormous traffic. By way of illustration, I may mention, that the contract prices - laying 6, 9, and 12 inch pipes, at the depths of 6 and 10 feet respectively, exclusive of the cost of the pipes, are as follows, in London and at Barnard Castle:—

*Comparative Cost of similar Work at London and Barnard Castle.*

| Diameter of Pipe. | Depth laid. | Cost, per Yard lineal. At London. | Cost, per Yard lineal. Barnard Castle. | Excess of Cost for similar Description of Work in London over Barnard Castle. |
|---|---|---|---|---|
| Inches. | Feet. | *s.* *d.* | *s.* *d.* *s.* *d.* | *s.* *d.* *s.* *d.* |
| 6 | 6 | 2 3 | 0 8 to 0 9 | 1 7 to 1 6 |
| ... | 10 | 3 10½ | 1 6 to 1 8 | 2 4½ to 2 2½ |
| 9 | 6 | 2 4½ | 0 8½ to 0 10½ | 1 8 to 1 6 |
| ... | 10 | 4 0 | 1 6¼ to 1 9 | 2 5¾ to 2 3 |
| 12 | 6 | 2 4½ | 0 9¾ to 0 10½ | 1 6¾ to 1 6 |
| ... | 10 | 4 0 | 1 8¼ to 1 10½ | 2 3¾ to 2 1½ |

Now, in London, the cost of merely relaying the pavement would amount to from 1*s.* to 1*s.* 10*d.* per yard lineal, which in most cases exceeds the whole cost per yard of laying the sewers at Barnard Castle, exclusive of the material. But it is also the fact, that the average depths of sewers in London is of necessity nearly double that of the sewers in our country towns and villages.

### Concluding Remarks.

As much misapprehension exists upon the relative value of pipe sewers as compared with brick sewers, Mr. Bazalgette, in his concluding remarks to his Report, touches upon the few simple reasons which render brick sewers of the form now generally adopted in London preferable, as a rule, to pipe sewers for the drainage of large towns. The rule upon this, as upon almost every other subject, must of course be open to occasional exceptions. Every one acquainted, however slightly, with hydraulic engineering, knows that the rapid conveyance of a fluid is essentially promoted by a smooth bore, and a channel so circumscribed as to present the least possible frictional surface, as compared with the sectional area of the fluid. It cannot be denied that these conditions are fulfilled *in each separate length* of a properly-made glazed stoneware pipe, of a diameter proportioned to the quantity of fluid to be discharged. Nevertheless, in town drainage there are other considerations of no less moment which often compel the engineer to forego an advantage in one direction to secure equal or greater advantages in another. This will appear when we consider the complex duty to be discharged by the sewers of a large town. Such sewers have to provide for three distinct objects—house drainage, subsoil drainage, and surface drainage. The house drainage may be considered as tolerably uniform in quantity, and the subsoil drainage nearly so. But the quantity of the surface drainage is very variable,—in times of heavy rain greatly exceeding the average quantity, and demanding a proportionate provision to meet such extraordinary exigencies.

Now, pipe sewers, though adapted for house drainage under the conditions already mentioned, are not adapted simultaneously either for subsoil or for surface drainage. When therefore in a large town pipe sewers are laid down for house drainage, the subsoil and the surface drainage must be provided for by a second system of sewers as numerous at least as the others, and of larger dimensions. It is therefore a manifest fallacy to compare, either in cost or otherwise, pipe sewers performing a single duty, with brick sewers performing a triple duty. The comparison to be worth anything, should be instituted between the double system of sewer required under the one practice, with the single system, which suffices in the other. On the other hand, the London egg-shaped sewers are admirably adapted to answer the triple purpose adverted to.

It thus appears, that (with the ordinary flow) the sewage runs through an 18-inch channel, differing (so far as the part of the sewer actually in use is concerned) in no respect from an 18-inch pipe sewer, except that it is made of hard brick instead of glazed stoneware.

The only supposable disadvantage attending the brick sewer is in respect of smoothness, and this is more imaginary than real. The pipe sewer, it is urged, has a glazed surface, whilst that of the brick sewer is comparatively rough, and the joints in the latter are much more numerous than in the former. But experience proves that greater nicety is practically attainable in laying the bricks true than in jointing the pipes; and the inequalities in the joints of the latter, though much fewer in number, cause stoppages more readily than the more numerous but smaller inequalites in the joints of the brickwork. Again after a short time, the surface of brick sewers and pipe sewers alike becomes coated with a slimy substance, and practically reduces them to an equality in respect of smoothness.

By here and there laying a few bricks dry (or some equivalent device) at or about the level of the springing of the crown, admission is given to the subsoil drainage far above the level of the ordinary flow of sewage, without at the same time permitting the sewage to escape and saturate the soil.

It is evident, that the enlarged upper portion of the sewer provides amply, and with considerable hydraulic advantage in point of form, for extraordinary accessions of storm-water. Should any of the numerous substances (such as rags, flannels, straw, scrubbing-brushes, nightcaps, kittens, &c.), which cause such serious and often insurmountable obstructions to pipe sewers, get into a brick sewer of the kind here described, so as to block up the ordinary channel, there would still be room enough above for the sewage to pass over them; and (if not removed in the meantime by flushing or manual labour) the powerful force exerted by the next storm would wash them to the outlet.

It is needless to dwell upon the great advantage of the large space afforded by the size of the sewer for workmen to enter it for cleansing or repairing it, for removing obstructions, and for remedying any derangement of the house drains running into it, without the costly expedient of breaking up the street and interfering with the traffic.

---

Appended to Mr. Bazalgette's Report are the respective Reports of the Local Boards of Health of the places to which his Report refers. We have given below a portion of that of Messrs. Robert Dymond and Sons, to Lord Palmerston, respecting the system of pipe draingae at St. Thomas, Exeter.

After detailing the system employed at St. Thomas's and the expenses incurred therein, Messrs. Dymond state, that the works of the Local Board include the construction of tanks to receive the sewage at the outfall. The cost of this portion of the works, including the purchase of about one and a-half acre of land, a right of way, &c., was about 700*l.*, a sum which is not included in the above 1671*l.* 10*s.* 3*d.* These tanks have been let for a term to a chemical manure manufacturer, at a rent which, though moderate, produces a return to the Local Board of about 6 per cent. per annum on their expenditure upon this portion of their works, or about 1¾ per cent. on the total cost of the public sewers and receiving tanks.

All the private drains are formed of glazed stoneware pipes; those receiving the contents of single waterclosets are of 4 inches diameter, and those carrying off the flow into sinks are of 3 inches diameter.

All privies and cesspools have been abolished, and waterclosets have been substituted for them. As a very considerable amount of house drainage has been executed by parties employed directly by the owners of the property, and not by the Local Board of Health, it is difficult to ascertain the exact cost of private works, but the following statement is believed to be accurate:—

| | | | |
|---|---|---|---|
| Average cost of private drainage works, including erection of waterclosets, or conversion of privies into waterclosets, per house | £2 | 17 | 1 |
| Ditto ditto private water supply | 0 | 18 | 1 |
| | £3 | 15 | 2 |

Messrs. Dymond then come to the second part of the inquiry, viz., how the drainage has answered, and whether the pipes have worn out, given way, or been stopped up; and they proceed:—

"The drainage, both public and private, has fully answered its purpose; the public sewers have now been in use for two years, and although, from the level character of the district, the best inclination to be obtained from the 15 and 18 inch main sewer is only 1 in 1000 for a length of 3347 feet, it has proved fully adequate to carry off not only the ordinary rainfall and house drainage, but extraordinary storms. No stoppage has occurred in a public sewer, and the greatest amount of deposit in them has been about 1½ inch. This is removed by the natural flushing afforded by rainy weather. As a matter of precaution, it was deemed prudent to provide a simple means of flushing the most level portion of the main sewer, but there has hitherto been no necessity for its use. In the private drains there have been about a dozen stoppages since the new works have been in operation. The poorer classes were accustomed to dispose of refuse of various kinds by throwing it into open pits in their courts or gardens, which served the double purpose of dust-bin and cesspool. It was not surprising that new habits of order and decency were not in all cases formed as rapidly as the new waterclosets were completed; and hence half the number of stoppages were found to have been occasioned by pieces of flannel, rags, or straw carelessly passed into the drain pipe through the closet pan. These instances are becoming more and more rare as the people discover that the inconvenience and expense arising from such act of carelessness fall on the perpetrator alone. The other cases of stoppage arose from the washing of fine gravel and sand from the surface of courts and paths into the stoneware syphon traps attached to sinks. By a change in the form of the sinks, this difficulty has been obviated; we apprehend that both description of stoppage would have occurred, of whatever materials the drains had been constructed. No pipes have worn out, nor do any exhibit a tendency to do so. In short, a properly-made stoneware pipe may be regarded as imperishable—a quality which is not possessed by any other material employed in the construction of sewers; pipes have occasionally been broken by careless workmen before being laid in the ground, but none have given way afterwards. Although the larger-sized pipes were not formerly of the thickness which we have in our later works thought it desirable to provide; and although a large proportion of these pipes were laid at a depth of more than 10 feet below the surface, no accident or failure has occurred from external pressure, the weight of superincumbent soil, or any other cause. The nature of the ground in which the pipes for the main sewer were laid—a river gravel—rendered it necessary to exercise much care in filling-in the trenches, lest the pipes should be broken by falling stones. The clerk of the works had instructions to see every pipe inserted in its proper direction and level, its bed duly formed, and the filling-in at the sides and top cautiously and tightly rammed. Attention to these instructions has rendered St. Thomas's free from the accidents and failures which have elsewhere occurred from neglect of these precautions."

The result has most completely justified their opinion. Up to about 18 inches in diameter, Messrs. Dymond entertain no question as to the superiority of stoneware over every other material. Below this size it is more economical than bricks, but above it brick is cheaper, and perhaps preferable on other grounds. Stoneware pipes are in their opinion unquestionably the best for house drainage, and they are as fully satisfied of their superiority in public sewerage. The choice of them in other places in which they are engaged in superintending works of this nature is a practical evidence of this. The chief element of success appears to consist in strict and zealous attention to minor details in execution. If this be given, there is no reason to apprehend any damage or obstruction in the main system, and, in the event of their occurrence on private premises, they are readily set right. They have found no difficulty in providing, by very simple means, for the removal of noxious gases generated in the sewers, for flushing if desired, and for ascertaining the locality of any stoppages.

## ON THE DRAINAGE OF BUILDINGS AND STREETS IN THE METROPOLIS.

By W. A. Boulnois.

[*Paper read at the Royal Institute of British Architects, March 20.*]

In venturing to offer a paper on this subject to the Institute, I have not been influenced by a desire to communicate any special experience or information of my own, but simply by a wish to induce a discussion upon the controversy which, as we all know, has long existed, upon the methods and schemes of house drainage. The question lately received a great deal of attention at the Institution of Civil Engineers, and complaints have been loudly made by some of the disputants that their opinions did not receive sufficient notice in those digests or summaries of the proceedings in which the Institution is wont to condense the information derived from a debate. Here they will be able to express their opinions without reservation, none of our principal members being, as far as I am aware, pledged, as they contend the principal members of the other house were, to one side of the question; and they will be reported precisely in proportion to the clearness and accuracy of their remarks.

Every member of this Institute is, I am sure, anxious that the subject of drains should be well ventilated, however doubtful he may be as to the manner in which the drains themselves can best be so. It would really appear strange to any man unacquainted with the deep-rooted prejudices, aud the hot-headed partisanship of Englishmen, that a matter involving their most important interest, their health, their money, and their pride, should not ere this have been fixed upon such principles, that though there might remain a disappointed opposing few, the vast majority would have been entirely of one mind. When we consider the composition and character of the respective Boards of Metropolitan Commissioners of Sewers, since the public has been roused to the need of efficient servants in that capacity, the talent and ability of almost all their officers, we are fairly surprised that a controversy should be still raging as well on the things to be done as the manner of doing them. It is not too much to say that the ablest men of the kingdom have occupied themselves generally with the sewer question. It has been the disagreement of professional men upon details, which has alone prevented their labour from bearing fruit. And now that we are nearer to a settlement of the question, we find that the finances necessary to carry out the measure have not been considered or provided for, as it was not worth while to prepare the way for expenditure whilst the manner in which the money should be spent was undetermined. Surely it should be the earnest wish of all right-minded men, without prejudice against new-fangled notions, as they are termed, on the one hand, or an absurd retention of theories unsupported by practice on the other, to arrive at such a conclusion on this subject as shall obviate the evils complained of. This is not to be done by avoiding controversy within such walls as these, or in papers and pamphlets in which facts and opinions can be stated and refuted, but by abstaining from abuse of all parts of a given system of drainage, because one's own nostrum is not in it; by abstaining from false and overstrained statements of wasteful expenditure as it is termed, because our own nostrum is not experimented upon; and especially from a system of hand grenade penny-a-line warfare, which has been the destruction of all the respect usually felt by the public for bodies of scientific men who are desirous to serve it with honour.

It is a custom with architects now—I think much more honoured in the observance than in the breach—to begin all descriptions of practice with a reference to the ancient methods. I cannot do the justice to this part of the subject which it deserves, and which many here present could, but in confirmation of what was said the other night as to the antiquity of the claims which most modern inventors set up, I may refer to some portions of tubular drains brought from Ephesus and Miletus by my friend Mr. Falkener, which are now on the table. I learn from him that there is ocular demonstration of the use of similar drains at Pompeii; in one case the hollow in which the pan was bedded in the wall clearly indicates its shape; it was on the first floor, and from the curious arrangement of the syphons, which are described as existing in the ornamental arches of the City, we may fairly conclude that the Pompeians had WATER closets. As the drains were laid under the ornamental pavements through the principal portions of the house, and centered in the impluvium passing away in one channel through the prothyrum or passage, we may conclude that probably, from a greater fall, better workmanship, and the constant running of water which took place from the fountain in each house, they did not require to be so frequently laid open as ours do. No excavations have been made which show the size of the sewers in the streets in Pompeii, and it is greatly to be wished that some one competent would investigate this subject—permission would readily be granted for the purpose by the authorities at Naples to any one so well recommended, as an advocate of the pipe system would now probably be, by the Secretary of State for the House Department.

At Pompeii there are indications that the same construction of the street water-courses under the pavement or trottoir, which exists now in the Corso, at Rome, was practised. I have endeavoured to explain this by the drawing on the wall: the water-course is entirely under the pavement, which is of travertine, hollowed to form a series of long arches over it. There are some advantages connected with this method which might warrant its adoption in our streets; a much greater fall could be given to the water-course so as to obviate those elongated puddles, which after heavy rains are not uncommon near the gulley heads in our streets; the kerbs would not be so much worn as they are at present from the custom of using them as trams by weighty carts, and the horses would be relieved from the strains necessary to remove heavily laden vehicles from them. I have been informed that this is the most fruitful cause of jibbing in horses, and that in some parts of London it is a serious injury to the omnibus proprietors.

The pipe drainage advocates having antiquity on their side as regards house drains, it is satisfactory, on the score of an even debate, to find for the large sewer advocates, the CLOACA MAXIMA at Rome. We are, however, indebted for more than would first appear of our present system to the Romans. Our system of sewers originated in the covering in of open watercourses, and at the Fleet-ditch and the Wallbrook sewers, old Roman brickwork is intermingled with modern work, or was until quite recently. The present adaptation of the sewers has been the growth of a long and very costly rule-of-thumb system. All the men who have since Wren's time been consulted about sewers, and they are not few, were probably unable to apply, even if they were acquainted with, the principles of hydrodynamics. They were employed on piecemeal improvements, and it is fortunate for us that the earliest of them did their work so well as to set tolerable examples before the ignorant parish authorities and inefficient surveyors, who, until comparatively modern times, have managed the drainage of London. It is a subject of great congratulation, as it seems to me, that of the 1000 miles of sewers constructed under the Commissioners, and the 50 miles of City sewers, there should be such a large proportion which is useful, when we consider its progressive development, the divided interests which have worked it out, and the uncertain and hap-hazard way in which the extensions to this great town have been made. It is quite certain, moreover, that we have derived all our present knowledge of the subject from the imperfections of the previous works, so that we have in that way largely benefited by the mistakes of our forefathers.

The division of the subject of the removal of refuse from the buildings and streets of the metropolis, which is most simple, and admits of the readest discussion, is into DRAINAGE, SEWERAGE, and OUTFALL. DRAINAGE has to be considered under the head of *subsoil drainage*, *surface drainage*, and *house drainage*. The necessity of subsoil drainage in a locality entirely sublaid by an impermeable stratum, such as the London clay, needs no argument; and though it has been, and is ignored by many sanitary reformers, it is in fact almost as important as the house drainage. Damp soils and damp basements to houses are as constant and as deadly destroyers of human life as all the foul emanations of undrained refuse. The economy of effecting this subsoil drainage by the same sewer which is to convey the house drainage admits of no question, as it seems to me; and it is very efficiently provided for by the construction now adopted in the sewers of the Metropolitan Commission, which are built in cement to the height of the internal flow, and in mortar over this, which admits of the percolation of the water in the soil above and around them. The City has long been pre-eminent in respect of its subsoil drainage over almost all towns in the world.

One of the places most insisted upon as an experimental proof of the efficacy of the pipe drainage is Tottenham. Now there is a portion of Tottenham, lately called Marsh-lane, but now Northumberland Park, where the system of the Board of Health has been most efficiently carried out by Mr. Pilbrow; the houses are well drained, but the subsoil drainage not being provided for, the basements after heavy rains stand in water; the year before last the water rose in the basements of some which I had occasion to visit, 18 inches, and had so saturated the walls as to injure them permanently. Had the drainage been according to the system of the Metropolitan Commissioners of Sewers, this most serious evil would have been avoided, and the house drainage equally good. I am aware that a sufficient fall could only have been obtained at a great distance. and that the present system is the only one the place could yet pay for; but it affords a strong proof of the great gain which, when there is opportunity, arises from the combining the subsoil and house drainage.

The surface drainage, by which is meant the removal of the rain-water, is that branch of the subject which opens up the question of small or large sewers. The rain-water which falls on a given area, would seem to be specially intended for the cleansing of the refuse which may be on the surface, and very good reasons should be given why this is objectionable as applied through the sewers before we depart from so natural and obvious a use of them. The chief reason given by those who seek to separate surface and house drainage is an economical one, the cost of the sewers they say may be reduced to such an extent that you can have two systems, one for house and the other for surface drains, at a less expenditure than you can construct your sewer large enough for both. Now granting for a moment that the systems of small sewers will do for *house drainage*, as perhaps it will in some special and favourable cases, it is unquestionable that sewers large enough for the passage of a man to clean them would be required for the rain-water or surface drainage in this metropolis; the detritus from macadamised roads forms a concrete much more difficult to remove than all obstructions in sullage, and no gulleys (of which one of the best forms as found in the experience of the Metropolitan Commissioners is exhibited on the wall,) are able to prevent this deposit from accumulating in our sewers.

We in this Metropolis, with our levels, if we desire to be able to cross our streets without boats, and occupy the basements of our houses for more than two hundred and fifty out of the three hundred and sixty-five days in the year, must have sewers for the rain-water, not of the theoretical size requisite to carry off a given rainfall, but of size sufficient to admit of these sewers being approached for cleaning. The economical reasoning therefore fails.

The theory so carefully elaborated in some of the treatises on drainage, of forming surface drains literally at the surface, and only covered by the requisite thickness of stone or other material to protect them from the carriage traffic, and admit of their being easily cleansed of the road-dirt, forgets that the front areas and rear portions of London houses, the gardens, and the basement areas are usually 12 or 14 feet below the street level, and totally neglects them.

Having then the necessity for large sewers for the *surface drainage*, and of deep sewers for the *subsoil drainage*, we are next to inquire into their applicability to *house drainage*, or the substitution of other methods. Great improvements have within the last half century taken place in the *house drainage* of the Metropolis independent of the question of the size of the drains. Cesspools are, I believe, no longer contended for. Water-closets are considered essentials by a class of people, whose fathers would have as soon expected to ride in their own coaches as use them; and that periodical and dreadful infliction upon Mr. Paterfamilias of "something wrong with the drains" is, within the houses at any rate, less frequent than formerly. This last effect is doubtless attributable to the general use of the tubular pottery drain; not that all the improvements have been made with it, but because the builders and bricklayers who would not use it, were compelled in support of their prejudice in favour of the old barrel drain, and for the honour of the cause, to build their brick drains somewhat more smoothly than they had been in the habit of doing. The main cause of improvement, however, is the information which was given to practical men by scientific men upon the necessity of an uniform inclination in place of the flat incline and sudden fall near the sewer, which was commonly adopted in house drains, and the knowledge which has reached even housemaids and footmen, that a good scour of water through the drains is better obtained by a plug under the lifted water-closet handle during the coming in of the water supply than by the old and time-honoured expedient of pouring pailful by pailful down the grating in the back area.

Greatly indebted we are to the sanitary reformers on this subject, and we may offer ourselves the same congratulations upon their experience as we do on the practices of our fathers; we know now what to avoid. Their 2-inch pipes from sinks, 3-inch house drains, and 4-inch combined drains, are now as much things of the past amongst practical men as a cesspool under the centre of the front kitchens; 4-inch pipes from sinks, and 6-inch from water-closets, are the smallest which practice has warranted us in adopting. Theory proves, and proves satisfactorily, that a 3-inch pipe with the inclination ordinarily obtainable in London, would be enough to carry off the refuse from a first-class house, but practice has discovered such frequent stoppages even of 4-inch pipes, that they are now scarcely ever used.

I could give the history of numerous and various individual failures which have arisen, but others will occur to all the members. We are sometimes told that these are *preventible stoppages*, and that the small drain gives increased cleansing power to the water in the contents, and is so much better as to warrant the adoption of the means to prevent the insertion of improper substances at greater cost than we are now accustomed to do: in other words, that the trap should be improved and altered. How often would even the 3-inch drain be quite full of water so as to push the substance in suspense before it? This great and inherent evil of *stoppages* is sometimes met by saying that you must teach the people not to put matters down the drain which will cause stoppage, and that a population must be thoroughly imbued with the belief that the omission and commission of sins against the drains will cause a recoil upon themselves in disease and death; but we must change the character of the human mind before this desirable period will arrive; do not men commit sins of omission and commission upon the ducts and sewers in their own bodies, knowing that they will recoil in the shape of disease and death?

The most fruitful causes of the failure of pipes have been the joints; butt joints are specially liable to this observation; when laid in ground which is not very solid and consistent, the lengths are liable to shift, and an irregularity causes a lodgment of a small portion of the matters floating down; once begun, the evil speedily accumulates, the obstruction gathers from each passing substance which is not of sufficient tenacity to resist it, and eventually entirely chokes the pipe.

With reference to whole socket pipes, practical men are divided in their opinion as to whether they are best set in clay or cement; for my own part I think it essential to pipe drainage that no extraneous matter should possibly get into the pipe from the outside, and I think they are best set in cement. All house drains are best waterproof; a stoppage may, if this is not the case, exist for a long time in a drain without detection, as the fluid sewage oozes through the joints and saturates the surrounding ground. In a gravelly or sandy soil this evil may have been proceeding for months without notice. Half-socket pipes I think are the best, as they offer the opportunity of removal without breaking them upon the occurrence of stoppages; and it is more easy to determine when they are accurately laid, the upper semicircles of the two pipes abutting against one another affording a good test of this. The thicknesses of the pipes have, with sound judgment, as it seems to me, been increased by the resolution of the Metropolitan Commissioners of Sewers; they must now be ½-inch for 4 inches, ¾-inch for 6 inches, 1-inch for 9 inches, and 1¼-inch for 12 inches. Beyond this, the Commissioners do not permit pipe drains within their jurisdiction, as they have been found to break and cause great damage and expense.

The glazing of the tubes inside, though very desirable and of indirect utility in causing a better pipe to be burnt than would otherwise be, is not of any material assistance to the flow of the sewage matter through them. There forms in all sewers a sort of slime against the sides and bottom, which is after a very short period as efficacious in giving a smoothness of bore as the most expensive glaze would be. Too much attention cannot be paid to the bedding of the tubes at a true inclination, a very small error in the levels being of much more importance than in a large drain, where there is opportunity for adjustment of an even inclination in the current; it is obvious that 3 inches wrong with a 6-inch tube on a very flat incline, will be equivalent to the stopping up of half the tube.

With reference to the question of using *back combined drainage*, or *a separate drain* from each house to the sewer in the street, there are many considerations which are not usually taken into account by those who advocate the first of these systems. We have seen that street sewers are necessary on account of the necessity for *surface drains*, and that they must be so large for this special purpose as to admit of their being applied also to receive the *house drainage* (I do not apprehend that the most earnest advocate of back drainage ever proposed that the surface drainage of the street should be at the rear of the houses). We have then to consider whether it is better that the block of houses should be drained at the rear in the back courts or gardens by a combined drain which is turned into this sewer at one point, or that each house in the block should have its separate opening into this sewer. I pass by the considerations of invasion of private property involved in the combined back system, and the more serious danger of intentional stoppage and cutting off the drains, of which perhaps nearly all of us here have seen instances, as they are by no means uncommon. I pass by the necessity which in almost all cases there would be, that the combined drainage of the whole block should flow under the end return house, and the much greater liability there would be that a stoppage should occur in the small drain, say 12 inches diameter, than in the sewer in the front, and that all the inmates of houses in the block would be the sufferers for the neglect of one. I pass by these considerations, though they are enough to prevent the adoption of back drainage without strong local reasons in its favour, and I come to the main point at issue between the advocates of one system and the other, viz. the economy. Now, first we must have a drain from the front area in all streets, so that we have the length of the drain from the front area to the water-closets and sink in the basement and the back area, if there is one, to set against the length of the drain from the water-closet and sink to the back combined drain, and the frontage of this combined drain along the house. Almost invariably with modern houses in blocks, there are rear projections, which are quite as wide as the front area, generally they are wider, we have therefore to set the extra length of the pipe in the house (on the supposition that the sink and water-closets are at the rear as they usually are) against the frontage, and we have in this to set 12-inch pipe frontage, and one 12-inch T piece, diminishing to 6 inches against a straight 6-inch pipe through the house. It is clear that in nineteen cases out of twenty, back combined drainage would be more expensive than separate front drainage, provided they were both equally well done. It suits well perhaps with the views of speculative builders in outlying parts of the town, where there are no basements to the houses, and surface drainage is not yet provided for—the parishes not having had the roads and pathways handed over to them—to obtain permission to insert all along the rear of their blocks, before the garden or back court fence walls are up, a cheap 15-inch drain instead of an efficient sewer in the street; but it is of immense importance that their views should not be complied with to the prejudice of the health of the inhabitants of their houses, and the property of the persons who purchase their interest in the houses when they have let them.

Were each man who builds in this country his own freeholder, there would be no question as to the combined back drainage—it would not be tolerated; and because we have a vicious system of leaseholds which enables such propositions to be entertained and to be hailed by some of the small builders, are we to be told that the Commissioners of Metropolitan Sewers, who have wisely permitted the system only under such local circumstances as make it obviously desirable, are neglecting the objects of their apppointment and stifling the truth?

We now come to the second division of the subject—SEWERAGE, by which is meant the arterial drainage from the house drains to the outfall.

We have arrived, in considering subsoil and surface drainage, at the fact, that a sewer larger than the theoretical size is necessary, and after making due allowance on that account, we can with tolerable accuracy determine what should be the sizes of the sewers. As they gradually approach their outfalls they receive increased amounts of drainage from the increased area they traverse; the average of the make of sewage over a given area of inhabited houses in London has been tolerably accurately obtained by experiment.

It is found that in six hours in each day, as much sewage comes down as during the remaining eighteen hours; the rainfall is taken by the engineers to the Metropolitan and City Commissioners at 2½ inches over the entire area, after making proper deductions for the effect of evaporation and absorption in dry ground, and upon the formula of the square root of the hydraulic mean depth, multiplied by twice the fall in feet per mile, minus one-tenth for friction, equalling the velocity in feet per second, the capacity of the sewer can be calculated. It is a fact seldom admitted by pipe sewer advocates, but nevertheless true, that many of the old London sewers are too small, as well as many too large, upon this principle.

It is sometimes forgotten in the controversy on the part of the pipe advocates, that upon true hydraulic principles, the sizes of the sewers as calculated for their drainage capability only, soon reach such dimensions as that pipes are no longer available, even if they answered their ends. Besides, were they laid with reference only to the immediate requirement in places where they would be sufficiently large for it, they do not admit of extension to embrace the drainage of an increased number of houses, a point very necessary to be considered on all grounds.

Pipe sewerage may be said to have been well tried in the Metropolis, and to have failed. On the wall are instances, by no means the worst, of the condition of pipe sewers, as ascertained by Mr. Bazalgette, the engineer to the Metropolitan Commissioners, by their order. Many of these it appears were habitually flushed, and the investigations were made by the officer to the Commission, solely with a view to ascertain the applicability of pipe sewers in the future operations of the Commission. The present shape adopted by the Commission answers, as far as its bottom goes, all the ends of a circular sewer in diminished friction, and as the perimeter widens, it must (by the well-known principle of hydraulics that the resistance of every particle of the fluid is in direct ratio to the perimeter of the section, and inversely as the area of its section) give beyond the semicircle a greater velocity in feet per second.

The sewers now built under both Commissions are constructed upon sound hydraulic principles, and we may hope that there is no waste of public money for want of an ample scientific knowledge, both of the requirements and the best method of answering them.

There are details connected with the sewerage which it is worth while to allude to, as many differences of opinion exist upon them: the ventilation of the sewers is one of these. It is admitted on all hands, I believe, that till we have a perfect water supply, and our sewers are scoured as those of Paris now are, by strong streams of water, provision must be made for the occasional passage of labourers in them to cleanse them. And even when this much-to-be-longed-for time arrives, entrance will be necessary for the repairs, which will be rendered more frequently requisite by the scouring. If the sewers are to have labourers in them they must be ventilated, and it is a question which is the best method of effecting this; many schemes have been proposed.

A direct air shaft leading to the centre of the street is adopted by the Metropolitan and City Commissioners, though they admit that it is open to great objection. A plan which has been used with success in many places, is to connect the rain-water stack pipes with the sewer. Mr. Varley, the water-colour painter, read a paper at this Institute, in 1846, descriptive of this method; his diagram is on the wall. Shafts and furnaces for draft have been proposed, but would entail enormous cost. It has been proposed to compel all persons having steam boilers for manufacturing purposes, as brewers, mechanical engineers, and the like, to admit the foul air from sewers to their chimney shafts; but it is doubtful whether this would answer. The chimney shafts would hardly always be in the highest levels and very long adits would have in most cases to be run to the nearest sewer. Dr. Buckland came down here one day to propose that the gas lamps, in certain requisite numbers, should be connected with the sewers by shafts, and that iron cylinders should convey the foul air outside the stalk of the lamp to the flame, which would consume it, or destroy its noxious qualities.

Some have proposed, that every house to be built or rebuilt, should be compelled to have a flue in the party wall for the use of the Commissioners of Sewers, should they need it, to ventilate the sewer at that part; this does not seem an impracticable plan, and perhaps it will be considered in the New Building Act, which, we have been informed, is now in the hands of the Board of Health. At any rate, ventilation in the sewers must be provided.

Flushing is a point to be noticed in the consideration of sewers. Great improvement has been made in this method of cleansing the sewers, and with a perfect water supply, there is no reason why it should not be extended to such a degree, as to almost entirely obviate other methods, except in flat situations, where raking will probably always be requisite.

A system of flushing has been proposed by Mr. Jennings (whose clever contrivances in connection with drainage details, entitle him to the thanks of all architects and sanitary reformers, and some of whose inventions surround us), in which the accumulated refuse of each day is released at a given moment from a receptacle constructed under each house, any number, say 100, such receptacles being opened at once by the aid of wires and cranks, or electricity, it is supposed a rush would take place down the sewers which would clear everything away with it. Another invention by Mr. Salter, to which my attention has been brought by Mr. Jennings, is the self-acting flushing gate, in which by an outflow pipe from the upper level, communicating with a tilted box on the lower level, or in the side entrance, the sewer itself, when full, forces up a catch lever and releases the gate. It is very ingenious, and is recommended from experience by the authorities at Leeds.

Time will not permit me to treat of the many other matters connected with the sewers, which will, I hope, come out in discussion, but we must pass to the OUTFALL, on which I can say but very little, except that having read digests of all the schemes

submitted in competition to the Commissioners of Sewers, I do not believe there is one except that of Mr. McLean, for intercepting the higher levels, and taking the lower under the Thames at Vauxhall, which is practicable, without such an enormous outlay of money as to quite preclude it from consideration.

Were Lord Palmerston for one week at the Sewers' Office, or even had he to make application there so frequently as we all have, he would have long considered before he took such a violent course as to declare the whole of the proceedings of the Metropolitan Commissioners, since they had been in office, erroneous. Lord Palmerston would have known, that at any rate they had endeavoured to get at the truth; he would have known, that seeing the rock the two previous Commissions had split upon, viz., chimerical scheming in the one case, and a neglect of detail for a grand measure in the other, Commissioners were now only anxious to do their work so that it should be lasting and beneficial. He would have known, that their officers were selected with the utmost care, and that no crotchets now took up the time of these officers; no endeavours to make out cases, which, if proved, could not be carried out without an entire remodelling of the whole Metropolis; no rival schemes within the very executive office of the Commission taking up the time which the public was paying for; and before he took a step likely always to deter sound men from engaging in the public service voluntarily, he would have waited till he was better informed than he could be by a letter containing heads of a controversy, most of which are long since settled in practical men's minds, and every one of which, had he asked information of the Commissioners, they could have given him sound opinions upon.

## IRON CUSTOM-HOUSE AND STORE, FOR PERU.

(*With Engravings, Plate* XX.)

Two large buildings of iron have recently been prepared by Messrs. E. T. Bellhouse and Co., of Manchester, intended for a custom-house and general store for the town of Payta, in Peru. Our Engravings represent these buildings half in elevation, and half in section. These structures have been erected complete in Messrs. Bellhouse's yard, and attracted considerable attention and interest, which was shown by the fact of their being visited and inspected by 25,000 persons in ten days.

The Iron Custom-House consists of a square block, 70 feet each way, of two lofty stories, surrounded by a balcony at the second-floor level, and an ornamental verandah, each projecting 2 yards from the face of the building. The roof inclines upwards from each side, meeting at a square platform 23 feet across, and above which rises a circular tower, 17 feet high, 15 feet diameter, which is surmounted by an upper circular tower and flagstaff. The edifice is inclosed by iron railings and gates, leaving a space of 10 feet on all sides; and the balcony and the platforms are inclosed by ornamental cast-iron railings. The external shell consists of strong cast-iron upright pilasters, and cross-pieces of wrought angle-iron, to which are bolted the galvanised corrugated sheets No. 16 wire gage. In this building, the corrugations of the sheets run in a vertical direction.

We need not here enter into a close description of the details of the building, as a brief account of the construction will suffice in connection with the section and details contained in our engravings. The pilasters are placed, at intervals of about 14 feet, upon base stones, from which they rise to the eave level, where they are connected by a cast-iron moulded eave-plate. From the top of the pilasters spring the trussed rafters of the roof, which incline upwards until they reach the square platform, and are firmly bolted thereto. This square platform consists of a strongly jointed framework of carpentry, covered with 3-inch plank and leaded, supported by columns which spring from stone bases at the ground line. The columns are so placed as to be covered by the partitions, thus being no obstruction to the passages or the rooms. We have previously mentioned the two upper towers, which are of iron; in the lower one is a clock having a four-feet dial.

The floor of the lower story is of 2-inch planks, grooved and tongued with iron at the joints. These planks are fastened down upon cast-iron bearers, which are supported by sleeper walls. The upper floor consists of timber joists, with the floor boards nailed on to the upper edges, and the ceiling boards below. In each story the interior is divided into a main central passage or hall 13 feet wide, with rooms and passages on each side. Stairs lead to the upper story, to the platform, and to the base of the upper tower.

The whole of the sides and ceilings of the various rooms and passages are lined with boarding, upon which Croggon's patent inodorous felt is nailed, which will be papered with a common lining-paper, and finished with coloured paperhangings. Windows, opening in the manner of French casements, afford light to the rooms. The bold projection of the balconies and verandahs, and the attention which has been paid to the details of design in the various pilasters, cornices, and mouldings, under the direction of Mr. E. Salamons, architect, have been productive of a good general effect in this edifice.

The Iron Warehouse or Store occupies a ground space of 120 feet by 90 feet. The walls are composed of strong iron pilasters (Bellhouse's patent), and galvanised corrugated sheets, the corrugations running in a horizontal direction between the pilasters. The entire building is covered by a roof rising to a peak in the centre, the framework of which is composed of trussed principals and bars of wrought-iron, covered with corrugated sheets.

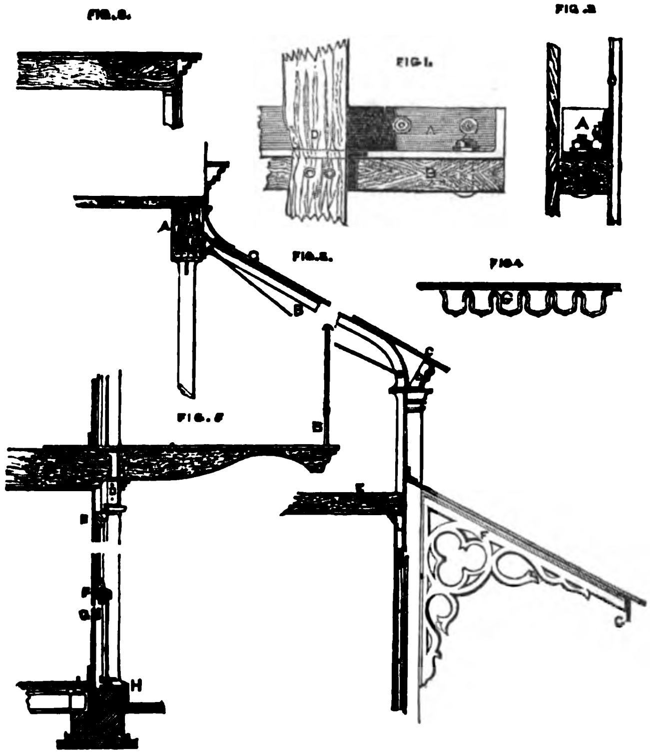

Fig. 1, of the annexed wood engravings, represents a side view, and fig. 2 a cross section, of the cross-bar of angle-iron A, and timber batten B, to which are attached the galvanised corrugated iron sheets on the outside, and the lining-boards D on the inside. In fig. 2, A, represents the wooden beam forming the curb of the square platform; B, the trussed principals of the roof; C, the corrugated iron sheets in the same; D, the cast-iron moulded cornice running under the eaves; E, the ceiling joist; F, the verandah, covered with corrugated iron sheets; G, the pendant, shown in elevation in fig. 4. In fig. 5, A, is the balcony; B, the railing; C, the floor joist; D, cast-iron beam carrying floor joists; E, the window top; F, window sill; G, cross rail; H, cast-iron base; I, the basement floor. Fig. 6, represents cornice and ceiling of the first circular tower, on the top of which rises the upper circular tower.

A covered inclosure, 60 feet by 30 feet, into which carts can be taken, is entered by a main arched grated opening, with gates, 32 feet high to crown of the arch, and 30 feet wide; the interior of the warehouse is entered from this inclosure. Light is admitted to the interior by means of windows at the sides and ends, in which are placed sliding casements for the admission of air for ventilation. Iron gratings are fixed on the exterior, and iron shutters on the inside of these windows.

The execution of these large iron buildings has been intrusted by Messrs. A. Gibbs and Sons, of London, to Messrs. E. T. Bellhouse and Co., and they have been constructed under the superintendence and direction of Mr. E. Woods, C.E., of London.

## ON WATER METERS.*

By J. Glynn, F.R.S.

[*Paper read at the Society of Arts, London, April 19th.*]

The inhabitants of large and populous cities require an ample supply of water, as one of the first necessaries of life; and as the people's wealth and civilisation advance, so does the demand for water increase.

If proof of this were needed, it would only be requisite to point to the splendid remains of the aqueducts and waterworks of ancient times; for the rulers of all nations and ages, except our own, seem to have thought it their duty to provide water in abundance for the health and comfort of their subjects.

In this kingdom, however, and more especially in this great metropolis, the case has been otherwise, and the supply of water has been left to become a commercial speculation and a means of employing private capital.

The consequence of this has been a limited supply, delivered at intervals, and received in cisterns considered large enough to contain as much water as the family of the house required for a day or two days' use; and this state of things continued until the public became so much dissatisfied, that the government has, to a certain extent, taken the matter into its own hands, and exercised the right of the strong against the water companies.

The people require a supply of water, when they want it, and as they want it; the wealthy inhabitants do not wish to be stinted; they demand a constant supply, continuous and unlimited, except by their own pleasure, and to pay for what they have by measure. But they do not want the cisterns: they are cumbrous; they are inconvenient; they get foul. They wish to open their water-tap whenever they like, and to have the water measured as they use it—like the gas—say at so much per thousand gallons.

In consequence of this demand, many ingenious persons have turned their attention to the matter, and exercised their wits upon it, so that not less than forty patents have been taken for inventions for measuring water and other effluent liquids and fluids—some of these machines being applicable to gas as well as water.

These patents bear date from 1824 down to the present time, and the Society of Arts, being sensible how very desirable it is to have a really good water-meter, has twice offered rewards for the best machine of the kind.

The essentials of a good water-meter appear to be the following:—1, that it should correctly measure and show the quantity of water delivered under various heads or pressures; 2, that it should not be liable to get out of order; 3, that it should be easily cleaned, oiled, or adjusted; 4, that the cost be not great, so that it may be generally used by householders. The majority of the water-meters hitherto invented have been deficient in one or more of these essentials.

In the Jury Report of the Great Exhibition, it appears that five of these contrivances were exhibited, but none of them so far perfected as to satisfy the conditions of a good meter. The jury do not even make honourable mention of any one, although they state how very much such machines are wanted.

Among so many inventive minds, it may be expected that their ideas would take various shapes, but as very few ideas are original, so in the attempt to develope that of a water-meter, we find that some other machine or contrivance previously known has been taken as the starting point in most cases.

As the cistern of the London dwellinghouse already mentioned receives and measures the daily supply, and by means of the well-known contrivance called a ball-cock, closes the tap when the cistern is full, it was thought that by having *two* little cisterns with floats in them, connected with inlet and outlet valves, to be opened and shut alternately by the floats, the cisterns might be filled and emptied by turns. Their contents being known, and the ebb and flow of the water registered, a very simple and compact meter for water delivered in large quantities at a low pressure may thus be made.

The same idea of twin vessels, and a reciprocating action by means of a diaphragm or flexible partition, has been further elaborated, something like the gas-meter upon that principle.

The reciprocating motion of a piston in a cylinder like that of a steam-engine has also been proposed, the water making its entrance and exit by means of a slide-valve, and a tolerably good water-meter has been so made; but there is some friction of the piston, slide-valve, "*tumbling-bob*," and other mechanism, which requires some force of head or pressure to overcome. If the force or head of water be considerable, its action is violent, but with an equable and moderate pressure an efficient but not a cheap machine may be constructed on the cylinder and piston plan.

Other forms of the steam-engine have also been proposed for water-meters, such as the disc engine, which combines the rotary with the reciprocating action. The water-wheel on a large scale, revolving in a circular case, has been tried in various ways, and is a favourite scheme, but not a successful one.

The clepsydra, or water-clock, in which water was formerly used to measure time, has been tried to measure water. In this a hollow drum or wheel, divided into chambers, has them filled and discharged in succession, each chamber or division containing an ascertained quantity of water; the wheel halts until it is filled, and moves when it over-balances and empties itself. Machines on this principle, however ingenious they may be, must be irregular in their action, and not suited for varying heads.

After this, come drums of many shapes, some receiving the water at their centre, others at their circumference. Of those taking the water at their centre, some resemble a fan-blast, some are like Appold's pump, and one like Barker's mill, which has ingenious contrivances for obviating friction, for continual lubrication, for straining the water as it enters, and for preventing acceleration of the drum or *mill part*—so to speak—of the machine, for which Mr. Siemens has a patent. There is a machine which is well known to sailors, and which has now for many years been before the public—Massey's Patent Log—for measuring the distance run by a ship. It is shaped something like a screw-propeller, but rather more like a fish's tail, when it uses it as a propeller. Suppose this put into a pipe, it will register the *rate* at which the water flows past. This is another type, and there are modifications of it in portions of screws, drums with spiral vanes, and so forth. Mr. Siemens has a patent of this kind, in which two or three spirals, so to speak, revolve in opposite ways, to prevent acceleration.

There are other forms also, but from what has been said, an opinion may be formed of the difficulties which attend the production of a perfect water-meter at a moderate cost; yet, as in most waterworks now in course of construction a constant supply of water can be delivered at high service to the consumer, it is highly desirable that he should be able to avail himself of such advantages, by using what he pleases, and paying for it by the quantity consumed. It is to be hoped that some water-meter will be invented, or some of those before us will be so improved as to meet the demand, and satisfy this Society and the public.

Since my paper was written—indeed in the course of to-day, upon coming here to see the several models sent in to illustrate the subject—I found there was one meter not mentioned in my paper, the invention of Messrs. Hanson and Chadwick, of Salford, near Manchester. This invention differs altogether from the meters alluded to in my paper both in arrangement and action. It consists of two flat semicircular bags of vulcanised india-rubber, in which the water is in the first instance received, a wire-gauze or sieve being introduced between the supply-pipe and the two inlet-passages. At the other extremities of the bags there are openings which allow the water to pass into the meter. The water, on entering these bags, sets in motion three conical rollers attached to a centre-spindle, in connection with the counting-wheels and dial. These rollers are kept constantly revolving, each revolution registering exactly the contents of the bags. Each bag is kept constantly distended with the water it receives, and as one of the rollers is constantly in advance of the outlet-valve, whilst another is immediately behind it, the quantity discharged is kept up with great regularity. There is one of the machines on the table, and I have this afternoon seen one at work at the New River Waterworks, where it delivered a steady stream of water at various pressures, and registered the quantity so delivered with considerable accuracy, and I am told that the difference of the delivery at moderate and high pressures is only 5 per cent.

## DESCRIPTION OF TAYLOR'S WATER METER.

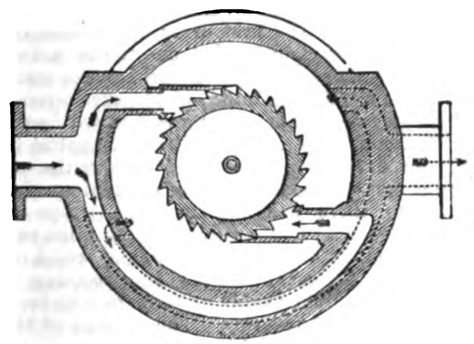
By Benjamin Fothergill.

[*Paper read at the Society of Arts, London, April 19th.*]

The invention of a meter more than thirty years ago for measuring gas, was considered to be the achievement of a most important object; they are now almost universally adopted, and there can be no doubt the result has been a public benefit. A machine for measuring water subsequently claimed the attention of men of mechanical genius, and a great number of patents have been taken out from time to time for water meters, but that which appeared plausible in theory, was found inefficient in practice. About two years ago the Corporation of Manchester advertised for a water meter; this was responded to by a large number of persons, and meters of all descriptions were sent to the Water Works Committee, for their inspection and approval. The meter in question was required to sustain the greatest pressure; the flow must not be interfered with by obstruction or friction, so as to hinder its ascent to the highest point of its source; it must measure correctly under every variety of pressure, and when subdued to the smallest amount of inlet, must indicate the quantity passing through the meter; and durability or non-liability to wear and tear must be an important feature, without which the machine would be of little value.

Mr. T. Taylor, of the Patent Saw Mills, Manchester, has had his attention directed to the subject for many years. He succeeded about twelve years ago in constructing one on the low-pressure principle, which was pronounced by Mr. William Fairbairn, to be perfect in its kind; in his testimonial he said "I have examined Mr. Taylor's Water Meter, and from a careful consideration of the principle upon which it is constructed, I am of opinion that it is one of the most efficient discoveries that has ever yet been made for measuring out and duly registering unapportioned quantities of water, &c." Other individuals also bore the like testimony. Mr. Taylor has invented five meters, all varying in their principle and action; four of these were considered to possess considerable merit, but failed to overcome all the difficulties previously noticed; the last, however, has been pronounced by competent judges to be perfectly satisfactory. This he patented December 15, 1852, and it has been before the Manchester Corporation. Since that time it has had the most severe tests, varying from the highest to the lowest pressure, and the result has been its approval by the Water Works Committee. There are now betwixt one and two hundred meters working in various parts of the country; they have been introduced into sixteen or eighteen towns, and have given universal satisfaction; there is one with a 12-inch bore pipe now working, and it is measuring the water supplied by the Corporation of Manchester to the township of Dukinfield, to the satisfaction of both parties concerned. The first meter made on this principle was fixed up at the extensive cotton-mills of Messrs. Birley, Manchester, where it has been working almost a year and a half, measuring from 35,000 to 36,000 gallons per day, and not the slightest disarrangement has occurred since it was fixed. Messrs. Birley have most confidently expressed their satisfaction in its principle and action.

Fig. 1.—Taylor's Water Meter.



The meter (fig. 1) consists of a cylindrical vessel or cistern, of a sized proportioned to the bore of the pipe that is to receive and discharge the water. Inside the above-mentioned vessel is a drum revolving on its axis in a vertical or upright position, and the stream passing through the meter is distributed upon the drum at each side of the meter. The registration is given by a train of wheels connected with the drum, and carried to the indicator, and by a combination of the under-mentioned mechanical arrangement forms the water meter patented by Mr. T. Taylor. The patentee claims for himself the under-mentioned peculiarities connected with his water meter:—

1st. The vertical position in which the drum is worked, the said drum being constructed of gutta-percha, thereby preventing liability to collapse or corrosion, the said drum being made to the specific gravity of water.

2nd. That the quantity of water contained in the meter be sufficient to cause the drum to be buoyant, by which arrangement the drum is made to revolve by the slightest action of the water against the blades or buckets of the said drum.

3rd. The arrangement or construction of thoroughfares or pipes outside the meter, communicating with the inside and round the drum for the delivery and exit of the water, and for causing a rotary motion in the water, thereby causing the drum, in addition to its buoyancy and vertical position, to be more certain of its liability to revolve under the slightest pressure of water. The construction of valves from the thoroughfares for the ingress of the water, which are so shaped that they bring the immediate action of the stream passing through the meter on the drum. The equal distribution and division of the stream (however small it may be), at each side of the drum, rendering its liability to wear and tear very slight, and whatever the pressure or power of the stream may be, by the above arrangement it is rendered neutral in causing more or less friction upon the axles or pivots of the drum, that being the same under any pressure and only sufficient to keep the drum in its position.

The above-mentioned valves are constructed after the plan of the common clack valve, which closes the apertures of the inlet, excepting a small tube fixed in the centre of the clack, and projecting so as to come into immediate contact with the buckets of the drum; the clacks are closed by a simple arrangement of a self-acting weight or lever above the valve, such weight being regulated by drawing it backward or forward on the lever (which being once regulated becomes a fixture and needs never be altered), so as to give more or less pressure on the clacks. The use or utility of these valves is occasioned by the fact that, although the drum may be neutral, yet there is necessarily a slight amount of friction to overcome in working the train of wheels to the indicator, which is done by the weight closing the clack and causing a compression of the stream, so that no water is allowed to pass but what forces through the clack tubes. This valve is only brought into requisition when a very small quantity of water is passing through the meter, and as the stream increases the leverage of the weight decreases, beyond which the valve is not required to insure correct measurement. If, however, on the contrary, the weight should not decrease in its power upon the valves when the stream becomes greater, and there was an increased pressure upon the clacks (as would be the case if a spring was in place of a weight), the result would be that the measurement would be incorrect, which has been discovered to be the case after repeated experiments with the spring in place of weights.

Its certainty of registration, its non-liability to wear and tear, and its certainty of working under the highest or lowest pressure, is caused by the buoyancy of the drum, its vertical position and the adaptation of the inlet pipes and compression valves to bring the stream, however small, into immediate contact with the drum and causing it to revolve.

The Waterworks Committee have ordered a variety of meters from Mr. Taylor, and, no doubt, as the merits of this invention become known to water companies, they will be generally adopted, and will be found to be a regulator of great economy, and will be estimated by the public as a protector of their just rights.

*Discussion.*—Mr. Chadwick wished, in making a few observations on the subject, to disclaim in the first instance being the inventor of the meter last brought under notice by Mr. Glynn, the design of it having been brought to him by a working plumber, George Hanson, of Huddersfield. He (Mr. Chadwick) was officially connected with the waterworks at Salford, and therefore it was that he had been led to take an interest in the subject, the Corporation being especially desirous that the quantity of water used should be correctly registered. They had tried various meters, but none of them had acted with the regularity and accuracy of that now upon the table (figs. 2 and 3), with which he had been experimenting for the last 18 months. Mr. Glynn had very correctly described the construction of the meter, which he believed had this advantage over all others, that, being air-tight, it would register any quantity of water used, however small, up to 1000 gallons per hour, which other meters would not do.

HANSON AND CHADWICK'S WATER METER.*

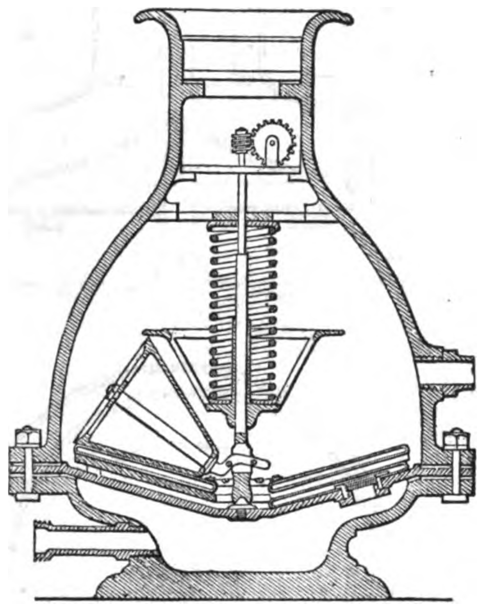


Fig. 2.

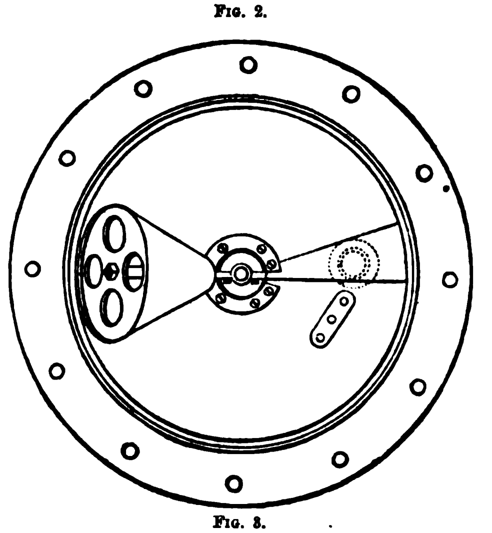

Fig. 3.

In saying this he did not wish to detract from the merits of Mr. Siemens' and Mr. Taylor's inventions, to which he was willing to give all praise. The first objection that would be raised by most persons to Hanson and Chadwick's meter would be as regarded the durability of the material used for the bags through which the water had to pass. He was assured by Mr. Mackintosh, the patentee of the vulcanised India-rubber, that however long it was exposed to the action of the water it would neither decay nor deteriorate; and as regarded wear and tear, from the form of the rollers there would be no friction upon the bags by which they could be injured. He had, therefore, no hesitation in saying that it would last in perfect order at least seven years—Mr. Mackintosh said twenty years. As to an objection that the bags might get unduly inflated, experience proved to him that that could never happen, as, when the rollers passed over the valves or openings in the bags, they never got an impetus in advance of the water; and a pressure of 200 feet had no greater influence upon them than a pressure of 3 feet, the rollers always going before the water. He might observe that he had not brought the meter under notice in his own neighbourhood, and, indeed, the first place in which it had been seen out of the workshop was at the works of the New River Company. He believed that this meter was a good contribution towards the production of a perfect water meter, and if it led to that result he should feel himself amply repaid for all the trouble and anxiety he had had with regard to it. He believed that no meter had yet been made so simple in construction; and having just been asked what would be the expense of it, he might observe that a one-inch meter, such as that on the table, would not cost more than 5*l.* or 6*l.* and a two-inch meter certainly not more than double that sum.

Lord Berriedale (the Chairman) could not allow Mr. Chadwick to depart without returning the thanks of the Society for his attendance there that evening. As regarded the durability of the material of which the bags were constructed, he could in some measure confirm the opinion of Mr. Mackintosh. He had had something to do with vulcanised india-rubber, having used it for springs in an invention which he had patented, and though he had had it at work for upwards of twelve months not one of the springs had broken, though they had been actually subjected to the action of oil instead of water.

Mr. Fothergill, in explanation of his paper, pointed out upon a plan the various portions of Mr. Taylor's meter, and stated that a valve had been so arranged as to regulate the stream of water, however small, so as to prevent too great diffusion, and thus cause it to impinge directly upon the drum. The meter would register 75,000 gallons an hour.

Mr. Siemens said he had, several years ago, directed his attention to the production of an efficient water meter, and Mr. Glynn having mentioned in the paper the result of his labour, he felt called upon to offer to the meeting a brief description of the contrivances he had adopted with considerable practical success. Fig. 4 was a sectional elevation, and fig. 5 a plan of one variety of his meter, and figs. 6 and 7 represented the working parts of another. Although very different in appearance, the two constructions, nevertheless, involved the same principle of action, namely,—the water acted by its impact upon oblique vanes that glided edgeways through the moving column, without interrupting or impeding the same, and that communicated their motion to a counter; the difference between the two being, that in the first arrangement the water moved in a direction parallel to the rotating axis, and, in the second, from the axis outwards. The water entered the meter, figs. 4 and 5 through a grating, and meeting the sides of the inverted cone (*b*), it was directed towards the axis, from whence it spread again outward over the conical block (*c*). The object of this operation was to spread the moving column of water uniformly over a measured annular area, after which there remained only to measure correctly the distance through which that column moved, and to register the same in expressions of gallons or other quantities upon a counter. For this purpose two drums (*d*) and (*f*), were provided, which were geared together, but were quite free to revolve in opposite directions, being made hollow, so as to float in the water, and all side strain upon the bearings being carefully avoided. The first drum was armed on its circumference with a set of right-handed, and the second with a set of left-handed screw vanes, of the same pitch, and of correct form, being cast of white metal in metallic moulds, specimens of which were placed on the table. The water was directed by stationary vanes upon the block (*c*), in a parallel direction against the vanes of the first screw drum, which it would turn in the exact ratio of its onward course, provided there was no friction. In proportion, however, as there was resistance the water would be deflected from its course, and would meet the vanes of the left-handed screw drum in a more obtuse angle, which tended to drive the same at an increased velocity, and, reacting upon the first drum, produced a remarkably uniform rate under the most variable circumstances of pressure. The motion of the drums was communicated to the upright spindle working in the chamber (*g*), where the motion was reduced several thousand times by screw gearing, after which it passed into the upper or counter chamber, through a stuffing-box. The counter consisted of two wheels of 100 and 101 teeth respectively, both gearing into the

* These woodcuts were made from the drawings attached to the specification. Since the patent was taken out, several alterations have been made in the details; the spiral spring has been dispensed with; the bottom of the cylindrical vessel has been made flat instead of inclined; three rollers are used in place of one; and a wire gauze or sieve has been introduced between the supply-pipe and the inlet-passages.

*Siemens' Patent Balance Meter,*

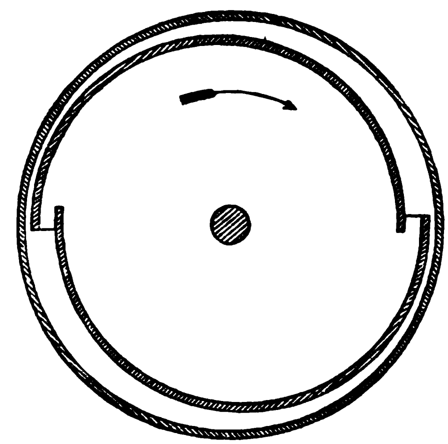

FIG. 7.

driving pinion—the one carrying a dial with 100 divisions, and revolving under a fixed pointer; and the other carrying a hand upon the dial. A reduction of from one to ten thousand was thus obtained, and registered by the two hands. Of these meters a great number had been used, and were found to work very correctly for from six to fifteen months, after which time, however, the spindles were frequently found to be destroyed by the corrosive and gritty nature of the water generally supplied to towns. It was, however, necessary that a meter should work for years without requiring the attention generally bestowed upon mechanism, although placed under the influence of many destructive agencies. These considerations determined him in favour of the construction with spiral vanes, as represented in elevation by fig. 6, and in plan by fig. 7, without the casing and counter, which latter was the same as before described. The water entered the revolving drum through the inlet (*a*), and, spreading outward, impinged upon its spiral sides, which yielded to the impact, and allowed the water to issue through two or more outlets at the circumference. The compensating agencies in this meter were two flys or wings (*c c*), which were dragged with the drum through the water, and which retarded the same in a greater measure at high than at low velocities. By this means, and by judicious proportions between the inlet and outlets of the drum, a rate of motion was obtained which was strictly proportionate to the quantity of water passed through, either at a high or low velocity. The principal advantage in this meter over the previous one was, that it had but one step or bearing, which was effectually protected from the water by working in a closed chamber filled with oil. In like manner the chamber containing the reducing gearing was also filled with oil. Of these meters from 200 to 300 had been in operation for upwards of twelve months, and no deterioration had been observed in their working parts. Both these varieties of meters possessed the essential requisite of overcoming casual obstructions, being powerful reaction propellers. In his experience, he had been struck with the powerful effects of concussions in the water-mains, caused by the shutting of sluice-valves. In some instances a thick brass plate, dividing the counter chamber, had been bulged upwards, indicating a pressure of several hundred pounds per square inch. For this reason he doubted very much the success of a piston meter, or, indeed, any meter which intercepted the flow of the water.

Lord BERRIEDALE said that, having heard the explanations relative to these different meters, the Society would now be glad if any gentleman present would give them a few practical hints on the subject, to point out any defects there might be in the meters before them. There could be no doubt that it was of the utmost importance, in order to insure a proper supply of water, that they should have a good and perfect meter. If they went back to the ancients, they would find that the Romans had constructed aqueducts—splendid works of art, of which no description could give an idea—to convey that most important element of comfort, water, to Rome. When he first saw these aqueducts, perhaps he exposed his own ignorance by expressing his astonishment that the Romans had been so ignorant as not to know that water would always rise to its own level. Had he first visited Pompeii, possibly he should never have made that remark. In that city water-pipes were laid down on the same system as in London at the present time, and it was remarkable that they had not yet the advantage of a good meter, by which every person could tell the quantity of water he consumed, and without which they would never get a good and constant supply of water at high pressure in any town.

Mr. YATES had only heard of the intended discussion that morning, or he would have been better prepared to make some observations on the subject. He held in his hand one of

Harrison's water and spirit meters, which was distinguishable by its extreme simplicity. The peculiarity of this meter consisted chiefly in employing the pressure of the fluid to act against two flexible diaphragms placed between chambers, into which it was admitted alternately, and which diaphragms yielded to the pressure alternately in opposite directions, displacing at every movement from the one chamber a quantity of water equal to that admitted into the other. Motion was thus given to spindles, which was ultimately communicated to the slides for the inlet and outlet of the water-spirit, and to the registering and indicating apparatus.

Mr. Chrimes, the manufacturer of Mr. Siemens' meter, produced a small meter, capable of registering 300 gallons of water an hour, which he took to pieces and explained. He stated, that the great difficulty which existed in the construction of a good meter was, to prevent the water getting to the clock-work, which it was liable to do, and thereby destroy its efficiency. In Siemens' meter this was accomplished by the clock-work of the dial being inclosed in a chamber filled with oil, the oil having the effect of preventing the deposit of calcareous or other matter from the water. The price of the meter he held in his hand would be 73*s.*; one measuring 600 gallons an hour, 94*s.*; 1200 gallons an hour, 5*l.* 5*s.*, and larger ones in a similar proportion. In conclusion, Mr. Chrimes stated that 300 of these meters had been at work during the last year, and that there had been no fracture in any one of them, with the exception that eight or ten had been burst during the late severe frost.

Mr. Greaves, of the East London Waterworks, had attended that meeting rather to learn than to instruct; but he might observe, that knowing the value of securing a correct measurement of water, he had made various experiments, with a view of ascertaining how that object might be accomplished. Hitherto, the meters produced had been of two descriptions—the piston and the screw—to which an addition had lately been made by Mr. Siemens' re-action meter, on the principle of Barker's mill, and by that of Messrs. Hanson and Chadwick, produced that evening, neither of which he had as yet tested. The results of his own trials had led him to the conclusion, that for the measurement of small quantities of water, at a low pressure, the piston-meter was the best; whilst for large quantities and high pressure, the screw-meter was preferable. With regard to Mr. Chadwick's meter, he was himself afraid that there would be great friction, and that a variable supply, through a varying pressure on the bags, would be thereby given. He had a tank, 12 feet wide by 3 or 4 feet deep, for the purpose of trying experiments, and though many inventors had brought him their meters for trial, he could not say that he had satisfactory results to communicate to the Society. It appeared to him, that nothing was more easy than to construct a bad meter—but a good one was the difficulty. Nearly every meter he had seen would register the quantity of water consumed with an uniform pressure and draught, but with a varying pressure and draught the result would be very different.

Mr. Mead was rather pleased to hear what had fallen from the last speaker, as his experience of water companies led him to believe that it was not desirable that they should have such a thing as a meter. Water was six times the price of gas, though the companies did not charge it so, not being able to prove the quantities used.

Mr. Harry Chester, as one of the public, expressed his conviction, that it was highly important to the whole population that they should have a good meter, applicable to every house, as by that means alone could they ever expect to get an improvement in the quantity of the water supplied to them. In his opinion, nothing was more absurd or unjust than the system of charging for water according to the number of rooms contained in a house. He did not say that the water companies were conscious of acting unjustly, because they had not yet found out the means by which they could charge every individual according to the quantity consumed. It would appear perfectly ridiculous, were a butcher to charge for his beef, or a boot-maker for his boots, according to the number of rooms a man had in his house; and, in his opinion, the principle upon which water was so charged was equally ridiculous and unfair. It was highly important to the health of the community, that water of the best quality should be supplied to the public, but there was nothing to tempt water companies to improve their supply. Sometimes, under the temporary influence of parliamentary inquiries or other agitation, they heard of various attempts being made to improve the water supply, but when the pressure passed away, the promised improvements passed away also. Under the present system, competition was altogether out of the question, and the consumer was obliged to take his supply of water from any company which had the monopoly of the district in which he resided.

Mr. Fothergill was in no way interested in Mr. Taylor's meters, beyond being consulted by that gentleman, but he knew that, in Manchester, the proprietors of steam-engines had found the meters very valuable as a means of testing the quality of coal consumed by the quantity of water evaporated. A friend of his who had three meters, told him he was saving more than 100*l.* per annum by the experience he thus gained of the quality of coal from different collieries, which enabled him always to obtain a supply from that colliery the coal from which he found to be most economical.

Mr. G. Cape, Secretary to the Lambeth Baths and Wash-houses Company, would not offer any observations upon the merits of the various meters on the table, as he was not an engineer, but would remark that one of the meters upon Mr. Siemens' improved principle was now in work at the establishment of which he was the secretary, and although it had not been tested by Mr. Simpson, the Engineer to the Lambeth Waterworks, from whence they obtained their supply, he believed it worked accurately, and he knew it had passed 1300 gallons in the space of one minute. He thought it fair to state, with respect to Mr. Siemens' meter, that one had been in use at the St. Giles's Baths and Wash-houses for some time, and that it registered to the satisfaction both of the Committee of that Institution and the Waterworks Company that supplied it. The great desirability of an effective water-meter, that would set at rest the discrepancies between the amount of water that consumers imagined they used and water companies that they supplied, could not be over-estimated. As an illustration of the great difference between the quantity of water supposed to be used and supplied, he might mention, that the Lambeth Baths for some four months were obliged to use water without any method of registration; when the calculations came to be made, the Waterworks believed the Baths' Company had used fourteen million gallons of water, and the Baths' Company, after most carefully going into the matter, felt convinced that, at the outside, they could not have used more than eight million gallons. If a correct meter could have been obtained, this great doubt would not have arisen. He merely mentioned this fact to strengthen the assertions of some of the former speakers, who had shown the great want of a water-meter.

Mr. Wright had had more experience with regard to gas than to water meters, though he had invented one of the latter himself. The meters brought before them that evening were of two descriptions—inferential and absolute measurers. Mr. Siemens' was an inferential and not an absolute measurer, the quantity consumed being inferred from that received by the meter. Such an instrument would never do for small consumers, who only required occasional and intermittent supplies, although it would do very well for establishments in which large quantities were used, and where the stream was kept constantly flowing. In order to be beneficial to the public generally, a meter must be an absolute measurer, and he believed that that could best be accomplished by means of a piston-meter. Mr. Taylor's meter was also inferential, and would therefore be equally inapplicable to the wants of small consumers. With regard to Mr. Chadwick's meter it appeared at first sight to be very efficient, and not likely to get out of order; but any practical man, with a very little reflection, would see that there was nothing more probable than that it would do so. In the action of the rollers upon the bags, if any hard substance got under the rollers, it would stop the egress of the water, and destroy the action of the machine. They could not make the holes of any gauze or sieve so small as to prevent calcareous and other deposits passing through with the water. There was no difficulty in measuring the quantities of water supplied to baths and wash-houses, or other large establishments; indeed, that might be done by a force-pump, or by a variety of machinery of a costly description. What they ought to ascertain was, the average price paid for water by each individual per service-pipe. He calculated it at 6*s.* per thousand gallons, which was about 50 per cent. cheaper than gas. The average cost of gas to each consumer was about 3*l.* per annum per service-pipe, and he did not believe that the average consumption of water per individual per service-pipe exceeded 30*s.* per annum, in consequence of the number of small consumers.

Mr. Greaves stated that the price of water was about 3*s.* per 1000 feet.

Mr. Wright said, that that only carried out his argument. The most economical meter produced to them that evening had been stated to cost 73*s.*, and to fix it would probably cost 10*s.* or 20*s.* more. Now, was it likely that any person would go to the expense of 3*l.* or 4*l.* to measure that which would probably not cost half that amount per annum. If fruit was sold in the street, and scales to weigh it were so dear as to double or treble its cost, did they not suppose that the scales would be dispensed with, and the price better djusted by selling the fruit by handfuls? In order to make water-meters available to the general consumer, they must be supplied at a cost not exceeding 15*s.*, while the fitting-up should not incur a further expense of more than 2*s.* or 3*s.* As he had already stated, there would be no difficulty in making a perfect machine for large consumers, but the difficulty existed in obtaining one sufficiently cheap for general use.

Mr. Yates stated, that the meter which he had produced would only cost 35*s.*, whilst it would measure the water with accuracy to half-a-pint.

Mr. Chester asked Mr. Wright whether he did not think that his argument stood equally as much against gas-meters, which were in general use?

Mr. Wright replied in the negative, as the meter in the case of gas, bore a nearer relative price to that of the article consumed than it would with regard to the water. He had supposed that the average price paid per service pipe by each consumer of gas was 3*l.*, whereas for water it was only half that amount, or 30*s.*, and therefore the water meter ought not to cost more than half as much as the gas-meter. He believed that many small cottages did not pay more than 10*s.* per annum for their water, and how could the holders of such houses afford to pay an additional shilling or two for the interest on outlay, and the keeping the meters in repair? The fact was, that water was much lower in price than gas, and any addition to its cost would press heavily on the smaller consumers, who were not also consumers of gas. There was also a greater difficulty in making a cheap water-meter than a cheap gas-meter, as the water would force its way through the stuffing-box, and thereby destroy the action of the index. The price of the gas-meter for two lights was 24*s.*, and 5*s.* or 6*s.* for the fixing; and looking at the relative price of the two articles, the cost of a water-meter ought not to exceed that amount. In reply to a question from Mr. Chester, Mr. Wright said that the tenant either paid for the gas-meter or rented it from the company at 4*s.* per annum, being an addition of 10 per cent, on the lowest charges of about 2*l.* per annum, which would be a very serious impost on the lower class of water consumers.

Mr. Adams was connected with a company for the supply of water to the City of Amsterdam, where they had 24,000 or 25,000 houses to supply. The capital of the company was 200,000*l.* which had been sufficient to buy the land, pay for the engines, and construct all their works. The authorities of Amsterdam, being very desirous of having the water supplied paid for by measurement, he had inspected a large number of meters, and he found that the price would be about 3*l.* each, which would have caused an addition of 70,000*l.* to their capital of 200,000*l.* This would have necessitated a greatly increased charge to the consumer. He found the inhabitants of Amsterdam very ready to take the water, but there was great difficulty in inducing them to pay for the pipes in their houses, and they would not pay for meters; and the company was, therefore, compelled to resort to the old system of the rule-of-thumb, The company had recently sent over one of Mr. Siemens' meters to be put up at the railway works, and he was quite sure that when an available instrument was invented no water company would object to its general application to the houses of its customers.

Mr. Glynn stated, that Parliament had recently insisted that there should be a constant and continuous supply to the houses of the metropolis, and that could not be done without the assistance of a meter. He believed that the discussion of that evening would, by directing attention to the subject, tend to the production of an instrument through which justice might be done both to the consumer and to the supplier.

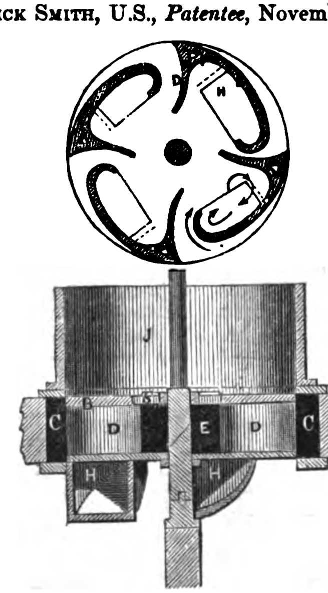
Mr. Foster (the Secretary), to show the injustice of the present system of charging according to the number of rooms, stated that the Society had to pay 8*l.* 8*s.* per annum for their water-rate, notwithstanding that the house was not used as a dwelling, and, consequently, their consumption of water was very small.

Mr. Scott trusted, that when a good system of measuring was discovered, no consideration of expense would stand in the way of its adoption. The necessary arrangements for the supply of water would become a legitimate charge upon the freeholder, as was the drainage of land, and no tenant would object to pay 1*l.* per annum for the benefit of 5*l.*

Lord Berriedale observed, that the objection to the cost of the meters he thought of little moment, as 3*l.* certainly would not go far towards furnishing a house with cisterns, which would be dispensed with by the introduction of the meter, and they would have the advantage of a constant supply of fresh water, whilst it now too often stagnated in the cisterns. He believed that they had very little to complain of in the quality of the water supplied to them, and that if they obtained it constantly fresh, it would be all they could require. He believed that one meter would be amply sufficient even for Buckingham Palace, whilst he could not conceive that one cistern would be of the slightest use in keeping that edifice supplied with water, and therefore there must be a saving between the first cost of meters and cisterns.

## WATER WHEELS.*

Frederick Smith, U.S., *Patentee*, November 22, 1853.



The upper disc B, is open at S, to communicate with the air-tube J, for the purpose of supplying the vacuum with air which the centrifugal force and discharge of the water forms in the wheel around the shaft. The water enters the wheel from the scroll pitch C, C, and acts first upon the buckets D; the water then follows the direction of the arrows along the bucket E, and H, and thence reacting on the bucket H, leaves it. The inventor says in his specification:

"A powerful force assisting in producing the curvature of the current of water as it leaves the inner end of the bucket D, is imparted by the strong draught of air through the tube J. This draught of air rushing into the wheel to supply the vacuum created as aforesaid, and assuming the natural lines of egress consistent with and induced by the arrangement of the wheel and its forces when in motion, acts upon those parts of the wheel over which it passes, producing in a greater or less degree the same effect as the water, thsu giving additional force to the action of the water in its discharge over the buckets H. One of the objects of the buckets E, is to keep the water out to the periphery of the wheel until it acts upon the buckets D. A portion of the buckets D and E, are inclined inward towards the water at the top for the purpose of giving the water a more direct action upon the buckets H, H. By this method of constructing the wheel the water is made to act directly upon the buckets D, D, and then flows round an easy curve previous to being discharged, and is made to act again directly upon the buckets H, H, from which it is discharged in a direction contrary to the motion of the wheel, thus combining the advantages of the impact and turbine wheels more fully than in any other.

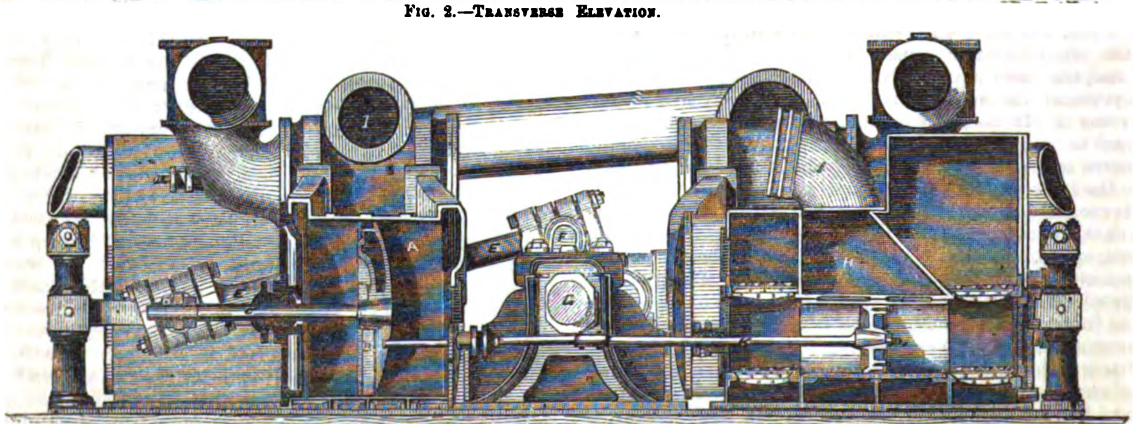

FIG. 3.—TRANSVERSE SECTION.

## DIRECT-ACTION SCREW ENGINES.*

DESIGNED AT THE ROYAL NAVAL ENGINEERS' CLUB, PORTSMOUTH.

It is gratifying to find that some, at least, of the engineers of the Royal Navy are not behind others of their class, in effecting improvements in screw propulsion, as the present invention sufficiently proves. The designers of the arrangement we are now about to bring before our readers do not lay claim to any great originality, their object being to bring together the best parts of all the known engines of the most eminent manufacturers, and to arrange them so as to obtain connecting-rods of greater length than any heretofore employed in such engines, and so as to admit of easy access to, and removal of, any parts that may become deranged, while the space occupied by engines of their construction will not be greater than that ordinarily necessary. The inventors attach particular importance to the increased length of connecting-rod obtained, believing it to be indispensable to the efficient and easy working of the engine, especially for high velocities.

The cylinders are on the principle of Messrs. Maudslay and Field's double-cylinder direct-action engines for paddle-wheel steam ships, but are placed horizontally instead of vertically, and with a different arrangement of the working parts, the cylinders having only sufficient space between them for the introduction of the connecting-rod, the T-cross-heads and lower guides being dispensed with, and the pistons attached directly to cross-heads of the ordinary form. In this manner great strength is combined with simplicity, and means of getting at the cylinder-glands, guides, &c., while under way, as well as at each of the connecting-rod bearings, are afforded. The air-pumps are fitted so as to give easy access to the valves, the pump-rods being worked directly from the piston. The slides, of which there is one for each pair of cylinders, are themselves cylindrical, the interior portion forming the induction pipes, the exhaustion taking place from the exteriors of them. By means of the belt round the slide casings, the required area of steam passage is obtained with a reduced travel of the valve, and a communication between the two cylinders is afforded, and thus the pressures on the two pistons are equalised, and the injurious effects that might arise through leakage are prevented. The feed and bilge pumps are placed between the cylinders, and worked directly from the cross-head, and the expansion-valves are fitted to the end of the slide casing, with the slide-valve passing through its nozzle. The slides are worked by the link-motion, and the arrangement of the starting gear is such, that the engineer is in direct communication with the stoke-hole, and thus has the engines and boilers both under his control at the same moment. The surfaces favourable to the radiation of heat, and those exposed to friction, are not greater than the corresponding surfaces in existing engines, but are, on the contrary, less than in many now adopted for screw propulsion.

The simplification of the arrangement of the working parts of screw engines obtained in this arrangement will be peculiarly favourable to the prosecution of examinations and repairs, giving ample room for these, at every part of the engines, and obviating the necessity of making the cylinders single and of very large dimensions, a practice which it is very desirable to avoid, for large cylinders, when priming to a considerable extent, as is frequently the case, occasion great apprehension and anxiety, and at times cause considerable damage, by bending the piston-rods, splitting the cylinder-covers, &c. We need scarcely add, that these engines will be found peculiarly applicable to all large screw vessels, such as our steam ships-of-the-line, and the Eastern Steam Navigation Company's monster ship of 10,000 tons burden.

The accompanying engravings represent a pair of marine-engines arranged according to this invention, fig. 1 being a plan, fig. 2 a transverse elevation, and fig. 3 a transverse section. A A, are the steam cylinders on one side of the ship. $A^1$ $A^1$, are those on the opposite side. B B, $B^1$ $B^1$, and C C, $C^1$ $C^1$, are respectively the corresponding pistons and piston-rods, the latter of which carry the cross-pieces D, $D^1$. Attached respectively to the centres of these cross-pieces D, $D^1$, are the ends of the connecting-rods E, $E^1$, the other ends of which are pinned to the crank-arms F, $F^1$, on the shaft G. H, $H^1$, are the condensers, of which the former is connected by the pipe I, to the cylinders A A, and the latter by the pipe J, to the cylinders $A^1$ $A^1$. K, $K^1$, are the air-pump rods, of which K, is directly attached to one of the pistons B B, and $K^1$, to one of the pistons $B^1$ $B^1$. The slide-rods L, $L^1$, are worked by the arms M, $M^1$, attached to the axes N, $N^1$, which have a rocking motion communicated to them from the link motions by means of the rods O, $O^1$, and the arms P, $P^1$. The remaining parts of the engines will be readily distinguished, and the arrangement of them understood from the remarks we have already made.

* From the 'Mechanic's Magazine,' No. 1596

## INSTITUTION OF CIVIL ENGINEERS.

*March* 14 *and* 28.—James Simpson, Esq., President, in the Chair.

Portions of these two evenings were devoted to the Discussion of Mr. Yates' Paper, *"On the Advantages of Uniformity in European Weights, Measures, and Coins"* (*ante* p. 154).

Reference was made to the practical working of the proposed change of the present currency to the French decimal system, and the numerous inconveniences to which commerce would be subjected in the re-adjustment of all contracts, debts, exchanges, &c. The intricacy of settling accounts would be infinite, and no corresponding advantage would result. The "franc" shown in the scheme, was not in reality equivalent to the French coin of that denomination; it was tenpence, and all the other coins would be equally fictitious.

Itwas assumed, that the first step towards fixing a decimal system must be the adjustment of the proportional value of the present coins, and eventually of a new issue; a corresponding arrangement of the weights and measures would soon follow. So many propositions of systems had been published, that it seemed as if every person who devoted attention to the subject had tried to invent a new scheme, rather than to devise the method of arriving at a decimal system with the greatest facility and the least derangement of the public convenience.

The following technical points were then considered with regard to coins:—1st. The standard of fineness; 2nd. The relation of coins to the denomination, or money of account, of the country wherein they circulated; and 3rd. The metallic standard.

*First.* The standard of fineness depended on the quantity of alloy introduced in the process of manufacture, or coining. If this were identical in all countries, great trouble would be avoided, but it was argued, that practically such an accordance was scarcely attainable, and in fact, that a table of exchange values met the difficulty of the present discordance.

*Second.* In order to show how difficult of attainment would be an assimilation and interchange of British coins with those of other countries, it was argued that in the United States of America, where the currency was practically based on a gold standard, the eagle, whose value of ten dollars = about 2*l*. 1*s*. English, and the half-eagle = 1*l*. 0*s*. 6*d*. or very nearly the English sovereign, it would be necessary to raise one standard, or to lower the other, in order to do away with the apparent difference of 2½ per cent. now existing, and this would involve the re-coining of the whole circulation of one or the other country, at a certain and great expense, and at the imminent risk of complicating all existing pecuniary engagements. It was urged, that the scheme of assimilating the present coins to the French franc, &c., was equally fallacious; in fact, that the new franc would only be 10*d*. English, and not of the exact value of a French franc, which equalled 9½*d*., and so on for the rest of the proposed series, thus showing a real difference of 4¼ per cent., which was too much to be sacrificed in mercantile or monetary transactions.

The dollar was argued to be equally fallacious as the unit, inasmuch as the various dollars of the several countries, and even of the same country, had different values, and not one of them possessed the precise value of fifty pence English, which had been assumed.

The case of the British North American colonies was quoted, as an example of the confusion resulting from the use of similar denominations of account, without identity of value. The result being, that in no two colonies did the nominal pound represent the same value.

*Third.* That which opposed the most serious obstacle was the metallic standard; there could be no real par of exchange between countries, without a previous agreement as to adopting either a gold or a silver standard, because the relative value of the two metals was constantly fluctuating. The discovery of gold in California and in Australia, followed by an excessive demand for silver for the East, would probably produce great changes; even at this moment, gold was partially displacing silver as a standard in France, where there was apparently in progress a change similar to that which had taken place in the currency of this country during the last century, ending in the final adoption of a gold standard in 1816; and it appeared very probable that gold would become the standard in France, as it was here. It was presumed that the advocates of the franc did not mean to return to a silver standard, as the greatest confusion in the monetary system must be the result.

The pound sterling being now admitted to represent the value of the quantity of gold contained in a sovereign,—all the siver and copper coins being mere tokens, representing certain fractional parts of the pound,—all pecuniary engagements had reference to the pound, and silver was a legal tender only up to forty shillings. It was argued, that the money of account should correspond with the money upon which existing contracts depended, and therefore the pound sterling should be decimalised, rather than attempt a spurious adaptation of the coins of this country to the system of any other nation. Any coins could be used provided their relative value to the integer was well understood, and that integer should not be less than the pound sterling. Wages were calculated in shillings by the artizan,—he knew that twenty of these shillings equalled a pound, and the subdivision of the shilling was of little importance to him, provided the value of the coin was low enough to represent the small articles suited to his means. This was the chief argument against the adoption of the "poor man's useful, precious penny," which had been strongly advocated. If the pound was adopted, the actual value of the present penny being stamped on it, would enable it to circulate without entailing any loss, and the new coins, as they were issued, would bear their correct relative value.

It had been stated, that the proposal of the penny as the integer had received the approval of the Chancellor of the Exchequer, but this was contradicted from authority; no particular scheme has as yet received official sanction. It was admittted, that during the progress of the change to the decimal system, some inconvenience must be experienced and be submitted to, but the embarrassment would not be excessive nor of long duration.

It was urged, that if the value of ten shillings was adopted as the integer, a simple scale of coins would be

| | | |
|---|---|---|
| 10 mils | = | 1 penny. |
| 10 pennies | = | 1 shilling. |
| 10 shillings | = | 1 eagle. |

This, like most of the other schemes for adopting a new nomenclature was disapproved.

It was contended, that the present was an appropriate moment for the proposed change, as there was a somewhat similar movement in the United States of America;—the Zollverein had held a monetary congress, and almost simultaneously there had been a meeting at Brussels relative to the international adoption of Lieutenant Maury's system of naval observations. The simultaneous change of coins, weights, and measures, was therefore urged.

On the other side it was contended, that any rash attempt to adapt the monetary system of this country to that of any other, must be productive of the greatest confusion, and of the most disastrous effects in all mercantile and financial transactions. After reviewing the history of English coins and weights from the period of the Norman Conquest it was shown, that the present gold standard tended to maintain the purity of the coinage; that the franc was not and could not be 10*d.* of the current coin; that the subordinate coins to the sovereign, being only tokens, none of them could be assumed as the integer; that the time was fast approaching, when, in France, the example of America must be followed, and a gold standard must be adopted; that the value of an English sovereign was so generally recognised, that it passed current in almost all countries, especially on the Continent; this might be due, to a great extent, to the care in the manufacture at the Mint and the critical supervision at the Bank of England, where any sovereign having lost more than three quarters of a grain in weight was detained, as being unfit for circulation; this perfection of examination was due, in a great measure, to the weighing and sorting machines of Mr. William Cotton, which had been described to the Institution. The present system being so nearly decimal, it would suffice to declare by Act of Parliament that the pound should be divided into 1000 farthings, and the change would soon work itself, practically, into all commercial transactions; during the transition, the present coins would be stamped with a decimal value; the actual loss would be only a small per centage on the value of present copper coins, and the new ones would at no very distant period displace them. The same process would take place with weights and measures, and in all cases the adoption of a new nomenclature was specially objected to.

The system proposed by General Sir C. W. Pasley in his work on the subject was described, and a statement was promised to be appended to Mr. Yates' paper, by which it was contended, that it was demonstrable that a simplification of the present English coins, &c., would be more advantageous than the adoption of any of the foreign systems, none of which were adapted to the commerce of this country.

After reviewing the arguments of the previous speakers, it was contended that the opposition to the author's views was untenable, as the benefit to be anticipated from the introduction of a decimal system was admitted, and it was only urged against it that it would be impracticable to get all countries to agree. Now, if England and her colonies adopted the system, already accepted in France, and which had made great advances in other continental states, there would be so large a preponderance in commercial transactions, that other countries would soon follow.

As to the anticipated debasement of the standard coin in any country, it was contended, that this would only occur in the event of war, and in violation of the international treaties which it would be necessary to make for establishing identity of values of coinage, and these exceptional cases should not preclude the adoption of a certain benefit. The only instance of such an occurrence, in time of peace, was that of a petty German principality whose coinage being debased, ceased to be received in exchange, and thus the disease brought its own remedy. The case was mentioned of the Zollverein, now including many millions of the German population, and of the *conventions-muntz*, generally passing current throughout the States, where there was a great diversity of coins. The southern States issued their several coins according to an arrangement, which insured an interchange between them; in fact, at Frankfort, coins of all the States were issued indiscriminately by the bankers. How much simpler would it have been to have taken one decimal system for all. If that were done in the case of England, francs and other pieces, bearing the British stamp, would pass as currently everywhere as the French coins were received in Belgium.

It was contended, that the arguments used against the French system of weights, measures, and coins, had only demonstrated its beauty and fitness for nations in all stages of civilisation; and this had been proved by the progress made in its establishment, not only in France, but in almost all countries, when accuracy of observation for scientific purposes was demanded.

It was argued, that any low denomination of coins, such as centimes, might in time be substituted for the *cowries* on the western coast of Africa, of which as much as 1000 tons had been brought in one year to Liverpool, to be re-exported for again trading on the same coasts.

The argument of the national feeling being opposed to fixing upon the franc for the unit, instead of the pound sterling, was urged to be unfounded, as the scale of coins showed that the existing sovereign and most of the other coins were retained for actual public service, when, if necessary, they could be stamped with their decimal value, and these would be used as long as they lasted; thus the new issue alone would be the radical change; and then only when everybody had become accustomed to the system.

It was contended, that in spite of the disinclination to change manifested by some persons, there was a very general desire in the mercantile community to substitute a decimal system of some kind for the present inconvenient mode of calculating; and assuming the French system to be that which had received not only the most careful consideration before adoption, but having now had the advantage of nearly half a century of practice, it was fair to presume it to be preferable to most of the schemes placed by their inventors before the public; and it was argued that the lower classes would have no difficulty in understanding and adopting so simple a system as that used in France.

As to standard measures of length; the origin of the metre was submitted to be more scientific and less rude than that of the yard; and the nautical mile, although very generally accepted in almost all countries, was based on the yard, which was merely an accepted or arbitrary standard, and therefore should not be the basis of a system.

As to weights and measures of capacity; the French system appeared to be based on such a simple and convenient standard, that it seemed impossible not to admit its advantages, and it was contended that no valid arguments had been opposed to it. All the weights and measures were, in practice, divided by the binary system, or into halves, quarters, eighths, and sixteenths, although it had been stated that such a subdivision was incompatible with the decimal system.

As Belgium had legally adopted the French system, and it had been generally received with favour, except in very remote villages, so it had spread to those of the German States most contiguous to France, and as its advantages became appreciated, so would its use be spread more widely. Convenience alone should not be studied for any system; to be perfect, it must possess exactness, convenience, and uniformity; and these attributes, were it was contended, eminently exhibited in the French decimal system.

It was related, that at about the period of the introduction of the sovereign to supersede the guinea, when Mr. Babbage was considering the details of the machine for calculating tables by difference, he essayed every other system, but was obliged to return to decimals; this turned his attention to the means of adapting the English coinage to a decimal scale; his proposition was to accomplish the end gradually, by the introduction of a silver coin of the value of two shillings as the unit,—calling it a "Prince." Then, after a time, to divide the pound sterling into one thousand farthings; other proportional new coins being gradually introduced, as the old coins were withdrawn. The question of the most convenient coins for commercial purposes was entirely apart from establishing the decimal system. These views were repeatedly but ineffectually impressed on the government of the day, but the only publicity given to Mr. Babbage's views was in the second edition of 'The Economy of Manufactures' in 1832. The delay in adopting some scheme of the kind had permitted the issue of nearly eleven millions and a half of half-crown pieces, and so far had interposed greater difficulty in the substitution of decimal coins for those now in use.

It was proposed, as a means of aiding in familiarising the public mind with decimal divisions, to have engraved on all thermometers, the Centigrade, as well as the Fahrenheit scale, so that in time the latter might be dropped and the former be adopted.

It was contended, that for all practical purposes of commere, and for professional and scientific calculations, it would be most convenient to take the sovereign as the integer, to divide it into shillings of the value of ten pence each, and the penny into five farthings; thus, in point of fact, the whole of the existing coinage would be brought as nearly as was practically necessary to a decimal system; and the present coins would be used until they were worn out, and they could be replaced by a new decimal currency.

The objection of the Astronomer-Royal to the adoption of the metre as a standard of length, was contended to be valid; there was no advantage in obtaining a standard from astronomical and other observations; in fact, the present standard yard, as recognised by law, appeared to be sufficient for all practical purposes. His proposition as to the chain and link was not, however, agreed to. On the contrary, it was argued, that by dividing the present foot into 10 inches, instead of 12 inches, and the inch into ten parts, a scale which was familiar to all draughtsmen and to many artizans, would be introduced, which would be easily understood and would soon be adopted. The foot would be divided into 100 parts, instead of into 96 parts; so that $\frac{1}{10}$ might be substituted for $\frac{1}{8}$, with very slight disadvantage. In which case the link of the measuring chain, instead of being represented by 7·92 inches, as at present, would be represented by 6·6 inches, which would be a very convenient proportion for calculation, and it would possess the additional convenience of enabling the superficial inches in a link to be represented by the same figures as those of the superficial feet in an acre; viz., 43·560 inches in one square link,—and 43,560 square feet in one acre.

As to weight, all that could be required was for the legislature to decree, that it would recognise no conventional values for the cwt. or the ton; but that the cwt. should be represented by 100 lb.. and the ton by 2000 lb.; the stone being then 10 lb. The lb might, if necessary, be decimalised, as it was at present by the bullion dealers, for the special requirements of that commerce; but even without that, the chief facilities would be acquired, and practice would soon render the system familiar and convenient.

It was considered of great importance to retain the present denominations, especially for mental calculation, which was so much practised, from the smallest retail traffic up to the most important branches of commerce and financial transactions.

*March* 28.—The discussion was taken on Mr. D. K. Clark's paper, "On Ruthven's Propeller" (*ante* p. 156).

It was contended that there was no novelty in the system of propulsion proposed by Messrs. Ruthven. Benjamin Franklin was among the first to notice it; he related, that as a boy, whilst bathing in a pool into which a wooden pump had been thrown to swell the timber, he got astride upon it and commenced pumping: to his astonishment he found that he was propelling himself across the water; subsequently he investigated the circumstances, and admitted the inefficient application of power. Sir Isambard Brunel attempted propulsion by means of a tube in which there was a diaphragm pushing the water before it, and acting upon a very light valve on the return stroke; this was only an elongated paddle-wheel with an intermittent and inefficient action. Mr. Bidder tried the system also, on board a canal-boat, and although quite aware of the loss of power incidental to it, he expected a compensation from the advantageous application of steam as opposed to animal power.

As to this particular case of Ruthven's and other similar propellers, it was argued that the reasoning in the paper was as totally at variance with the actual results of the experiments as with the received laws of hydraulics. To show this, it sufficed to state that according to the paper, the useful effect realised was 64 per cent. of the power of the engine, stated at 40-horse power (indicated), which would give 25½-horse power useful effect; but it was stated in the experiments that the nozzles were 10 inches diameter each = together $1\frac{1}{10}$ square foot area. The head of water was $8\frac{6}{10}$ feet = to a pressure of nearly 540 lb. per foot, or to a total pressure of about 580 lb., which represented also the resistance of the vessel at 9½ miles per hour, giving therefore a useful effect of 14¾-horse power, instead of 25½-horse power, as stated in the paper.

It was an error to state that the maximum of useful effect was when the velocity of the issuing water was equal to that of the vessel, or when the water dropped vertically from the nozzles; it could be shown that in that particular condition there was not any development of useful effect. The actual operation of the system of propulsion was then shown to be analogous to the assumed case of a closed vessel of any shape, filled with a fluid of given density, and under a given pressure; it was evident, that so long as the vessel remained in that normal state, no propulsive force would be exerted in any direction, the whole being *in equilibrio;* but on an aperture being made in either of the sides of the vessel, it was obvious, that the area of the opening being relieved frrm pressure, the equilibrium would be disturbed, exactly by the extent of that aperture into the head, and there would be a corresponding force exerted in the opposite direction.

To apply this to the case under consideration, a vessel must be imagined, containing water under a pressure = to 3 feet, which was the head due to the velocity of the vessel, in the experiment. By making an aperture of about 3¼ feet area, there would be an unbalanced pressure of about 580 lb., equivalent to that of the former statement; but the velocity of issue would be 14 feet per second, and the power used would be about 15-horse power. But if the aperture was assumed to be reduced to $1\frac{1}{10}$ square foot = the area of the two nozzles; then it would require $8\frac{6}{10}$ feet head to produce the same pressure. The velocity of issue would be 23 feet per second, and the power would be about 25-horse power; thus the power required was exactly in the ratio of the velocity of issue, or inversely as the square root of the head. The loss was therefore 60 per cent. instead of 12 per cent., as stated in the paper.

But the fundamental error in the paper, was the omission of the loss of power arising from picking up the water in a state of rest, and communicating to it the velocity of the vessel. Supposing the water to be composed of an infinite number of globules, possessing weight, and being in a state of rest, they must all be raised to the head due to the velocity of the vessel, and then to the additional head requisite for propulsion. In the present case, the quantity of water issuing from the nozzles was 25 feet per second; this required to be raised 3 feet, to be equivalent to the velocity of the vessel—demanding therefore the exertion of 9-horse power. The results of the experiments would be more correctly stated thus:

| | Horse Power. |
|---|---|
| Useful effect | 14¾ |
| Power consumed in raising the water to the velocity of the vessel | = 9 |
| Power used in propelling the water through the nozzles | = 25 |
| Total power expended, exclusive of the friction in the water-ways and of the engine itself | = 34 |

The absence of indicator diagrams was regretted, as tending to throw a doubt on the results; but it was admitted that the boiler surface, and the actual consumption of fuel, bore out the statements of the paper.

It was contended in reply, that though engine power was consumed in getting the water up to the speed of the vessel, it did not necessarily follow that an equal amount of power was further required to expel the water. This single employment of power could be arrived at by properly forming the water passages, so as to avoid all concussions of the water by rectangular bends, or by sudden enlargements or alterations of form; and the desired object was stated to be, so to proportion the dimensions of the engine and the propeller, that the effluent speed of the water in one direction would be equal to that of the vessel in the other. In this case it was stated, 100 per cent. of the engine power, minus fractional resistance, would be usefully available.

That, practically, there were situations in which such a propeller might be found very serviceable. For instance, in crowded rivers, where paddle-wheels were objectionable, amidst ice, in shallow water where the screw was not available, and in many other situations, where any great projections from the sides of the hull were undesirable. As an example, it was stated that it would be very desirable for the purposes of the Fire Brigade, to have the means of bringing up the large floating-engine at all times of the tide and under all the circumstances of ice, of an encumbered stream, or of shallow water, at a speed of ten miles an hour, propelled by its own engines. Experiments had already been made upon one of the floating-engines, which although very imperfect were sufficient to prove the adaptability of the system to the wants of the Fire Brigade.

In fine, it was contended, that although there still remained much to be done to demonstrate the practical efficiency of so great an innovation, the experiments were sufficiently successful to induce further investigations, and which the author was requested to continue and to report to the Institution.

*April* 4.—After the reading of the minutes of last meeting, it was observed that the statements in the paper on Ruthven's propeller had been misunderstood; as it had been assumed that the paper stated the useful effect realised as 64 per cent. of the whole power of the engine at the pistons; whereas it was really stated to be 50 per cent., and that the useful effect was 64 per cent. of the power delivered to the wheel-shaft: which would materially affect the deductions then made. That one most important element in the calculation was lost sight of, namely, the duplicate pressure of reaction due to the efflux of water through the side of a vessel at rest; the whole unbalanced hydraulic pressure being twice the hydrostatic pressure due to the height of the column of water. It was contended, that this duplicate pressure must exist to some extent so long as the effluent velocity of the water exceeded the receding velocity of the vessel; and that it diminished in some ratio with the receding speed of the vessel, and vanished only when the vessel had acquired the effluent velocity of the water,—when the simple pressure due to the head of water remained. Therefore, that some allowance must be made for this duplicate pressure; and that, assuming it to decrease uniformly with the difference of speeds, the power would be thus estimated when the speed of the vessel was 62 per cent. of that of the effluent water, leaving 38 per cent. of excess:—

$1 \times 100 = 100$ per cent. when the speed of the vessel was equal to that of the effluent water;

$1{\cdot}38 \times 62 = 85{\cdot}56$ per cent. when the speed of the vessel was 62 per cent. of that of the effluent water:

Leaving 14·44 per cent of loss, by excess of speed, as originally deduced in the paper.

It was added, that the proportion of the useful effect would be more simply estimated in the ratio of the squares of the speeds, as was done in the paper, thus:—

$$100^2 : 38^2 :: 100 : 14{\cdot}4 \text{ per cent.}$$

The proposition of the power employed was reduced nearly to common algebra, by separating the various causes and effects: the useful effect, in proportion to the power employed, was shown to be a maximum when the speed of the boat was equal to the velocity of the effluent water, the "vena contracta" being taken into consideration. The ratio of useful effect to power employed was shown to be $\frac{2\ N}{N^2 \times 1}$. The velocity of the effluent water being to the velocity of the boat as N to 1.

It also appeared, that taking the sum of the useful effect, that is, in driving the boat, added to the effect not so employed or wasted, was in all cases equal to the power employed; it was of no importance, theoretically speaking, whether the water was pumped up from the bow, the sides, or the bottom. The subject was investigated in three different ways, each giving the same result.

It was stated, that in 1848 Mr. Purkis being engaged in the construction of a fan-blower, thought the same principle might be adapted to the propulsion of a boat, and tried it in a model, about 4 ft. long and 8 in. wide, with a small engine and two fans, each 2 inches in diameter; with this he attained a speed of three to four miles per hour. He then built another boat 25 feet long, and 4 feet wide, fitted with an engine with two cylinders 4 inches diameter and $4\frac{1}{2}$ inches stroke, driving two fans 12 inches diameter of the same form as the fans of Appold's pump; the water issuing from two orifices, each of 25 square inches. With this apparatus, the boat could only hold her way against a tide of about 3 miles an hour. On the substitution of two fans of 7 inches diameter and the reduction of the propelling orifices to 7·75 sq. inches each, the boat attained an estimated speed of nearly 8 miles an hour. It was admitted that these experiments were imperfect, but they tended to corroborate the statements of the performances of Ruthven's propeller. The arrangement of Purkis' boat differed from Ruthven's chiefly in there being three holes on each side of the vessel—one to propel her ahead,—one astern,—and one midship to supply the pump; each being supplied with a valve to close the orifices not in action, and to act instead of the curved nozzles of the *Enterprise*, which were supposed to be objectional in absorbing power.

*Loysel's Hydrostatic Percolator*.—At this meeting there was exhibited in the library a very simple and ingenious apparatus, designed by Mons. Loysel, for extracting colouring matters from dye-woods, and also for obtaining infusions or extracts of vegetable substances, for medicinal or other purposes. The principle of action was that of direct hydrostatic pressure, applied by a simple and inexpensive apparatus. The substance to be operated upon was placed within a cylinder whose bottom was finely perforated; a similar pierced diaphragm was then placed over it, so as not to produce any pressure; the liquid, either cold or hot, was poured into an upper reservoir, whence it descended by a centre tube to beneath the lower diaphragm, and was forced upwards by the pressure through the superposed substance, every particle of which it saturated in its passage, expelling the air and carrying before it all the finest portions, to the upper strata, against the underside of the upper diaphragm. When a sufficient quantity of liquid had been passed, or the infusion was completed, a cock was opened, which permitted the infusion to return from above, by its own specific gravity, through the substance already operated upon, thus completing the abstraction of any colouring or other matter not previously taken up, and at the same time filtering the liquid. By a second and similar process, anything still remaining in the substance could be extracted. It was practicable, by varying the height of the column, to give any degree of pressure, and by the application of a lamp, or, in a large apparatus, of a coke fire, the temperature of the decoction could be maintained as might be desirable. By another modification, the steam generated in a small boiler regulated the action of the apparatus. The system was described as being adapted to very numerous purposes, and the familiar application of it to making coffee, was exhibited; the apparatus consisted of one vase, either of glass, china, or metal, whose cover, on being reversed, formed the reservoir and pressure column, and in a very few minutes, clear, strong coffee was produced. It was stated, that in an apparatus adapted for a large establishment, four gallons of coffee had been made in twenty minutes. The apparatus appeared to possess the merits of great simplicity, of facility of management, and of being easily cleaned, and the infusion of the substance operated upon was perfect.

---

The first Paper read was "*On the Prevention of Smoke in Engine and other Furnaces*." By James Simpson, jun.

The annoyance of smoke incidental to the increase of habitations and to the extension of manufactures, in all cities and large towns, had been noticed reprehensively even as early as the time of Charles the Second, in whose reign it was proposed to legislate on the subject, and in 1697, Dr. Papin devised a scheme for forcing air down a pipe immediately above the incandescent fuel, to induce more perfect combustion.

The attention of parliamentary committees was devoted to the subject in the sessions of 1819 and 20, and again in 1843, when a very complete history of the subject was given in the report, with a clear recapitulation of the scientific evidence, recommending a freer admission of air to the furnaces as the "great, if not the only principle, for preventing smoke." In 1845, two other committees reported, "that opaque smoke issuing from steam-engine chimneys might be so abated as no longer to be a public nuisance;" and in 1853, the "Smoke Nuisance Abatement Act" was passed, and was ordered to come into force in August 1854. This Act rendered it compulsory on owners of engines and furnaces, to provide means for preventing the emission of opaque smoke, and it applied also to steam vessels navigating the Thames above London Bridge.

An enumeration was then given of the local acts into which clauses had been introduced for abating the nuisance of smoke; whence it appeared that there had been an anxious desire to find means of attaining so desirable an end, and the double furnace fired alternately, now so extensively used at Manchester, was alluded to.

The chemistry of combustion was then examined, in order to show that to imperfect combustion alone must be attributed the annoyance, as well as the serious pecuniary loss, now experienced in the emission of opaque smoke from furnaces generally. It was shown that a good furnace should prevent the formation of smoke, by burning all the carbon of the gas evolved; or in other words, by combining at a certain temperature each atom of carbon in the gas with two atoms of oxygen, before it left the furnace: which combination was the best for giving out heat and for evaporating fluids, with the least expenditure of fuel.

The various methods of introducing atmospheric air to the furnaces, and of diffusing it among the gases, were then examined, showing that the admission should be through numerous apertures, so arranged as to permit accurate regulation, as a greater quantity was required after the period of adding fresh fuel than when the fire was burning brightly and freely. The various mechanical means and apparatus proposed for this object were reviewed, and it appeared that in many of them the combustion was to a certain extent imperfect, and the machines were liable to derangement; that the alleged saving of fuel depended chiefly on the manner of stoking, and that it might be attained by a judicious modification of the grate of any well-set boiler, and by a greater amount of attention on the part of the fireman, without any mechanical appliances.

The regulation of the air supply by machinery had been found to fail, in many instances, on account of the variation in the qualities of the fuel, and it was contended that it was more advisable to entrust it to the discretion of the fireman, than to rely upon self-acting apparatus, which might, however, be advantageously used for indicating the state of the furnace.

The employment of Anthracite and Welsh steam coal was advocated, not only on account of the absence of opaque smoke during their combustion, but also on account of the economy arising from their great evaporative power.

The second Paper was "*On the Management of Furnaces, and the Prevention of Smoke*," by C. Wye Williams, Assoc. Inst. C.E.

The object of this communication was to endeavour to remove the mystery which had hitherto obscured what was asserted to be one of the simplest and best understood processes of nature—namely, the combustion of the gaseous products of coal. A short analysis of the chemical details connected with the subject was given, to show that the existence of flame did not imply the combustion of gas. That it was but the preliminary state of high temperature of the numerous atoms of the carbon of the gas which was caused by the intense heat produced by the combustion of the other constituent—the hydrogen.

In effecting the combustion of the gas generated from the coal in a furnace, the first process was merely mechanical, and consisted in bringing the atoms of the gas, and those of the air, into the most intimate state of mixture; such mixture being the *sine quâ non* of subsequent chemical union. The mode or means by which this chemical admixture could be effected, in the most rapid and intimate manner, involved all that art or human ingenuity could do towards producing perfect combustion.

As to the mode of effecting this mixture, or of bringing together the atoms of air and gas, reference was made to the Argand gas burner, as supplying a good illustration: the only difference being, that in the Argand burner, the gas was projected among the air in numerous small jets, or films; whereas, in the furnace, the process was reversed, the air being brought to the gas, in a similar manner, by means of numerous orifices. In both cases the effect was identical, and might be compared to the rose of a watering pot, or of an artificial *jet d'eau*—namely, the producing, on the instant, the largest area of surface for mutual and atomic contact. Models and drawings were exhibited, showing the facility and simplicity with which, both in land and marine furnaces, hundreds of small orifices were introduced, so as to effect the most intimate mingling of the air with the gaseous products of combustion.

It was stated, as the result of considerable experience, that it was a matter of perfect indifference in what part of a furnace or flue the air was introduced, provided this all-important condition was attended to and satisfied—namely, the effecting the mixture of the air and the gas before the temperature of the latter was reduced below that of ascension or kindling. This, according to Sir Humphrey Davy, should not be under 800° Fah., as ignition could not take place at a lower temperature,—that fact being the principle of safety in the miner's lamp.

Previously to the introduction of the tubular in preference to the flue system in marine boilers, it had been supposed that the introduction of the air on the Argand principle, by a perforated plate behind the bridge, satisfied all that nature required in producing perfect combustion. The tubular form of boiler, however, rendered a different arrangement absolutely necessary. This was occasioned by the run, or distance between the bridge and the tubes, being so very short, and consequently, the passing along that distance being so limited in time, that the mixing and combustion could not be adequately effected. This, after numerous trials and expedients, led to placing the orifices of admission in the front, or at the doorway end of the furnace. The system adopted by boiler-makers, of contracting the doorways of marine boilers, much impeded a successful application of the Argand principle. The enlarging the doorway opening, as shown in the models, however, afforded sufficient space for the required number of $\frac{3}{4}$ or $\frac{1}{2}$ inch orifices. By this arrangement, the length of the furnace, from the door to the bridge, was thus, as it were, added to the length of the run. By this mode of construction, the Argand principle had been applied with great success to marine boilers.

The next point considered was, as to the quantity or gross volume of air required, and the area of aperture necessary for its introduction. On this head, it was stated that a great practical error had been frequently committed, as it had been stated that it would suffice if the aperture should be equal to $1\frac{1}{4}$ square inch for each square foot of fire surface in the furnace, in the case of single furnaces; and of but half a square inch or ·5-inch for each square foot of grate-bar surface in the case of double-furnaced boilers. These proportions were now asserted to be wholly insufficient, and in fact were not sufficient to allow of one-fourth the required quantity of air to pass. In practice, it had been ascertained that for bituminous coal, from 4 to 6 square inches were required for each square foot of furnace; and for anthracite, from 2 to 4 square inches, according to the quality of the coals and the amount of draught. The models and drawings exhibited were stated to be conformable to those proportions.

With reference to the supposed necessity for skilful firemen, the paper stated that the only duty that should be required from the firemen was, the keeping the bars fully and uniformly covered; for if the back end or the sides of a furnace were left uncovered, the air would pass through them, instead of passing through the air-distributors, as that passage offered the hottest and shortest route to the chimney. In fact, it was stated, that unless the bars were well and equally covered, it was impossible to regulate or to control the admission of the air.

As to the use of self-acting valves to regulate the admission of the air, it was stated that after numerous plans had been tried during the last ten years, all had been discarded in practice, being found to be worse than useless. The generation of gas, and the admission of the air through the uncovered portion of the bars, created such irregularity as to defeat all efforts at uniformity, and it was impossible, by any self-acting valves, to obviate the effects of such irregularity. It was observed that the pyrometer, a model of which was exhibited in action, proved the inapplicability of such valves, and furnished the only reliable test, as to the quantity of heat produced and properly applied to the generation of steam. It was also observed, that the colour of the products of the furnace, at the chimney-top, was but a source of error,—the sight-holes and pyrometer supplying all that was necessary, and by which the firemen could alone safely and practically regulate the admission of air.

*April* 11.—The evening was entirely devoted to the discussion of the above Papers "On the Management of Engine and other Furnaces, and the Prevention of Smoke." An explanation was given, by means of a diagram, of the several divisions of the process leading to the combustion of the gas in furnaces. The first division gave the mere relative gross bulk of gas and air required for combustion. In the second the mechanical mixture of the gas and air was described, such mixture, or contact of atoms, being essential to the subsequent chemical union. The third exhibited the several constituents of gas and air:—the former being hydrogen and carbon; the latter, oxygen and nitrogen; the relative volumes of each were given, and it was shown that ten volumes of air were absolutely essential to the combustion of one volume of gas. The fourth division showed the proportions in which those constituents combined. The nature of flame and smoke was examined; showing, that the intense heat caused by the combustion of the hydrogen was the direct cause by which the temperature of the carbon was raised to that of white heat, which produced the luminosity of flame. This process was illustrated by reference to the mode of producing the intense heat and luminosity required for the oxy-hydrogen microscope. In the latter, the piece of lime, or carbon, on which the heat was projected, was instantly raised to the temperature of extreme luminosity, neither the lime or carbon, however, suffering rapid combustion. In the former, the carbon of the gas was raised, by the same means (the combustion of the hydrogen), to the high temperature, but could not suffer combustion until it was brought into contact, in its turn, with its equivalent of the oxygen of the air. If, however, that supply of air was not provided before the carbon lost its high temperature, it returned to its previous and natural state of a black substance, and gave the black character to the products, called smoke.

The first important condition was then shown to be, the providing the required quantity of air. Reference was then made to the area recommended by some authorities, as being sufficient to allow the quantity to enter a furnace. It had been considered, that even half a square inch of aperture for each square foot of furnace grate, was sufficient for the combustion of the fuel. This was, however, stated to be insufficient for practical purposes. The proper area for admission being from 4 to 6 square inches for each foot of grate, according to the extent of draught and the nature of the coal. This serious difference was supposed to have been caused by an erroneous calculation of the rate of the current of air entering. For, if half a square inch of area was all that was allowed, the air must have a velocity ten times greater than could be shown to have been ever attained. Thus, supposing a furnace to be 4 feet by 2 ft. 6 in., equal to 10 square feet of bar surface, this would effect a combustion of 2 cwt. of coal per hour, and require for the gas alone, a supply of 10,000 cubic feet per hour, or, for 20 cwt. of the coal, 100,000 cubic feet.

The following comparison of velocities of the entering air for the supply of the gas, gave some idea of the cause of underrating the required area of admission:—

| Air aperture per sq. ft. of grate. | Velocity of draught per second. | Quantity of air per hour. | Quantity for each ton of coal. |
|---|---|---|---|
| 6 sq. inches ... | at 5 ft. per sec. ... | 7,500 cub. ft. ... | 75,000 |
| 6 sq. inches ... | at 10 ft. per sec. ... | 15,000 cub. ft. ... | 150,000 |

then, if the area were reduced to half a square inch, it would require a velocity of 80 feet per second to provide for the admission, within the given time, of the necessary quantity. By close observation, by means of an aërometer, the velocity of the entering current was estimated at from 8 to 10 feet per second if the draught was good, and from 5 to 8 feet when it was but moderate.

Again, it was observed, that by admitting the air through numerous thin films or divisions, the velocity was necessarily reduced by mere friction through so many half-inch orifices as were exhibited in the models and drawings on the table. The mode of admitting the air by numerous small orifices, as practised by Mr. C. Wye Williams, was then considered, and it was shown, that the great object to be effected was the division of the air on its admission to the furnace, so that no more atoms were brought into contact with the atoms of gas, at any one moment, than were required for their successive union and combustion. If this were the case, combustion and heat would be generated, continuously, as the gas and air came into contact. If, however, the air entered in a body, or even in a film, in larger quantities than could be taken up by the gas, before the temperature was lowered, a refrigeratory effect must be the consequence—smoke would be formed and fuel would be wasted.

It was asserted, that the phrase "burning smoke," was improper, inasmuch as the smoke did not exist until the gases had left the furnace; this was demonstrated by a diagram, showing that on distilling coal in a close vessel, and forcing in a small quantity of air, a jet of gas issued, which, on ignition at the orifice, was almost colourless, then merged into flame, and ultimately became opaque smoke.

It was stated, as an argument for the necessity of some stringent measure with respect to the engine furnaces in all large towns, that in the last nine years, between 1845 and 1853, eight hundred and one new chimney-shafts had been erected in the metropolis, for manufactories, breweries, &c. Some few of them might have been merely rebuilt after destruction, but the large majority caused additional impurity in the London atmosphere. From 1845 to 1851 the greatest number built, in one year, was ninety-nine; but in 1852 one hundred and eleven were constructed, and in 1853 the number rose to one hundred and twenty-three.

It was contended, that in dealing with the smoke question, too much stress had been laid on the chemical part of the subject, as also, that the statement of its being "impossible to burn smoke" had complicated that which was in itself a simple question. All that the public cared about was, that by some means the black or brown visible smoke should be prevented from forming, or be consumed if its formation was incidental to perfect combustion. The air necessary to perform this could be admitted anywhere; either through a split bridge,—by the fire-door,—by an infinite number of holes,—between plates with narrow spaces,—or by others arranged like Venetian blinds. Practically, the end could be attained by the mechanical systems of Juckes, Haseldine, Hall, and others, or by the double-furnace boilers of Galloway, Rose, McGavin, and others, or by the systems of Williams, Prideaux, and many others.

The objections alleged against all these plans were illustrated, and it was stated that with ordinary boilers, the admission of air invariably reduced the evaporative power, or caused waste of fuel, unless there was a sharp draught and spare boiler power; but that when these latter requisites were secured, the air might be admitted in any way practically found most convenient.

The arrangement proposed by Mr. Prideaux was noticed as the most creditable mechanism yet brought forward, but its neatness was its only recommendation, as it could not improve the draught, nor could it aid in "burning smoke" better than would be done by merely leaving the furnace door ajar. The remarkable coincidence, between the arrangement of the parallel plates in Prideaux's fire-door, and that of Williams' well-known and long-practised system was also noticed. It being stated, as fundamental principles, that in the former system, "the door of the furnace should be double, and the air should pass into the furnace through a series of perforations in the inner plate. By this arrangement, three important results are secured.—1. The heating of the air.—2. Its subdivision into minute jets. (This is the precise principle and operation of Williams' argand furnace.)—3. The keeping of the outer surface of the furnace-door comparatively cool, and thereby both economising heat and preventing its radiation outwardly, to the annoyance of the attendants."

Drawings were exhibited of a double flue and double furnace-boiler, whose action was stated to be very satisfactory; the proportion of air space provided in that case was one square inch to each square foot of grate area. The admission of too large quantities of cold air immediately behind the bridge had been found prejudicial, and the system of admitting the supply of air through the perforations in the fire-door was generally preferred. The system of alternate firing, and of having ample boiler space and good draught, was insisted upon.

It was stated, on behalf of the mechanical methods of firing, that at Price's candle manufactory, at Vauxhall, three methods, Jucke's, Hazeldine's, and Hall's, were employed with success. The general principle, of a continuous supply of fuel at the front of the fire, by means of moving bars carrying the coal forward, was common to all these apparatus. The air was admitted only from below and between the bars, which were always covered with fuel. The objections urged against these machines were, the first cost and their liability to derangement. These, however, were now diminished, particularly with those of Juckes and Hazeldine, to which preference was therefore given in the construction of new furnaces. They were found to produce almost perfect combustion, and to make a great saving of fuel with other practical advantages.

Two cases were mentioned, as illustrative of the necessity of admitting the air above the incandescent fuel—the first was that of the ventilating furnaces in pits, where it was essential to raise, to a certain temperature, the largest amount of air, by passing it through or over the fuel in a furnace, in such a manner as to render the air as light as possible, and not to encumber it with smoke;—the second was that of coke ovens, which were now constructed in pairs, and were worked alternately, in such a manner that the early smoke from one oven mingled with the later development of gases from the other oven;—by this means the appearance of any opaque smoke was entirely prevented.

In reply to the arguments in the papers, and to some of those used by the speakers, it was urged, that even with the best construction of furnaces, skilful firemen must be employed, and that it was desirable the subject should be divested of all complexity, and should be rendered clear to the meanest capacities. Instances were given of the advantageous employment of mechanical methods of stoking, particularly at the brewery of Messrs. Truman, Hanbury, and Co., where sixteen sets of Juckes' apparatus had been used for several years, and had induced a great saving of fuel, as well as insured undeviating regularity of temperature in the furnaces. The self-acting systems practised by Brunton, and by Parkes, many years since, were alluded to, and the reasons for their use being discontinued, were given; the alleged defects of these systems where shown not to exist in the apparatus of Juckes, Hazeldine, and Hall, but that even they were up to this time unfit for use in steam vessels, where it had been imagined that mechanical means of firing would have been most advantageous, but where in reality the heat in the furnaces was so intense as to destroy any machinery attached to the fire-bars. The success attendant on Mr. Houldsworth's system for preventing smoke, and on his invention of the metal rod pyrometer, was described.

The general result of the investigation appeared to be, that, although for certain large establishments the mechanical methods of firing were successful, it could not be expected they would be adopted for every furnace in the smallest manufactory; therefore, a good system of mingling a due proportion of atmospheric air with the gases evolved during combustion, was essential, and the method employed by Williams appeared to fulfil the required conditions.

## CELTIC MONUMENTS IN IRELAND.

Many an English traveller who has visited Egypt, would in all probability be surprised to learn that, comparatively speaking, at his door, there exists a monument which, as a writer whose name I cannot recall, says, if built on the banks of the Nile instead of the Boyne, would be considered one of the oldest of the Pyramids. At a short distance from the town of Drogheda, the three great mounds of New Grange, Knowth, and Dowth present themselves to view, at the distance of about a mile from each other; and the casual observer would probably look upon them as great natural hills, one of which is covered with wood, and another having had until lately a stone building on its summit. Those, however, who have examined the structures of ancient times at once perceive the artificial character of these vast pyramids.

The monument of New Grange consists of an enormous cairn, or hill of small stones, occupying the top of a slope to the north of the river Boyne. It covers something less than two acres, and is at the present day about eighty-feet higher than the adjoining surface; but its height, as well as the beauty of its outline, has been lessened by the excavations made at different times into its sides and upon its summit, for the purpose of obtaining materials for building and road making. Ten large blocks of stone still remain of the circle which, apparently, surrounded the mound in ancient times, and it is said that a great pillar of stone once crowned the summit.

The writer visited this monument of the Celts about two years since, and penetrated into the interior, having previously procured a lighted stick and a candle. The entrance is formed by large flags, and a singularly carved stone, sloping outwards, ten feet long and about eighteen inches thick, attracts attention from the spirals and volutes cut upon it. A narrow passage formed of stones of great size gives access to a large chamber constructed of stones of enormous magnitude. Some of the stones were probably taken from the bed of the Boyne, but the rock of which others are composed is not to be found in the neighbourhood. All the great stones of the passage and chamber must have been transported from a distance, although the smaller ones forming the greater portion of the hill may have been procured on the spot. The passage, formed of upright stones and covered with enormous flags, is sixty-three feet long, and about six feet high, although at the entrance it is somewhat lower, and as it nears the chamber it rises to the roof; some of the stones have fallen inwards, but in general it is three feet wide. When I reached the chamber, I blew upon the lighted stick, and lit the candle. After a moment I could perceive through the thick darkness that reigned in this mysterious chamber, a grand dome-shaped roof, tapering to a centre, and three recesses or crypts formed of enormous blocks.

I cannot at present give descriptions of the rude carvings cut into the stones, and sometimes standing out in relief, but the reader who is curious about such matters will find much interesting information, together with the necessary illustrations, in Wild's 'Beauties of the Boyne,' which work I have consulted in giving the above details. I must not omit to mention, however, a remarkable circumstance which struck that gentleman when investigating this ancient structure. He found that the carvings extended over those surfaces of the stones which had been completely hidden from view, and he infers that they were carved before occupying their present position. A portion of the chamber opposite the entrance having fallen in, part of the under surface of a great flag has been exposed to view. It has, like most of the other stones here, a brownish outer polish. In the exposed carvings, the indentures have assumed more or less of the dark colour and polish around, but in this instance the marks of the tool are here as fresh as if done but yesterday.

There is a large oval stone, hollowed like a basin, in each of the recesses; the one in the right-hand chamber is three feet long, and stands upon another basin, while the other chambers have only one such sarcophagus.

A comparison with the Egyptian pyramids will suggest itself to every one,—their central chamber, with one or more sarcophagi, and long entrance passage. A series of chambers, which Mr. Wild compares to those found beneath the great central chamber in the largest pyramid of the Sakkara range, has been explored in the mound of Dubhadh, or Dowth. As there is no access to the interior of the remaining mound, the comparison cannot be continued further for the present. It is a curious fact, however, that among the other carvings at Dowth, the lotus, or lily leaf, is represented most accurately in relief. E. P. H.

## NEW PATENTS.

### PROVISIONAL PROTECTIONS GRANTED UNDER THE PATENT LAW AMENDMENT ACT.

*Dated December 17, 1853.*

2945. J. S. Cockings, Birmingham—Improvements in buttons and other dress-fastenings; part of which is also applicable for other purposes

*Dated December 21.*

2971. J. Jones, Glasgow—Improvements in propelling vessels

*Dated January 16, 1854.*

102. G. F. Wilson, Belmont, Vauxhall—Improvements in treating castor-oil, and obtaining products therefrom

*Dated January 18.*

123. R. Galloway, Lambeth—Improvement in admitting air to furnaces where tubular boilers are employed

*Dated January 19.*

127. J. Spiller, Battersea—Improvements in measuring and mixing, crushing, grinding, and pulverising wheat and other substances

*Dated February 20.*

399. R. C. J. Prevet, Paris—Improvements in treating textile plants for obtaining pulp for manufacturing paper

*Dated February 23.*

436. C. Walker, Bury, Lancaster—Improvements in purifying water for steam-boilers

*Dated February 24.*

449. R. J. Green, Birmingham—Improvements in the manufacture of corrugated elastic materials

456. A. E. L. Bellford, Castle-street, Holborn—Improvements in turn-tables for railways. (A communication)

*Dated February 27.*

470. E. Chappuis, St. Mary Axe—Improved apparatus for the diffusion of light, called "Illuminators."

475. R. A. Brooman, Fleet-street—Improvement in the manufacture of tinfoils or sheets. (A communication)

*Dated February 28.*

478. T. Denny, Strasbourg, France—Improvements in engraving

483. W. Simpson, Tovil Upper Mills, near Maidstone, Kent—Improvement in employing in the manufacture of soap a product obtained when manufacturing pulp from straw

*Dated March 3.*

517. J. A. Boyle, Alfred-place, Bedford-square—Crushing or reducing to powder, pulp, or wash, any matter.

*Dated March 4.*

525. E. Rowland, Manchester—Improvements in machinery or apparatus for manufacturing bricks or tiles from clay or other plastic materials

529. F. Abate, George-street, Hampstead-road—Improvements in printing on and ornamenting surfaces

531. F. H. Wenham, Effra-vale Lodge, Brixton—Improved hydraulic machine for registering or indicating the flow or quantity of fluids, and obtaining motive power

*Dated March 6.*

535. J. Galloway, Bolton-le-Moors, Lancaster—Improvements in the construction of cocks, taps, and valves

537. S. A. Chapin, Trafalgar-square, Westminster—Improved mode of purifying smoke produced by the combustion of coal or other substances, and for condensing and collecting the solid and other matters contained in smoke and vapour arising from the combustion, smelting, burning, or roasting of fuel and other substances. (A communication)

539. J. Ronald, Patrick Bank, near Paisley—Improvements in printing yarns and threads

541. J. R. Morton, Oxford-street—Improvements in shades and reflectors applicable to certain descriptions of lamps, lanterns, or chandeliers

*Dated March 7.*

543. J. Johnson, Church-street, Leatherhead—New stop for railway and other carriages

545. F. Rixon, Cockspur-street, Westminster—Improved apparatus for lowering and disengaging ships' boats

*Dated March 8.*

547. T. Dunn, Pendleton, Lancaster—Improvements in machinery and apparatus for moving engines and carriages from one line of rails to another, and for turning them

548. H. B. Barlow, Manchester—Improvements in waterproofing and finishing textile fabrics and yarns. (A communication)

550. G. Beardsley, Coal-pit-lane, Nottingham—Improvements in round or circular machinery for the manufacture of textile and looped fabrics

551. R. Boyell, Derby-road, Nottingham—Portable safety-guard for the prevention of fire, applicable alike both to public and private buildings, and which said portable safety-guard is also applicable as a reviver.

552. J. D. Brunton, Truro, Cornwall—Improvements in wind-guards or chimney-tops, for promoting ventilation in coal-mines

553. W. I. Cookson, Newcastle-on-Tyne—Improvement in the reduction of lead ores

555. W. S. Losh, Wreay Syke, Cumberland—Means of decolouring resins

556. G. Devincenzi, Grosvenor-street—Improvement in producing ornamented and figured surfaces, and surfaces for printing from

557. J. Aitken, Longsight, near Manchester—Improvements in obtaining motive power

558. W. Warne, Lower Blowing House, St. Austell, Cornwall—Improvements in tubular steam-boilers or generators

559. J. Brown, Leadenhall-street—Improved method of swinging furniture and other articles for travelling by sea or land, and other purposes

560. J. Blair, Irvine, Ayr—Improvements in beds or couches, and other articles of furniture

*Dated March 9.*

561. W. W. Good, Moorgate-street—Improvements in machines applicable for thrashing or winnowing

563. G. T. Selby, Smethwick, Warwick—Improvements in machinery for the manufacture of tubes and pipes, and for shaping tubular and certain metal articles

564. J. H. Johnson, Lincoln's-inn-fields—Improvements in machinery or apparatus for finishing fabrics. (A communication from D. P. Pepin and A. Roy)

565. W. B. Johnson, Manchester—Improvements in strengthening the ends of tubes to be attached to boiler-plates, or to be used for other such purposes

566. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improved reaping machine. (A communication)

567. W. Young, Queen-street, Cheapside—Improvements in lamps

568. J. H. Swan, Glasgow—Improvements in the tuyeres of blast and other furnaces and fires

569. F. E. S. Garnier, Paris—Improvements in machinery for preparing flax and othe textile materials

570. H. Lamy, Paris—Improvements in preserving animal and vegetable substances

*Dated March 10.*

572. E. A. Desrousseaux, Roubaix, France—Improvements in looms for weaving

573. W. Peace, Haigh, Lancaster—Improvements in machinery for measuring, indicating, and registering the flow of air, gas, and other liquids, and for governing the speed of steam or other engines

574. S. Moseley, Hull—Improvements in the manufacture of artificial palates for the adaptation of artificial teeth

575. J. Lawrence, Leeds—Improved rotatory engine

576. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in the manufacture of candles. (A communication)

577. J. Buchanan, Leamington Priors, Warwick—Improvement in communicating motion to or from the ordinary crank or an eccentric.

578. W. Day, Beverley, York—Improvements in the construction of covered carts and other like vehicles, which may be used as dwelling-places or travelling-houses

579. F. Whitehead, and W. Whitehead, Crayford, Kent—Improvements in raising, forcing, and supplying water and other liquids

580. W. Mill, Hunter's-lane, Birmingham—Improvements in inkstands or ink-holders

581. A. V. Newton, Chancery-lane—Improvements in the manufacture of raised printing surfaces. (A communication)

582. A. V. Newton, Chancery-lane—Improvements in the mode of purifying coal-gas, and of obtaining during the manufacture of the gas a certain purifying material, and in apparatus to be used in purifying gas. (A communication)

583. D. P. Lefevre, Paris—Improved railway-break

584. Z. Boitteux, Epinal, France—Improvements in the machinery for sculpturing and carving

586. J. Patterson, Beverley, York—Improvement in machines for washing cloth and similar materials

587. J. H. Johnson, Lincoln's-inn-fields—Improvements in the manufacture of hollow jewellery. (A communication from J. M. Payen)

*Dated March 11.*

589. J. Maynard, Drury-lane—Improvement in strings for pianofortes and other stringed musical instruments

590. W. T. Monzani, St. James's-terrace, Bermondsey—Improvements in bedsteads and packing-cases or boxes to contain the same and other articles

591. J. Wright, Manchester—Improvements in machinery or apparatus for "curing" and "liquoring" sugar by centrifugal force, without acidifying or injuring the syrup. (A communication from J. Reid, Jersey, U. S.)

592. W. Tytherleigh, Birmingham—Improvements in the manufacture of tea-kettles

593. W. Symington, Gracechurch-street—Improvements in apparatus for heating air by means of steam

595. J. H. Johnson, Lincoln's-inn-fields—Improvements in lighting. (A communication from A. Martin, Paris)

596. J. Sparrow, jun., Tettenhall-road, Wolverhampton—Improvements in shears for cutting iron or other metals

597. J. Buchanan, Leamington Priors, Warwick—Improvements in the propellers and apparatus used for propelling vessels

*Dated March 13.*

598. L. Whitaker, J. Diggle, and G. Howorth, Haslingden, Lancaster—Improvements in machinery or apparatus for spinning cotton and other fibrous materials

599. J. H. Johnson, Lincoln's-inn-fields—Elastic breeching apparatus for cannons. (A communication from G. M. Knevitt, New York)

600. B. Latchford, St. Martin's-lane—Improvements in saddlery or harness

601. J. Glenny, Strand—Portable camp-bed

602. E. Haeffley, Radcliffe, Lancaster—Improved mordaunt to be used in printing and dyeing textile materials and fabrics; applicable also to the process of bleaching

603. E. Haeffely, Radcliffe, Lancaster—Improvements in the manufacture of stannates of soda, potash, and ammonia

604. J. Wright, Park-street, Kennington—Improvements in the construction of furnaces for the purpose of consuming more effectually than heretofore the smoke contained therein

605. J. Walker, City-road—Improvements in raising stamps employed for crushing, and rams or monkeys employed in pile-driving and other like operations

606. G. Hopper, Houghton-le-Spring Iron Works, Durham—Improvements in pins for railway-chairs

607. J. H. Johnson, Linclon's-inn-fields—Improvements in sewing-machines. (A communication from A. E. Figuier and E. Cherault, Paris)

608. A. E. L. Bellford and P. Ristori, Castle-street, Holborn—Improvements in inflating life-belts, buoys, and articles of a similar nature. (A communication)

*Dated March 14.*

609. F. Russell, Clarence-gardens, Regent's-park—Improvements in apparatus for clearing obstructions on railways

610. A. W. Conner, Crooked-lane, Cannon-street—Improvements in the apparatus used for moulding bricks and lumps

611. J. H. Swan, Glasgow—Improvements in drying bricks, tiles, and other articles made of brick-earth

612. J. Hands, Epsom—Improvements in kilns

613. J. Woodford, Hatton-garden—Smoke-consuming rotary grate

*Dated March 15.*

614. R. A. Brooman, Fleet-street—Improvements in sector presses. (A communication)

615. P. A. Lecomte de Fontainemoreau, South-street, Finsbury—Improvements in producing waterproof stuffs. (A communication)

617. T. Kaye, Huddersfield—Improvements in the manufacture of gas, and in the apparatus employed therein

618. T. S. Holt and C. H. Holt, Manchester—Improvements in steam-boilers

619. J. P. Oates, Lichfield, Stafford—Improvements in the manufacture of bricks, tiles, pipes, and such other articles as are or may be made of clay

620. L. Whitaker and G. Lyons, Haslingden, Lancaster—Improvements in grinding or setting the main cylinder of carding-engines used for carding cotton and other fibrous materials

621. J. Houston, jun., Glasgow—Improvements in working steam-boilers, and in apparatus connected therewith

622. A. Trueman, Swansea, Glamorgan—Improved furnace for the calcination of copper ores and other mineral substances

623. W. Weatherley and W. Jordan, Chartham, near Canterbury—Improvements in steam-boilers

624. A. E. P. Legros, Paris—Improvements in preserving timber, and generally all kinds of wood

625. T. W. Keates, Chatham-place, Blackfriars—Improvements in the means of distilling tupentine and other resinous matters, and in manufacturing boiled or drying oils

626. G. Pead and C. Wyatt, Conduit-street, Regent-street—An instrument for readily ascertaining the wear of the bearings of railway carriages

627. M. Binns and J. Pollard, Bradford, York—Improvements in apparatus for combing wool, cotton, silk, flax, or other fibrous substances

*Dated March 16.*

628. C. Poisson and L. J. Martin, Paris—Improvements in printing fabrics. (Partly a communication from H. L. Talle, Paris)

629. R. Weare, Princes-road, Woolwich—Improvements in the construction of galvanic batteries, and in apparatus connected therewith

630. D. Bethune, Toronto, Canada West—Improvements in the construction of vessels propelled by steam

631. F. W. Emerson, Trereiffe Chemical Works, near Penzance, Cornwall—Improvements in machinery for pulverising, washing, and amalgamating quartz, and matters containing gold and silver
632. J. Cavanah, Liverpool—Improvements in sails for navigable vessels, and in the apparatus for working them
633. J. Lilley, Birkenhead, Chester—A new material, suitable for spinning either alone or combined with other fibres, and suitable to the manufacture of pulp; also certain machinery employed in the preparation thereof
634. J. G. Marshall and P. Fairbarn, Leeds—Improvements in machinery for combing flax, tow, wool, hair, and other vegetable or animal fibres

*Dated March* 17.

635. J. Gerard, Guernsey—Macninery for cutting and stamping soap
636. W. Holt, Bradford—Improvements in reed-pipes for organs
637. R. W. Harris and T. Patstone, Birmingham—Improvement or improvements in shades or glasses for gas and other lamps
639. T. W. Scott, South Devon-place, Plymouth—Improvements in the preparation or manufacture of Devonian limestone
640. A. Hendry, Port-Glasgow, Renfrew—Improvement in heating bakers' ovens
641. G. H. Barth, Mornington-crescent, Hampstead-road—Improvements in the mode of supplying and administering gases for the alleviation and cure of certain diseases
642. T. Basnett, Liverpool—Improved mode of compensating for the deviation of the needle of ships' compasses occasioned by local attraction
643. J. Hughes, Bethnal-green-road—Improved mode of operating the Jacquard apparatus of looms employed in figure weaving

*Dated March* 18.

644. G. W. Reynolds, Birmingham—New or improved fabric to be used in the manufacture of stays or corsets
645. J. Hyde and J. Harpur, Stockport, Chester—Improvements in the construction of spindles and flyers for roving and slubbing frames
646. J. Hick, Soho Iron Works, Bolton-le-Moors, Lancaster—Improvements in apparatus for heating the cylinders of steam-engines
647. W. Thorne, Barnstaple, Devon—Improvements in reducing metallic ores
648. W. Dantec, New Quay, Liverpool—Improvements in purifying water
649. P. M. Parsons, Duke-street, Adelphi—Improvements in the construction of the permanent way of railways

*Dated March* 20.

650. P. R. Hodge, Moorgate-street—Improvements in reducing metallic ores
651. E. de Mars, Paris—Improvements in windlasses or capstans. (A communication from F. Femé)
652. R. Tempest, J. Tomlinson, and H. Spencer—Improvements in the method of cleansing sheep's wool, and in the machinery or apparatus connected therewith
653. J. Bird, jun., Manchester—Improvements in the manufacture of silk into threads required for woven fabrics, for sewing and for other purposes, and in machinery to be used for these purposes
654. H. Moore, Junction Foundry, Hull—Improved template for facilitating the building of iron ships and vessels
656. F. Loret-Vermeersch, Malines, Belgium—Improvements in looms for weaving
657. J. Horton and R. Polglase, Stepney—Improvements in the construction of ships' boilers, girders, tanks, gasometers, and other like structures or vessels
659. W. L. Webb, New Broad-street—Improvements in pulverising, washing, and amalgamating quartz, and matters containing gold and other metals
660. J. Longbottom, Leeds—Improvements in combining atmospheric air with hydrocarbons for the purposes of light and heat. (A communication)
661. J. Perkins, Kennington—Improvements in metallurgy, especially applicable to the production of type and ornamental forms.
662. J. Perkins, Kennington—Improvements in working metals, especially adapted for producing surfaces for blocks for printing calicoes, silks, paper, and other fabrics
663. J. Young, East Smithfield—Improvements in brewing
664. R. A. Brooman, Fleet-street—Improvements in sewing-machines. (A communication)

*Dated March* 21.

665. W. Stevens and W. Stevens, jun., Birmingham—New or improved machinery for grinding and polishing lenses
666. J. D. Pfeiffer, Rue Princesse, Paris—Improvements in book-binding. (A communication)
667. J. Hansor, Wandsworth-road—Improvements in the manufacture of illuminating gas
668. J. Polson, Paisley, Renfrew—Improvements in the manufacture of starch

*Dated March* 22.

669. R. Roberts and G. Coppock, Heaton Norris, Lancashire—Improvements in looms for weaving
670. A. V. Newton, Chancery-lane—Improvements in japanning leather and other fabrics. (A communication)
671. E. Keirby, Radcliffe-close, Manchester—Improved reed for looms
672. J. Sheringham, Edwardes-square, Kensington—Improvements in the construction of kettles and other like domestic utensils, and in the means of supporting or retaining the same in proper position when in use
673. W. Fast, Goswell-road—Improved ventilator
674. G. Sterry, Worcester—Improvements in the manufacture of mouldings, suitable for cornices, picture-frames, architectural decorations, and other like purposes
675. H. Maderson, Clapham, and G. W. Warren, Lambeth—Improved safety-guard for gun-locks
676. T. S. Watson, West Strand—Improved railway-traverser
677. J. Healey, J. Foster, and J. Lowe, Bolton-le-Moors, Lancaster—Improvements in certain parts of machines used for preparing, slubbing, and roving cotton and other fibrous materials
678. J. H. Robinson, Hebden-bridge, York—Improvements in steam-boilers
679. W. D. Skelton, Leeds—Improvement in preparing flax for spinning
680. R. O. White, Swanscombe, Kent—Improvements in the manufacture of Portland cement

*Dated March* 23.

681. B. England, Leigh, Lancaster—Improvements in the manufacture of woven fabrics, and the machinery or apparatus employed therein
682. E. D. Coës, St. Denis, France—Improvements in the preparation of certain substances for the purpose of printing and dyeing fibrous materials and fabrics
683. W. V. Greenwood and J. Saxby, Brighton—Improvements in railway signal-lamps
684. F. Seiler, Interlaken, Switzerland—Improvements in the manufacture and construction of solid and veneered tesselated, and other shaped woodwork, suitable for floorings, buildings, works of art, and other purposes
685. L. Whitaker and Dr. Ashworth, Haslingden, Lancaster—Improvements in power-looms for weaving
687. A. Lister, Birmingham—Improvements in the manufacture of metallic castings
688. J. Newman, Birmingham—Improvements in the manufacture of metallic tubes
689. S. Holman, Colney Hatch—Improvements in machinery for raising and forcing fluids; part of which improvements is also applicable to the guiding of piston-rods generally, and other rods

*Dated March* 24.

690. R. Montgomery, New York—New and useful improvement in corrugated metals, and in machinery for producing the same
691. H. Room and W. Morton, Birmingham—New or improved method of ornamenting metallic bedsteads, and such other articles of furniture as are or may be made of metal
692. R. Doidge and J. Cloves, Birmingham—Improvement or improvements in the manufacture of rolls to be used in shaping and impressing sweetmeats and plastic materials generally
693. B. Fothergill and W. Weild, Manchester—Improvements in obtaining and preparing the fibres of plaintain, penguin, and other vegetable substances for manufacturing purposes
694. S. Humphreys, Green-street, Leicester-square—Improved apparatus for the heating or distilling of fatty, oily, and resinous matters. (A communication)

*Dated March* 25.

696. W. Wood, Monkhill-house, near Pontefract, York—Improvements in machinery or apparatus for the manufacture of carpets and other fabrics
697. E. Bagot, Llaneley, Carmarthenshire—Improvements in the manufacture of rails for railways
698. J. Lochead, Kennington, and R. Passenger, Union-street, Southwark—Improvements in the manufacture of glass or other vitrified substances
699. J. Robertson, Glasgow—Improvements in lifting or transporting heavy bodies
700. W. Neilson, Glasgow—Improvements in marine steam machinery
701. T. Gibson and W. Knighton, Stavely Works, Chesterfield—Improvements in moulding and casting metals
702. T. J. Smith and J. Smith, Queen-street, Cheapside—Improvements in the manufacture or construction of pocket-books, portfolios, and similar articles
703. W. A. Biddell, Great Sutton-street—Improvements in alarums and signals to be used in or on railways, ships, houses, buildings, plantations, or other places, for the purpose of giving audible or visible signals in cases of danger or alarm
704. G. Beaumont, Halifax, York—Improvements in machinery or apparatus for the manufacture of solid, hollow, and ornamental bricks

*Dated March* 27.

705. A. E. Forty, Kennington, and W. Haynes, New Kent-road—New composition of materials suitable for mouldings, and for most purposes for which leather and gutta-percha have been or may be employed
706. H. A. Archreau, Paris—Improvements in treating powders of charcoal, coke, coal, peat, and generally all matters obtained by the carbonisation of mineral, vegetable, and animal substances, and in applying the said powders to useful purposes
707 A. Prince, Trafalgar-square — Improved method of hardening fatty and oily matters employed in and for the manufacture of candles. (A communication)
708. F. Phillips, Hall Farm, near Brandon, Suffolk—Improvements in machinery or apparatus for cutting, grating, or preparing vegetable substances
709. J. A. Manning, Inner Temple—Improvements in the treatment of sewerage

*Dated March* 28.

711. J. Hipkiss, Birmingham—New or improved dress-fastening
713. H. A. Archereau, Paris—Improvements in galvanic batteries
715. J. Roberts, Bruton-street, Bond-street—Improvements in the construction of cabriolets
717. W. Hähner, Leghorn—Improvements in the manufacture of muriatic and sulphuric acids. (A communication)
719. W. Hähner, Leghorn—Improvements in the manufacture of alkaline sulphites, and in purifying and treating gases. (A communication)

*Dated March* 29.

721. J. H. Johnson, Lincoln's-inn-fields—Improvements in the construction of millwork, and in the mode of driving the same; part of such improvements being applicable for transmitting motive power generally. (A communication from H. F. Negrier, Toulouse, France)
723. R. H. Causton, Battersea—Improvements in the manufacture of mill-bands

*Dated March* 30.

725. J. F. Lucevilliard, Dijon, France—Improvements in fastening or sustaining to the body the various parts or objects of body clothing, equipment, and harnessing
726. W. Corrall, Albert-street, Mile-end—Constructing the several parts of vehicles of hollow metal tubing or pipes
727. W. Johnson, Lincoln's-inn-fields—Improvements in galvanic, electric, and magnetic apparatus. (A communication)
728. W. Tucker, Old Brompton, and W. Adams, Kensington—Preventing the escape of fuliginous smoke from shafts and flues
729. E. Townsend, Massachusetts, U. S.—Improvement in machinery for sewing cloth or other material. (A communication from A. Swingle, Massachusetts)
730. H. Cowley, St. Giles, Oxford—Manufacture of bricks, either solid, moulded, or perforated, by improved machinery
731. J. Sandys, Electric Telegraph Works, Upper Whitecross-street—Improvements in electric telegraph instruments
732. T. R. Crampton, Buckingham-street, Strand—Improvements in crushing, washing, and separating ores and minerals
733. P. J. Passavant and J. Cure, Bradford, York—Improvements in machinery or apparatus for combing wool and other fibrous substances
734. W. Simpson, Birmingham—Improvements in apparatus for communicating alarm-signals on railways
735. H. Y. D. Scott, Queen's-terrace, Woolwich—Improved cement, applicable as a mortar, or for moulding purposes
736. E. C. Willis, Cambridge—Improved mode of manufacturing gutta-percha into sheets
737. A. V. Newton, Chancery-lane—Improved construction of hone. (A communication)

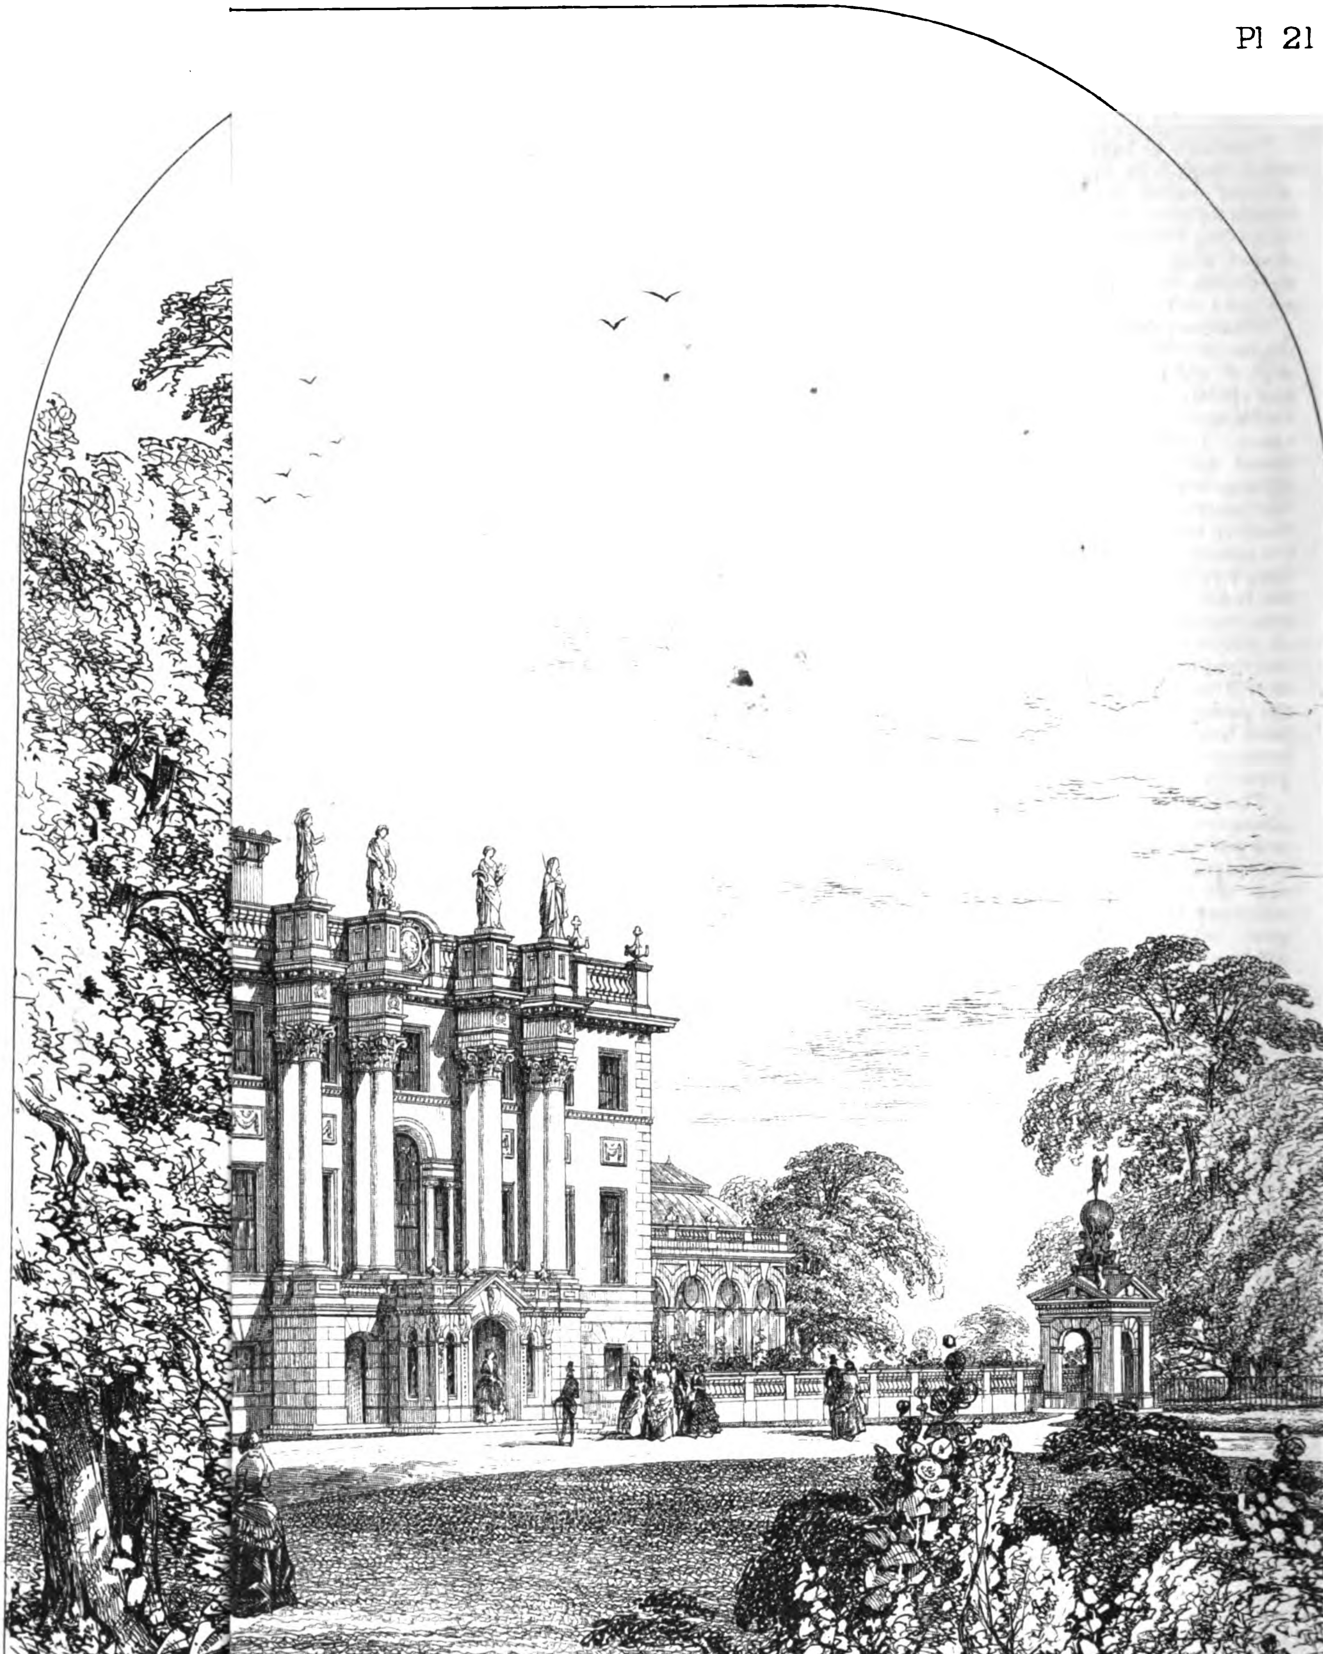
*Dated April* 1.

744. D. Forbes, Edinburgh—Improvements in facilitating a reference to books
746. J. Inshaw and J. Parker, Birmingham—Improvement or improvements in suppressing the smoke and increasing the draught of the furnaces of locomotive and other steam-engine boilers
750. A. V. Newton, Chancery-lane—Improvements in sewing machinery. (A communication)
752. J. H. Johnson, Lincoln's-inn-fields—Improvements in printing fabrics, and in the machinery or apparatus employed therein. (A communication)
754. G. Brocklebank, Point Blackheath, Kent—Improvements in obtaining metals from ores
756. G. F. Wilson, Belmont, Vauxhall, and W. Walls, Glasgow—Improvement in dyeing Turkey red

---

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

828. H. Kemp, Creekmoor, Dorset—Improvements in the preparation of wood for planking and sheathing ships and other vessels; also in house, ship, and pier building, railway-sleepers, &c., and all other purposes whatsover where wood is required.—April 8



J. R. Jobbins

R E .

James K. Collins Architect

## HOOTON HALL, CHESHIRE.

(*With an Engraving, Plate* XXI.)

Previous to the alterations, the main portion of the building was a large, bold, square building, of the style practised by the Adams' during the latter part of the last century. It was built wholly of stone, but possessed however scarcely any architectural character, and the offices, including a very fine kitchen and a chapel, were contained in a long, straggling wing building on the north side, adding nothing to the general effect, but appearing almost totally disconnected.

The object sought in the alterations has been to give a greater degree of dignity to the house itself, and to make the offices group with it, and form a consistent portion of the whole, in an artistic and effective manner. The principal additions are—To the main building, a new cornice and balustrade, surmounted by enriched vases. To the entrance front, four detached Corinthian columns, raised upon a rustic basement, and intended to support four figures, each about 8 feet high, representing the four Seasons. In the centre, above the cornice, the crest of the proprietor, R. C. Naylor, Esq., has been sculptured in bold relief, surrounded by his motto, "Hoc age." To the entrance, a commodious porch has been formed, which cannot fail of being a great convenience to the house, for previously there was not the slightest protection from the weather beyond the actual door itself. On the eastern or garden front, a balcony 8 feet wide has been erected, supported on coupled Doric columns, and extending along the whole front. It will be approached through French casement windows, from the centre room upon the principal floor. Rusticated quoins also have been placed at the angles of the building, and a moulding worked round the whole of the windows, which previously were perfectly plain.

The portion of the wing building next the main house has been almost entirely rebuilt, and surmounted with an open balustrade, and pedimented attic windows, forming some excellent servants' bedrooms, stores, &c., which were much wanted. At the angle next the chapel a tower of bold proportions has been erected, about 100 feet in height, having a rusticated basement, a lofty story with Corinthian pilasters at the angles, and an open balustrade with enriched vases, the whole surmounted with an elegantly-proportioned lantern, from which a fine view is obtained of the Mersey and the surrounding country. The lantern is domed and terminated with a copper gilt vane. Within the dome are three bells, and in the principal story of the tower a clock will be fixed, having four faces, which will be made to strike both hours and quarters. One of the rooms in the tower will be fitted up as a smoking-room. The chapel, which previously appeared only as a portion of the offices, now is made to form a distinctive feature in itself, and has received sufficient ecclesiastical character to make its sacred purpose apparent, and yet arranged in harmony with the rest of the building. The windows, which partake somewhat of a Byzantine character, will be filled with stained glass. At the extremity of the chapel is the side porch, which serves both for the chapel and a side entrance to the house.

On the south side of the main building, and attached to it, is the new conservatory, 75 feet in length and 28 feet wide internally. It is formed by an open stone arcade, with enriched spandrils, keystones, balustrade, and cornice. The openings will be filled in with glass in large squares, and the roof will be composed entirely of glass and iron. A communication has been made from the conservatory into the principal drawing-room by an elegant iron staircase; the doors into the drawing-room, and sashes on each side, will be filled with large sheets of plate-glass.

On the garden or eastern side of the house, and around the conservatory, will be formed a beautiful parterre, laid out in elegant designs, and most tastefully arranged with sculpture, vases, &c., by W. A. Nesfield, Esq., who has already been making vast improvements in the park and grounds, and who will probably arrange and greatly improve the drives and approaches to the hall.

The parterre will be inclosed by an open balustrade, and at the south-west angle will be erected an elegant architectural entrance, which will terminate the façade of the western or entrance side of the hall very agreeably. It will be surmounted by a figure of Flora descending to the earth with flowers. The Earth, which will be represented by a large globe, will be supported on the shoulders of three kneeling figures—the whole cast in bronze.

The stone used in the additions and alterations (with some few exceptions) is the same with which the house was originally built — the sandstone from the Stourton-hill Quarries, near Birkenhead.

The architect is Mr. James K. Colling, and the builders Messrs. A. and G. Holme, of Liverpool. There is a drawing of the alterations in the present exhibition of the Royal Academy.

## NEW SMOKE-CONSUMING AND FUEL-SAVING FIREPLACE.

WITH ACCESSARIES ENSURING THE HEALTHFUL WARMING AND VENTILATION OF HOUSES.*

By Neil Arnott, M.D., F.R.S.

[*Paper read at the Society of Arts, London, May* 10*th*.]

The great evils connected with the common coal fires are:—1. Production of Smoke. 2. Waste of Fuel. 3. Defective Warming and Ventilation of Rooms. We shall consider these in order:—

1. *Of Smoke in the Interior of Houses and in the External Atmosphere.*—The proverb which declares a smoky chimney to be one of the greatest troubles of life, may suffice in relation to the interiors; in regard to the exterior, many particulars have to be noted. Examination of the question has ascertained that in London alone, on account of its smoke-loaded atmosphere, the cost of washing the clothes of the inhabitants is greater by two-millions and a half sterling a year (that is, twenty-five times one hundred thousand pounds), than for the same number of families residing in the country; and this is seen to be but a small part of the expense when we consider the rapid destruction of all furniture in houses, as of carpets and curtains, of articles of female apparel, of books and paintings, of the internal decorations, and even of the external surface of the stones of which edifices are built. For personal cleanliness it is necessary to be almost constantly washing the hands and face. Flowering shrubs and many trees cannot live in the London atmosphere, so that the charm of a garden, even at considerable distances from town, has almost ceased with the extension of the buildings and increase of smoke. A growing flower, if exposed to the atmosphere, is always covered with blacks or sooty dust, and defiles the hand which plucks or touches it. Sheep from the country, placed for a few days to graze in any of the parks, have soon a dingy fleece, strikingly apparent when others newly arrived are mixed with them. And this atmosphere, so damaging to inanimate things and to vegetable life, is inimical also to the health of man, as proved by numerous facts recorded in the bills of mortality. Many persons, with certain kinds of chest weakness, cannot live here. Many children brought from the country are soon seen not to be thriving. The coal-smoke, then, may be called the great nuisance and opprobrium of the English capital.

2. *Of Waste of Fuel.*—Count Rumford, a writer of great authority in such matters, after making many elaborate experiments, declared that five-sixths of the whole heat produce in an ordinary English fire goes up the chimney with the smoke, to waste. This estimate is borne out by the facts observed in countries where fuel is scarce and dear, as in parts of continental Europe, where it is burned in close stoves, that prevents the waste. With these a fourth part of what would be consumed in an open fire, suffices to maintain the desired temperature. I have myself made experiments here in London with like results. To save a third part of the coal burned in London alone, would save more than a million sterling a year; and when coal is very dear, as during last winter, the saving would be much greater. Then it is to be considered that coal is a part of our national wealth, of which, whatever is once used can never, like corn or any produce of industry, be renewed or replaced. The coal mines of Britain may truly be regarded as among the most precious possessions of the inhabitants, and without which they could never have attained to the importance in the world which the extraordinary development of their mental and bodily faculties has now given them. It is enough to say that without coal they would not have had or used the steam-engine. To consume coal wastefully or unnecessarily, then, is not merely improvidence, but is a serious crime committed against future generations.

* From the 'Journal of the Society of Arts.'

3. *Of Defective Heating and Ventilating in Dwellings.*—Calling a thousand a week the average rate of mortality in London alone, it was found in the middle of last winter, that nearly 700 additional deaths occurred owing to the intense cold which then prevailed, and against which, evidently, the existing arrangements for warming and ventilating were insufficient. Not a little of the premature mortality at all times, and of the spread of epidemics, and of the low condition of health among the people, is doubtless owing to the same cause.

We shall now inquire whether it be or be not possible in a great measure to avoid the three great evils above described, and at the same time to secure other advantages.

### I.—Smoke.

Is it possible to avoid or to consume smoke—in other words, to produce a smokeless coal fire?

Common coal is known to consist of carbon and bitumen or pitch, of which pitch again the elements are still chiefly carbon and hydrogen, a substance which, when separate, exists as an air or gas. When the coal is heated to about 600° Fah., the bitumen or pitch evaporates as a thick, visible smoke, which, when it afterwards cools, assumes the form of a black dust or flakes, called blacks, or smut, or soot. If that pitch, however, or pitchy vapour, be heated still more, as it is in the red hot iron retorts of a gas work, or in rising through a certain thickness of ignited coal in an ordinary fire, it is in great part resolved into invisible carburetted hydrogen gas, such as we burn in street lamps.

Now when fresh coal is thrown upon the top of a common fire, part of it is soon heated to 600°, and the bitumen of it evaporates as the visible smoke, which immediately rises. Of such matter the great cloud over London consists. If the pitchy vapour, however, be heated to ignition by the contact of a flame or of ignited coal near the surface, it suddenly becomes in great part gas, and itself burns as flame. This is the phenomenon seen in the flickering and burning which takes place on the top of a common fire. But if fresh coal, instead of being placed on the top of a fire, where it unavoidably must emit visible pitchy vapour or smoke, be introduced beneath the burning, red-hot coal, so that its pitch, in rising as vapour, must pass among the parts of the burning mass, it will be partly resolved into the inflammable coal gas, and will itself burn and inflame whatever else it touches. Persons often amuse themselves by pushing a piece of fresh coal in the centre of the fire in this way, and then observing the blaze of the newly formed gas.

Various attempts, beginning perhaps with Dr. Franklin's have been made to feed fires always from below, and so to get rid altogether of smoke. Another more recent one was made about thirty years ago, by an ingenious manufacturer in London, Mr. Cutler. He placed a box filled with coal under the fire with its open mouth occupying the place of the removed bottom bars of the grate, and in the box was a moveable bottom, supporting the coal, by raising which the coal was lifted gradually into the grate to be consumed. The apparatus for lifting however, was complicated, and liable to get out of order, which, with other reasons, caused the stove to be little used. The moveable bottom rested on a cross-bar of iron, which in moving was guided by slits in the side of the coal-box, and was lifted by chains at each end, drawn up by a windlass, and this windlass was turned by bevil wheels, of which one had to be moved by a winch in the hands of an attendant. Mr. Cutler was not aware that others had been engaged in the same pursuit, and took out a patent for his apparatus. A trial at law, however, afterwards decided that he had no patent right.

In the new fire-grate which I am now to describe I have sought in every part the greatest possible simplicity which could give complete efficiency. The combination is represented in the accompanying engraving. The charge of coal for the day is placed in a box immediately beneath the grate, as shown in the diagram at the letters *e, f, g, h*, and is borne upwards, as wanted, by a piston in the box, raised simply by the poker used as a lever, and as readily as the wick of an argand lamp is raised by its screw; the fire is thus under command, as to its intensity, almost as completely as the flame of a lamp. There are notches in the piston-rod for the point of the poker, and a ratchet catch to support the piston when the lever is withdrawn.

The coal-box of an ordinary fire may have a depth of 7 or 8 inches, which will receive from twenty to thirty pounds of coal, according to the area. In winter an inch or two more depth of coal may be placed over the mouth of the box before the fire is lighted, and in warmer weather the box will not require to be quite filled, that is to say, the piston at the time of charging needs not to be lowered quite to the bottom. If it become desirable on any account, as will happen with kitchen fires, to replenish the coal-box in the course of the day; it may be done almost as easily as to put coal on a common fire; thus, when the piston has been fully raised, so as to have its flat surface flush with the bottom bar of the grate *e, f*, a broad flat shovel or spade, of the shape of the bottom of the grate, is pushed in upon the piston, and it becomes at once a temporary bottom to the grate and a lid to the coal-box. The piston being then allowed to sink down to the bottom of the coal-box, the spade or lid is raised in front by its handle, and opens the box, so that a new charge of coal can be shot in. The spade being then withdrawn, the combustion goes on again just as in the morning. That the opening of this lid may be wider, the second bar of the grate is hinged, and yields to the upward pressure of the spade.

This fire is lighted with singular ease and speed. The wood is laid on the upper surface of the fresh coal filling the coal-box, and a thickness of three or four inches of cinder or coked coal left from the fire of the preceding day is placed over it. The wood being then lighted, instantly ignites the cinder above, and at the same time the pitchy vapour from the fresh coal below rises through the wood-flame and cinders, and becomes heated sufficiently to inflame itself, and so to augment the blaze. When the cinder is once fairly ignited, all the bitumen rising through it afterwards becomes gas, and the fire remains quite smokeless ever afterwards. A fire-place supplied with coal from below was used by a distinguished engineer in town for ten years, and the fact that his chimney had not to be swept in the whole of that time, proved that no soot was formed.

In the new grate, because no air is allowed to enter at the bottom of the coal-box—for the piston-rod fits its opening pretty accurately—there is no combustion below, but only between the bars of the grate, where the fuel is completely exposed to air, and near the mouth or top of the coal-box. The unsatisfactory result of some other attempts to make such a fire have been owing, in part, to the combustion extending downwards in the coal-box, because of air having been admitted below, and then consequent melting and coking of the mass of coal, so as to make it swell and stick, impeded the rising of the piston.

A remarkable and most valuable quality of this fire is, its tenacity of life, or its little tendency to go out or be extinguished. Even after nearly all the coal in the grate, surrounded by the fire bars, has been consumed, the air will dive into the coal-box and keep the fire there gently alight, like a torch burning from the top downwards, until nearly the whole contents of the box are consumed, and thus the fire will remain burning for a whole day or night, without stirring or attendance. and yet at any moment it is ready to burn up actively when the piston is raised.

In certain cases, as during long nights, it may be desirable to ensure the maintenance of combustion with rather more activity, and for this purpose there is a slide in a small door at the front bottom of the coal-box, by which a graduated admission of air may be allowed. That door itself is open before lighting the fire, to allow of the removal of any coal-dust or ash which has fallen down past the edge of the piston.

Before lighting the fire in the morning, the little ash which remains with this form of combustion is removed from off the piston. The fire is extinguished at night by allowing it to exhaust itself, or by lifting out the few lumps of coke or caked coal which remain. The morning charge should be such that enough cinder or coke may be left for the smokeless lighting of the next day.

By the means now described, then, the first-named evil of the production of smoke is effectually combatted.

### II.—Waste of Fuel.

We now come to consider whether the *waste of fuel* which occurs in common open fires can be prevented.

Count Rumford, as the result of his own experiments already referred to, declared that five-sixths of all the heat produced in a common open fire passed up the chimney with the smoke, and therefore to waste; and he appealed in corroboration to the experience of the continent of Europe, where close stoves are used, which do not thus waste heat up the chimney, and where a much smaller allowance of fuel than is here needed in open fires suffices. I have, in my own house, a striking illustration of the matter in a peculiar enclosed fire, which, for fourteen years past, in a large dining-room, has maintained, day and night, from October to May, a temperature of 60° or more, accompanied with good ventilation, by an expenditure of only 12 lb. of coal for 24 hours, or about a fourth of what would be used in an open fire burning for 15 or 16 hours. This fire is lighted about the beginning of October, and is not extinguished until the following May. The aperture by which the fresh air enters the stove to maintain the combustion sufficient to warm that room, is about ⅞-inch in diameter. If this be compared with the aperture of a common chimney-pot, which has a diameter of 10 inches and an area or size 150 times greater than my stove, and one thinks of the rapidity with which a column of dense smoke filling that pot escapes from it when the fire is burning briskly; and reflects further that such column consists entirely of the warmest air from the room, blackened by a little pitchy vapour from the fire, there is proof of prodigious waste, and room for reasonable hope that a saving is possible. To see how a saving may be effected, the exact nature of the waste in such cases has now to be explained:—A single mouthful of tobacco smoke, on issuing, immediately diffuses itself so as to form a cloud larger than the smoker's head, and soon would contaminate the whole air of a room, as would also the smoke and smell of wood, paper or other combustible burned in a room. Now, the true smoke of a common fire is not the whole of what is seen issuing from the chimney top, but only little driblets or jets which shoot up or issue from the cracks in the upper surface of coal which forms the fire. These jets, however, quickly diffuse themselves, like the tobacco smoke, in the air around them, that is to say, in the large volume which fills the space left over a common fire, and over the hobs, if there be such, at the side of the grate. The whole of the air so contaminated, and which may be in volume 30, 50, or 100 times greater than that of the true smoke, is then all called smoke, and must all be allowed to ascend away from the room. It is evident, then, that if a cover or hood be placed over a fire, such as is represented by the letters *y*, *a*, *b*, in the diagram, so as to prevent the diffusion of the true smoke or the entrance of pure air from around to mix with it, except just what is necessary to burn the inflammable gases which rise with the true smoke, there would be a great economy. This has been done in the new fire-place, with a saving of from one-third to one-half of the fuel required to maintain a desired temperature. In a room the three dimensions of which are 15 feet, 13½ feet, and 12 feet, with two large windows, the coal burned to maintain a temperature of 55° in the coldest winter days, has been 18 lb. for 19 hours, or less than a pound per hour.

And it is to be remarked that not nearly the whole possible saving has been effected in the case referred to; for the grate was an old one imperfectly altered, and as the true smoke, little diluted, is very hot air when it leaves the ignited coal, and if it were made to pass, in contact with a vessel containing water or colder air, it would give up for use a considerable part of its heat. In many cases such saving will be profitably effected. Under the present imperfect forms of open fire, the whole of the hot smoke passes away as certainly as here, but at present is so much diluted with the colder air of the room, that ordinary observers do not perceive, and, consequently, do not regret, the fact.

In many cases the contraction of the space over the fire will be more conveniently made in brickwork than by a metallic hood. Where the hood is used, unless it be made a boiler or water-vessel, it should be lined with tile to prevent that overheating which would cause in the room some smell of heated metal.

The stalk of the hood at *y*, passes closely through a plate or other stopping at the bottom of the chimney, so that no air shall enter the chimney but through the hood; and there is a throttle-valve or damper in the hood-stalk, at *t*, giving a perfect control over the current of air that passes through. No part of the apparatus is more important than this valve or damper, and its handle or index must be very conspicuous, and have degrees of opening marked on its plate as clearly as the points are marked on a compass-card. When the valve is quite open, the chimney acts to quicken the combustion like that of a blast-furnace, or like a forge-bellows; but, by partially closing the valve, the current may be diminished, until only the most tranquil action remains. The valve should not be open in general more than just enough to let all the burned air or thin smoke, which is scarcely visible, pass through. When the valve is once adjusted to the usual strength of chimney action, it requires little change afterwards.

In many cases it is desirable to be able to command and modify by a moveable plate, the size of the front opening of the hood or fire-place, as well as the opening of the chimney throat. By the proper adjustment of the two, the desirable brightness of the front of the fire may be maintained.

The chimney-flue above the upper opening of the hood should have its sides made slanting, so as not to harbour dust or any soot which, from any careless use of the fire, might be produced. The size of the chimney-flue is not important.

The answer then to the second question, as to the possibility of saving fuel, is by the facts here adduced, given in the affirmative.

### III.—Defects of Heating and Ventilating.

The third and last of the great evils of the present open fires is that there are great irregularities and deficiencies in their heating and ventilating actions, which bear so powerfully on the public health. The hood and its damper, as influencing these, may appear perhaps of more importance than as saving the fuel.

The hood and its damper, by allowing so small a quantity of air to pass through in comparison with what rises in an open ordinary chimney, lessens in the same degree the cold draught of air towards the fire from doors and windows, and which are to the inmates common causes of winter inflammation and other diseases; and for the same reason the heat, once radiated from the fire towards the walls of the room, not being again quickly absorbed and carried away by such currents of cold air as are referred to, remains in the room, and soon renders the temperature of the whole more equable and safe.

Still more completely to prevent cold draughts approaching from behind persons sitting around the fire, the fresh air for the room is conveniently admitted, chiefly by a channel which leads directly from the external air under the floor to the hearth, and there allows the air to spread from under the fender. The fender, exposed to the fire near it, becomes hot; the cold, fresh air then rising under it takes from it the excess of its heat and so becomes itself tempered before it spreads in the room. The two evils of excess of heat and excess of cold, meet to neutralise each other, and to produce a good result.

The importance of general ventilation, again, is strikingly exhibited by such occurrences as the following, which was related at the meeting of scientific friends at which I first described the new fire-place, by Mr. R. Chambers, of Edinburgh, as having happened not long ago in Glasgow. A large old building, which had been formerly a cotton-mill, was fitted up as a barrack or dwellinghouse for persons of the working classes, and had nearly 500 inmates. Like all foul and crowded human dwellings, fevers and kindred diseases soon became prevalent there. After a time a medical man who was interested obtained permission from the proprietors of the neighbouring chemical works, in which there was a lofty and very powerful chimney, to make an opening of 1 foot in diameter into the side of the chimney for the ventilation of the lodging-house. He then connected with this a main tube from the lodging-house, which had branches running along all the passages or galleries, and from the ceiling of every separate room a small tube communicated with these branches. Soon after, to the surprise as well as to the delight of all concerned, severe diseases entirely disappeared from the house and never returned.

Now the chimney of the new fire-place, although not very tall, has a ventilating power scarcely inferior to that of the Glasgow chemical works. The arrangement of the hood with its valve, as above described, by allowing only unmixed and very hot smoke to enter the chimney, instead of, as in common chimneys, smoke diluted with many times its volume of colder air, increases the draught just as it does the heat of the chimney, and through an opening then made into the chimney from near the top of a room, all the hot, foul air in the room, consisting, perhaps, of the breath of inmates, smell of meals, burnt air from candles, lamps, &c., and which else accumulates and stagnates at first near the top of the room, is immediately forced into the chimney and away. This is strikingly proved by placing near the ventilating opening a light body, as feathers or shreds of paper suspended to a thread, and seeing with what force it is drawn into the opening.

In the diagram the opening is represented at the letter *v*, having the common balanced chimney-valve in it, which, by the wire descending to a screw within reach of the hand, can be left open to any desired degree.

That valve I recommended many years ago, and its use has become pretty general over the country, but, in many cases, what I described as an essential concomitant—the contraction of the chimney-throat and the space over the fire—has been omitted, and the proper action of the valve has been prevented.

This is what I had to say on the correction of the third of the great evils of the common fire, and I hope it has been shown to be possible to construct an open fire-place, scarcely differing in appearance from an ordinary English fire-place, with its pleasing associations, but which shall be smokeless, saving much fuel, and ensuring the healthful warmth and ventilation of our houses.

There are yet subordinate advantages of the new arrangement of fire-place, among which the following may be noted.

1. Chimney-sweeping can scarcely be wanted where there is no soot.

2. Chimney-flues without soot cannot catch fire, and, if fire were in any way there introduced, by shutting the hood valve it would be certainly extinguished. Thus a large proportion of the conflagrations of buildings may be avoided.

3. The huge evil (almost universal) of smoky chimneys cannot occur with this grate.

4. The occasional sudden rush of air towards a hot wide chimney, when the door is opened, and which carries readily the light muslin dress of a lady towards the grate and inflames it, cannot happen with this grate.

5. The danger of sparks from exploded pieces of coal thrown on the carpet does not exist here, for all the coal is first heated and coked while deep in the coal-box, and covered over. Thus a fire-guard is not wanted on this account.

6. The strong draught of a voracious fire in one room, or in the kitchen of a house, cannot disturb and overcome the action of other chimneys in the house, as is now very common.

7. The strong draught of any well-constructed fire-place may, by a connecting tube be made to ventilate any distant rooms, staircases, cellars, closets, &c.

8. The strong and copious draught caused by momentarily opening the hood valve or damper will prevent the diffusion of dust when the fire is stirred or disturbed.

9. The chimney-valve, by its powerful ventilating effect, obviates all objections to the use of gas-lights in houses, thus leaving the beauty, cleanliness, cheapness, and many conveniences of gas unmarred. Explosion from accidental escape of gas in a room or house, of which occurrence there have been some destructive instances, cannot happen where there is the ventilating chimney valve, for cold coal-gas entering a chimney-flue produces a more powerful draught than hot air does.

10. The improved chimney draught in attic or upper rooms will make these more valuable, and will increase the comfort of low houses and cottages.

11. It would, moreover, be convenient occasionally to carry the flue of a close stove, or bath, or the ventilating tube from lamps in staircases, into any acting chimney.

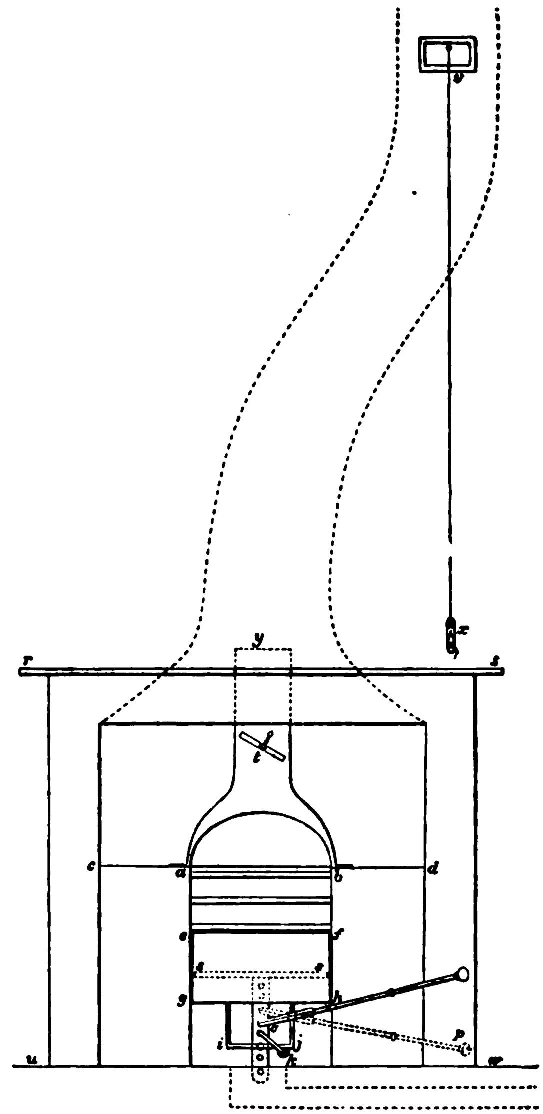
12. This torch-fire (as some have called it, because it burns from above downwards, like a torch or candle) is remarkably adapted also for the purpose of the kitchen.

13. The change of any existing grate of an old fashion into this is easy and inexpensive, and by having a piston-plate with holes it can be used as a common grate.

14. Any kind of coal or coke may be used in this grate, even the small culm or coal-dust, which is very cheap. In a common grate, coke or Welsh stone coal would be objectionable, because containing chiefly heavy carbonic acid instead of the steam and carburetted hydrogen of bituminous coal, and the gas, which is poisonous, might spread in the room, but by the strong draught of the hood this could not happen.

I might extend this list, but I need not.

Before concluding I may direct attention to the remarkable fact, only of late well understood, that of the only four great necessaries of life, or things which Providence has left to man in various parts of earth to procure for himself, namely, fit air, temperature, aliment, and work alternating with rest,—the skilful management of a domestic fire goes far to secure the two first-named, viz., fit air and warmth; but these are the last which men come to understand well, because they are invisible and impalpable, and, therefore, to be perceived only by the eye of the mind after much cultivation.



The diagram represents a common fire-place with mantel *r s* or chimney piece, two jambs, and a common grate with two bars and bottom, to which four parts, the essentials of the new fire-place, are added. *e f g h*, is a box or receptacle of iron to contain the charge of coal for the day, with its open mouth placed where the bottom bars of the grate had been. It may stand on feet on the hearth, or may be fixed to the grate. Besides its fixed bottom *g h*, it has also a moveable bottom *s s*, like a piston, on which the coal immediately rests, and is lifted as wanted, or let down as the piston moves; a piston-rod passes through the fixed bottom, steadied by a guide-hole in the stirrup or bar *i j*, below. The piston-rod has notches or openings in it to receive the points of the poker *p o*, which, acting as a lever, having its fulcrum in the foot of the box or otherwise, lifts the piston. A catch or pall *k*, falls into the notches as the piston rises, to prevent its return until desired. In the centre of the bottom front is a door which is opened at will to admit a little air if wanted, or for removing small coal or ashes which fall past the piston. Where the grate is set low a small opening is made in the hearth to allow the end of the piston to descend.

*a b y*, is a hood or cover for the fire, like an inverted funnel opened in front, placed over the fire to contract the open space there, and to receive the true smoke of the fire and convey it little diluted into the chimney-flue at *y*. *t*, is a valve or damper, placed in the narrow part of the stalk of the hood to give complete control of the current of air passing through. There is an index externally, showing clearly always the position of the valve. *y v*, marks the direction of the chimney-flue in the wall, having generally to bend to one side to avoid the fire-place of the room immediately above. *v*, is the ventilating chimney-valve, admitting air from near the top of the room to the flue, balanced nearly on its centre of gravity so that the least pressure from without opens it inwards, but any pressure from within, as of smoke, closes it. There is a wire descending from the valve, with a screw or loop-peg, for partially or wholly closing it. There is a channel underneath the hearth by which fresh air, directly from the atmosphere, enters the room, to be warmed under the fender or near the fire, and then to spread in the room. It has a controlling-valve.

## ON THE DRAINAGE OF BUILDINGS AND STREETS IN THE METROPOLIS.

A discussion took place at the Royal Institute of British Architects, upon the paper read by Mr. Boulnois, on the above subject (*ante* p. 181), commenced by the Chairman (Mr. Mocatta), who congratulated the meeting on the very able manner in which a subject of vital importance to the health of the metropolis had been brought forward, and hoped that its discussion might elicit valuable opinions to assist in the adoption of a perfect system of drainage throughout the country. Considering that this great question had been much discussed, and that more experiments had been made in this than in any other country, it was most extraordinary that they had not hitherto been able to arrive at any correct conclusion on the subject.

Mr. Garling said, that he was much gratified to learn that Mr. Boulnois had a decided objection to the use of pipes for sewers, and also to small sewers generally. Indeed, he considered pipe *sewers* to be both defective and unscientific for the metropolis or for any large town, as the sewers for such places ought to be large enough to enable workmen to enter, and examine and cleanse them. A 12-inch pipe sewer had been lately made in Hatton-garden about 1000 feet long, intended for the drainage of the houses, as well as for the surface. This size he considered vastly too small, even to carry off the water from the area it was constructed to drain. For in a thunder storm, such as sometimes occurred, and which, therefore, ought to be provided for, sufficient water might fall in one hour to fill such an aperture completely full for a length upwards of three miles long, or about some sixteen times its extent, so that in the event of a stoppoge, or the water not running off with sufficient velocity, the consequences might be most serious; and, indeed, there were now repeated complaints of its being the cause of stoppages and overflows in the street in heavy rains, though with very little more than the surface water from the street at present running into it. With reference to this pipe sewer, Mr. Garling afterwards observed, that in order to aid its current, it was laid with a fall of 1¼-inch in 10 feet, or equal to 55 feet in a mile, a fall so utterly impracticable on a large scale, that supposing a sewer with such a current to be laid down in Oxford-street (which was about 1¼ mile long) and with a water bed 12 feet deep below the surface of the street at one end, it would be 60 feet above that surface, or as high as the roofs of the highest houses at the other end. The liability to fracture of pipes used as *sewers* was another objection to the system for the drainage of any large city, from the difficulty of ascertaining the exact place of the defect. The drainage of houses by pipes, assuming a separate drain to each, was less objectionable; but even in house drains a pipe, 6 inches bore, was not ordinarily large enough. He thought there could be no doubt that small drains became stopped up much more frequently than large ones; and he believed that the water ordinary flowing in from closets and sinks was not sufficient to cleanse the small drains commonly used. He knew an instance of a small drain, only 10 feet long, which was connected with a 4½ inch soldered soil and rain-water pipe, being choked up for some months, notwithstanding there was a head of water standing 45 feet high in the pipe, and when the drain was opened, the water flowed from the opening like a fountain, spouting up seven or eight feet, and yet it had not been able to force its passage through this short length of small drain. Again, there was an absolute necessity for the admission of air into drains, or the water would not flow; this may be an air vent having communication with the external air as high up as possible to avoid smell, or else with the sewer, which latter some might think strange. A very frequent cause of drains being stopped was their being "air-bound," as it was termed; and another evil resulting from this was, that if the air was not allowed to flow into, and escape from the drains by some other way, the water would be drawn out, or forced out of the air traps, as the case might be, and a stench would arise in consequence. If a drain was not as hermetically sealed as it could be by art, except the necessary vents just named, it would always smell; and a frequent defect causing this was the imperfect connection of the soil and rain water pipes with the drain. These pipes should always have proper flanges at the junction bedded in brickwork in cement. One objection to pipe drains was, that in case of a defect it was difficult to discover its exact position without breaking up, perhaps, the entire drain, or great part of it; and therefore a cemented brick drain, or a drain covered with slate or stone, was preferable in that respect; and this remark of course applied equally to pipe *sewers*. With regard to back drainage he quite agreed with the arguments urged by Mr. Boulnois; and a further objection was to be found in the fact that what was an area or a back garden at present might hereafter, and perhaps very soon, be built upon, and converted into a house or warehouse; and, therefore, a drain properly placed there as an external drain at one time, would afterwards become an internal one. Experience had amply shown the force of this remark, not only in the city, and in places like Oxford-street and Piccadilly, where scarcely a back yard was left, but in the suburbs. Moreover, in back drainage, which was not separate drainage of each house, there would also be a difficulty arising from the opposing interest of the different occupiers, who would constantly object to having the drains in their premises opened to discover defects, from which perhaps their neighbours, and not themselves, might be sufferers. The drainage of every house should be distinct from that of the neighbouring houses—there should be no drain runnning from one house under the others—in which case the basement at the lowest level might suffer from the defect in the drain of the higher one. A case came to his knowledge in Spencer-street, where a house became almost uninhabitable from the stoppage of the drain in other property which it ran through at the back, and the occupant had made repeated efforts to get it opened, but without success. His appeal to the ground landlord's agent was in vain; neither the parish authorities, nor the Commissioners of Sewers, he was told, could give him any relief; and he at last found that his only resource would be to apply to the Court of Chancery. Cases of this kind would constantly occur under the back drainage system, and an immense amount of litigation and inconvenience would ensue. Nearly thirty years ago he had himself advocated in a public journal many parts of the system recently proposed. He had then declared that no sewerage whatever ought to go into the Thames at any place above Grays; that on the North side of the river there should be a main sewer—say from Chelsea to Grays Reach; that at or about Chelsea there should be large tidal reservoirs to be filled at high water, and at about two-thirds ebb this water should be used occasionally for the purpose of flushing the sewers; and that two large reservoirs should be formed at Grays apart from all dwelling-houses, where the sewerage should be alternately first in one and then in the other, decomposed by chemical means, and removed in barges. Mr. Garling concluded by repeating his objection to pipe sewers and small drains of all sorts. As a general rule he scarcely knew a small drain that did not choke up, nor a large one that did.

Mr. Haywood, C.E., with reference first to the question of main sewers, stated that he was not a thoroughgoing advocate for brick sewers alone, having himself used and intending still to use pipes; but he did so only to the extent to which, in his opinion, pipes might properly be applied, and not to the extent of the telescopic system as it might be termed. And in this he differed with many advocates of the tubular system. He considered that every town should be judged of by its own conditions and that the main streets of all towns of ordinary size should' have sewers large enough for men to enter, the minor streets being left to the judgment of the engineer. It was necessary that sewers, or ducts of some kind, should be provided for carrying off rain water or storm water, house drainage and subsoil drainage: the latter was a most important point, because a dry basement was a most invaluable advantage; and it was almost as important that a house should be dry, as that it should be free from smells. The question of the best mode of accomplishing all the desired objects was in reality how this could be most economically performed, for it might be done in two or three ways.

Some persons advocated three sets of sewers for this purpose. He thought, however, that as a new theory could not be tested for many years, until it was so, a brick sewer, large enough for men to enter, which had been found to answer all the purposes, as being the most simple, was the best. He was convinced that a brick sewer would be found to answer every purpose that could be effected by two or three sets of pipes. Sewers ought to be monumental in their character, and if constructed in our day, none of us ought to except to see them replaced by new ones. They ought, indeed, at least, to last for a century, and the sewer in the main street of a town ought never to be broken up till it was worn out. A sewer, whether of brick or pipe, so small that a man could not enter it, should never be employed in such a street. That brick sewers would drain the subsoil effectually might be illustrated by the fact that throughout the city generally they had been able to lower the surface of water in the gravel as much as six or eight feet; and the basements of many houses, which twenty-five years ago had been almost useless, were now available for the stowage of the most costly materials, such as silks and other goods, and numerous other purposes. He believed the rateable value of the property thus gained was not less than from 20,000*l.* to 30,000*l.* a year. He had now a great number of sewers which had not been opened for years, and which, he believed, never would need to be opened again. With regard to stoppages in pipe sewers, it was stated by their advocates, that it was very easy to obviate them, as they were always found to be preventible stoppages, but where stoppages occurred repeatedly from similar causes they could not be called preventible, but rather constant and unpreventible stoppages, and to that every sewer was subject. Within the last few days one of his pipes had been stopped from end to end. He had built about 120 or 130 pipe sewers, and having used extreme care in their construction he had only had one breakage. With regard to the breakage of pipes, of course that could be obviated, as it would be very easy to make pipes strong enough for all purposes, and the breakage of pipes could not be well alleged as a reason for not using them. He had had two or three trifling stoppages in his pipe sewers, and recently there had been one of a serious nature in Leadenhall Market, a place, the surface of which, of course, could not be broken up with impunity, or without causing great inconvenience. The houses draining into that pipe sewer were occupied by respectable tradesmen, to whom money was not an object, and every appliance had been used in the houses to make both drains and sewer self-acting. The pipe, however, was stopped from end to end, and he could not tell the cause of it, nor whether that cause was preventible or not. He had opened the sewer in three places in a length of 135 feet, but had not broken the pipes. It was doubtful whether that sewer could ever be restored to its integrity again. Referring to one of Mr. Boulnois' diagrams he stated, that when a soft bed of deposited matter once accumulated in a sewer, it became a nucleus which impeded everything passing through it. If he might be permitted to allude to published books, he would refer to a blue-book which contained a diagram of the sewer in Holborn, which was within his jurisdiction. In the first place the sewer in this diagram was placed upside down; and further it appeared that a diagram similar to Mr. Boulnois' was shown to a witness, who was asked two or three extraordinary leading questions, with a view to show that the brick sewer in Holborn was five or six times the necessary size, because a pipe of the size shown would carry off all the water of Holborn; but the party had forgotten, or probably did not know, that it was intended to carry off not only the Holborn water and foul matter, but that of a large area adjacent. There was a curious general advocacy of the tubular system in this blue book, with a vast amount of theorising on this subject, which, if it proved anything, would prove that a 2-inch pipe was large enough for any house of a moderate size. The size, however, of a drain must be determined by practice, and when the advocates of the very minute system of drains objected that drains, as generally constructed, were double or treble the necessary area required, he (Mr. Haywood) would only reply that, even in determining the sizes of their own drains, they had exceeded the size which their theory pretended to show was sufficient, and they did so because they said that practically it was necessary to have larger than that given by theory, which he quite agreed with, and would state, that according to his *practice* a 3-inch drain was not large enough for a house. Ventilation of sewers was absolutely necessary, otherwise they would ventilate themselves into the houses. The plan of ventilating into the centre of the street, although a bad one, was perhaps the best that could be adopted at present, as it brought the stream of foul air where it could be the easiest diluted and carried off. With regard to ventilating by the rain-water pipes he had found it to answer, although many complaints were made of smell being perceptible in the houses through such mode of ventilation; where the foul air had been conveyed above the chimney-stacks, it appeared in certain conditions of the atmosphere that the effluvium descended again. It was rather a medical question whether it would be better to ventilate in the centre of the street or by the peoples' dwellings, but for himself he was in favour of employing flues; and he thought that a compulsory measure (such as appeared to be getting fashionable) to make manufacturers allow the use of their flues and tall chimneys for the purpose of ventilating the sewers, might be introduced with advantage,—but he would say nothing as to the justice of such a measure. With regard to the drain pipes of Rome and Pompeii he imagined that the Romans collected and applied their fæcal matter to agricultural purposes, as was now done on the continent generally, and that the pipes, of which a specimen was on the table, only carried off the superfluous water of the house. At present one of the great difficulties in Paris was the increasing habit of using water-closets, which had greatly diminished the value of manure, which had brought them hitherto a rental of about 30,000*l.* a-year; and although they abused the Londoners for polluting their river, one of the engineers of Paris had told him (Mr. Haywood) that he was much afraid they would be compelled to do the same, unless the usage of water was restricted. Whatever sized pipes the Romans used to carry off water, it was certain that they used large and flat-bottomed sewers, and the charge of those sewers was deemed a highly important office, as he hoped it would also become in this country. Back drainage in this metropolis, he considered, would be fraught with the greatest inconvenience. Where two, three, or four waterclosets were close together, one drain might be employed, but to carry the drain through the property of many different occupiers would be a most serious disadvantage. Without interdicting this system in all cases he thought it wrong to lay it down as a general principle, and he quite concurred in the opinions stated by Mr. Garling on this point. The public not seeing the objections to this plan might be carried away by its first cheapness, but the ultimate inconvenience of it would be very great.

The debate on this subject was continued on April 3rd, Mr. W. S. Inman in the chair, when a communicatisn was read from Mr. S. Morris, in which the writer adverted to a suggestion made by himself some years ago to the Commissioners of Sewers, for obviating the inconvenience attendant upon syphon sewers during high tides, whenever the quantity of rain falling exceeds the capacity of the sewers, which are then resolved into reservoirs, and having no exit at the flood-gates, cause an overflow in the localities in which they are situated. Mr. Morris proposes that the water be allowed to find its way to a suitable level by the simple law of gravitation, where pipes should be provided for its further progress, similar to those employed by the water companies, which, within certain well-known limits, would allow of such undulations as the intervening surface might require. Thus a reservoir at Piccadilly might have its eduction-pipe carried below the level of St. James's-park and the lowest parts of Westminster, and raised up over the embankment of the river, so as to pour a continuous current into the Thames at all states of the tide. Intercepting sewers of very considerable length would by this be wholly obviated, and the enormous expense of construction avoided. The pipes, it may be mentioned, would not exhaust themselves, but act on the principle of intermitting syphons.

Mr. Bazalgette, among other observations, corrected an inaccurate statement in an article in the *Builder*, headed 'Progress of the Manufacture of Tubular Drain Pipes,' which stated, that "it is estimated that in the metropolis about 15,000 houses have been drained with 4-inch tubular drains, and about half as many with 6-inch drains, while upwards of 250 miles of pipe-sewers have been laid in streets;" whereas the total number of houses drained within the last four years amounted to 26,978, of which 4926 were drained in 1850; 8581 in 1851; 6271 in 1852; and 7200 in 1853. Of this number, 20,000 (instead of 7500, as stated in the *Builder*) were drained with 6-inch pipes. Mr. Bazalgette further remarked, that although the numbers had been erroneously stated, it was true that 4-inch pipes had been largely used, but it was equally true that they *had failed* to a great extent, and caused a considerable amount of inconvenience. The present Commissioners of Sewers were often called upon to take up 4-inch and lay down 6-inch pipes, and although they did not feel justified in spending the public money in that way, it was being done to a great extent by private individuals. In the same manner, the quantity of pipe sewers ("upwards of 250 miles") have been greatly overstated in the article referred to. They had however been extensively employed, and, as the diagrams of Mr. Boulnois proved, they had often been incautiously applied. Without entering upon a crusade against pipe sewers, he would state what the Commissioners of Sewers, with his entire concurrence and recommendation, were now doing. During the last year, they executed about 22 miles of public brick sewers and 6 miles of pipe sewers, whilst private individuals had executed about 12 miles of brick sewers, and about 85 miles of pipe sewers and drains; making a total of nearly 35 miles of brick sewers, and nearly 92 miles of pipe sewers and drains. This statement would show that the Commissioners did not advocate any exclusive system, but that under certain circumstances and for minor branch sewers they considered pipe sewers advantageous. The old practice of brick sewers led to a large expenditure, but did not end in failures nor produce disease, whereas if the use of the modern pipe was carried beyond its proper limits, failures and obstructions occurred, together with an amount of injury to the public health which could not be estimated by pounds, shillings, and pence. Some of the new theorists on drainage announced their systems as the most "economical and efficient," but "the cheapest and best house in London" was generally neither the cheapest nor the best, and a system of drainage which might be most expensive in the first instance might be the cheapest in the end. It had been strongly asserted, that pipes or small sewers were self-cleansing, whereas large or brick sewers had a sluggish flow, and became in fact merely elongated cesspools. He could state most positively from experience, that this was not the case. It was true that some of the large sewers in London were not self-cleansing, but this was because they were situated in low and flat districts, with their outlets pent up for eight hours at a time by the tide; but from their size they were easily entered and cleansed by workmen, and certainly pipe sewers in the same situations would allow deposit to be made in the same ratio. In fact, taking the best and most modern forms of brick and pipe sewers of the last ten years, and laying them side by side with a tolerable fall under exactly the same circumstances, he could assert that the self-cleansing powers of both would be equal. The representations in blue-books of brick sewers half filled with deposit, were drawn from old sewers without sufficient water flowing through them, many of them now abandoned, and were not fair representations of the existing state of the London sewers. Mr. Bazalgette proceeded to show, by reference to the diagrams, that the proportion of the sectional area of the sewage water to the frictional surface of the sewer or drain over which it flowed, in conjunction with the fall, governed the self-cleansing power, and that egg-shaped brick sewers of proper dimensions had the advantage over small pipe sewers in this respect, especially in the event of overcharge from storm-waters, whilst they also enabled men to remove the heavy road-drift which was so likely to produce stoppages in the latter. All sewers became in time covered internally with a slimy surface, which produced an equality of smoothness between bricks and pipes, and in execution the bottom of a brick sewer could be made more uniformly smooth, and consequently less likely to create an obstruction than a pipe with numerous joints. Comparing 4-inch with 6-inch pipes, Mr. Bazalgette applied the theory of the proportion of area to frictional surface, and contended that the scouring power in the former, when three-parts full, would be practically the same as in the latter when half-full, and that the 6-inch pipe had an advantage in allowing small substances to pass, which in the smaller pipes would remain, and become the nucleus of an obstruction. With reference, also, to the use of small pipes, it was obvious that a larger pipe would allow for a greater amount of sinking in the ground on which it was laid than a smaller pipe. Pipe sewers should therefore be laid larger than the *theoretic* size, to allow for casualties and defects. On the subject of combined back drainage, Mr. Bazalgette admitted that there were circumstances in which it might be economical and advantageous, but as a general rule applied to London, it would be neither the cheapest nor the best system. The experiments and formulæ of the great philosophers who had studied this subject could not be disregarded, and it was evident from these that a torrent of rain or storm water could not pass through a 6, 9, or 12 inch pipe from a large area. One of the diagrams before the meeting represented the Fleet Sewer, with a sketch of a locomotive engine within it, as a scale to show its immense size, but he (Mr. Bazalgette) knew that on one occasion a few years ago even that sewer was not large enough to carry off the flood water from Hampstead, &c. Whether separate or combined house drainage were adopted, a sewer in the middle of the street for the surface drainage was essential in all large towns, whatever might suffice for mere country roads; and this point, though it materially affected the question of economy, had been overlooked by the advocates of back drainage. Mr. Bazalgette produced a drawing in illustration of the comparison between separate and combined house drainage, and contended, that, both for economy and efficiency, the former system was the better one. In the separate drainage system, each house drain could be probed from the common sewer, without interfering with the adjoining houses in any respect. He further adverted to the difficulty arising from the conflicting interests of different owners, which would prevent the removal of obstructions without the exercise of the legal powers vested in the Commissioners, and likewise referred to the frequent erection of workshops or warehouses in the rear of houses, which would render back drainage further objectionable. Upon the whole, except in poor outlying districts, where as a matter of economy, or to get rid of the greater nuisance of a cesspool, combined drainage might be introduced, the separate system was the best. He considered that in the case of valuable property, where stoppages in the streets and injury to trade was of the most serious consequence, it was essential to adopt large sewers and the separate system, as that which would interfere the least with the trade and traffic. Mr. Boulnois had dwelt upon the breaking of pipe sewers, but he (Mr. Bazalgette) was of opinion that the manufacture of pipes had been greatly improved, and that they might be made strong enough to bear any amount of pressure; although of course the cost was increased by the additional thickness. He considered the half-socket as the best kind of joint. As to the ventilation of sewers, he found that pipes from them carried above the roofs of houses were liable to the escape of effluvium by leakage, or that the smell was brought down to the windows by eddy currents in certain states of the atmosphere. He believed that a system of ventilation by furnaces, as adopted in mines, would be the best plan; but that in the meantime the present system of ventilation, through gratings into the middle of the street, was the best plan that had been practised. He could not approve of Mr. Boulnois' suggestion of a channel for the surface water beneath the foot-pavement, used in the Corso at Rome, inasmuch as straw and dirt would be washed into it, producing floodings, and causing much trouble and inconvenience.

Mr. Burnell, C.E., referred to the plan called "en encorbellement," formerly adopted in Paris, of using a small channel worked in the granite kerb and under the pavement to carry off the surface water. It had been there found, however, that horses were very liable to slip and break their legs in consequence of these gutters, and the use of them was therefore generally discontinued. The Romans confined their proceedings to land drainage and surface water—a description of which was to be found in Columella's, Cato the elder's, and in Varro's works "de re rustica;"—any system like the modern sewerage did not exist at Pompeii, or in any other Roman town. Mr. Boulnois had adverted to the system of sewerage adopted in Paris, and he was sorry to observe that Lord Shaftesbury had praised that system in the House of Lords. The fact however was, that there was no sewerage, in one sense of the word, in that city, and although a few houses and hospitals were said to have had their sewage conveyed into the main drains, this practice rendered private parties liable to a heavy penalty, which the Municipality rigidly enforced. The whole extent of the main drains executed in Paris up to the year 1852 was about 90 miles, whereas the Commissoners of Sewers in our own metropolis had executed 35 miles in one year. All the sewers of Paris were large enough to allow a man to enter; the bottoms were segmental, and the minimum fall was about 2 in 1000. But in Paris there were cesspools beneath *every house*, and although great care and superintendence was exercised in their construction, and excellent materials were used (*meuliere and hydraulic lime*), the filtration from the cesspools was so considerable that the well waters had been pronounced by chemists to be unfit for the ordinary purposes of life. Any person who had walked the streets of Paris at night, could not have failed to discover that all these cesspools were necessarily opened occasionally. Mr. Burnell added, that it was too much the practice in blue-books and with Boards of Health to assume, when any convenient phrase or formula had been hit upon that it expressed a fact. Thus the terms "self-cleansing sewers" and "sewers of deposit" had been much used; but a sewer was a passive object, and consequently these expressions were as erroneous in grammar as they were repugnant to common-sense. The expressions "hill-top" and "valley-water" were exposed to the same comment. The Board of Health had laid it down as one of these "formulæ," that 80 gallons of water per diem should be allowed as a proper supply to each house, but at Croydon 200 to 500 gallons had been given to each house to carry out the cleansing of these—so-called—self-cleansing small tubular drains. Amongst the objections to back drainage one had been overlooked, namely, that the land upon which it was effected became public property, and therefore the introduction of the system would occasion an interference with private rights, to which the people of England were unaccustomed. Still cases might arise in which, from peculiar circumstances, back drainage might be desirable; and in the course of his own experience he had been asked by the Commissioners of Sewers to allow another property to be drained through that for which he was concerned; but on another occasion when he proposed back drainage for two houses, and offered to give up their yards to the public, the Commissioners of Sewers refused to allow it.

Mr. Papworth inquired what Mr. Bazalgette considered to be the greatest amount of internal pressure to which a 6-inch pipe would be subjected.

Mr. Bazalgette did not assume any pressure till a stoppage took place, and then it would depend upon the head of water.

Mr. Papworth then inquired what head of water could be stopped up in a 6-inch pipe?

Mr. Bazalgette said, that he was not prepared to answer that question from any practical experience.

Mr. Inman suggested that the answer would be given by Mr. Bazalgette's stating the hydraulic proof which he usually put upon drain pipes.

Mr. Bazalgette said, that hydraulic proof was not applied to the pipes; the actual test to which they were subjected was the external pressure which would crush them. The 6-inch pipes bore the test, but the 15 and 18 inch pipes were so frequently crushed, that until the manufacture was improved, the Commissioners would not use any larger than 12-inch diameter. In practice, it was found that the 6-inch pipes did not burst, but became stopped up. The external pressure would vary with the depth at which the pipes were laid, and the nature of the soil. He was not aware that pipes were proved by internal pressure, but he knew that when they were first introduced the Board of Health endeavoured to employ them as water-mains, and in those cases they burst, and iron pipes were substituted.

In answer to a question from Mr. Papworth, Mr. Haywood, C.E., said, that the gullies in Paris were not trapped, and that a vast quantity of fæcal matter passed into the sewers, notwithstanding the Municipal prohibition.

Mr. Burnell stated, that according to the experiments of M. Boussingault, there was at least ten times as much ammonia in the atmosphere of Paris as there was in the open country.

Mr. Haywood gave the particulars of the pipe sewer in Leadenhall Market, which had become stopped up, as stated by him at the last meeting. It was 135 feet long and 12 inches in diameter, with a fall of 1 in 120; eight houses drained into it, and these were all fitted with waterclosets and syphon pans. It was stopped up from end to end, and he was unable to state the cause, and whether it arose from preventible causes or not. No doubt pipes could be made strong enough to bear 200 feet head of water, but the difficulty was, to join them securely, and this was the cause of the failure when the Board of Health attempted to employ 2-feet pipes for water mains.

Mr. Doulton expressed his regret that views of the most opposite nature, and carried to the greatest extent in each direction, had been expressed by the advocates of the different systems of drainage. Thus they had at one time been told that there was no necessity for brick sewers at all, and at another that it was extremely improper to lay a 12-inch pipe under a carriage way. Again, a 4-inch pipe was said to be sufficient for any house drainage, and soon aftewards it was acknowledged, that though a 9-inch pipe might be sufficient, a 12-inch pipe would be better. At first, pipes were made exceedingly and injudiciously thin, but now it was contended that a 12-inch pipe should be 1½ inch thick. It appeared to him that the truth lay midway between these extremes. The same remark applied to the diagrams of the drains and sewers. In the blue-books there were illustrations of brick sewers which would almost prevent any person building a brick sewer again, whilst some of Mr. Boulnois' drawings showed such representation of defects and stoppages in pipes as would deter any one from laying down a pipe again; indeed, he believed these drawings would have produced a very erroneous impression if the apparent facts had not been modified by the remarks of Mr. Haywood and Mr. Bazalgette. Considering that the pipe sewers had been so recently introduced, that they were laid under very disadvantageous circumstances by persons unacquainted with the proper mode, and that many persons were prejudiced against them as a novelty, he thought it wonderful that there had not been more stoppages than had actually occurred. He attributed those stoppages to the defective way in which the pipes had been laid. Why a concrete foundation should be applied to brick and not to pipe sewers he could not imagine, and if concrete had always been applied to the latter, as it was now, he believed the occasional sinking would have been prevented. Mr. Haywood had very properly stated that pipes could be made of any required strength, and engineers and architects were to blame if they did not stipulate for a proper amount of strength. As soon as the rage for cheapness which existed a year and a half ago had subsided, the pipes were made thicker, but of course the cost was increased in proportion; and it should be borne in mind, that excellence in the manufacture was more essential than mere thickness, the thickest pipe not being always the strongest. A 12-inch pipe, 1 inch thick, if well vitrified, would be stronger and better than if its thickness were increased to 1¼ inch or 1½ inch, as the manufacture and burning would be better with the inch thickness. Experience had suggested many improvements in laying the pipes, and the failures bore but a small proportion to the amount of pipes laid. Pipes were now being laid with great prudence and judgment, in such a way that they might easily be approached from side entrances and examined, and they were laid in straight lengths and not upon the intricate system adopted two years ago. He did not consider the porous nature of brick to be favourable for the formation of the slimy coating to which some value had been attributed: the vitrified internal surface of the tube would be more certain in its effects.

Mr. Fowler observed that Mr. Boulnois had divided the subject into three branches, and that of these the first two had to his mind been satisfactorily disposed of. The third branch of the subject, that of *outfall*, or ultimate disposal of the sewage matter, remained for discussion, if the meeting thought it desirable; and he therefore proposed that its consideration should be adjourned till another evening.

Mr. Christopher differed with Mr. Bazalgette as to the greatest amount of deposit being found in old and abandoned sewers. In his own district (Hammersmith) there were two main sewers. One of these, which had only been constructed ten years, was frequently liable to most serious deposit, and had now been for three months in course of emptying by hand labour, being filled up to two-thirds of its capacity by solid deposit. The other was an older sewer (3 ft. 6 in.), and although there was a large flow of water down it occasionally, it also was being emptied. Mr. Bazalgette's theory as to the scouring power would not apply when a deposit had been formed; and the cleansing he had referred to absorbed the whole local sewer rate of 6*d.* in the pound, with the exception of a small margin for staff, &c., leaving nothing whatever towards constructing new sewers.

Mr. Bazalgette stated, that he had intended his remarks to be of general application. The sewers of London, for the most part, were clean where they had a tolerably good fall and a moderate quantity of water passing through them, and if the road-drift could not be carried away, they might be kept clear by raking. It was plain that the sewers mentioned by Mr. Christopher had not sufficient fall in proportion to the quantity of water passing through them to make them self-cleansing, and pipe sewers in the same circumstances would be constantly stopped up. In these instances, the deposit could be removed without disturbing the sewers or breaking up the streets, which would not be the case with pipes.

Mr. Pocock said, that in the question of sewers, as in other affairs, only practical men knew how and when to modify

the theory, as modified it must be occasionally. The frequent changes and interruptions which had occurred in the proceedings of the bodies having the management of the sewers, even when they were going on satisfactorily, had tended to impede rather than to promote improvements. He proceeded to narrate a case in which he was concerned, where he had erected, at different periods, two sides of a square. In the first instance, he had applied to the Westminster Commissioners for permission to put in a 3 ft. 6 in. sewer, which he thought large enough to drain thirty-six houses, and seeing no prospect for years of getting any outlet to the south, he proposed to connect this sewer with another to the northwards, and although certainly this was not the most direct way to the Thames, the Commissioners would not have objected to draining a level surface as he proposed, if it had not been for the opposition of an energetic theorist in the Board, who would not listen to the proposition, simply because the new sewer was to the north of the Thames, and therefore, as he contended, *must* drain directly towards it. The consequence was, that the Board, after several years delay, spent a considerable sum to lower a 2 ft. 6 in. sewer, into which he had to drain his 4 ft. 6 in. sewer (the size insisted on) through an intermediate 1 ft. 6 in. barrel drain. When the reign of this body had come to an end, he erected sixteen houses on the other side of the square, and again proposed a 3 ft. 6 in. sewer, but now nothing would do but a 9-inch pipe! This however he resisted, and was fortified by one of the contractors, who said he would advise him to have cesspools rather than a pipe sewer, and that he would build him a 3 ft. 6 in. sewer for the same cost as the 9-inch and 12-inch pipe sewer, to which the Board were at length willing to accede. He (Mr. Pocock) resisted the Board until his tenants complained, when he urged them to complain of him to the Commissioners, and the result was, that they gave way, and he put in the 3 ft. 6 in. brick sewer. Generally, although a 6-inch pipe would make a very good house-drain, it was impossible to use a pipe for a sewer in a public road with either economy or efficiency. The chief advantage of a pipe was its economy, and this advantage ceased if a pipe was more than 9 inches in diameter, for an 18-inch brick barrel drain was not more expensive than a 12-inch pipe. The frequent complaints against the opening of the public roads for the repairs of sewers, gas, and water pipes, sufficiently showed the tendency of the public mind, and should be a warning to advocates of pipe drainage.

Mr. Inman proposed the thanks of the meeting to Mr. Bazalgette and the other gentlemen who had given them the benefit of their experience, and moved the further adjournment of the discussion. He stated, that the use of drain tiles, and the system of flushing sewers were not modern inventions; that the latter had been found in the ruins of Fountains Abbey; and he described the ingenious system by which, in the time of Cardinal Wolsey, the water of the moat, which surrounded Hampton Court Palace, had been made to flush and carry off the sewerage of the palace. The original supply of water from Coombe was conducted under the River Thames by an aqueduct, known as the Longford river, and these services were maintained to the present time in perfect operation.

## MACHINERY FOR TREATING GOLD QUARTZ AND OTHER METALLIC ORES.

Lemuel Wellman Wright, *Patentee*, July 2, 1853

(*With Engravings, Plate* XXII.)

In no age—no epoch of time—has mankind been more energetic in exploring and investigating into the metalliferous ores underlying the surface of the earth. The vast discoveries which have been made in the present century at home, on the continent of America, the continental island of Australia, &c.; the number of people employed directly and indirectly connected with these discoveries, and the transfer of our redundant population to other lands, all combine to mark it as a march of improvement of the greatest and most significant importance to the whole habitable globe in regard to the development of new employment, frequent intercourse with the most remote portions of the world, and the progress of civilisation.

Some of the principal sciences are here essentially requisite, embracing a geological and mineralogical knowledge of regions, localities, and individual strata; the direction of lode; the dip and strike of beds where minerals are to be found; their classification; laws of matter; machinery to be employed in reducing and separating the ore; and the chemical mode of extracting the metals.

Geology, considered as including mineralogy, treats of the external configuration of the earth, tracing the windings and indentations of its shores, the inclinations of the soil, the directions of its mountains, and the courses of its rivers; all which is sometimes called Physical Geography. Penetrating the interior, it analyses the nature of its productions, determines the positions of the different layers and crusts of the earth, and describes the alterations which have taken place, and are still taking place, from the action of water, heat, electricity, and of the great energies of nature.

Chemistry is employed to recognise, by analysis or decomposition, what elements enter into the formation of a compound body; to determine, by synthesis or recomposition, what bodies will result from particular combinations; to describe the peculiar properties of each element or of each combination of elements. The Scientific Practical Machinist has to employ certain materials that will resist and endure, so arranged and designed in the best form, that by mechanical means and the employment of the least power, the forces of adhesion and cohesion may be entirely destroyed, without derangement of parts, with great economy in working;—he has to provide the means of converting substances apparently worthless into valuable products.

The Machinist must also provide means on a large scale for carrying out the views of the Chemist in regard to amalgamation and other processes, so as to economise labour and shorten the process; he must therefore have a knowledge of physics, the changes and laws to which matter is subject, and the mutual actions going on.

It is evident that science cannot exist, nor could its lessons be made productive by application, without machinery. In the history of every science we find the improvements of its machinery, the invention of instruments to constitute an integral part, applied science in all its forms, and the fine and useful arts, are the triumphs of mind gained through the instrumentality of machinery.

Each therefore has his own wide and extensive domain, demanding his attention and judgment; and therefore, supposing correct information is required about the best form of machinery to be applied, you must not consult the geologist, mineralogist, chemist, or mining agent, but the machinist or engineer, and *vice versa*.

Some minds, unacquainted with the application of machinery to certain purposes, are in raptures with something that is novel, and generally consult a geologist or chemist, who, also struck with its novelty without being able to inquire into its practicability, gives way to ecstatic delight (in a similar manner to an Indian who has seen something novel), and calls on the world to patronise it, without giving the subject that calm reflection and judgment, as to its applicability, durability, and fitness, which come within the province of the engineer. This has hitherto been the case,—the consequence has been failure, disappointment, and a retardation of mining operations.

Scientific practical means are still required for the purpose of permanently assisting those who are engaged, or those who intend to direct their attention to the development of mineral wealth at home and abroad, so as to economise time, lessen manual labour, and amply reward all.

The machinery hitherto employed has been unable permanently to succeed, although the talent of the United Kingdom, as well as that of other nations, has been continually directed towards this object; so as to bring into practical use, machinery so constituted and arranged in all its parts as to be capable of crushing, washing, and separating the necessary amount of metal from the ore, repay the adventurers, and at the same time combine durability under the very heavy work to which the machinery must be subjected.

The desired amount of work to be performed cannot, upon mechanical and chemical principles, be obtained when the crushing, washing, and amalgamating is performed in one and the same operation, as the amount of gold to be obtained will be diminished in proportion to the rate the machine is forced to obtain quantity. It has been found, from experience and vast outlay of capital, that nearly all the inventions of machinery hitherto applied to this important subject have failed more or less from proceeding on erroneous principles, coupled with the fact of the peculiar arrangement and combination of parts rendering them incapable of resisting the heavy work to which they were subjected. Their public support may solely be attributed to their novelty; and therefore, as a caution, mining adventurers, in deciding on machinery, should only be guided by practical results continued for a considerable period of time.

It may with truth be alleged that no system of heavy balls of iron, whether revolving on inclined or horizontal basins, can be recommended as practical, when considered in reference to the heavy work to be performed. In a system having a heavy metal ball or balls, say 2 tons weight, connected to and moving freely within a hollow vessel, the ball or balls resting on and moved by an inclined iron basin with teeth cast on its bottom, working into another bevil wheel connected with the prime mover, a great many serious practical objections may be urged. If a large piece of quartz passes under the ball, it is raised from the basin, and again falls on it with a momentum due to two tons falling through the height raised; as this continually occurs during the first process of crushing, this succession of heavy blows disarranges the crystallisation of the iron, and will after a time fall to pieces. Again, there are difficulties connected with the teeth cast on the bottom of the basin, as they are liable to snap asunder, and the ball or balls will wear the inside of the basin into an irregular circular groove.

From the preceding observations, and an attentive consideration of the bearings connected wtih the important application of practical machinery to the wants of the miner, we have great pleasure in submitting for public approval and support, the recently patented machinery by Mr. L. W. Wright. The operations connected with Mr. Wright's Patent Machinery are divisible into four distinct and separate processes:—

1. Crushing the quartz or other material by degrees.
2 Pulverising the quartz or other material into an impalpable powder.
3. Mixing, washing, and separating the lighter from the heavier particles, according to their specific gravities, by means of centrifugal motion.
4. Amalgamation by quicksilver, and the application of steam to inside of machine, conveying heat to the washed and separated materials, and thus assisting the ready amalgamation.

### I.—Crushing Machine.

This machine consists of a heavy iron horizontal central driving-cylinder *a*, revolving on the same shaft as a heavy fly-wheel. Around the central cylinder are five smaller iron cylinders *b, b, b*, the shafts of which rest in adjusting blocks supported on projecting brackets of framework, provided with adjusting screws *c*, so that the cylinders can be placed in contact with central cylinder, or apart from it, as may be desired. The shaft of central cylinder and fly-wheel rests in plummer-blocks *d*, connected to iron framing. The two iron cheeks or frames *e, e*, are connected together by iron tie-rods. The machine is fed from a hopper *f*, fixed at the top.

*Action of Machine.*—Motion is conveyed from the prime mover to the central cylinder and fly-wheel shaft by means of a strap and pulley or bevil wheels *g*. The quartz or other material is fed through the hopper, and passes successively between the smaller and central cylinders, causing the smaller cylinders to revolve by contact, and is then received into a box situated below the machine. The distance between the smaller and central cylinders gradually diminishes until the fifth or last cylinder is in contact with it.

### II.—Pulverising Machine.

This machine consists of two vertical iron rollers *h, h*, weighing about five tons each, having solid peripheries connected to centre piece (through which a horizontal shaft *i*, passes) by a solid iron web. The rollers work loose on the horizontal iron shaft, the ends of which fit into grooves in iron steps, which are bolted to the framing. The rollers rest on a circular iron disc-plate *j*, on the bottom of which are cast strengthening-ribs. Iron gatherers are fixed to the inside of the disc to keep the quartz continually under the rollers.

A vertical iron shaft *k*, passing through the horizontal shaft, is connected to the circular disc-plate by means of bolts passing through the circular projecting piece of the vertical shaft, and screwed up on bottom of the disc by means of nuts. The bottom of vertical shaft is turned true, and works in an iron step fixed (at the ground-line) to the framing. The vertical shaft is driven by two bevil-wheels *l, l*, at its upper extremity, and conveys motion to the circular disc and to the rollers by contact.

*Action of Machine.*—The crushed quartz, being taken from the Crushing machine, is received on the disc-plate, and sufficient water added to form an adherent mass. Motion is conveyed from the prime mover to the bevil wheels, vertical shaft, the disc-plate, and iron rollers by contact, causing them to revolve in their own planes. The gatherers keep the material continually under the rollers until it is reduced to an impalpable mass.

### III.—Mixing, Washing, and Separating Machines.

The impalpable powder is put into the Mixing machine, which consists of a narrow, rectangular wooden vessel *m*, in which revolves an iron wheel *n*, provided with paddles. Sufficient water is allowed to run into the vessel until a certain consistency has been attained; the material passes under the paddle-wheel, where it is thoroughly agitated, and then flows down a trough *o*, connected near the top to the washing and separating machine.

The Washing and Separating machine consists of a wrought-iron cylinder *p* (shown in section), about 12 feet high and 7 feet diameter, having a spherical bottom. Inside of this cylinder revolves an agitator *q q*, which is connected to a vertical iron shaft *r*, driven by two bevil wheels *s, s*, in connection with the prime mover. At the bottom of the cylinder is an eduction-pipe *t*, for drawing off extraneous matters, fitted with a cock. The cylinder is also provided with another pipe *v*, fitted with a cock near the bottom of the cylinder for withdrawing the metals.

*Action of Machine.*—The machine is nearly filled with water, motion is conveyed from the prime mover to the bevil wheels and agitator, when the mixed quartz material is allowed to flow into the machine from the trough. The agitator is made to revolve at such speed as will be sufficient to suspend the earthy matters, causing the centrifugal force to throw the particles outwards from the centre of revolving column of semi-fluid mass, arranging themselves according to their specific gravities, the heaviest particles of the metals being near the axis of cylinder, and the lighter more remote. The heaviest particles, as gold and other metals, will gradually fall in or near the axial line of cylinder, and form a conical mass at the centre of spherical bottom, from which they can be withdrawn by the pipe and cock *t*, at the termination of the operation, through which the light extraneous associated matters are withdrawn.

### IV.—Amalgamating Machine.

This machine, which is shown in section, is similar to the Crushing machine; the only differences are, that the peripheries of the two rollers *u, u*, are convex, and work in a corresponding circular concave revolving plate *w*, space being left between the rollers and sides of concave plate for the separated and washed material to be amalgamated with quicksilver. The inside of the rollers is covered in, and each divided by four compartments connected by passages with hollow transverse horizontal iron shaft, *x x*, through which high-pressure steam passes. The condensed and blow-off steam finds egress from the rollers into the hollow horizontal shaft, and passes out near the vertical shaft or centre of machine.

*Action of Machine.*—Motion is conveyed from the prime mover to the bevil wheels, vertical shaft, concave plate, and rollers by contact with concave plate (as in the Crushing machine). High-pressure steam passes along hollow horizontal iron shaft to the different compartments in rollers, and thus communicates heat to the quicksilver and material placed in the concavity of disc, and accelerates the amalgamation; the condensed and blow-off steam passing off from the hollow horizontal shaft near centre of machine.

The advantages of the Machinery before enumerated may be briefly stated:—

1. The employment of separate machines, instead of performing all the processes in one operation. By this means we have greater regularity in feeding; a greater amount of quartz can be crushed, washed, and separated, and gold amalgamated, in a given time, without being obliged to force any of the processes.

2. The ore is reduced by degrees, by means of plain open surfaces, without complication in parts, using heavy cylinders capable of adjustment, and a heavy fly-wheel, which condenses and preserves a part of the power exerted previously to the commencement of the process; and having its force concentrated, its effects are exceedingly powerful; avoiding sudden shocks or blows, which deranges the crystallisation of iron, and tending to the ultimate destruction of the machine; the least susceptibility of derangement, and the slight uniform wear of every part.

3. The Pulverising machine does not receive any blows, on account of the quartz being reduced by the crushing process; and according to the fineness of the powdered quartz obtained by this machine, depends the efficacy of the washing and separating process.

4. The washing and separating process removes all the extraneous associated earthy matters, depositing together the heavy matters, as metals, in small bulk; so that when presented to the quicksilver the amalgamation is more rapid, and more gold obtained than by other machinery.

5. The use of high-pressure steam applied to the inside convex rollers; the increased facility given to the amalgamation by means of the circular concave plate; and the communication of heat from rollers to the quicksilver and materials.

6. The application of the machinery to metalliferous ores containing other metals, as copper, lead, &c., which do not require the amalgamating process.

## GRAND TRUNK RAILWAY OF CANADA—VICTORIA BRIDGE, MONTREAL.

The works of this important railway are making rapid progress towards completion. The total amount already received on account of the share and debenture capital of the Company (A series) is 1,525,250*l.*, of which 486,810*l.* is in advance on account of future calls. The arrears amount to 36,280*l.* The line from Montreal to Portland will be finished in July next; the junction from Richmond to Quebec, 100 miles in length, will be opened in August. The 392 miles of railway thus comprised will complete the communication between the three most important cities in the district.

In the event of the shareholders of the A series not taking up two-thirds in shares and bonds of the reserved or B series, the directors deemed it advisable to enter into the contracts for the prosecution of the works from St. Thomas, forty miles below Quebec (to join the Quebec and Richmond line), and between Montreal, Kingston, Toronto, Guelph, and Stratford, so that the line shall be opened from Montreal to Prescot, and between Toronto and Stratford, a distance of 210 miles, in the autumn of next year; and the other sections, giving a total length of 876 miles, in October 1856. The Directors have effected a satisfactory arrangement with the representatives, in England, of the Great Western Railway Company of Canada, by which both companies agree to suspend those portions of their respective lines that excited mutual jealousy.

Owing to the engineering difficulties to be encountered in spanning the river St. Lawrence in the vicinity of Montreal, it was deemed advisable to consult Mr. Robert Stephenson, who accordingly proceeded to Canada last year, and, assisted by Mr. A. M. Ross, the Company's Engineer-in-Chief, prepared a report, which we give in full, as follows:—

### Report of Mr. Robert Stephenson.

"Gentlemen,—Absence from England, and other unexpected circumstances, have prevented my sooner laying before you the results of my visit to Canada last autumn, for the purpose of conferring with your engineer-in-chief, Mr. Alexander Ross, respecting the Victoria-bridge across the river St. Lawrence, in the vicinity of Montreal. The subject will necessarily render itself into three parts, viz.—First, the description of bridge best adapted for the situation. Secondly, the selection of a proper site. Thirdly, the necessity for such a structure.

Regarding the first point, I do not feel called upon to enter on a discussion of the different opinions which have been expressed by engineers both in England and America, as to the comparative merits of different classes of bridge, and more especially as between the suspension and tubular principles, when large spans become a matter of necessity. It is known to me, that in one case in the United States a common suspension-bridge has been applied to railway purposes, but from the information in my possession from a high engineering authority in that country, the work alluded to can scarcely be looked upon as a permanent, substantial, and safe structure. Its flexibility, I was informed, was truly alarming, and although another structure of this kind is in process of construction near Niagara, in which great skill has been shown in designing means for neutralising this tendency to flexibility, I am of opinion that no system of trussing applicable to a platform suspended from chains will prove either durable or efficient, unless it be carried to such an extent as to approach in dimensions a tube fit itself for the passage of railway trains through it. Such bridge may doubtless be successfully, and perhaps with propriety, adopted in some situations, but I am convinced, that even in such situations, while they will in first cost fall little short of wrought-iron tubes, they will be more expensive to maintain, and far inferior in efficiency and safety. I cannot hesitate therefore to recommend the adoption of a tubular bridge, similar in all essential particulars to that of the Britannia over the Menai Straits in this country; and it must be observed, that the essential features being the same, although the length much exceeds that of the work alluded to, none of the difficulties which surrounded its erection will be involved in the present instance. In the Britannia, the two larger openings were each 460 feet, whereas in the proposed Victoria there is only one large opening of 330 feet, all the rest being 240 feet. In the construction of the latter, there is also every facility for the erection of scaffolding, which will admit of the tubes being constructed in their permanent position, thus avoiding both the precarious and expensive process of floating and afterwards lifting the tubes to the final level by hydraulic pressure. In speaking of these facilities, it is a most agreeable and satisfactory duty to put on record that the government engineering department has, throughout the consideration of this important question, exhibited the most friendly spirit, and done everything in its power to remove several onerous conditions which were at one time spoken of as necessary, before official sanction would be given for the construction of the work.

On my arrival in Canada, I found that Mr. A. M. Ross had collected so much information bearing on the subject of the site of the bridge that my task was comparatively an easy one. Amongst the inhabitants of Montreal, I found two opinions existing on this point—somewhat conflicting; the one side maintaining that the river should be crossed immediately on the lower side of the city, where the principal channel is much narrower than elsewhere, and where also the Island of St. Helen's would shorten the length of the bridge;—the other seeming to be in favour of crossing a little below Nunn's Island. Sections of the bed of the river at both points had been prepared, and a careful study of these left no doubt on my mind that the latter was decidedly the one to be adopted. In addition, however, to the simple question of the best site for the construction of a bridge across the St. Lawrence, my attention was especially called to the feasibility of erecting and maintaining such a structure during the breaking up of the ice in spring, when results take place which appear to every observer indicative of forces almost irresistible, and therefore such as would be likely to destroy any piers built for the support of a bridge. I have not myself had the advantage of witnessing these remarkable phenomena, but have endeavoured to realise them in my mind as far as practicable by conversation with those to whom they are familiar; and, in addition to this, I have read and studied with great pleasure an admirable and most graphic description, by Mr. Logan, of the whole of the varied conditions of the river, from the commencement of the formation of ice to its breaking up and clearing away in spring.* To this memoir I am much indebted for a clear comprehension of the formidable tumult that takes place at different times amongst the huge masses of ice on the surface of the river, and which must strike the eye as if irresistible forces were in operation, or such as, at all events, would put all calculations at defiance. This is no doubt the first impression on the mind of the observer; but more mature reflection on the subject soon points out the source from which all the forces displayed must originate. The origin of these powers is simply the gravity of the mass occupying the surface of the water with a given declivity up to a point where the river is again clear of ice, which, in this case, is at the Lachine Falls. This is unquestionably the maximum amount of force that can come into play; but its effect is evidently greatly reduced—partly by the ice attaching itself to the shores, and partly by its grounding upon the bed of the river. Such modification of the forces are clearly beyond the reach of calculation, as no correct data can be obtained for their estimation; but if we proceed by omitting all consideration of those circumstances which tend to reduce the greatest force that can be exerted, a sufficiently safe result is arrived at. In thus treating the subject of the forces that may be occasionally applied to the piers of the proposed bridge, I am fully alive to the many other cir-

* See *Journal*, Vol. XVI., 1853, p. 245.

cumstances which may occasionally combine in such a manner as apparently to produce severe and extraordinary pressure at points on the mass of ice or upon the shore, and consequently upon the individual piers of a bridge. Many inquiries were made respecting this particular view, but no facts were elicited indicative of forces existing at all approaching to that which I have regarded as the source and the maximum of the pressure that can at any time come into operation affecting the bridge. I do not think it necessary to go into detail respecting the precise form and construction of the piers, and shall merely state, that in forming the design, care has been taken to bear in mind the expedients which have hitherto been used and found successful in protecting bridges exposed to the severe test of a Canadian winter, and the breaking up of the ice of frozen rivers.

I now come to the last point—viz., the necessity of this large and costly bridge. Before entering on the expenditure of 1,400,000*l.* upon one work in any system of railways, it is of course necessary to consider the bearing which it has upon the entire undertaking if carried out, and also the effect which its postponement is likely to produce. These questions appear to me to be very simple, and free from any difficulty. An extensive series of railways in Canada, on the north side of the St. Lawrence, is developing itself rapidly; part of it is already in operation, a large portion fast progressing, and other lines in contemplation, the commencement of which must speedily take place. The commerce of this extensive and productive country has scarcely any outlet at present, but through the St. Lawrence, which is sealed up during six months of the year, and therefore very imperfectly answers the purposes of a great commercial thoroughfare. Experience, both in this and other countries, where railways have come into rivalry with the best navigable rivers, has demonstrated, beyond the possibility of question, that this new description of locomotion is capable of superseding water-carriage wherever economy and despatch are required; and even where the latter is of little importance, the capabilities of a railway, properly managed, may still be made available, simply for economy. The great object, however, of the Canadian system of railways is not to compete with the river St. Lawrence, which will continue to accommodate a certain portion of the traffic of the country, but to bring those rich provinces into direct and easy connection with all the ports on the east coast of the Atlantic, from Halifax to Boston, and even New York, and consequently, through these ports, nearer to Europe. If the line of railway communication be permitted to remain severed by the St. Lawrence, it is obvious that the benefits which the system is calculated to confer upon Canada must remain in a great extent nugatory, and of a local character. The province will be comparatively insulated, and cut off from that coast to which her commerce naturally tends; the traffic from the west must either continue to adopt the water communication, or, what is more probable—nay, I should say certain—it would cross into the United States by those lines nearly completed to Buffalo, crossing the river near Niagara. No one who has visited the country, and made himself acquainted only partially with the tendencies of the trade which is growing up on all sides in Upper Canada can fail to perceive, that if vigorous steps be not taken to render the railway communication with the eastern coast through Lower Canada uninterrupted, the whole of the produce of Upper Canada will find its way to the coast through other channels; and the system of lines now comprised in your undertaking will be deprived of that traffic upon which you have very reasonably calculated. In short, I cannot conceive anything so fatal to the satisfactory development of your railway as the postponement of the bridge across the river at Montreal. The line cannot, in my opinion, fulfil its object of being the high road for Canadian produce until this work is completed; and looking at the enormous extent of rich and prosperous country which your system intersects, and at the amount of capital which has been already or is in the progress or prospect of being expended, there is, in my mind, no room for question as to the expediency—indeed, the absolute necessity—of the completion of this bridge, upon which, I am persuaded, the successful issue of your great undertaking mainly depends.

I am, &c.,

ROBERT STEPHENSON.

*24, Gt. George-street, Westminster,*
*May 2nd*, 1854."

## IRON FLOORS—WAREHOUSE, CORPORATION-STREET, BELFAST.

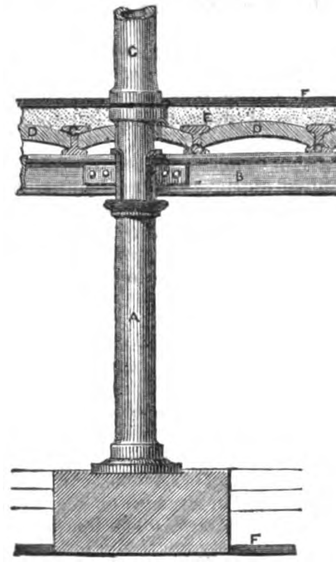


FIG. 1.

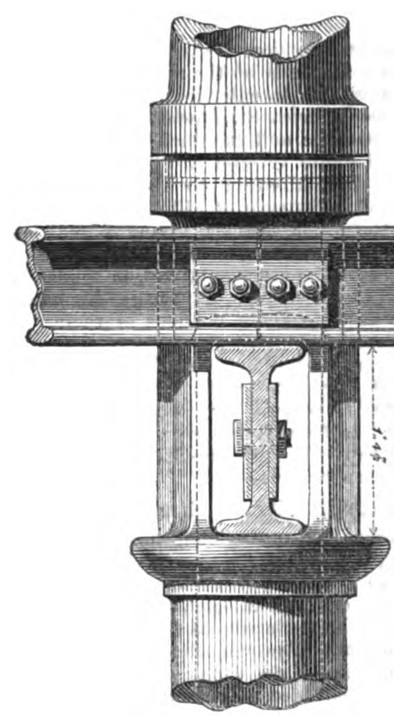
FIG. 2.

FIG. 3.



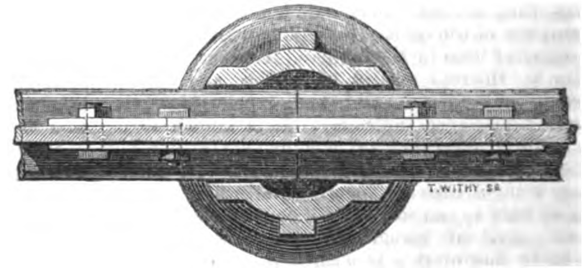


FIG. 4.

THIS extensive warehouse has been recently erected by Mr. Thomas Jackson, of Belfast. The frontage is 50 feet, and depth 40 feet. It is five stories in height, and has the floors and roof constructed on Messrs. Fox and Barrett's principle, with the exception of arches of perforated bricks, springing from the iron joists, and laid to a flat curve in Roman cement—being substituted for the wooden strips adopted by Messrs. Fox and Barrett. The annexed engravings represent the detail and method of rendering the floors fireproof. Fig. 1 is an elevation of one of the columns supporting the ground-floor, and showing the brick arches and joists in section; fig. 2 is a view showing the girders in section, and eyes in the top of the columns for receiving the same; fig. 3 represents a view of the column, joists, and girders on a larger scale; and fig. 4 a sectional plan of the same. A, is the lowermost column of the stack; B, the rolled iron girders, 8 inches deep with 4-inch flanges, which pass through the head of the cast-iron columns, and carry the rolled iron joists C, 5 inches deep with 2½-inch flanges; D, D, are the arches of perforated brick, springing to a flat curve from the flanges of the joists, and covered by a layer of concrete E, upon which is laid the seyssel asphalte floor.

The floors and roof are approached by a spiral staircase of cut stone, in a tower exterior to the rear wall of the warehouse. The building is occupied as a flax, yarn, and linen store. The ground upon which the warehouse stands is (like a considerable portion of Belfast) very soft and yielding, being an alluvial deposit of sand, shells, &c., to a depth of about 38 feet below the surface, under which is a bed of retentive blue clay. Piles of 40 feet in length were accordingly driven in, in double rows, with four under each metal column. The heads of the piles are about 4½ feet below the surface, to allow of a strong Memel framing above, united by bolts, straps, &c., and filled in between and at either side with closely-built brickwork, set in hydraulic mortar. On this is laid a course of sandstone, 4 feet broad, and 10 inches thick, in large slabs, roughly squared and dressed, in order to embrace the framing and footings on each side.

The front of office story, to the level of first ware-room floor, is of chiselled sandstone, channel-jointed, as also the cornices, copings, stringcourses, window-sills, &c. The stone was procured from the Kenmuir Quarries, near Glasgow. The rest of the walls are built of Beart's perforated bricks.

The asphalte flooring and roof was laid by the Metropolitan Mineral Rock Asphalte Company, and the joists and girders were rolled at the Bedford Iron Works.

## RAIN AT DIFFERENT ELEVATIONS.

By Thomas Hopkins, M.B.M.S.

Much labour has been employed to ascertain what are the quantities of rain that fall at different heights in the atmosphere, in the same locality. Assuming that the theory of the formation of rain which has been here advanced, is substantially correct, it will be apparent that the relative amounts that fall at various elevations, in a vertical column, will not be the same. When a large quantity is formed within a cumulous cloud and carried to a great height, where, through the expansion of the atmospheric gases, the drops of rain are thrown off laterally to a considerable distance into cold air, they may soon acquire a temperature as low as that of the clear air at the superior elevation;—and should they afterwards, in their fall to the earth, have to pass through warm air fully charged with vapour, the cold of the rain would condense upon the drops some of the vapour, when each drop would be enlarged in its descent. These drops, if collected at different elevations, would obviously, as they approached the earth, furnish larger quantities of water.

But the rain from a cloud may fall not beyond, but within the warmth of that cloud, and consequently may itself continue warm for the elevation, as long as it remains within the cloud, and the part of the atmosphere below the cloud and nearer to the earth, may be sufficiently dry to cause evaporation to take place from the surface of each drop of rain whilst it is falling. Each will then become smaller as it descends, and the whole of them will successively constitute smaller quantities of water the nearer they approach the earth, as could be shown if rain gauges were placed at various heights to receive it. It is, indeed, apparent that in this way some rain that has been produced in the higher regions of the atmosphere, often wholly evaporates during its descent, whilst other rain may bring to the earth only a small part of that which was falling at a great height.

Let us suppose a wind to blow against the sloping side of a ridge of land, rising to a height of say 1600 feet, and suppose this wind at the level of the sea to have a temperature of 57°, and a dew-point of 52°. It is evident that the part of the wind near the surface would pass over all the lower portion of the slope and up to 1500 feet as a dry wind, neither producing rain nor forming cloud;—because the air from the low level would not be sufficiently raised and cooled in its ascent to condense any of the vapour which it contained. But when this air was driven to the top of the slope, it would be sufficiently cooled by expansion to form cloud. Under these circumstances, rain might form near the top, whilst it would be fine weather over the lower part of the slope.

But suppose the wind at the surface to have a dew-point of only 4° instead of 5° below the temperature, and it will be perceived that the cloud would then be formed, not only near the top, but down to a level lower by 400 feet; and any rain that might fall from the cloud, might alight on the whole of the slope that was between the top and 400 feet below it. If the dew-point were only 3° below the temperature at the surface below, cloud would begin to form 700 feet lower than the top, and generally in such a wind the nearer the dew-point approached the temperature at the level of the sea, the lower would cloud form against the slope of the hill, from which rain might fall. As the dew-point at the surface, however, is seldom as high as the temperature, but in general considerably below it, it follows that rain will seldom fall from a cloud that is near the surface, over either the sea or the low ground. But it will often fall from a small height above the sloping sides of rising land and more especially against the higher parts of such land. Where rain is produced near the level of the sea 50 days in the year,—it may occur against a height of 1000 feet 100 days, and at a height of 2000, 150 days. Hence in many places it rains more frequently against the sides of hills than on the sea shore, or the low intervening ground.

Cloud is however formed and rain falls from it, not merely in that part of the atmosphere that is near the surface of the earth, but also at very considerable heights above it. As we ascend from a low level in the open atmosphere, the dew-point ordinarily approaches nearer to the temperature, until at some moderate, though varying, height they often are the same, when cloud begins to form. And a whole column of air so circumstanced, being carried against the slope of rising land, would be all raised, and the upper as well as the lower part of the column would be cooled by the diminution of incumbent pressure, and that portion of the atmosphere which had its dew-point nearest to the temperature, would have vapour within it converted into rain the earliest; so that even over hills rain may be produced at a considerable height above the surface of the ground. The rain which descends on low lands, as well as on the sea, generally comes from a considerable height in the atmosphere; this is known and acknowledged, whilst it is commonly supposed that that which falls against the sides of hills is always produced near their surfaces; this, however, is not necessarily the case, as the rain there, as in other parts, may be formed at considerable heights above the surface. The actual heights at which clouds are formed by ascending streams of moist air, are determined by the degrees of saturation of the different strata of the atmosphere; but when a portion of the lower air is taken to a great height, and there allowed to expand in full proportion to the diminished pressure, a moderate degree of saturation near the surface is sufficient to produce cloud. Winds, however, when they blow against the sides of hills, often convey portions of air saturated in various degrees at different elevations, from low levels to superior heights, and thus produce clouds and rain at various elevations.

Again, the whole of a thick stratum of air may, with due relation to the height of each part, be so fully saturated with vapour as to permit the cold consequent on a small rising to form cloud in nearly every part of it; or, the cloud may form first at the top, or at the bottom, or in any other part of the stratum, according to the degree of saturation of the part, and the cold of the elevation that is attained; and each elevation, as has been shown, is liable to be temporarily saturated by conversion of floating cloud into vapour. It is obvious too that, while a wind is blowing, each part of the land will not receive all the rain that is formed directly over it,—but only that which descends to it, the remainder being carried on by the wind;—and in hilly countries it may, and indeed does commonly fall against the rising ground. The higher ground thus frequently receives not merely the rain which is formed directly over it, near the surface, but also, successively, parts of that which had been formed over lower levels, but at greater distances from the surface: and the highest ground may consequently receive portions of what had been formed at different elevations above all the lower levels.

It may possibly be supposed, from what has been here advanced, that when a stratum of saturated air is moving over flat ground, the motion alone of the air would not produce cloud, or rain, but that it required to be forced up a hill to produce such a result;—this, however, would not be correct. The atmosphere, in moving over the surface of the globe, presses on the lowest level with a certain force:—this creates friction, which retards the advance of the lowest part of the air, and the retardation is successively communicated, though in inferior degrees, to the higher parts. The less retarded and higher parts, therefore, climb and pass over the lower until the air which in a particular locality constituted the lowest stratum, attains a considerable height, where it expands and acquires the temperature belonging to the superior elevation, when rain may be produced. Against the sloping sides of rising ground, both the causes that have been here pointed out are in operation during a wind, producing a rise of the air through its being forced up a hill by its horizontal motion, and also through retardation in the lower part by friction against the surface, and both of these causes contribute to the production of rain in such situations.

A direct line drawn through the atmosphere from the western edge of Lancashire, to the top of the ridge which separates that county from Yorkshire, would be, say about forty miles in length. Now, if the land rose parallel with that line, from the operation of the causes just explained—rain coming from the west would, on an average of years, fall along the line in quantities increasing with, and determined by, the elevation of each part. The quantity might be, say 20 or 30 inches in the year at the western edge, and 40 or 60 inches, or some other quantity, at the highest part, the intermediate parts having quantities proportioned to the elevation of each part. That we have not such regularly increasing quantities of rain now actually falling along the line, is attributable to the irregularities of the ground, and even to the trees and buildings, which produce partial obstructions, cross currents and eddies, varying to all conceivable extents. But the surface of the earth at the various levels, as well as the sea, has, as has been already explained, a supply of rain which is produced by a different cause, namely, the daily heating of the air, near the surface, by the sun. This, however, has been fully treated of in former papers.

In stating that much rain frequently falls among hills, it is not intended to intimate that the quantity goes on increasing with the height of the hills, however lofty they may be. The probability is, that over each rising land the quantity of rain increases up to some certain height—above which it diminishes, until at some elevation no rain will fall;—these heights will vary according to the temperature and dew-point of the locality. Where both temperature and dew-point are high, a strong ascending current may be produced, and the maximum quantity of rain may fall at a considerable elevation: where both are lower, the maximum quantity may be found at a much lower level. The greater or less continuity of the rain will also have its degree of effect. Continuous rain warms the atmospheric space up to a height greater than an occasional shower does, and that warmth may prevent condensation taking place from new supplies of vapour until they attain a higher level; whilst a large part of the vapour which a sudden cool and moist wind may bring, may be condensed at a moderate height, if the locality has not been previously warmed by condensation. When the atmosphere is fully saturated with vapour and the dew-point is at 80°,—as has been already stated, the vapour constitutes about one forty-eighth part of the whole, whilst with a dew-point of only 32°, the vapour is only one two hundred and fortieth part of the atmosphere. Now if from any cause air with a dew-point of 80° should be raised to a height that will reduce its temperature below that degree, it will evidently have a part of its vapour condensed. And if this air should ascend high enough to be cooled down to 32°, it must have all its vapour between the 48th and the 240th part of the atmosphere, converted into water to fall as rain. It is evident, therefore, that the greater part of the vapour which ordinarily exists in ascending moist air, must be condensed at some moderate height, seeing that but little of it can, in an aëriform state, pass into the very cold elevated regions of the atmosphere. The ascent to the upper regions being accompanied by decrease of temperature, whatever point of tropical heat at the surface we start from, the constant decrease of temperature will at last find the point of condensation, and therefore within some limit the cold will condense nearly all the vapour contained in the air, and above that limit but little rain can fall, because there is but little vapour left to produce it. If rain began to descend as soon as condensation of the vapour commenced, it would not be difficult, in a given state of the atmosphere with relation to the temperature and dew-point, to determine at what heights the various quantities of rain would be formed; but when it is formed, heat is liberated and an ascending current is produced, and we do not know what will be the temperatures and ascending forces of the currents. although we do know that as the air rises it must be under the influence of laws of expansion and cooling, and that the vapour which it contains is under those laws of condensation, and of liberation of heat, to which it is subjected in our mixed atmosphere.

The ridge of the Yorkshire hills, already alluded to, may be considered as 1600 feet high. The ridge of Helvellyn may be taken at 3000 feet; Ben Nevis as 4000 feet; and the highest ridge in Norway, as 8000 feet in height. Now let us suppose the same wind to blow against the western side of all these ridges, which wind near the surface of the globe has a temperature of say 57°, and a dew-point of 52°, a kind of atmosphere not uncommon in the summer of this part of the world. When it rose to a height a little above 1500 feet, it would average a temperature of 52°, the same as the dew-point, and, when passing over the Yorkshire hills, would form a slight cloud. In ascending Helvellyn it would, at the top, have a temperature of say 47°, and the vapour which it had contained between the dew-point at the surface and the temperature at the top of the mountain would be condensed, and some of it might fall as rain. The same wind, in climbing Ben Nevis, would acquire a temperature of less than 44°, and vapour would be condensed until the dew-point was reduced to that degree. In ascending the mountains of Norway, the freezing point would be reached at a height of 7500 feet, when all the vapour which the wind had contained between the dew-point of 52° at the surface and of 32° at the height of 7500 feet, would be condensed, and might fall as rain. Now the atmosphere of 52°, with a dew-point at the same degree, has vapour amounting to say a 120th part of the whole, whilst an atmosphere with a temperature and dew-point of 32° has vapour to the amount of only a 240th part, or not more than half the first named quantity. So that omitting the influence of heating by condensation, one-half of the vapour which the supposed atmosphere contained when at the level of the sea, where it would appear a clear and dry air, would be condensed, and might fall as rain, when it ascended to a height of 7500 feet. And any further condensation of the remaining vapour that might take place at a greater height, would be followed by congelation; and snow, instead of rain, would be produced.

Mr. Miller, in a paper read to the Royal Society, on May 18, 1848, gives a number of important meteorological facts relating to the Lake district of Cumberland and Westmoreland. The statement of the falls of rain that take place in many parts of this locality are very valuable, on account of the different heights of the parts above the level of the sea where the rain gauges were placed, and the particular shape of the face of the country. For a long time it had been known that the fall of rain became greater, as the ground rose from the low level of Lancashire to the top of the ridge which separates that county from Yorkshire; and it appears that the same general fact is, to a certain extent, observable in Cumberland, Mr. Miller having found that the fall was small at Whitehaven and other places in the low country near the sea, compared with that which took place up the valleys and on the mountains of the interior country. And that gentleman, after stating many facts, attempts to exhibit a law which determines that the amount of rain shall increase up to a certain height, and decrease above that height. He says—"It seems probable that in mountainous districts the amount of rain increases from the valley upwards to an altitude of about 2000 feet, where it reaches a maximum, and that above this elevation it rapidly decreases." Now, although the facts thus given are important in themselves, and afford a certain degree of countenance to the hypothesis advanced; yet neither the facts nor the reasonings founded on them are sufficient to warrant the general conclusion drawn from them by Mr. Miller.

A return is given of the quantities of rain that fell in twenty different places in Cumberland in the four years 1845-6-7 and 8; and of these places we may, in the first instance, take three as a sufficient number to show how far the facts harmonise with the law thus laid down, namely, Whitehaven, Wastdale-head, and Seathwaite—the first being on the sea-coast, the second, inland, at the mouth of the mountain pass of Sty-head, and the third, beyond that pass, and in the valley of Borrodale. In these three places there fell in the years named the following quantities of rain, namely:—

| | At Whitehaven, 90 Feet above the Sea, in inches. | At Wastdale Head, 166 Feet above the Sea, in inches. | At Seathwaite, 240 Feet above the Sea, in inches. |
|---|---|---|---|
| 1845 | 49·207 | 108·55 | 151·87 |
| 1846 | 49·134 | 106·93 | 143·51 |
| 1847 | 42·921 | 96·34 | 129·24 |
| 1848 | 47·344 | 115·32 | 160·80 |
| Mean | 46·589 | 106·60 | 145·63 |

Now, the differences in the heights of these three places are not very great, but the differences in the quantities of rain that fell are enormous—quite enough to warrant a suspicion, that the very large amount that fell at Seathwaite is not attributable to the height of that place above the sea. But in addition to those three places, there is the Pass of Sty-head, 1290 feet high, situated between Wastdale-head and Seathwaite, on which a rain-gauge was placed; it is, however, so cold there in the winter, and the gauge is so much affected by snow and ice at that season, as to prevent reliance being placed on it during that portion of the year. Yet we may compare the quantities of rain that fell in the summer months only at Sty-head and Seathwaite, as given by Mr. Miller—they are for the six summer months of 1848—

| | Inches. |
|---|---|
| Seathwaite, 240 feet above the surface of the sea | 68·96 |
| Sty-head, 1290 feet above the surface of the sea | 60·35 |

Here we find no increase in the quantity of rain that falls above 240 feet of height where the gauge is placed in Seathwaite. On the contrary, the quantity is greater there than at Sty-head, 1050 feet above it. This fact furnishes rather strong presumptive evidence, that the quantity of rain that is received in a gauge, at any particular elevation, is not proportioned to the height at which the gauge is placed.

In comparing the quantities of rain that fall at various heights, including great elevations, it is obviously necessary to compare them during the summer months alone, as has been done when comparing Seathwaite and Sty-head Pass; and the facts that are principally relied upon by Mr. Miller, and from which he draws his general conclusions, are the quantities of rain that fell in twenty-one months in 1846 and 1847 in six places, namely:—

| | | Inches. |
|---|---|---|
| The Valley (Wastdale) | 160 feet above the sea, | 170·55 |
| Sty-head | 1290 " | 185·74 |
| Seatoller | 1344 " | 180·23 |
| Sparkling Tarn | 1900 " | 207·91 |
| Great Gable | 2925 " | 136·98 |
| Scaw-fell | 3166 " | 128·15 |

But these facts although they countenance the hypothesis advanced, do not afford conclusive, or even strong, evidence upon the subject. The Valley we see, 160 feet high, has 170·55 inches; whilst Seatoller, 1344 feet high, and consequently 1184 feet higher than the Valley, has only 180·23 inches, not 10 inches more of rain; whilst Sty-head, 54 feet below Seatoller, has 5½ inches more of rain than that place. There is another place noticed by Mr. Miller, called Brant Rigg, 500 feet high, between the Valley and Sty-head, which received 12½ per cent. less of rain than the Valley, which is only 160 feet high, showing that here less rain fell in the higher than in the lower parts; and there are other anomalies that might be pointed out. It is, however, such a place as Seathwaite that shows, in the most palpable and striking way, that the amount of rain which is received by the ground in a particular locality is not determined by its height. Seathwaite, not more than 240 feet above the sea, receives more rain than any of the places having a greater elevation; and Mr. Miller candidly admits that he is "unable to offer any satisfactory reason for the great excess of rain at Seathwaite over all other valleys."

In order to account for the great and unequal quantities of rain that fall in different parts of this district, it is necessary that we should remember the causes which determine the formation of rain at various heights in our atmosphere, as already explained. The following figures will show the heights at which vapour would be condensed under certain circumstances; that is to say, with the air and dew-point of the vapour at the surface both at 59°, when the tension of vapour is equal to half an inch of mercury, the wind at the time blowing up a valley and sloping sides of a mountain. The lowest stratum of air being 59°, the temperature and dew-point would be reduced at a height of—

| | | |
|---|---|---|
| 300 feet to 58° | 1200 feet to 55° | 2100 feet to 52° |
| 600 feet to 57° | 1500 feet to 54° | 2400 feet to 51° |
| 900 feet to 56° | 1800 feet to 53° | 2700 feet to 50° |

And all the vapour that existed in the air between the dew-points of 59° and 50° would be successively condensed by the time that the air and vapour reached the height of 2700 feet, and rain, the product of that amount of condensation, would be produced at the various heights as the cooling proceeded.

There is, however, a second process going on under such circumstances as those just described, which, as it modifies the first, it is necessary again to notice. When condensation of vapour takes place heat is liberated, and the temperature of the locality is raised. The gases in the part are then warmed, and they expand and ascend to a greater height, where they are further cooled, and where they condense more vapour. So that the vapour is condensed in the first place by the atmospheric mass being forced up the inclined plane of the land, mechanically, as a wind—and, secondly, by the ascent produced by the heating power of condensing vapour; and whilst the mass of air and vapour is carried up from both these causes, it is moving forward horizontally as a wind. In the locality, then, the wind moves mechanically towards the upper part of the valley, whilst from the heating effects of condensation, it is ascending above that part; the condensing vapour will therefore be liable to be carried above the highest part of the land, and the greatest quantity of rain may fall beyond that part. And, further—after the vapour has been condensed, and the rain formed at a certain considerable height in the atmosphere, it has to descend from that height, and will be liable, while so descending, to be carried forward horizontally by the wind, and will reach the earth at a part beyond that over which it was formed.

Now, to apply this general statement and reasoning to the case under consideration: let us suppose that air saturated with vapour of the temperature of 59° passes from the sea-coast, near Ravenglass, towards the mountains as a south-west wind. When this wind reaches land 300 feet high, it will be cooled by ascent 1°; and will have all the vapour condensed that is contained between a dew-point of 59° and one of 58°. When it reached land 600 feet high, 2° of vapour would be condensed; 900 feet 3°, and so on in succession, 1° more for every 300 feet of height up which the air was forced mechanically. Add to this the vertical ascent produced by heat from condensation, and the actual progressive motion of the condensing vapour will be intermediate between the two. Supposing the two forces to be equal, the mass would proceed forward, ascending at the angle of 45°. Sty-head Pass is 1290 feet high—the atmospheric mass, therefore, when it reached Sty-head would be cooled, say 4°, and it would be liable to be carried over the head of the Pass, rising at an angle of 45°. We might therefore expect, from the known laws of condensation of vapour, and of the action of wind, that, under the circumstances described, a larger amount of rain would fall beyond Sty-head, than either in the approach to it, or on the top of it; and accordingly it is the fact that a larger quantity of rain falls in Seathwaite, which is a little beyond the Pass, than in any part between Seathwaite and the sea.

In such a locality the saturated air, forced by the rise of the land, to ascend, entering the wide mouth of the Valley, which contracts in breadth as it proceeds, rushes through the narrow gorge in the upper part, and over the top of the mountain pass, with great velocity and force; condensation, therefore, will take place to a greater extent along this particular and comparatively low line, than where the ridge of the mountain is higher by 2000 feet. The higher parts stop the passage of the wind, which makes its way where there is the least resistance, and this is over the pass of the mountain ridge; and as the horizontal rush of air is here particularly strong, any rain that is there formed, or that has been carried thither, will be liable to be borne forward until the air loses some of its velocity in the comparatively open space beyond the Pass where the rain is likely to be deposited—just as running water deposits sand when it reaches a wider and comparatively still part of a river. In the case stated, the air was supposed to be saturated with vapour, but if it should not be fully saturated, but have a dew-point of, say 1° below the temperature, the only difference would be that condensation would not begin until the mass of air climbed 300 feet,—a dew-point of 2°, 600 feet; and other dew-points in proportion.

We see, then, why the largest quantity of rain should fall in Seathwaite when a south-west wind blows from the sea over Sty-head, as Seathwaite is favourably placed to receive much of the rain brought by that wind; but other winds blow in this district during a large portion of the year, and as much more rain falls at Seathwaite than in any other part, these other winds must, we presume, also bring rain to that place. To see how this is effected, we have to examine the shape of the neighbouring country, and particularly in the directions from which rainy winds come; and we may perhaps obtain a tolerably good idea of what that shape is from an account given in Hudson's 'Guide to the Lakes.' In this work, page 118, it is said—"I know not how to give the reader a distinct image of the main outlines of the country, more readily than by requesting him to place himself with me in imagination upon some given point, let it be the top of either of the mountains, Great Gable or Scaw-fell; or rather, let us suppose our station to be a cloud hanging midway between those two mountains, at not more than half a mile's distance from the summit of each, and not many yards above their highest elevation; we shall then see stretched at our feet a number of valleys, not fewer than eight, diverging from the point on which we are supposed to stand, like spokes from the nave of a wheel." Now, this imaginary point in the air is nearly over Sty-head Pass. The writer then proceeds to describe Langdale, the Vale of Coniston, the Vale of Duddon, Eskdale, Wastdale, Ennerdale, and the Vale of Crummockwater, and Buttermere. And he goes on to say, that "such is the general topographical view of the country of the lakes; and it may be observed that, from the circumference to the centre, that is, from the sea or plain country to the mountains specified, Great Gable and Scaw-fell, there is in the several ridges that inclose these vales, and divide them from each other—I mean, in the forms and surfaces —first, of the swelling ground, next, of the hills and rocks, and, lastly, of the mountains—an ascent of almost regular gradation from elegance and richness to their highest point of grandeur and sublimity." Nearly all these eight valleys, in the low flat country, present wide openings to receive any wind that may be blowing towards them—they contract towards the centre where the ground rises; and the wind, whether it blows from, say, the south, south-west, the west, or the north-west, will force its way over the lowest points of the central chain, and be disposed to discharge rain on the country a little beyond those points. Borrodale is just in this situation, and must therefore receive rain from every moist wind that comes from a southern or western quarter, in the way that has been described; and Seathwaite seems to be in that part of Borrodale which receives the largest quantity of rain.*

The large fall of rain in this village is then to be considered a result of various rainy winds blowing up the different valleys, and particularly those which lie to the south and west of it, as those winds force the mixed masses of air and vapour to rise to the lower parts of the elevated ridges that are at the heads of these valleys. At or above these parts the vapour is largely condensed, and the rain that is formed is carried forwards and deposited on the low ground beyond the ridge; but though deposited there it evidently descends from a great height.

Speaking in general language, it may be said that the largest quantities of rain fall from warm and moist atmospheres, as such atmospheres contain the largest quantities of aqueous vapour; and the rain is formed by the condensation of a part of the vapour, at a height dependent on the elevation that is attained by the atmospheric mass when forced to ascend, and the difference between the temperature and the dew-point in that mass. If the rise of the land is great and abrupt, approaching a vertical cliff, the larger part of the rain might possibly fall on the low ground in front of the cliff, the mass of air being unable to pass over it, until such a height was attained as would leave little uncondensed vapour existing in the air. In such a situation it is evident, that one gauge placed at a low level in front of the cliff might receive more rain than another fixed at any height above it. And it is equally clear, that when rain is formed whilst passing over an elevated ridge, that rain might be received either in a gauge placed beyond it, only a little lower, or in one not farther beyond it, but fixed in a deep valley below, as is, in fact, the case with the gauge at Seathwaite. We may therefore conclude, that in a country containing lofty mountains and deep valleys, with much irregularity of surface, the height of the gauge into which rain falls does not indicate the elevation at which it was formed—that elevation being determined by the laws of cooling of the aqueous vapour that is contained in our mixed atmosphere, whilst the vapour is diffused through the gases.

* Since this was written, another part that is contiguous has been found to receive more rain. It is stated that the quantity of rain that fell annually at Seathwaite, on an average of five years, 1845 to 49, was 142·19 inches. In 1850, it was 143.96 inches, whilst it was computed that at Sprinkling Pass no less than 189·49 inches fell.

The following account has been furnished to me of the

*Fall of Rain in a year at Cuchullin Lodge, in the Isle of Skye, being the Mean of the Two Years, from Sept. 1, 1849, to Sept. 1, 1851.*

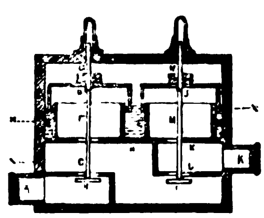
## GAS METERS.*

MOSES POOLE, *Patentee*, August 8, 1853.

THIS invention consists in an apparatus for regulating the supply of gas or other aëriform fluid. The main or supply pipe, where the regulation is to take place, is arranged to communicate in succession with two or more chambers, each having a governor or regulator.

The annexed engraving shows a vertical section of an apparatus combined according to the invention, having two regulators or governors acting in succession, but other apparatus may be made with more than two to act in succession in a similar manner. The form of regulator or governor preferred is that where an inverted vessel is employed fixed to the valve, the action of which is to be regulated: but the form of the parts may be varied, so long as two or more regulators are combined to act in succession as herein shown and described. No claim, however, is made to the governors or regulators separately when two or more are not combined to act on and regulate the same supply. A, is the

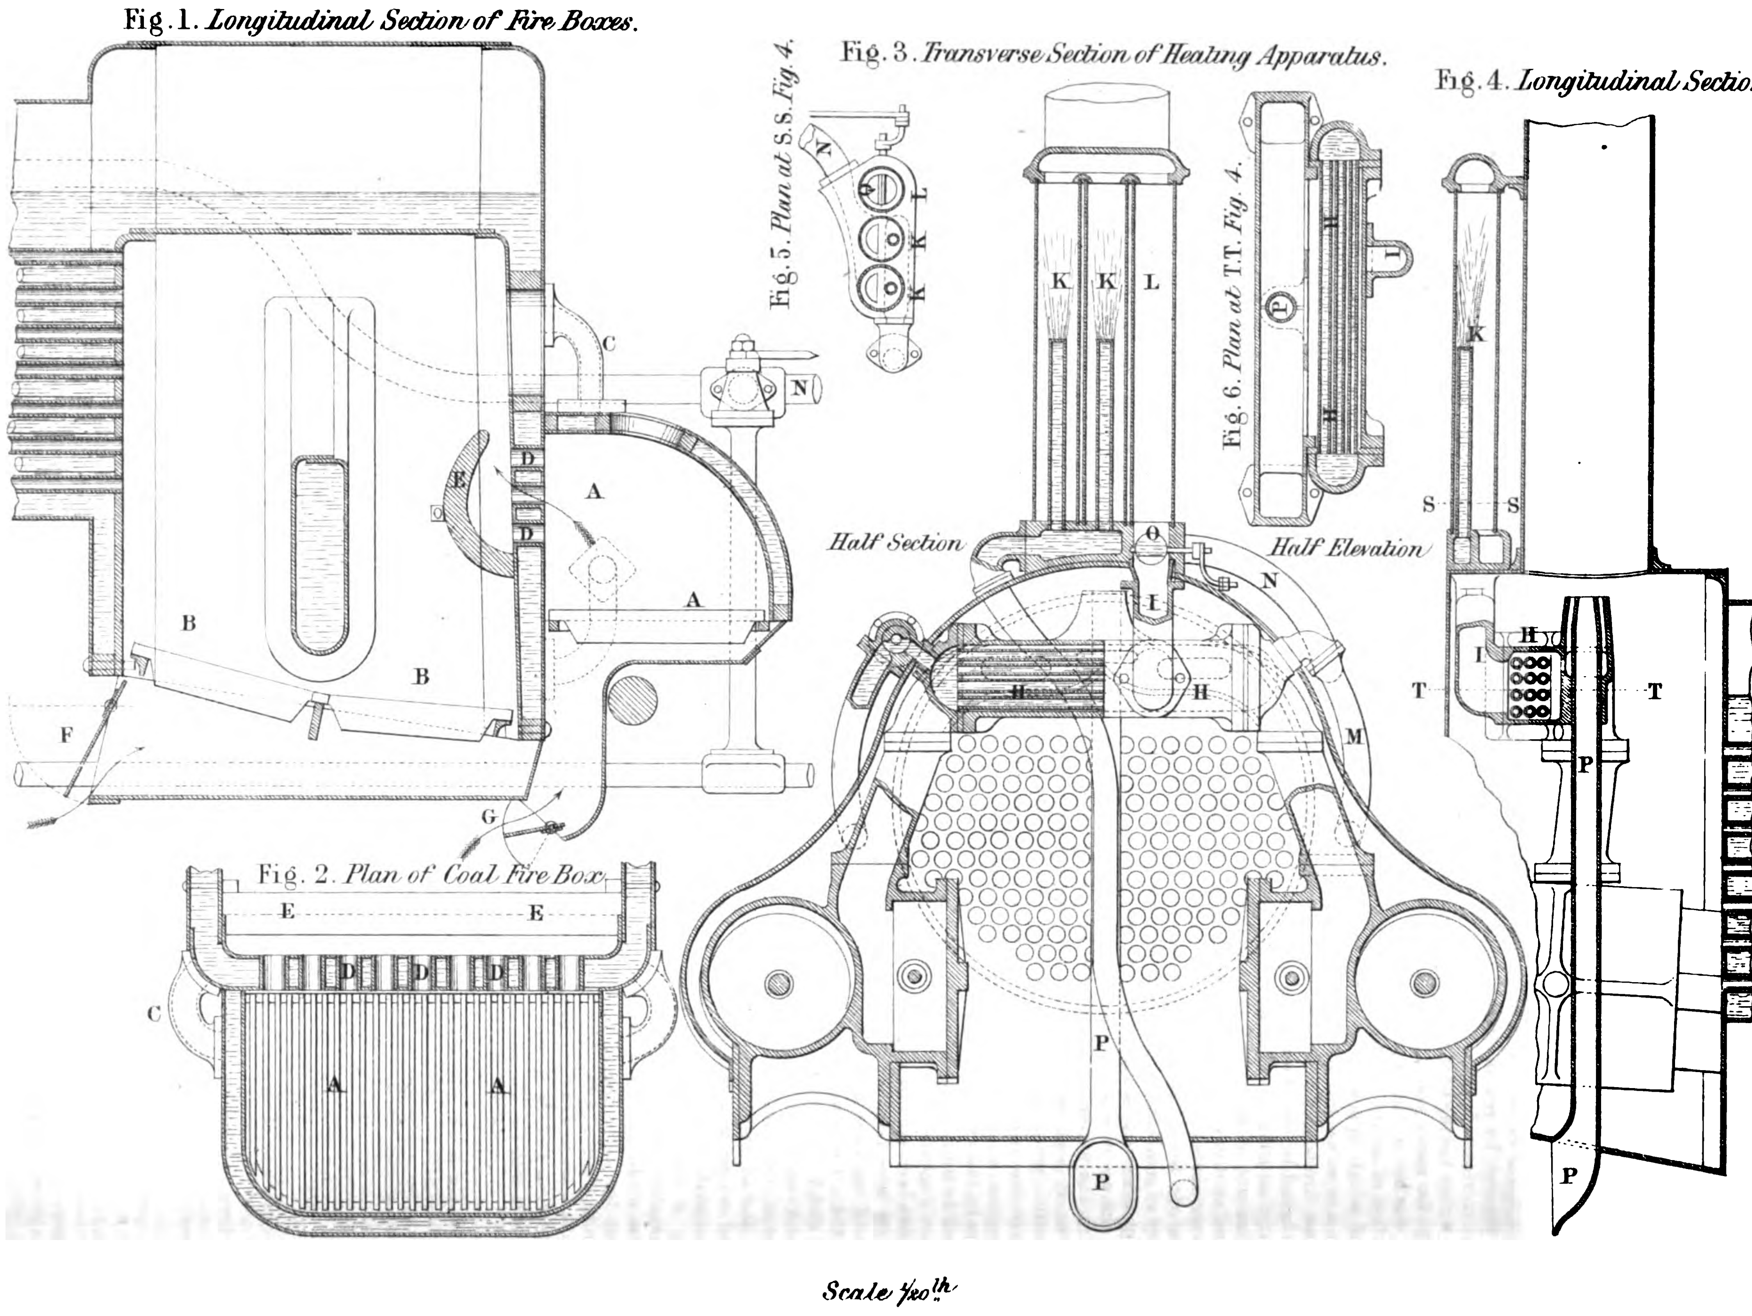


inlet for the gas or aëriform fluid; B, is a chamber, the opening C C, out of which is capable of being more or less closed by the valve O, which is on the stem F, to which the inverted vessel D, is fixed, the edges of which dip into mercury or other suitable fluid at E E, there being weights G G, on the vessel D, according to the degree of pressure it is desired to regulate or bring the supply of gas or other aëriform fluid to, when it passes away at the outlet K. The gas or other aëriform fluid coming into the chamber B (above the desired pressure), will to some extent be regulated by its acting on the first regulator by raising the vessel D, which will also raise the valve O, in the compartment B, towards the opening C C, till the quantity of the gas allowed to pass into the chamber H, of the apparatus will be brought to nearly the desired pressure. The gas or aëriform fluid in the chamber H, passes through the opening J J, into the compartment K, and acts on the inverted vessel L (which is affixed to the stem N), by which the valve O, in the chamber H, is more or less closed, according to the pressure of the gas or aëriform fluid in the chamber H, is more or less an excess of the pressure that it is desired the gas or aëriform fluid should go off at the outlet K. By using a succession of regulators or governors, any want of correctness of the regulation of the first will be compensated for by the succeeding one or ones.

*Claim.*—The combination of two or more governors or regulators so that they may come into action in succession.

* Reported in the 'Repertory of Patent Inventions.'

# IMPROVED LOCOMOTIVE ENGINE.



## IMPROVED LOCOMOTIVE ENGINE.*

By Joseph Beattie, of London.

(*With Engravings, Plate* XXIII.)

[*Paper read at the Institution of Mechanical Engineers.*]

The economy of fuel in working locomotive engines is a subject of great importance to railway companies, and has attracted considerable attention for many years; but at no period since the introduction of railways has this subject been of such moment as at the present, by reason of the great demand for coal, and consequent increase of price.
