As a concrete illustration of this tendency to doubt, even when conclusive proof has been shown, we may be pardoned for mentioning here an actual fact which recently came to our notice. It was at the big demonstration at Pittsburg, on the day that the President was there, with other dignitaries, to witness a "real" coal-dust explosion. The particular doubter in this case was not one of the outsiders, but one of our very own, an old mine foreman who had probably never put in a day's labor outside of the sight of coal dust.

Some time before the time set for the "blow-up" we came across him and his Davy making very careful tests for methane, which he did not find. Having satisfied himself on this score, he pulled from a pocket an envelope, and, scraping a bit of dust from this ledge and from that, he put it all in the container and sealed it. We became interested and learned that he had been sent by his employers to witness the demonstration, and, either on their or his own account, was gathering the dust. As though it were any profit for the government men to pull off any tricks on the very men the demonstration was inaugurated to benefit!! But evidently this logic did not occur to the old pit boss. Having deliberately sealed the envelope and placed it carefully away, he remarked to a group of more or less amused bystanders: "There may be somethin' in it besides dust."

Then, while waiting for the explosion, and during one of those intervals between the different attempts to set the blast off, he added with a contemptuous smile spreading across his poor, mine-scarred old features:

"If there *is* nothin' in it but just dust I wouldn't be afraid to light the shot with a squib and sit around a rib corner till it went off."

We are rather inclined to the belief that after seeing what the shot did, the old mine foreman changed his mind. Our imagination doesn't have to stretch far to see the surprise that was awaiting him when that dust he had so carefully chosen proved, on analysis, to be the exact duplicate of many tons lying scattered throughout his mine.

Electric Cables for Mines

By William White

Electric-cable installations in collieries are extremely important, and this is not an attempt to deal with the subject in anything like its entirety. While both the insulated-return and the earth-return systems have merit, it would not be fair to let the subject go without mentioning that earth-return systems in mines have sometimes brought about accidents. Most of these affairs could have been avoided, but unfortunately, the troubles reached their culminating points before anything effective was done to prevent them. In one instance, the driver of a coal cutter received a serious shock, which was traced to where the trailing cable was clamped on to the machine. At this point it was necessary to put a sharp bend in the earth wire in order to get it into its terminal and at each time this was done a strand was broken, until finally the few remaining strands were insufficient to carry the current, and they fused. This caused the whole machine to become alive, and the man on the front was shocked from the haulage rope. The trouble was cured by altering the terminal arrangement, and splicing in another earth wire, so that in case one wire broke the other would prevent the machine from becoming alive.

There is danger in using single-core armored cable utilizing the armor for the return on an earth circuit in mines, especially for feeding coal cutters. In such situations the blowing of the fuse in the circuit occurs repeatedly, and apparently cannot be stopped. When such a fuse blows it occasionally starts an arc onto the sides of the gate-end switch box, and this arc may persist until all the internal parts have melted. This by no means uncommon accident has occurred in boxes lined with asbestos ¼-inch thick and where mica plates have been tried. An expensive box has been put to work for a night shift, and taken out again in the morning useless, with a hole fused through the lid. This is difficult to remedy unless one does away with the system (these remarks apply to direct-current practice).

In many mines the road signals are an ever-present source of dissatisfaction. This is probably because they are often left in the care of the rope splicer or some other handy man. Among the many causes of failures may be mentioned bad jointing along the road, zinc eaten away, porous spots which are of no use, terminals and wires so badly covered by crystallized salamoniac that they are no use, hopeless muddle of wires at battery, bells all out of adjustment, and so on. When the importance to the working of the mine of an effective system of road signals is considered, it is astonishing that in so many cases such matters have been left to unskilled men. In one case where this sort of thing had been occurring, the whole outfit of road signals was put under the charge of the electrical staff, and after they had been put into thorough working order and adjusted, they were examined daily, with the result that very little trouble occurred afterwards in that part of the colliery due to such causes.

It is not too strong an assertion to say that many miss shots in mines are caused by the shot-firing cable, which is usually very cheap twin braided material. In most cases it gets wet and in addition to this it is quite usual to find on examination that the joints made by the mine deputies are not very satisfactory. The number of misfires in such cases may easily reach 50 to 60 per cent. of the total shots and it is, of course, a rule in an efficient mine that these have to be reported and reasons given for the occurrence. In one case where misfires were distressingly frequent, as a last resource the case was placed in the hands of the electrical staff, and after all the bad joints in the shot-firing cable had been made good, and the cable itself had been dried, the electrician fired shots repeatedly with such satisfactory and certain results that the matter was placed permanently in his charge, and a new set of cables was given out so that one set could be dried and repaired while the other set was in use. By this simple method it was found that in subsequent practice misfires were rare.

Life of Treated Timbers

The following was compiled by the Forestry Division United, States Agricultural Department, relative to the life of timber treated with creosote:

Species	Average Years Untreated Life	Average Years Treated Life
Cedar........	12 to 15	25
Chestnut......	8 to 10	20
Lodgepole pine.	5	20
Western yellow pine.	6	25
Cypress.....	12	25
Juniper....	10 to 13	25
Redwood.....	12 to 15	30
White oak ..	8	20
Douglas fir..	8	20

Moving Minerals in Thin Flat Beds

Swinging Chutes, Scraper Conveyers, and Shaking Conveyers for Transporting Minerals Underground

Written for Mines and Minerals

WHILE not sure, the writer is under the impression that "swinging chutes" were first introduced in the gold mines of the Witwatersrand, South Africa, where the ore bed was so flat that broken material would not slide down ordinary chutes to the ore pockets. The device adopted at one mine at least consisted of a sheet-iron trough suspended from the roof by chains as shown in Fig. 1. Into this chute ore is shoveled at the upper end and moved downwards by swinging the chute without snubbing. Ore or coal will not readily start and slide by gravity unless the pitch of the chute is 32 degrees, or it is given momentum; if, however, it is given momentum it will slide downwards on a comparatively flat plane. In the case in question the swinging chute is moved back and forth, and the momentum the ore attains on the forward swing prevents its moving with the chute on the backward swing, thus the ore is kept in motion so that it slowly goes to the lower end of the chute.

FIG. 1. SWINGING CHUTE IN STOPE, SOUTH AFRICA

In the case of thin beds of coal having an inclination of less than 25 degrees it is difficult to move the coal to the haulway, for which reason the small coal beds in the United States have not been exploited to any great extent. In Iowa, Pennsylvania, and possibly in Illinois, where longwall is practiced in comparatively thin flat beds, conveyers have been installed, and in one or two places in the anthracite fields of Pennsylvania, where the beds are small and the coal valuable, scraper lines have been adopted to move the coal to the haulways. In the Vinton Colliery Co.'s mines, at Vintondale, Pa., the "B" or lower Kittanning seam, is worked longwall. It is 42 inches thick and has a pitch of about 8 degrees. The coal is cut by an air machine. Between the machine and the conveyer shown

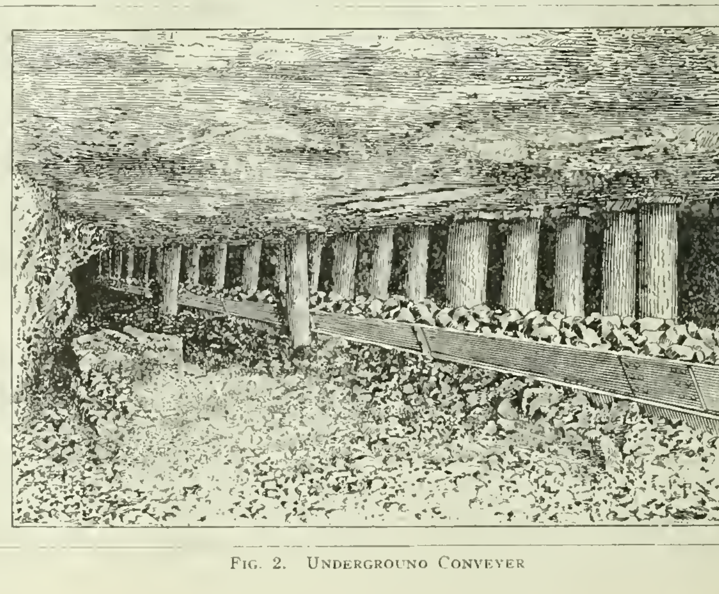

FIG. 2. UNDERGROUND CONVEYER

in Fig. 2 is a row of props, and on the gob side of the conveyer two rows of props. The conveyer trough or pan is made of ⅛-inch steel plate 12 inches wide at the bottom and 18 inches wide at the top. It is 6 inches high and set on strap-iron standards. The conveyer is made in sections of 6, 12, 15, and 18-foot lengths. These are connected by ½-inch flat-headed bolts, thus making the apparatus portable; and when connected it has the arrangement shown in Fig. 3.

The car-loading end of the conveyer is inclined for a distance of 45 feet to allow clearance for the mine cars. This arrangement has been modified so that the head, or car-loading end, is now like that shown in Fig. 4.

Mr. J. I. Thomas read an interesting paper on "Mechanical Conveyers Applied to Longwall Mining" at the Coal Mining Institute of America, June, 1907, which will be found in Vol. 28 of Mines and Minerals. According to Mr. Thomas the complement of men required to mine a block of coal with 250-foot face is 13, composed of "block boss," machine runner and helper, driller, and shot firer, engine boy, head man, and six loaders.

The "block boss," or leader of the crew, has direct charge of the block. He must be a man who has some knowledge of mining and the care of machinery and possesses good executive ability. The balance of the crew, with the possible exception of machine men, are generally non-English-speaking men.

In preparation for the day's work, the machine has cut one rail (30 feet) on the previous afternoon. In the morning this coal is shot down and the loaders begin work immediately. It requires from 4½ to 5 hours for the machine men to finish the cut. The machine is then overhauled and moved up in position to start the return cut. After finishing their own work, the runner and his helper go back on the block and make preparations for the moving of the conveyer. This consists of setting a line of props, called the line row, about 8 feet apart, and a distance from the conveyer equal to the depth of the undercut. As these are placed, the old line row, which is now against the conveyer, is withdrawn. The pulling jacks for moving the conveyer are distributed along the block 40 feet apart and placed in position.

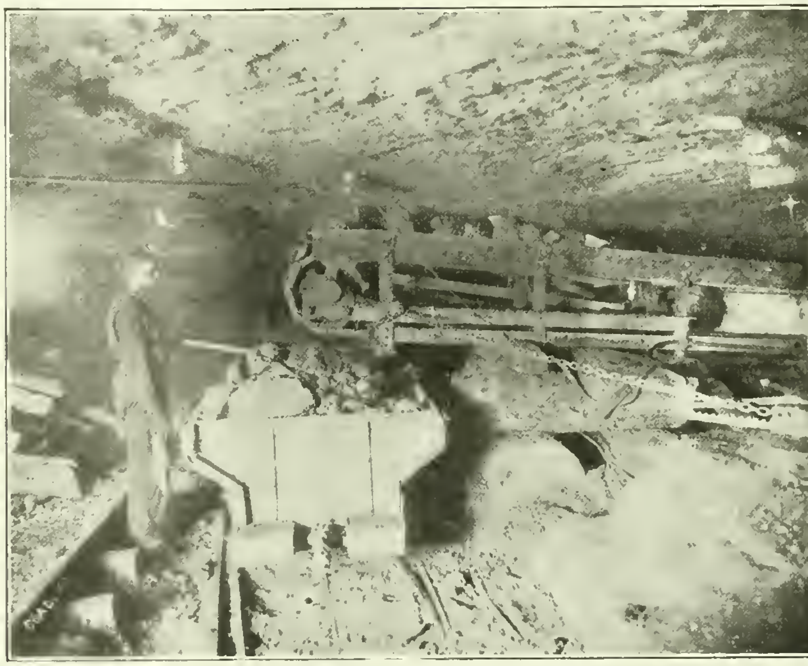

Fig. 4. Head End of Main Conveyer

The shot firer keeps closely after the machine, and is through shooting shortly after the undercut is finished. He then starts from the far end of the block to drill holes in the new face. It usually takes him about 2 hours to drill the entire width of the block.

Each loader is supplied with a pick and shovel and a piece of sheet iron 9 inches wide and 6 feet long, which he attaches to the conveyer to act as a sideboard. As each loader cleans up his place he moves forward to the head of the line. This continues until the coal is loaded out, which usually requires about 6½ hours.

When cleaned up, the drive is reversed and the timber which has arrived on the last trip, is run through on the conveyer to the points on the block where it is required. When this is accomplished the power is shut off by means of a valve located at the top of the block heading. The hose is disconnected from the main feedpipe and the conveyer is moved up to the line row. This lateral move of the conveyer requires very little time, very seldom exceeding 5 minutes. A break row, consisting of two rows of props set 2 feet apart, is now placed along the lower side of the conveyer. These props are set on a cap piece, placed on a small pile of slack, and wedged at the top. Two break rows are all that is necessary to protect the block. In the meantime, a portion

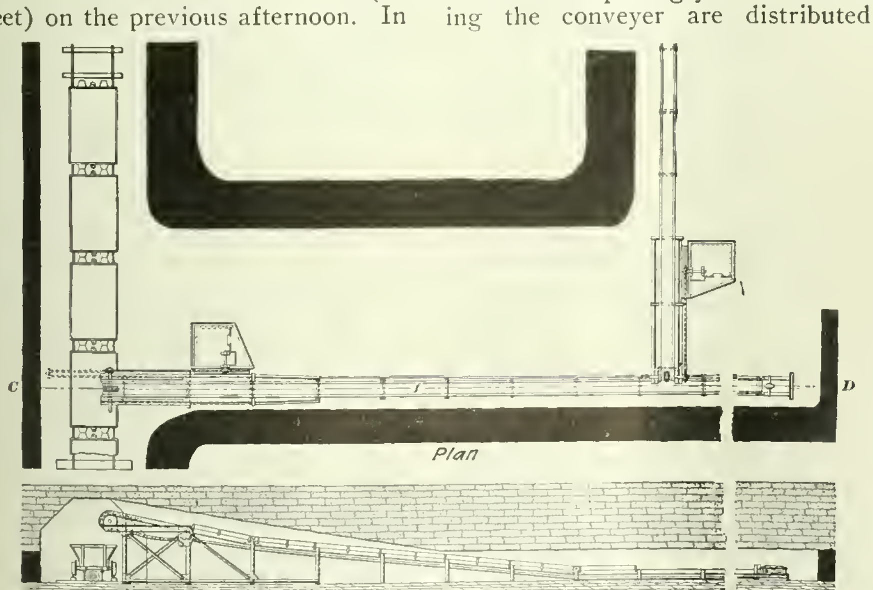

Fig. 3. Arrangement of Conveyer

of the crew are engaged in pulling out the extra break row. This is the most hazardous work on the block, and is given personal attention by the block boss. Axes are used in this operation, and about 75 per cent. of the props recovered are practically uninjured.

While the block crew are employed timbering, the conveyer man and hoist boy make the necessary connections, and go along the conveyer with a pump jack and level it up. They also build a crib at the head end, which is so placed as to prevent the roof from breaking over into the block heading.

When the timber drawers have advanced such a distance from the machine that the noise of the exhaust will not annoy them, the machine begins cutting, and is usually able to cut 30 feet before the shift is over. With a 5-foot undercut the block furnishes 125 tons of coal. Four cuts a week are obtained from each block, which makes a daily average of 100 tons. This system was worked for several years, when it was improved by the use of a triple-conveyer system.

The most recent advancement made is termed the Eichhoff system. It moves the coal forward by a swinging and rocking motion given to the chute, which is worked by a compressed-air motor. As it is possible that this or some similar machine may be found useful in some fields in this country it is described. Fig. 5 shows the device in plan and elevation. The sheet-iron chute *a* is suspended from the roof by chains, in such a way that it will have a uniform inclination to the car. At *b* there are rockers arranged as shown. These are given a reciprocating motion by the motor, and also an up-and-down motion by the wheels traveling on the artificial planes. In addition to this motion the motor *c*, Fig. 5, is supplied with springs on the crosshead arms which are compressed on the backward motion of the piston and give a quick release on the forward movement of the piston. This jerk aids materially in moving forward the coal in the chute. The motor shown is in line with the chute and is connected with it. By means of the lever *d* fastened at one end to the front crosshead and by the other end to the upright *e*, reciprocating motion of the motor is transmitted to the chute. It can be seen that when the roller end of the chute is raised the springs are compressed, and that when the wheels start down the plane the springs give a quick acceleration to the chute. This quick movement gives momentum to the chute and the coal, but the coal continues its movement after the chute has been brought to a stop by the piston of the motor. The motor is sometimes placed to one side in a breakthrough and the motion imparted to the chute by a wire rope. The arrangement suggests flexibility and ready movement from place to place, as the motor is on skids and the chute can be hung from the collar of a temporary three-piece timber set.

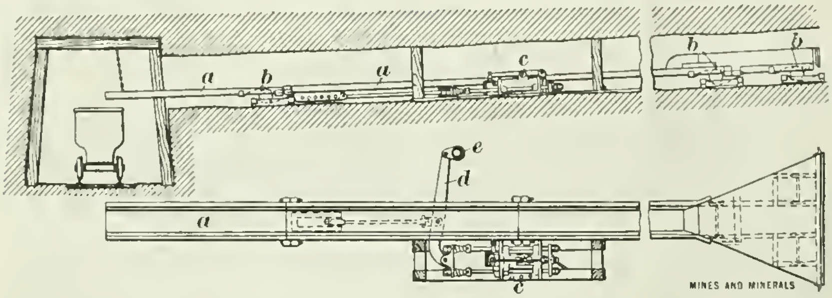

Fig. 5. Eichhoff Conveyer System

Portable Apparatus for Firedamp Analysis

A portable apparatus for the analytical determination of firedamp in an airway in which a lamp will burn, has been devised by Dr. J. S. Haldane. The apparatus, which is simple, is enclosed in a strong case 13 in.×11 in.×3 in. It consists of an air burette, a combustion pipette, and a bichromate cell which furnishes a current to heat a platinum spiral. The apparatus is intended for use by those who are not chemists. In principle it depends upon the burning of the firedamp by means of a hot platinum wire and the consequent change in volume of a measured quantity of air. The air is drawn into the burette, which is graduated, and then forced into the combustion pipette where the firedamp is burnt. Then the air is again forced back into the burette after passing through a water-jacket to absorb the water formed and to cool the air. The change in volume is then noted on the burette. One minute is sufficient to burn the firedamp.

By the use of this instrument the percentage of firedamp can be determined within one-tenth of 1 per cent., but it cannot be used in places where there is more than 6 per cent. of firedamp, as the burette will be too short.

Old Rails as Stringers

When wooden rails are used as stringers to which the trolley wires are attached where the roof is high, it is found that they are frequently broken. Moreover, the wood will rot sooner or later, according to the conditions at the place where it is used. In collieries where a change has been made from mule haulage to motor haulage, a quantity of old light rails often are on hand and not in use. These, as well as any old rails which have served their purpose for track work, can be used as stringers to support the trolley hangers and the trolley wire. It is not necessary to bore holes in the rail. Any blacksmith can make a clamp which will fasten on to the bottom of the rail, out of $2'' \times \frac{1}{4}''$ flat bar iron. It is made in two pieces, a chair which will hook over one side of the bottom of a rail, Fig. 1, and extend beyond the bottom at the other side, so that the second piece, which presses on top of the bottom part of the rail on the opposite side, can be bolted to it by the same bolt which holds the yoke of the trolley hanger, thus both the clamp and the hanger will be firmly held.

The rail is set in the hitches on each side of the roadway and may be firmly held in place with a little cement mortar.

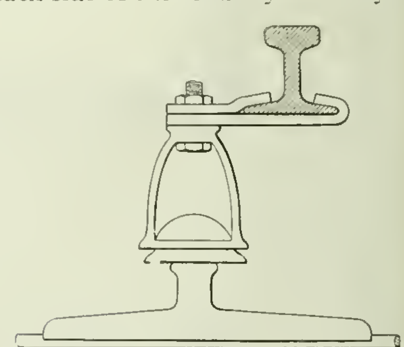

Fig. 1

This device especially where second hand rails can be used is cheap to make and install and will be exceedingly long lived.

"Telling Hogan"

Can We Impress Upon the Miner the Importance of Well-Known Facts Regarding Explosions?

*By John Verner**

Hogan's joking remarks about the Bureau of Mines, appearing in the November number of Mines and Minerals, in at least one respect, are worthy of serious consideration: for in his droll harangue can be seen the sober truth that the greatest possible success in promoting the safety of our mines cannot be secured, unless Hogan can be induced to accept the advice of those qualified for the job, and, being convinced of its soundness, give his willing and intelligent help in the work for the prevention of accidents. It must be realized by all who understand the situation that he will prove a very helpful factor in this respect, probably as valuable as the well-informed and well-intentioned superintendent, and in some instances perhaps more so; because my knowledge of human nature permits me to say that the former's suggestions and advice to his fellow miners regarding their individual and collective protection against danger and disaster will be more readily accepted and followed by them than the instructions and requests of the latter. I admit that the teaching of Hogan appears to be a big and difficult undertaking. He has his own peculiar views about things, and he is generally inclined to overestimate the value of mere practical experience and to underestimate the value of technical training; but he also knows many useful facts, and I believe he can be taught successfully, if these facts are rightly used and correlated and their full meaning is made plain to him in simple terms.

Hogan declares that he knows that hard coal dust does not explode and that soft-coal dust does explode and is willing to "lave it go at that." I do not believe that Hogan by this remark intended to show indifference on his part to the acquirement of helpful information or to convey the impression that he has no desire to increase his knowledge regarding the causes of explosions, and I think he only intended to express his inability to understand the technical presentation of the matter. If that is true, then Hogan's failure to grasp the meaning of technical terms should make him all the more eager to get possession of the facts for his own interpretation. As he cannot develop all the facts himself, he must depend on others to furnish them and they should come from a reliable source. The Bureau of Mines is a reliable source in this respect. It has conducted its experiments and tests for several years and has established a large number of facts relating to explosions, many of them more or less well known before, some of them new, but all of them useful. As Hogan knows a few facts himself, it seems to me that his better understanding of the reasons why coal dust explodes is not depending on the discovery of new facts, but rather on his own efforts to get the facts already known and all the information concerning them he can obtain. To start him along this line I will give him a few facts regarding explosions for his consideration.

Hogan knows that every shot fired in a mine produces more or less wind and that this wind is driven away from the shot ahead of the flame. He knows that the force of this wind varies greatly; with one shot it may be very small, with another it may be strong enough to move heavy objects and become a menace to life. He may or may not know that this wind wave, after its extremely short duration, is succeeded instantly by a reactionary air wave of proportionate force, but if he has had the opportunity to observe the behavior of "windy" shots at close range, as I have had, he knows. I have observed the actions of a number of these dangerous shots, not because I was inquisitive in this respect, but because in each case the opportunity was forced on me. With all these shots I noted the wind wave coming from them, its stoppage and its immediate reversal, but in one case the rapidity of change in the air movement was particularly plain and distinct. I was standing near a door when the windy shot occurred. The door was violently forced open about half way and instantly and violently closed again. This was followed by continued vibrations of the door, decreasing rapidly in force. All this transpired within very few seconds. I will add that there was no ignition of the dust by the shot and that the mine was entirely free from gas.

The above facts have been known almost from the beginning of mining coal by blasting, they are old and common, and on that account perhaps may be considered of little value, and yet they appear to have an important part in preventing or promoting an explosion. Hogan may disregard my views in the matter, but I want him to take the evidence and form his own conclusions.

Several years ago I witnessed a number of tests at the Pittsburg Experiment Station. In one test a mixture of gas and air, the amount of gas being 8 per cent., was confined in the gallery. The test was made to demonstrate whether or not this highly explosive mixture could be ignited by an electric spark. The firedamp was quickly exploded in this manner. In a subsequent experiment another explosive mixture was prepared and confined as in the previous test and was then fired into by a shot charged with a permissible explosive. In this case the firedamp was not exploded, notwithstanding the fact that the shot produced a much larger flame than the electric spark. In explanation Mr. Clarence Hall says: "The flame temperature of all explosives exceeds the ignition temperature of inflammable gas and dust mixtures, but fortunately the flame of a permissible explosive properly detonated is of such short duration that under the conditions of blasting coal it does not ignite the inflammable mixtures." This is undoubtedly true; but it is also more than probable that, if the flame produced by the permissible explosive could have been applied to the inflammable gaseous mixture in the gallery without the commotion caused by the firing of the shot, there would have been an explosion. Evidently the wind or pressure wave preceding the flame repelled the firedamp and kept it momentarily beyond the flame's reach, and when the immediate reaction occurred and the gaseous matter was drawn back into the space from which it had been expelled, the flame had either died out or, if still in existence, its temperature had been reduced below the ignition point. It may therefore be concluded that the danger of igniting the firedamp by the flame, having a temperature, according to Mr. Hall, in excess of the ignition temperature of the inflammable gas mixture, was at least materially reduced, if not entirely averted by the repelling action of the wind or pressure wave preceding the flame.

During the meeting of the International Mining Experiments Stations Conference last September a number of tests were made in the Bruceton

*Inspector of Mines, Chariton, Iowa.

mine to demonstrate the behavior of dust explosions. In one, the test main entry for a distance of 500 feet from its mouth was spread with fine fresh coal dust, 1 pound of dust being used per linear foot of entry. The cannon, charged with $2\frac{3}{4}$ pounds of black powder, was placed at the end of the dust zone, or 500 feet from the mine mouth, the muzzle of the cannon facing the entrance. No dust was placed behind the cannon. When the shot was fired the dust exploded, the flame extending back of the cannon into the dustless space over a distance of 50 feet. In another test the dust was spread in the same manner as before, but the dust zone was extended 150 feet and the cannon was placed 550 feet from the mine entrance with the dust charge extending 100 feet behind the cannon. When the shot was fired the dust in front of the cannon exploded as before and, as in the other test, the flame, preceded of course by a wind or pressure wave, was again projected 50 feet to the rear of the cannon into the now dust-charged zone but failed to explode the dust. It should be remembered that the dust used in these tests was readily inflammable, was specially prepared and carefully spread under conditions highly favoring its ignition and therefore the failure to fire the dust behind the cannon, although the flame in that direction measured 50 feet in length, may also be accepted as good proof that the mere projection of a long flame, if preceded by a wind or pressure wave, is not sufficient of itself to ignite the dust present with explosive results.

These examples are good, but I want Hogan to take a larger view of the matter. During the last 10 years eight explosions of dust, causing the loss of eleven lives, occurred in Iowa. All these explosions were of rather limited extent, and only in two cases, where the workings were yet within a few hundred feet of the shafts, did they extend to the surface. The mines of Iowa are non-gaseous and generally dry. About four-fifths of the total coal output is blasted from the solid by the use of black powder. Sprinkling or otherwise wetting the dry dust in rooms and other working places is not practiced, but the shots are examined before they are charged and fired by shot firers after the miners have left the mine. The average yearly coal production in this state for the last 10 years, mined by the use of powder, was in excess of 5,000,000 tons. I will assume that each shot fired yielded 5 tons of coal; on an average there were then 1,250,000 shots fired for each explosion. I will assume further that only 1 per cent. of these shots or 12,500, a very low estimate, were tamping blowers or otherwise ineffective. From every one of these shots, good and bad, flame of greater or less length was projected, preceded by a wind or pressure wave driving what dust there may have been present away from the flame. The evidence of the results of the million and a quarter shots shows conclusively that the mere projection of flame under the condition named is comparatively harmless, and, inferentially, that the repelling action of the wind or pressure wave tends to prevent the rapid ignition of the dust in large enough quantities to produce explosive effects. If this interpretation of the evidence is correct, it is then apparent that the voluminous ignition of the dust by the flame of the one shot that caused an explosion occurred during the period of reaction and that the flame was of unusually long duration.

Let Hogan take the facts and judge for himself. The Lost Creek mine, in Iowa, was opened in 1901 and in January, 1902, the workings had become so extensive that about 100 men could be employed. The mine was non-gaseous, dry, well ventilated and in good condition. Although there was some dust, it was not permitted to accumulate, and in this respect the mine was kept exceptionally clean. The coal was blasted from the solid and shots were fired twice a day, at noon and at quitting time in the evening. The miners prepared and fired their own shots, and, as the use of fuse was not permitted, they were well tamped. On January 23, 1902, the miner in room 10, second north on the east side, fired at quitting time a shot which blew the tamping, but did no damage whatever. The room, about 500 feet distant from the hoisting shaft, had been driven about 50 feet, was slightly dipping and had no cross-cuts connecting it with adjacent rooms. On January 24 the miner recharged the hole and fired it at noon. The result was a terrific explosion causing the death of 20 miners and injuring many more. In looking for the primary cause of the explosion it was apparent that it could not have been due to a difference in dust conditions. The quantity of dust in the room and its immediate vicinity was not increased over night nor was its condition changed otherwise in any way. The effects of the firing of other shots in the nearby working places could not have been contributing factors in starting the explosion, because the shot in room 10 was the first shot fired at noon. There was this difference, however. The shot at noon had not only blown the tamping again, but also had found vent through a horizontal fissure in the coal that had been made by a shot fired several days before. The flame issuing from the fissure evidently had been of unusual intensity and duration, for when I examined the room in the morning of January 25, I found that the roof along the face in front of the fissure had been cracked and blistered by the great heat, while further out from the face toward the room mouth the roof was far less affected in this respect. Notwithstanding the absence of a cross-cut, I found the air in the room pure and fresh, due to the effects of natural ventilation. The presence of several persons and lights at the face increased the air movement in the room perceptibly, and when I placed my lamp on the floor between the rails the air-current was sufficiently strong to deflect the flame horizontally toward the face. Now, as this air movement was produced by the difference of only a few degrees between the temperature of the air at the face of the room and the temperature of the air in the entry, what would be the probable result if, through the effects of the shot, the difference in temperature between the two points was 1,000 or 1,500 degrees? Evidently, the force of the return air wave would be increased tremendously and a fierce draft would result, rushing along the bottom from the entry toward the face of the room, raising and sweeping along with it the dust in its path, a great volume of a highly inflammable mixture of dust and air would thus be injected into the flame still burning at the face, and instantaneous ignition of the mixture would follow with explosive results.

A comparison of the results of the shot fired in the Lost Creek mine on January 23 with the recharged shot fired on January 24, permits the conclusion that the starting of a dust explosion, other conditions being the same, depends on the intensity of heat and flame developed by a shot or other inciting agent capable of producing heat and flame. That this conclusion is justified, is further shown by the results of a series of trials to start an explosion at the main entry face in the Bruceton mine. At the time of the trials the entry face was 1,250 feet distant from the mine entrance. Flush with the entry face a cross-cut connected the main entry with the air-course. The whole length of the main entry from the face out was charged with dust, 1 pound per linear foot, and the cross-cut and a small part of the air-course were similarly charged, so, apparently, a better opportunity for dust ignition by the flame of the shot was provided than existed in previous tests, resulting in explosions, where the dust for primary ignition was available in one direction only. The hole at the entry face contained the usual charge of $2\frac{3}{4}$ pounds of black powder and was tamped with 4 inches of clay. The shot failed to cause an explosion. In the next trial, made precisely under the same conditions, failure again resulted. I stated before, that, in my judgment, the primary projection of flame, preceded by the wind or pressure wave caused by the expansion force of a shot, does not ignite the dust explosively. Flame projection of the first blown-out shot in room 10 in the Lost Creek mine did not cause a dangerous ignition of the dust, and immediately subsequent events proved that there was sufficient dust present to start an explosion. In the two Bruceton tests, flame projection into carefully prepared and amply charged dust zones also failed to produce explosions.

The men in charge of the Bruceton experiments were determined, to have an explosion and so they prepared for a third trial. In this test the hole in the face of the entry was charged as before with $2\frac{3}{4}$ pounds of powder. Another charge of $2\frac{3}{4}$ pounds of powder was put in the cannon that had been placed in the cross-cut near the entry in such position that the flame from the cannon's mouth was projected along the entry toward the mine entrance. As the shots were fired electrically, their explosion was simultaneous. This time there was no failure and the result was a violent explosion.

In looking for the causes responsible for the failure to explode the dust in the first two trials, careful consideration should be given to any known difference in conditions as they existed in the tests productive of explosions and in the tests that failed. Two differences are readily apparent. First, in all the previous tests, resulting in explosions, the greatest distance between the location of the shot and the mine entrance was about 850 feet, while the distance between the mine entrance and the face of the main entry where the shots were located in the unsuccessful trials was 1,250 feet. Increase in distance between the mine openings and the shot fired appears to have a preventive influence (the matter is explained further on). In this case the difference in distance was only 400 feet and consequently its preventive influence, if it existed, was correspondingly small, but its possible effects should be considered, for the margin between safety and danger is often very narrow and little causes may have great effects. Second, in previous tests made to note the effects of shots fired in the face of the main entry, then 750 feet distant from the mine entrance, the cross-cut from the main entry to the air-course was 100 feet from the face. With the cross-cut so located the shots fired in the face of the entry produced explosions of the most violent types. In the trials that failed, the cross-cut was located right at the face and it should be determined if this fact has any bearing on the results. Hogan knows about the wind preceding the flame of a shot and he is sufficiently informed regarding conditions affecting mine ventilation to know that, if a given force produces an air movement of a certain velocity through a single channel, and a second similar channel, starting from the point of force, is provided, the velocity of the air movement in either channel will be materially less than the former velocity in the single channel, and he also knows that an increase of the lengths of the channels will result in a still further reduction in the speed of the air flow. Then, assuming the shots to have been of equal force, it appears that, on account of the presence of the two channels starting from the main entry face, the velocity of the air wave preceding the flame in the trials that failed was less than in the previous successful tests. The reduction in velocity brought two results. One was that less dust was blown from the shelves, the other that the recoil or the return air movement had less force and velocity. Hogan will readily understand the first result and I shall try to explain the meaning of the second. The return air movement toward the point where a shot was fired is due to two causes, first, the contraction through rapid cooling of the gaseous matter in the immediate vicinity of the shot; second, the well-known draft-producing effects of heat and flame. Both forces work combinedly. For the purpose of illustration, I will only consider the effects of heat at the main entry face; and to make matters as plain as I can, let it be assumed that a shaft is sunk at the main entry face in front of the cross-cut and that the natural heat of the mine near the face is sufficient to produce an air-current, the shaft being the upcast. The air is now traveling on the main entry and on the air-course and from the latter through the cross-cut to the shaft. A greater air velocity on the main entry is desired. This may be accomplished in two ways: first, by closing the cross-cut at the face and causing all the air to travel on the main entry; or, second, by leaving the cross-cut open, and artificially increasing the heat at the bottom of the shaft until the desired air velocity on the main entry is produced. Evidently, as the return air movement in the trials that failed was too weak to be effective, it could have been increased by firing one shot with the cross-cut closed; or, with the two channels open, by increasing the heat by firing two shots simultaneously. The latter process was used in the third trial that resulted in exploding the dust. By firing the two shots together in this trial the force of the wind or pressure wave preceding the flame was increased, and consequently it stirred up and dislodged from the shelves a greater quantity of dust than in the former trials, the reaction was greater and materially accelerated through the effects of the much increased heat at the face, and these combined influences produced a dust-charged draft, highly inflammable, that rushed along the bottom toward the heat center and flame area at the face and fired there with explosive results.

I have given Hogan only facts as they appeared at the starting points of explosions because it is the knowledge of such facts he needs most. He knows the terrible consequences of big explosions and there can be no doubt about his willingness to do all he reasonably can to help in the work of preventing these disasters, but he cannot be sufficiently effective in this respect because he has not the necessary thorough rudimentary knowledge to enable him to understand the combination of factors and the influence of each that tend to bring them about.

He must know the nature of the danger in all its essential details before he can fairly judge the value and effects of proposed means of prevention and apply them intelligently according to the needs in each case. This rudimentary information should be made available to Hogan not only to enable him to recognize dangerous conditions in his own working place and to use the right means for their removal, but also to make him fit to become a competent instructor and adviser of his less experienced neighbors.

The Letter Box

Readers are invited to ask or answer any question pertaining to mining, or to express their views on mining subjects in this department. All communications must be accompanied by the name and address of the writer—not necessarily for publication. The editors are not responsible for views expressed by correspondents.

Fossils in Coal

Editor Mines and Minerals:

Sir:—Some time ago I was told by a miner in one of the anthracite mines near Scranton that he had a fossil fish which he found in the mines. I did not see it and I have been taught that no fishes existed at the time the anthracite coal measures were laid down. I would like to know if any one else has found any fossils supposed to be fishes in such coal measures.

Pittston, Pa.

Mine Drainage

Editor Mines and Minerals:

Sir:—In dip workings, I desire to drain a sump that holds 10,000 gallons and that fills every 12 hours. Will a pump located 30 feet vertically above the sump, with a 3-inch suction pipe 1,000 feet long, and a discharge pipe 4 inches in diameter, and 3,000 feet long, with a 20-foot vertical lift, work satisfactorily? If so, what size pump is necessary to handle the water without constantly emptying the sump?

T. E. R.

Millsboro, Pa.

Source of Blackdamp

Editor Mines and Minerals:

Sir:—Some workings near the surface have been making blackdamp quite steadily and it is something of a mystery what is the source. There are numerous breaks to the surface in the territory affected and the part where the most blackdamp is found is nearly under a large slack pile. It has been suggested that fire is starting in the pile and the gas from it gets into the mine through cracks to the surface. If this is so, would there not likely be carbon monoxide in dangerous quantities as well as blackdamp? No indications of the former have been discovered.

Miner

Booster Fans

Editor Mines and Minerals:

Sir:—As a matter of interest to mine officials, and to settle constant controversy, I would ask my colleagues in the coal-mining industry to aid in the settlement of the following question: Are "booster" fans of any real service, and is the service they render of sufficient amount to justify their installation?

By the term "booster" fan, I mean an auxiliary fan set up some place along the air-course and operated with the idea of increasing the volume of air supplied by the main fan.

I would request statements from mine officials who have had practical experience with "booster" fans as to actual results obtained; and also from those who have studied the matter from the standpoint of flow of air in mines, as to the conclusions they have formed.

Mine Manager

Denver, Colo.

Gases From Acetylene Lamps

Editor Mines and Minerals:

Sir:—In your November issue Mr. T. S. Almond requested information on carbide gases in mines. In this isolated place, not having a "Chemistry" at hand I will not attempt to answer the second question.

From actual experience I can answer the first question.

The mines of this company, Cia. Minera Jesus Maria y Anexas, are gold mines. The vein is narrow, dips 26°, and is broken and faulted. Drifts on the vein become impassable if neglected for several months. There are several openings to the surface. There is no system of artificial ventilation. Drifts are driven as far as possible, about 300 feet, then a connection is made with the level above. As can be imagined, before a connection is made these drifts have very poor air and become very hot from the continual slow movement of the mountain along the broken vein. A temperature of 100° F. is common in the drifts.

Candles were formerly used. In the hot places only the best American candles, at a cost of 15 cents per man per day, could be used; in other parts of the mine a cheaper candle, costing $12\frac{1}{2}$ cents per man per day was used. In an endeavor to cut down this expense many other methods of lighting were tried, among them being coal oil, a mixture of one-fourth coal oil and three-fourths lard oil, ordinary miners' oil, and carbide in acetylene lamps. The costs per day per man were: coal oil and lard oil, 6 cents; miner's oil, $15\frac{3}{4}$ cents; and acetylene or carbide lamps, 5 cents. The carbide was not only the cheapest but was the most satisfactory in all ways. It is not smoky, and for a given amount of light does not require nearly as much oxygen. By using it, the men can drive a drift much further before connecting with the next level than before. The air is clearer than when any of the other lights, not excepting candles, were used, and the surveyor can take longer sights. I have heard of coal miners objecting to the odor of acetylene, claiming that the gases given off when it was burned were poisonous. In our mine, where there is practically no ventilation, after being underground a few minutes we do not notice any odor, and it has no ill effect whatever on the men, and this statement could not be made of the smoke and gases resulting from the use of the various oil lamps tried.

The lamps we use are "Baldwin, No. 34." When several men are working in a stope, two of these lamps yield as much light as six candles. The costs given are in United States currency and are based on each man having one light. They were given me officially by Mr. V. York.

G. W. Pfeiffer

San Jose de Garcia, Sin., Mexico

Acetylene Dangers

Editor Mines and Minerals:

Sir:—The three letters concerning the possible harm that may come from the use of acetylene lamps published in your issue for December fail to emphasize what seems to me to be a very important point, namely, that ordinary commercial calcium carbide contains several impurities, notably calcium sulphides and phosphides. On adding water these give rise to the more or less poisonous gases hydrogen sulphide (H_2S) and phosphine (PH_3) which contaminate the acetylene and give it the familiar strong odor. These gases can be removed by passing through a solution of chromic acid (CrO_3) and the resulting pure acetylene is odorless and harmless, as your correspondents state. But if acetylene gas without such purification, which is of course impracticable in the ordinary miner's lamp, is inhaled in any quantity, the poisonous nature of the two gases mentioned will be revealed by the appearance of headache and other symptoms. Again, if such impure acetylene is burned and the products of combustion breathed in, the injurious effects on the kidneys and other organs from the sulphur dioxide (SO_2) formed from the H_2S, and the irritating action on the lungs and throat produced by the phosphoric acid ($P_2O_5 + H_2O$) formed from the PH_3, cannot fail to be noticed sooner or later. It is therefore incorrect to state, as your correspondents seem inclined to do, that the use of acetylene lamps is without deleterious effects on the health of the miner.

Assistant Professor of Mineralogy
Lehigh University

Shaft Sinking

Editor Mines and Minerals:

SIR:—I read with interest your article on "Shaft Sinking in South Africa," in November MINES AND MINERALS, and while reading it, it brought to mind my experience in shaft sinking in the Vogelstruis Deep property, Florida, South Africa. Our record for 1 month in a three-compartment shaft, 10 ft. × 23 ft. over all, excavating in quartzite, was 145 feet; although instead of sinking by hand we had five machines, one man and a boy to each machine. The men would go down, rig up their machines, drill the bottom over, pull down, and blast the sinking holes before coming off shift. The other conditions were similar to those of the article referred to. In my belief, no men should be down the shaft when the timbermen are lowering the wall plates and end plates. In one instance an end plate fell to the bottom and severely hurt a Kaffir, and although it was purely accidental, yet, the best are liable to make mistakes, and that is why no workmen should be in the shaft during the time of lowering timber. I also think it would be a great saving of time if two or three men were employed to put in the timber in shafts, for it would give the men who were sinking more time, and enable them to sink to a greater depth every month. I think considerable time would be saved in the Lake Superior district if self-dumping skips were used instead of buckets. The skip holds more, and empties into a pocket on the surface holding probably twenty or thirty skips, so that while the men are drilling, the pocket on the surface can be emptied. Again, time would be saved, which is now employed in knocking up the catches on the bucket, dumping, pulling it back, putting on the catches, and pulling up the protection door. The bonus system seems to meet with the hearty approval of the men wherever it has been tried, as it not only gives the men a better pay, but it makes them eager to make a record, and gives better satisfaction between master and men. I think one of the greatest assets a company can have is the good will and hearty cooperation of its men.

SAMUEL HARRIS
Negaunee, Mich.

Stone Dust in Mines

Editor Mines and Minerals:

SIR:—I am surprised to know that our mines at Delagua, Colo., are the only ones in the United States using stone dust.

If the steam men who have several haulage roads will treat one with stone dust, and then make comparisons with conditions in the "wet" roads, I believe they will be converted. All our pit bosses who had experience with water before the adobe dust was applied are now enthusiastic stone dust men.

The credit for introducing a machine for distributing stone dust in mines rests with Mr. W. J. Murray, vice-president and general manager of the Victor-American Fuel Co., and I believe the appliance serves a very useful purpose at a trifling cost. The machine consists of a small Roots blower, belt driven from a 3-horsepower direct-current motor, the whole arrangement with dust hopper carried on a small truck 9 ft. × 3 ft. The motor takes current through a trolley pole, and the whole outfit consists of a locomotive, mine car carrying dust, and the machine. There is a 3-inch rubber hose attached to the blower, and two men can cover from 1 to 2 miles of entry in a night, spraying the dust on the roof and sides. The finer dust is carried long distances in the air-current when distributing is going on, but I see very little or no dust in the air during the day time. So far, the use of stone dust here has caused no inconvenience to the workmen, nor has it delayed the traffic underground, something which cannot be said about the use of water.

After a roadway has been treated by hand, all ledges cleaned free from coal dust and filled with stone dust, all necessary shelves erected and loaded, and the floor having been reasonably cleaned, then the blower can travel on the roadway and give another coating of stone dust, and also from time to time when coal dust begins to collect on the stone dust on the projections. These subsequent treatments can be done rapidly and at small cost. To secure safety the roofs and sides must be loaded with stone dust, or adobe dust, as heavily as possible. The machine will not give that heavy first supply which is requisite, and the work will have to be supplemented by hand.

Where the bulk of distributed dust settles on a floor, and the floor is cleaned from time to time, the adobe dust is removed with the small coal and dirt, consequently, after that, there is no benefit from the dust which reached the floor. Stone dust placed on roof and side projections, either natural or artificial in the form of shelves, remains there during the life of the mine to act as a diluent should ever the occasion arise, and money spent placing dust in those places gives a permanent return.

A comparison between the stone dust and steam or water methods is too big a proposition to be dealt with in this letter; but after a varied experience with water I favor the stone or adobe dust method unreservedly. I believe it gives more safety when properly applied, is less costly, and is more sanitary.

A mine may be treated with water for 5 years or for 25 years, and if the water supply fails, the condition is as dangerous as ever in 2 or 3 days. Time does not reduce the cost of steam or water method, but it does reduce the cost of the stone-dust method. Stone dust does not evaporate.

You are probably aware that a large number of the mines which have "blown up" in the last 18 months were water-treated. Cokedale, near here, which was considered a "safe" mine, and was so well watered that the miners complained about having to travel through the water on the roads, blew up and the flame swept through the workings from the face to the outside. This mine is not fiery, open lights are used throughout. A commission visited this mine a few weeks before the explosion, and I take this extract from their report: "It is a pleasure to say that in the Cokedale mine there was very little dust, in fact we were unable to find a suitable sample for analysis." A blown-out shot was the cause, and I venture to say that if the entries had been stone-dusted the explosion would have been confined to the room in which the shot was fired.

In conclusion, will say that the work of stone dusting all the Delagua mines is not yet complete. The work is proceeding.

Samuel Dean

Scientific Management

Editor Mines and Minerals:

Sir:—As a student of efficiency engineering applied to mining, I am much interested in query of "Superintendent, Pittsburg, Pa.," in December Letter Box. I am sorry that space will be lacking if I write fully, therefore, if Superintendent will correspond with me I will be only too glad and very much obliged to him if he will submit his conditions to me.

Each individual case needs its individual handling, although the same general rules can be applied. By a close unbiased, unprejudiced study of the conditions in the mine and mill, of the men and their state of mind, by a comparison of what his mine and mill are doing to what they should do, and to what others of equal size are doing, by a comparison of his machines, what they do to what they should do, by analyzing his organization, his mill layout, and by cultivating his sense of proportion, he can apply the principles of the efficiency engineer. However, as I have mentioned before, specific cases need specific handling.

M. L. Becker
703 E. Illinois St., Urbana, Ill.

Editor Mines and Minerals:

Sir:—In reply to "Superintendent" in your December issue, I would state that there are several engineers engaged in efficiency work among collieries of Pennsylvania and West Virginia. This work not only covers the general problems of scientific management, but also goes exhaustively into the preparation of the output, haulage, ventilation, drainage, methods of accounting, organization and kindred problems with a direct view to reducing the cost per ton; and it is a matter of gratification that our Captains of Industry are sitting up and taking notice. Stephen T. Williams

New York, N. Y.

Moisture in Coal

Experiments by E. H. Archibald and J. N. Lawrence on the drying of bituminous and anthracite coal under different conditions are described which show that the U. S. A. official method (heating for 1 hour at 104°–107° C.) gives figures for moisture, which are much below the true value, the error in the case of some bituminous coals amounting to 40 per cent. of the true content of moisture. The errors, probably mainly due to the oxidation of iron, or sulphur, or both, and to the incomplete expulsion of moisture, are much greater for bituminous coal than for anthracite. For determining moisture in bituminous coal, it is recommended that the coal be heated in a current of dry air at a temperature not below 110°C. and the moisture expelled be absorbed by anhydrous calcium chloride. (J. Ind. Eng. Chem., iv, 258.)

Coal Mining Notes

By Special Correspondents

CAPE BRETON, N. S.

The collieries of the Glace Bay district have had the most successful year in the history of the industry. The output of the Dominion Coal Co. for 1912 will exceed 4,500,000 tons showing an increase on the output for 1911 of over 500,000 tons. This company has now in operation 15 collieries, and two in course of development. Several others are projected in the near future.

For a number of years past the Dominion Coal Co. has been perfecting a scheme for the general electrification of its collieries, and the four newest mines are operated exclusively by electric power. The use of electricity underground has so far been restricted to the driving of pumps, the current being introduced into the mine through boreholes. The motors are all placed in fireproof pump houses. The mining machines are driven by compressed air, obtained from electrically driven compressors on the surface.

A new power station was recently completed, which is interesting, in that the boilers are of a novel type, so far as is known the first of their kind in America, although a number are being successfully operated in England. These boilers are the invention of the late Lieutenant Bettington, who was recently killed by a fall from an aeroplane in the British Army maneuvers. The boilers are fed by dust fuel injected into a vertical combustion chamber under pressure, the dust being consumed in a vertical jet some 20 feet in height. The combustion chamber is lined with firebrick set in without cement. Vertical water tubes are arranged in a circle around the firebrick lining, the superheater tubes being coiled spirally around the vertical tubes. The flame temperature in the combustion chamber reaches 2,500° F., and all the combustible matter of the fuel is consumed, the irreducible residue falling into the pit as molten slag. The walls of the combustion chamber are said to need no relining as they are automatically kept at one thickness by the deposition of molten slag, the thickness being regulated by the cooling effect of the surrounding water tubes.

The present installation consists of three boilers, two of which are now under steam. It is as yet too early to say what results may be expected from this innovation, but so far they justify sanguine hopes.

The electrical part of the plant consists of two 2,000-kilowatt turbogenerator units, the turbines taking live superheated steam.

ALABAMA

Mr. Carr McCormack has resigned as superintendent of the Flat Creek mines of the Pratt Consolidated Coal Co. and accepted the position of general manager of the property of the Milner Coal and Railroad Co., at New Castle, recently acquired by Erskine Ramsay and G. B. McCormack, of Birmingham.

A fire at the Banner Mines of the Pratt Consolidated Coal Co., December 7, destroyed the tipple, coal bins, and coal washers entailing a loss of $40,000. The company expects to be loading coal in 2 weeks over a temporary structure. The old structure is to be replaced by a steel and reinforced concrete structure.

The coke ovens of the New Castle mine are being fired. The 250 ovens at this plant have been closed down for the past 3 years.

The car situation is still short. The coal production will go above past years; it is expected to go above 18,000,000 tons.

Iowa Mine Report

The report of the State Mine Inspectors of Iowa, for the 2 years ending June 30, 1912, shows that there has been one fatality in Iowa for every 220,462 tons of coal mined, and for every 251 persons employed inside the mines, or at a rate of almost four per thousand employed. The following are the figures:

District	Inside Fatal	Non-Fatal	Production	Inside Employes
1	21	90	5,355,697	6,727
2	23	78	4,893,097	5,047
3	22	126	4,301,708	4,788
Totals...	66	294	14,550,502	16,562

Of fatal accidents, 60 per cent. were caused by falls of roof or coal, as were 53 per cent. of the non-fatal. Two fatalities were due to explosions of dust ignited by blasts.

Answers to Examination Questions

Second Grade Mine Foremen, Pennsylvania, Bituminous, 1912, (Concluded)—Colorado Mine Inspectors, 1911

QUES. 17.—What regulations should a mine foreman enforce to prevent accidents to drivers, motor men, and all other employes on haulage roads?

ANS.—No person must be allowed to travel to and from his work on any locomotive road unless no other road is provided for the purpose, and no person other than the driver or trip rider shall be allowed to ride on the loaded cars.

Drivers must not leave a car or a trip where another car or trip is liable to run into it, nor where it will interfere with the ventilation; in running down grade, cars must be kept under control by brakes or sprags; drivers must see that no one is allowed to ride upon loaded cars or drive a mule or horse in their place; and when opening a door must see that it is properly closed after the trip has passed.

Trip riders must see that all hitchings and couplings are in good condition and that the cars are properly coupled before the trip starts. Any defects must immediately be repaired or made good, and, if this is not possible, the trip rider must hold the trip and at once notify the foreman or assistant foreman. The trip rider must not allow any person to ride on the loaded trip at any time, nor upon the empty trip without the authority of the mine foreman. The speed of the trip shall not exceed 6 miles an hour.

The motor man must keep a sharp lookout and sound his bell or whistle frequently when coming near the parting or landing, and must not exceed the speed allowed by the mine foreman. He must see that the motors, cables, and controlling parts are kept clean and that the headlight is burning brightly when the locomotive is in motion. He must allow no person but the attendant to ride on the loaded trip.

QUES. 18.—(*a*) From what source would you obtain useful data to govern you in driving toward old abandoned workings likely to contain water or gas, and how would you proceed to tap same to comply with the law, and (*b*) if there was a head of water of 125 feet, what thickness of barrier pillar would you leave?

ANS.—(*a*) Absolutely reliable information as to the near approach of active workings to abandoned ones can only be obtained from an examination of accurate maps. This is particularly so if present workings must be kept the legal distance of 50 feet from the old ones. When the distance to the old workings is less, it sometimes happens that there is a seepage of water or even gas from the old, through the coal, to the new workings. Bore holes drilled ahead may tap the old workings. Water in old workings may legally be removed by driving a passageway to drain it off. If gas cannot be removed by the ordinary methods of bratticing, etc., one or more bore holes not less than 6 inches in diameter must be sunk from the surface to some high point in the old workings that the gas may have an opportunity to escape to the surface.

If the workings are approaching abandoned workings supposed to contain either water or gas, two bore holes must be maintained not less than 12 feet in advance of the face, and must be driven the same distance into each rib and at intervals of not more than 8 feet apart; and all headings, under these conditions must not be more than 8 feet wide. Old workings must not be tapped until all employes except those actually engaged in the work have left the mine. Those actually employed in the work must be under the immediate supervision of the mine foreman and must use nothing but locked safety lamps.

(*b*) The law states that the barrier pillars must be 1 foot thick for each $1\frac{1}{4}$ feet of head of water. In the case in question, the head is 125 feet, so that the pillar required is $125 \div 1.25 = 100$ feet.

QUES. 19.—What method would you use in extracting pillars in the mine by mining machines under ordinary conditions of roof and floor?

ANS.—It is not generally possible to use mining machines, even of the pick type, to undercut all the coal in pillars which are being drawn, because the weight of the roof causes the coal to settle on the chain and so stop its motion. As a general rule a cut-through is made across the pillar some 10 to 12 feet back from the break-through at the face. This cut-through may be from 8 to 12 feet in width, and the stump left will be of about the same dimensions. In some cases all this stump may be undercut by machines, but it will generally be necessary to get this with a pick. Another cut-through may then be made by machine, leaving a second stump to be removed (probably) by hand; and similarly until the pillar is removed. The details as to the width of the cut-through, size of stump, arrangement of pillars, etc., will probably be different in each mine.

QUES. 20.—What would be the height of the motive column for upcast and downcast shaft in a case where the depth of each shaft is 300 feet, and the temperature of the down cast 32° F., and the temperature of the upcast 48° F.?

ANS.—The motive column is a head of air of such a height that it will equal the difference between the weight of the downcast and upcast columns of air.

The formula for the motive column is $M = D \times \frac{T-t}{460+t}$, in which D is the depth of the shaft in feet and T and t are the temperatures of the upcast and downcast shafts, respectively. The motive column for the upcast air would be $D = 300 \times \frac{48-32}{460+32} = \frac{300 \times 16}{492} = 9.75+$ feet. That for downcast air would be $D = 300 \times \frac{48-32}{460+48} = \frac{300 \times 16}{508} = 9.44+$ feet.

It must be understood that these two heights are equivalent to each other, the difference being accounted for by the difference in weight of 1 cubic foot of air according to the temperature.

QUESTIONS ASKED AT THE EXAMINATION FOR STATE MINE INSPECTOR, COLORADO, 1911

QUES. 1.—If you were driving rooms 30 degrees off the entry, how far apart would you turn the rooms in order to have each room 35 feet wide and leave a 25-foot pillar?

ANS.—As shown in the Fig. 1, the distance between the center lines of

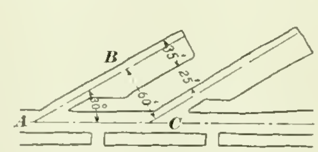

FIG. 1

any two rooms measured at right angles to the direction of the rooms is $25+35=60$ feet. In the right-angled triangle ABC we have given the angle 30 degrees at which the rooms are turned off the heading, and the side opposite it, which is the distance between room centers, or 60 feet. We have to find the hypotenuse AC, which is the distance along the entry between the stations at which the sight plugs are set for driving the rooms. $Hy. = \frac{\text{side opposite}}{\text{sine}} = \frac{60}{\sin 30°} = \frac{60}{.500} = 120$ feet as the distance apart of the rooms measured along the entry.

QUES. 2.—If you had a double acting pump running at a piston speed of 90 feet per minute, the diameter of the plunger being 10 inches, how much water per hour would it discharge?

ANS.—A double-acting pump delivers water through the full length of its stroke, hence the discharge per minute is equal to the volume of a cylinder whose length is the distance traveled by the plunger, or 90 feet, or $90 \times 12 = 1,080$ inches, and whose area is equal to that of a circle of 10 inches diameter $= .7854 \times 10^2 = 78.54$ square inches. This volume when multiplied by 60 and divided by 231 (the cubic inches in a gallon) will give the discharge in gallons per hour. We then have, $\text{Vol.} = \frac{78.54 \times 1,080 \times 60}{231} = .34 \times 1,080 \times 60 = 22,032$ gallons per hour.

QUES. 3.—Name and describe the different gases common to the mines of Colorado. What are their dangers to life, and their injurious effects on the workmen employed therein? Give also their symbols, specific gravities, and properties. Where are they found? How produced? State other effects on combustion.

ANS.—As the coal mine gases of Colorado differ in no way from those of other states, reference should be made to the answers to this and similar questions which have appeared in MINES AND MINERALS during the past 6 months.

QUES. 4.—How many cartridges 15 inches long and $1\frac{1}{2}$ inches in diameter can be made from a full keg of powder 11 inches long and 9 inches in diameter.

ANS.—This problem is solved by finding the volume of the two cylinders, respectively, $15 \times 1\frac{1}{2}$ and 11×9 inches, and dividing the greater by the less. The volume of any cylinder is equal to the area of the base multiplied by the height or altitude, and the area of the base is equal to the square of the diameter multiplied by .7854. The problem may be placed in the following form: $\frac{.7854 \times 9^2 \times 11}{.7854 \times 1.5^2 \times 15} = \frac{81 \times 11}{2.25 \times 15} = \frac{891}{33.75} = 26.4$. Ans.

QUES. 5.—Of what is the atmosphere or the air composed?

ANS.—The atmosphere is composed, by volume, of 79.3 per cent. of nitrogen (symbol N) and 20.7 per cent. of oxygen (symbol O), with about 1 per cent. of argon, xenon, krypton, etc., rare gases allied to nitrogen. The percentages by weight are nitrogen 77 and oxygen 23. In all normal air there is more or less watery vapor, and minute amounts of carbon dioxide, ammonia, vegetable matter, etc., which vary from one place to another. In cities traces of sulphuric and hydrochloric acids may be detected by analysis, and near smelting plants are to be found acids of which the base is sulphur, arsenic, or the like, depending upon the nature of the ores being treated thereat.

QUES. 6.—Is spontaneous combustion possible in a coal mine If so, what are the probable causes producing it, and what means would you employ to prevent it?

ANS.—Yes, spontaneous combustion is possible in mines and is particularly apt to occur in those where the coal contains much water, as in the lignite and subbituminous mines of Colorado and Wyoming. The oxidation of iron pyrites if it occurs in considerable amount *may* cause spontaneous combustion, but the oxidation of the coal itself seems to be the chief cause of the trouble. In Colorado, the water-bearing lignites of the northern field often ignite spontaneously, while such action is very rare in the bituminous fields of the southern part of the state. The only way fires originating through spontaneous combustion may be prevented is to leave no coal in the gob; that is, by loading everything out, and taking the pillars clean, a matter of great difficulty. With our present systems of mining the prevention of gob fires from spontaneous combustion is practically impossible. About all that can be done is to clean up as well as is economically possible, and then keep a close watch upon all places, both abandoned and working, that a fire may be detected in its early stages before it has had time to acquire dangerous headway.

QUES. 7.—If you were assigned a colliery of 400 acres with five veins, the third and fourth being mined, the fifth or bottom vein just being opened and you were about to mine pillars; state briefly what restrictions you would impose for the safeguarding of life, limb, and property, there being no unusual conditions.

ANS.—Regardless of how the pillars are drawn, the two upper and unmined veins will be badly disturbed and in a very unfavorable condition for safe and economic working, the roof being broken and the floor very irregular. Of course the effect of pillar drawing in No. 3, upon Nos. 1 and 2 will depend upon the thickness of No. 3, and the distance between it and No. 2. Had the upper veins been of a quality such that the market would absorb their product, the better practice would have been to have worked No. 1 first, and while drawing its pillars to have carried on the advance work in No. 2, and similarly until all the seams were worked out in regular order beginning with the uppermost. Under existing circumstances the best course would be to begin drawing the pillars in No. 3 first, and after a break of the rocks (surface break) has been secured, to begin on those of No. 4 seam; keeping the drawing in No. 3 always a little ahead or further advanced than that in No. 4.

QUES. 8.—What is a safety lamp? Why is it safe?

ANS.—This has been answered several times in these columns recently.

QUES. 9.—What is afterdamp, and what would be the composition of the afterdamp from the explosion of firedamp containing a large volume of air and what would it likely be if the firedamp contained but a small quantity of air?

ANS.—Afterdamp is a term applied to the gaseous products resulting from what is known as a mine explosion. It was first supposed that afterdamp was the result of the explosion of methane and air, or firedamp, but since it is now recognized that coal dust enters into practically all explosions in bituminous mines, the term afterdamp is now used in the sense given in the definition; that is, to include the gases resulting from any mine explosion.

Under the circumstances stated, where there was an ample supply of air, the reaction in the explosion would be $CH_4 + 2O_2 = CO_2 + 2H_2O$; that is, 1 volume of methane would combine with 2 volumes of oxygen to form 1 volume of carbon dioxide and 2 volumes of watery vapor.

Authorities differ as to the composition of afterdamp resulting from the explosion of firedamp containing too little air to completely burn the methane. Doctor Brookman has shown that under such circumstances the firedamp does not form carbon monoxide, but does form ethylene, otherwise known as olefiant gas. On the other hand, Doctor Otto Brunck states that carbon monoxide is formed probably upon the reaction $2CH_4 + 3O_2 = 2CO + 4H_2O$.

QUES. 10.—The depth of a shaft is 400 feet and the power required in the ventilation of the mine is 37.8 horsepower, find the required area of the furnace grate necessary to produce this power.

ANS.—If we let A equal the required grate area in square feet, D equal the depth of the shaft in feet and HP equal the horsepower required to produce the ventilation, the formula usually employed is $A = \frac{34}{\sqrt{D}} \times H.P. = \frac{34}{\sqrt{400}} \times 37.8 = \frac{34}{20} \times 37.8 = 1.7 \times 37.8 = 64.26$.

QUES. 11.—In the event of a mine fire, how would you approach the burning section of the mine; and where workmen are employed in extinguishing the fire, what precaution should be taken to prevent the dangers always to be expected in such cases?

ANS.—In event of discovering a mine fire all men except those actually employed in fighting it should be sent from the mine, the helmet crew should be notified to prepare for possible duty, and some one should volunteer to approach the fire as close as possible to obtain information as to its location, extent, etc. The fan should be kept at such a speed that the coal will burn as far as possible to CO_2, which is non-explosive. If the fan is slowed down too much and the fire has considerable headway, there is danger of the coal burning to CO, which is highly poisonous and likewise explosive. However, the fan should not be speeded up, as the fire will then be intensified. In fighting the fire, it should be approached from the intake side so that the workers will not be compelled to breathe the gases given by it. In a mine which does not generate firedamp the chief source of danger will be from CO, which may be formed as stated, and helmets may have to be worn, or the helmet crew may be called upon to revive those who may have been overcome. If methane is given off by the seam the work of extinguishing the fire is extremely dangerous and a destructive explosion is almost certain to occur. In such a case the fan should be stopped, all openings sealed tight, and an attempt thus made to smother the fire. If this is not possible, the mine must be flooded. The actual work of fighting the flames at and near the fire depends so entirely upon local conditions, which will differ in each case, that it is not possible to give them here.

QUES. 12.—What, in your opinion, constitutes an efficient and safe hoisting plant for a coal mine? Describe in detail, from the foundation of the engine to the delivery of the carriage at the tipple.

ANS.—The hoisting engine should be of the duplex type and of such size that each cylinder singly will be capable of picking up and handling the entire load on the engine at any point in the shaft. The engine and drum should be firmly anchored to a a heavy foundation of masonry or concrete by a sufficient number of bolts. If the engine is of the second-motion type, the gear-wheel and pinion should be so protected as to avoid the possibility of anything dropping between them and breaking the teeth. The appliances for the safe hoisting of the men should be of the best design and material. The brake should be such that it can be quickly applied by the engineer while standing at the throttle; it should be capable of stopping and holding the cage and its load at any point in its journey. An indicator should be so fixed as to show plainly the position of the cage in the shaft at any time and the hoisting rope should be marked with white paint to indicate the near approach of the cage to a landing. The throttle for shutting off the supply of steam to the cylinders should be positive and certain in its action, and its mechanism should be such that it cannot fail to act at the proper moment. The rope drum of the engine should be of sufficient diameter to avoid producing an undue bending strain on the hoisting rope. The hoisting rope should be capable of hoisting a load at least five or six times that ordinarily coming upon the engine. The head-sheaves should be well secured at the top of the head-frame, and should have such a diameter as not to produce an undue bending strain in the hoisting rope. The rope should be thoroughly secured in the socket by which it is connected with the cage, and bridle chains should be used connecting with the safety catches. The cages should be supplied with proper hoods or covers, and safety catches, and each landing should be provided with substantial safety gates and a proper arrangement of wings or keeps on which the cage may rest while being loaded and unloaded. A speaking tube convenient to the engineer should extend from the engine room to each landing. Proper signaling apparatus should be kept in good working order, so that the engineer cannot fail to understand all the signals as given.

QUES. 13.—A shaft is in the form of an equilateral triangle whose perimeter is 30 feet. What quantity of air is passing down the shaft when the velocity is 280 feet per minute?

ANS.—It is first necessary to find the area of this peculiarly shaped shaft. As the triangle is equilateral each side is one-third of 30, or 10 feet long. The perpendicular height of an equilateral triangle is equal to the length of one side (10) multiplied by .866025, or 8.66025 feet. The area is equal to one-half the base multiplied by the perpendicular height, or $\frac{1}{2} \times 8.66025 \times 10 = 43.30125$ square feet. The volume passing per minute is $43.30125 \times 280 = 12{,}124.35$ cubic feet per minute. Calculations such as this need not, for actual use, be carried to so many decimal places. It will answer every purpose if the area of the shaft is called 43.25 square feet, or even 43 square feet. The area may also be found from the formula $A = \sqrt{s(s-a)(s-b)(s-c)} = \sqrt{15 \times 5 \times 5 \times 5} = \sqrt{1{,}875} = 43.30+$. In this formula, s is equal to one-half the sum of the sides, or one-half of $30 = 15$, and the values of the terms $(s-a)$, $(s-b)$, and $(s-c)$ are obtained by subtracting the length of each side, which is 10 feet, from s or 15. As the sides are all of the same length, 10 feet, $(s-a) = (s-b) = (s-c) = 15-10 = 5$ feet.

QUES. 14.—If, after the miners have started to work, you discovered a fire on the intake airway, what course would you pursue?

ANS.—This question has been answered several times in these columns during the past year. The question is so general in its nature, so many places may be imagined where the fire may be supposed to have started, and there may be so many and such varied local conditions to be taken into consideration, that a plain, concise, definite answer cannot be given.

QUES. 15.—How would you proceed to clear a shaft that is filled nearly to the top with carbon dioxide?

ANS.—In case an air compartment has been carried down one side of the shaft while sinking as, of course, should always be done, a fan erected over it should be able to clear the air. If a fan is not available, steam or compressed air forced through pipes opening near the bottom of the shaft may be used to dilute the air sufficiently so that a fire basket will burn, and a circulation thus be started. In event of there being no air compartment, the problem is difficult. As CO^2 is heavier than air it may be slowly and laboriously bailed out in the sinking buckets, or the cages may be boxed in and used in place of buckets. Or steam or compressed air may be introduced near the bottom of the shaft, and when the air is sufficiently diluted so that lights will burn, an air compartment may be built. In this last case, it would be better to first introduce the air near the top of the shaft and after clearing that portion and building a brattice to form an air compartment over which a small fan should be erected, clear another length of the shaft, build the air compartment, and similarly until the bottom is reached.

QUES. 16.—An entry is parallel to a land line and 150 feet from it. If the rooms turned off the entry run at an angle of 45 degrees with the entry, what distance can they be driven?

ANS.—It is assumed that it is the center line of the entry which is 150 feet from the land line and that the rooms are to be driven exactly to the

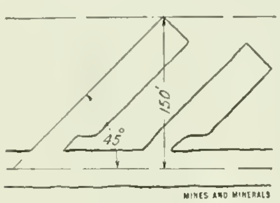

FIG. 2

line without leaving a barrier pillar, which is, ordinarily, not good practice. By referring to Fig. 2 it is seen that the answer is obtained when we have found the hypotenuse of a right-angled triangle, whose sides are each 150 feet and whose acute angles are each 45 degrees. If one acute angle of a right-angled triangle is 45 degrees the other is 45 degrees, and if one side is 150 feet, the other is the same; the hypotenuse may be found from the relation, Hy. $= \sqrt{150^2+150^2} = \sqrt{45,000} = 212.132$. That is to say, measuring from the center line of the entry, which is the customary engineering practice, the rib of the room may be driven 212.132 feet, when it will just touch the land line. If a 10- or 20-foot barrier pillar is left, the distance is not as just obtained, being less. If a table of natural sines is available, the better way to find the hypotenuse is by substituting in the formula

$$\text{Hypot.} = \frac{\text{side opposite}}{\text{sine}} = \frac{150}{\sin 45°} = 212.13 \text{ feet}$$

It should be noted that the .13 of a foot is negligible, as rooms are not driven this close. To allow for carelessness on the part of the miners and to prevent running over the line, the rib would ordinarily be driven 210 feet from the center line of the entry, or 204 feet (about) from the rib. If the entry was wide or narrow at this particular point the distance from the entry rib to the face might be more or less than this 204 feet (about) and it would be better to measure from the center line of the heading which is fixed by the mine surveyor, and the position of which may always be determined by the mine foreman by sighting along the line plugs.

QUES. 17.—With a fan 8 feet in diameter making 240 revolutions and passing 62,000 cubic feet of air per minute, when the water gauge stands at 1 inch, what is the equivalent orifice.

ANS.—The size and number of revolutions of the fan do not affect the equivalent orifice of the mine which is found from the formula. $A = \frac{.0004\,q}{\sqrt{i}}$, in which A = the area in square feet of the equivalent orifice of the mine, q = the quantity of air circulating per minute = 62,000 cubic feet, and i = the water gauge = 1 inch. By substituting, $A = \frac{.0004 \times 62,000}{\sqrt{1}} = .0004 \times 62,000 = 24.80$ square feet. The factor .0004 is sometimes given as .00038, in which case $A = 23.56$ square feet, but it is obvious that the simpler term, .0004 is close enough.

Airways With Circular-Shaped Tops

Since the departure of the old type of pick miner to that land where all good miners eventually go, a sheared entry, and particularly one with the roof shaped in the arc of a circle, is difficult to find. They are, however, occasionally met in old mines, and the calculation of the area of their cross-section has proved a source of trouble to many; to overcome this the accompanying solution is offered.

What is the area of a heading the lower part of which is a rectangle 6 feet high and 8 feet wide, the roof being in the arc of a circle with a rise of 2 feet?

The dimensions of the heading are shown in Fig. 1. In the formulas, the length, $A\,B$, is known as Ch, the chord. The rise of the arc, forming the roof above the "spring line" or point where the curved portion begins, is $E\,F$ in the figure and is known by the letter H, in the formula.

The radius R, of the circle of which the arc $A\,E\,B$ is a portion, is first found by the formula, $R = \frac{Ch^2+4H^2}{8\,H}$. In this, Ch is the length $A\,B$, or 8 feet, and H is the length $E\,F$, or 2 feet. Substituting these values, $R = \frac{(8)^2+4\times(2)^2}{8\times 2} = 5$ feet. That is, the line $A\,O = B\,O = R = 5$ feet.

The angle, $A\,O\,B$, or C, at the center of the circle and subtended by the chord (Ch) $A\,B$, or what is the same thing, by the arc, $A\,E\,B$, is found from the formula, $\sin \frac{1}{2}C = \frac{Ch}{2\,R} = \frac{8}{10} = .80000$. The angle corresponding to this natural sine is 53° 7.0863′. This is the half of the angle C, and the whole angle is, of course, 106° 15.6126′. The minutes must be reduced to the decimal parts of a degree by dividing by 60. The angle is, thence, 106.2604°. The area may now be found from the formula, $A = .008727\,R^2\,C - \frac{Ch}{2}(R - H)$, in which the first term is the area of the sector, $E\,A\,O\,B$, and the second term is the area of the triangle, $A\,O\,B$. By

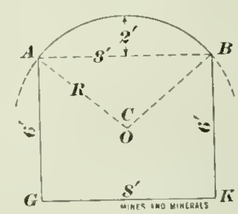

FIG. 1

substituting the various values, $A = .008727 \times (5)^2 \times 106.2604 - \frac{8}{2}(5-2) = 23.18 - 12 = 11.18$ square feet. For all practical purposes the angle C may be taken to the nearest whole degree. Thus, if we use 106° instead of the more exact 106.2604°, the area of the sector (the first term of the formula) is 23.13 instead of 23.18, which difference is much less than that probably due to errors of measurement in the lengths of the lines $A\,B$ and $E\,F$, respectively equal to Ch and H.

The area of the lower, or rectangular, portion of the airway is, of course, $6\times 8 = 48$ square feet, so that the area of the entire heading is $11.18+48 = 59.18$ square feet.

In a coal mine at Doncaster, near Sheffield, England, while a shaft was being sunk, immense quantities of water were encountered rendering the pumps useless. Those in charge adopted the freezing process. All around the shaft, down to the depth of 130 meters, auxiliary holes were drilled, through which a freezing mixture was introduced. In this way the ground in the vicinity of the shaft was frozen, as also was the water, thus forming around the original shaft a safeguard which made a continuance of the work possible. After the shaft had been walled up water-tight, hot water was run through the auxiliary pipes, which were then removed.

ORE MINING & METALLURGY

Mammoth System of Fume Control

Bag House and Apparatus at Mammoth Copper Co. Smelter that Operates Successfully in a Farming Region

By Al. H. Martin

THE control of smelter fumes has developed into an imperative problem in California. Valuable properties are idle in various sections of the state because of agitation against smelter smoke, and the output has fallen from the 53,568,708-pound mark of 1909 to about 35,000,000 pounds for 1912. The Shasta copper belt, the foremost copper region of California and one of the leading copper districts of the world, has been particularly affected, as the mines are situated in an agricultural country and the farmers have waged incessant warfare against the operators. As a result the magnificent plants of the Balaklala, Bully Hill, and Mountain copper companies are idle, and hundreds of thousands of dollars in the form of costly buildings and equipment are going to waste. The vast developed reserves of commercial ore lie idle, because the sulphur fumes generated by their reduction prevent their operation. The Mammoth Copper Co. alone has succeeded in keeping its smelter in commission, and by compensating the grangers for alleged losses from fumes, and the erection of a combination cooling-pipe and baghouse annex, the plant continues to maintain a heavy output.

The Mammoth mines are situated near Kennet, on the Sacramento River. The ores are sulphides in the form of massive pyrites containing large percentages of chalcopyrite. The ore carries about 3 per cent. of copper and 4 per cent. of zinc with gold and silver values averaging \$1.50 to \$2 per ton. The noxious gases are neutralized to a certain extent by the zinc forming oxides in the furnace. The plant contains five furnaces, but only three are operated. The furnaces have tuyère dimensions of 50 in.×180 in., with capacities of 425 tons per day. About three-fourths of this is copper ore, the balance consisting of silicious ore, lime, and coke.

The fumes from the hoods are received by steel gooseneck takedowns and delivered into two hopper-bottom brick flues. Each flue has a length of 260 feet, and the dust settles through the hopper bottoms into a collecting chamber of brick and steel. Four 8-foot steel pipes lead the gas from the chamber into a second collecting compartment terminating in a steel flue 15 feet in diameter. This leads into the fan chamber where the gas is violently agitated and cooled by two Sirocco fans operated by 400-horsepower motors. Under the tremendous draft of the fans the gas is driven into a chamber commanded by the cooling pipes. There are nine sections of these pipes, with five pipes to a section. The pipes are arranged in three divisions, whereby the smoke is first driven slantingly upward, thence horizontally and finally permitted to emerge from the final sloping section. By this means a considerable percentage of the solid material is deposited in the pipes and the bag house has less to handle. Each pipe is 200 feet long by 4 feet in diameter. Sprays are located at intervals and the pipes constantly cooled with jets of cold water. It was early found that the temperature of smoke must be reduced to a low point to prevent injury to the costly woolen bags in the baghouse, and this the cooling pipes and sprayers have accomplished.

FIG. 1. BAG HOUSE AND COOLING PLANT, MAMMOTH SMELTER

The bag house contains 3,000 woolen bags, each 34 feet long by 18 inches wide. The bags are attached to mechanical shaking devices and discharge into hoppers placed directly beneath. Short pipes connect the bag house with the collecting chamber receiving the fumes from the cooling tubes, and practically all the solid matter carried by the fumes is arrested either in the pipes or by the bags.

With three furnaces in commission, the bags collect approximately 25 tons of solid material per day, consisting largely of zinc sulphates and oxides, with some gold, lead, and silver and traces of copper.

A portion of the material that is deposited in the bag-house hoppers is collected, mixed with the fume secured from the pipes, and briquetted. The remainder of the bag-house product is stored pending the adoption of a satisfactory and economic method for extraction of the zinc and other minerals.

After passing through the bags the smoke is permitted to escape from the four bag-house vents. During its passage through the flues, pipes, and bags the gas is largely diluted by atmospheric air, and the sulphuric gas is sufficiently reduced to permit its escape into the outer air in compliance with the regulations prevailing in California. The system, of course, is unable to prevent the escape of sulphur dioxide, but the treatment has sufficiently neutralized the noxious vapors to allow the operation for 2 years, and the fact that the Mammoth Copper Co. is operating in an intensely hostile region conclusively demonstrates the value of the method here used.

One of the greatest problems to be mastered after the plant went into commission was the reduction of gas temperatures sufficiently to prevent damage to the bags, and the cooling pipes and sprayers presented a satisfactory solution.

Foreign Mining Costumes

By C. L. Bryden

The American mining man abroad is impressed with the costumes worn by the miners of the different countries, and even in different sections of the same country.

Fig. 1. Chapel at Himmelsfürst Mine

The peculiarity of the Cornish miner's outfit is his hat and the way he carries his candle. The hat is broad-rimmed, stiff, and heavy. In the Cornwall district a plastic clay is obtained to act as a candlestick. A mass of clay about the size of a baseball is kneaded into shape by the hands, and, after passing the candle through its center, is slapped onto the crown of the hat where it holds firmly. As the candle burns shorter the miner pushes it through the clay. The candles are made specially hard as the heat in the lower levels of the tin mines would soon melt the ordinary candle.

The costume of the German miner is quite elaborate. During parades by the Bergleute it is an interesting sight to see the different costumes worn by the miners. The Freiberg district of Saxony is of special interest as the old traditions and costumes are followed. In the Mining School at Freiberg some of the professors and students wear coats similar to the miners, except that they are made out of better material, and may have buttons of silver or gold, a velvet collar and black or gold braid decorations on the sleeves half way between the elbow and the shoulder. Metallic cross hammers are placed on each sleeve just above the braid and smaller ones on each side of a stand-up velvet collar.

Fig. 2 shows two American professors in the costume of the Saxon miner at the mine Himmelsfürst, which is one of the few mines of the Freiberg district which is profitable to operate. The mines belonging to the government have not been on a paying basis for some time and it is expected that they will be closed in 1913.

The peculiar hat is of stiff felt, quite heavy, but good to protect the head from falling rocks and bumps. A piece of muslin cut to fit and cover the head and having long streamers to tie in a bow in the back is worn under the hat.

The coat is made of strong material comparatively light in weight. It fits loosely around the body, but the sleeves are tight from the elbow to the wrist. A large collar serves as an extra protection to the shoulders. The buttons on the coat are very conspicuous and are both useful and ornamental. The useful buttons are in the center front of the coat and on the sleeves; the ornamental ones are the two rows on each side of the chest. Cross hammers are on each button.

Another noticeable thing is the revolving leather apron worn by the miners. This is of practical value as in these ore mines a great deal of the cobbing is done and when the miners sit down to cobb, the leather serves as a protection against the cold, damp rock. This portable seat is worn by the engineers and superintendents as well as by the miners themselves.

Fig. 2. Costumes of Saxon Miners

The lamp box is made of wood and lined with brass. Centered in the bottom of the box is a small cup to hold a candle. A little to one side is a wooden peg upon which the miner can put a specially made oil lamp, if he wishes to use a glass slide front, which, when not in use, is slid into a compartment at the back of the box. The glass front is only used in rapidly moving air-currents. On the back of the box is a long copper hook, which serves as a handle or as a hook by which to hang the lamp on a leather strap passing around the miner's neck. Trousers are of the same material as the coat. Leather boots with hob-nail soles, and a stout cane with a sharp metal point complete the outfit. In the case of parades and celebrations a great deal of other paraphernalia is appropriated for decorating the persons of those taking part.

Fig. 1 is a view of the chapel at Himmelsfürst, where the miners worship every morning before entering the mine. They enter one door and pass out of another after services to a small room in which is a ladderway to a landing where the miners descend to their work by means of a man engine. Himmelsfürst has one of the few man engines now running in Europe.

The pipe organ shows how music is instilled into the German and how it accompanies him even to the mine. The chapel benches are made of very heavy timber and show the wear of many years. On the pillar in the center of the room, is the notice of the sanitary engineer: "Nur in den Spuckhapf spucken," which translated literally into English would read "Only in the spittoon spit." Similar notices are posted throughout all parts of the plant.

Deep Michigan Shafts

Shaft No. 4 of the Calumet & Hecla Mining Co. is considerably more than 8,000 feet long. This distance of more than $1\frac{1}{2}$ miles is measured along the shaft, which is really an incline having pitch of 37° 30'. In this same region there are the four deepest mine workings in the world. Shaft No. 5 of the Tamarack mine, near Houghton, Mich., has opened up the earth to a distance of more than a mile from the surface.

Within 1 mile from this shaft are the three next deepest shafts in the world. They are Shaft No. 3 of the Tamarack mine which, together with a 300-foot winze, penetrates to an actual depth of 5,553 feet; the Red Jacket vertical shaft, of the Calumet & Hecla Co., 4,920 feet deep; and another Tamarack shaft that is 4,450 feet deep. Very deep precious metal mines have been opened at Grass Valley, Cal., and in Bendigo, Australia.

Rock House of Quincy Mining Co.

Methods Used in Hoisting, Dumping, Handling and Cleaning Rock and Ore at No. 2 Mine

*By T. C. Desollier**

The Lake Superior methods of handling copper ore or copper rock, as it is locally termed, have undergone many improvements during the past few years, both with respect to underground and surface operations. It is the purpose of this paper to describe briefly one of the combination shaft rock houses, commonly known as "rock house." As the various rock-handling systems in the district work toward the same end—that of crushing copper rock—it is only the intermediate steps that differ in the rock houses of the various companies. It is thought that the following remarks relating to Quincy No. 2 rock house might be of interest as illustrating the best practice devised by the Quincy Mining Co. Past experience has shown that it is advisable to break the rock at the mine to a size that can be fed to the steam stamps at the mill. The material, as it is hoisted to the surface, varies from fine material to large masses of native copper, copper rock, and poor rock, weighing at the maximum several hundred pounds.

The Quincy No. 2 rock house has reinforced-concrete foundations; steel frame construction; and is sided and roofed with corrugated iron. The bins are cylindrical, with flat bottoms, and instead of having inclined floors built to the discharge gates, they have rock dumped into them until the angle of the floor assumes a natural slope down which ore will slide to the openings. The building is 150 feet long by 30 feet wide except where the "large stamp" rock bin, 44 feet in diameter, is situated.

The crusher floor, as shown on the flow sheet, Fig. 1, is above the stamp rock bin *a* and 45 feet above the discharge aprons to this bin. In order to accommodate the variations in the rate of hoisting and delivery of railroad cars for shipping, the stamp rock bin has a capacity of 2,000 tons.

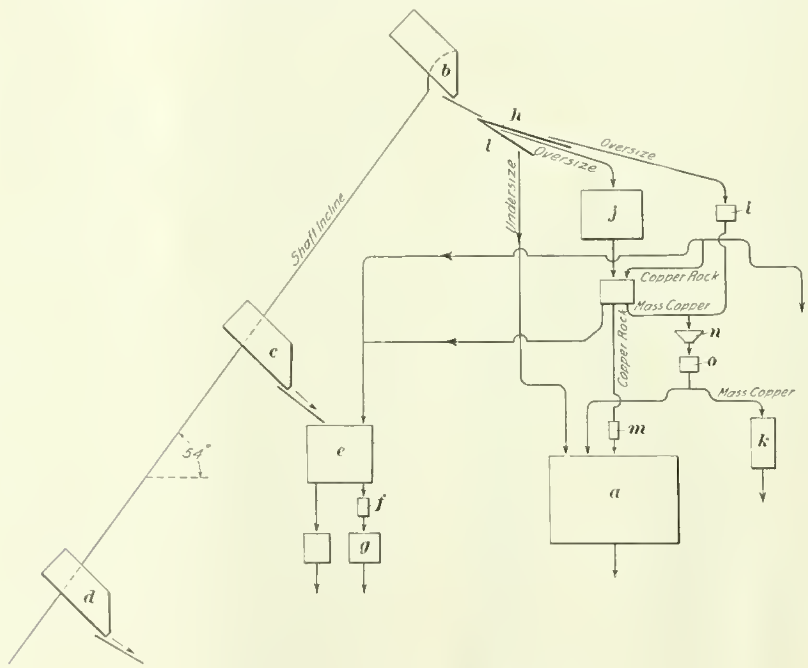

Fig. 1. Flow Sheet, Rock House No. 2

Above the collar of the shaft, the stringers for skip tracks are inclined at an angle of 54 degrees, until the hump *b*, Fig. 1, is reached, where the front wheels of the 8-ton skips, which are run in balance, follow the regular track gauge, while the wide flanged back wheels ride on the hump, thus lifting the back of the skip higher than the front end and causing it to discharge. The skip has three points of discharge *b*, *c*, and *d*. The upper dump *b* is for ore; the middle dump *c* is for rock broken while sinking the shaft or driving bottom-level crosscuts. The lower dump *d* is for mass copper and dull drills.

*Hancock, Mich. Paper Prepared for the Houghton Meeting of the Lake Superior Mining Institute, August, 1912.

Dumps c and d are provided with sliding rails which are thrown by levers operated by the lander on his receiving the proper signal. Fig. 2 shows in detail the sliding rail. The slide a moves up and down parallel with the rail, the sliding rail b moves laterally. By moving a upwards, by means of a lever and reach rod, the rails b are moved to the left, opening a space of 5 inches through which the narrow front wheels of the skip pass while the wider hind wheels keep on the rails, thus dumping the skip as shown. After dumping, the movement of slide a to the right places the rails b in position so that the skip can pass without dumping if so desired. The lander is stationed in a building at one side of the shaft collar, where he transmits the signals to the hoist engineer as communicated to him from the underground chute

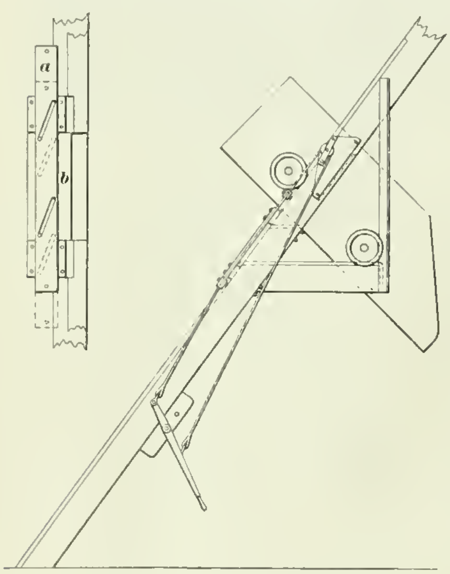

Fig. 2. Sliding Rail Skip Dump

man. The lander without leaving this room manipulates the sliding plates as described. An 8″×8″ steam hoist in one corner of the building, is for handling timber, cranes and other supplies; also for the track forms used to remove damaged slope cars from the slope track. The man cars, water skip, and rock skips are suspended from cranes and can be quickly swung into place and put in operation.

The head-sheave wheels, 12 feet in diameter, and wood filled, are 119 feet vertically above the collar of the shaft. These are securely stayed by means of a batter brace. The first skip dump d, Fig 1, has a slope of 30 degrees which gradually flattens out to a platform of the right height to load mass copper into railroad cars or drills into wagons. The floor of the slope and the platform is of concrete faced with old rails having the flanges up. Mass copper weighing as much as 8 tons is loaded on the railroad cars by means of an 8-ton chain block suspended from a crawl supported by 18-inch, 55-pound, I beams over the railroad track. When rock is hoisted the second dump c is opened by the lander and the skip discharges into a reinforced-concrete chute, which empties into a cylindrical steel bin e, 13 feet in diameter. The rock is drawn off by two chutes, one of which feeds the 24″×18″ jaw rock crusher f, which breaks the rock to a size suitable for concrete and road work. Under the crusher is a cylindrical steel bin g, 9 feet in diameter from which the crushed rock is loaded into wagons or railroad cars. The second chute from poor rock bin e delivers the coarse rock into a vertical 5-foot-diameter tube in which is a slightly inclined reinforced-concrete block to break the fall. A discharge chute is connected on the tube for loading rock into cars or wagons.

When copper ore is hoisted, the top dump b is used. The ore is discharged on a steel dumping plate, arranged so that the lip of the skip might remain in a position close to the steel dumping plate and not cause the rock to be violently thrown from the skip. The copper rock dump was designed in order that the skip would discharge into a pocket, which would fill until the rock took its natural slope, the rock then discharging onto the grizzlies h. It was found during the erection of the building that there was a mistake of about 3 feet between the blueprints and the steel construction, and a steel dumping plate was substituted.

The dumping plate spreads the rock upon 6-inch steel grizzly bars approximately 16 feet long, set at 16 degrees, and having 20-inch openings. Immediately above the grizzly bars is a battery of heavy bars, which serves the double purpose of breaking the fall of the rock and spreading it upon the grizzlies. The oversize from the grizzlies passes down on a reinforced concrete chute, striking a second battery of bars, then drops vertically into a bin having its side open toward a 3,000-pound drop hammer at i. Between bin j and the hammer is a 15-inch, 42-pound I beam carrying a traveling 8-inch 2-ton air lift. This I beam is bent in the shape of a horseshoe and permits the air lift to be used at either crusher, or poor rock chute. Here the oversize, if mass copper, is cleaned of the poor rock under the hammer; if copper rock, it is broken to a size that can be handled by the crushers; or, if poor rock, it is thrown into a chute leading to the poor rock bin.

In case the broken oversize is small mass copper, it is thrown into a mass-copper chute leading into a cylindrical steel bin k, 6 feet 8 inches in diameter, which discharges into railroad cars. If it is mass copper too large for this chute, it is loaded onto a pan, swung from a crane, and lowered outside the building to a reinforced-concrete platform at the right elevation for loading on a railroad flat car.

The undersize from the 20-inch grizzlies falls upon a second grizzly l, composed of $3\frac{1}{2}$-inch steel bars, 6 feet long, set at 30 degrees, and having $2\frac{3}{4}$-inch openings. The undersize from this grizzly passes directly into the stamp rock bin a, below the crusher floor. The oversize is discharged into a cylindrical steel bin j, 14 feet in diameter, holding approximately 10 skip loads of rock. The outlet from this bin is by two chutes 19 feet apart. Vertically sliding steel doors, 4 ft.×$4\frac{1}{2}$ ft., with replaceable steel linings, operated by 6″×36″ air cylinders, control the feed into steel chutes set at 30 degrees. This feed is directed into the two 36″×24″ jaw rock crushers m, and is regulated by a hinged apron, which is operated by a 6″×18″ air cylinder. One man at each chute feeds the crusher, and picks out the poor rock and mass. The poor rock goes into a chute leading to the poor rock bin e. The mass is stored upon an inclined semicircular chute n called the "copper pan," on which it slides to a small steam hammer o, where it is cleaned from the poor rock, and thrown into a chute leading to the mass copper bin. This steam hammer is run by a third man, who handles the trolley, cleans the mass copper, oils and has charge of the machinery.

The crusher jaws are made of manganese steel, and are set to crush to 3 inches. The crushers running at 140 revolutions per minute are operated by a 12″×24″ steam engine running at 110 revolutions per minute. A 75-horsepower electric motor occupying less space is installed, and is ready to run in case of a breakdown to the engine.

The rock from the stamp-rock bin is loaded into railroad cars for the mill by means of discharge aprons operated by 5″×13″ air cylinders.

Three men handle upwards of 1,000 tons of rock every 12-hour shift, change man cars and skips, and load all timber and supplies that are lowered underground. Between shifts when the large mine air compressors are not in operation, power for the operation of the air lifts and air controls is furnished by a small 11″ ×11″×12″ Westinghouse air pump, so arranged that when the air pressure from the mine compressor drops, the air pump starts automatically. A combination of check-valves prevents loss of this air into the underground system and, likewise, when the air pressure from the compressor is raised, the air pump is automatically stopped. This system of handling material has shown an average rock house cost of less than 2 cents per ton.

Controlling the Direction of Bore Holes

Apparatus Employed in Surveying the Holes and for Deflecting Them as Desired

In Bulletin No. 91, of the Institution of Mining and Metallurgy, there is a description, by John I. Hoffman, of a means for controlling the direction of diamond drill bore holes, as practiced in South Africa, and of which an abstract is given here. By means of this contrivance, when it is found by a survey of a bore hole, that it is deflecting from the intended course, it is possible to change the direction so as to bring the hole back toward the direction originally intended. And it has also been possible to purposely deflect an auxiliary hole from a deep bore hole, so that the vein might be cut in two places, as shown in Fig. 2, and the drilling of another long hole be avoided.

The surveying instrument, Fig. 1 (*a*), which is now exclusively used on the Rand for determining the direction of bore holes, was invented by Mr. Oehman and improved upon by Mr. A. Payne-Gallwey. The instrument is an electric light photographic apparatus and consists essentially of a gun-metal tube in two halves, *a*, connected by a coupling, *o*. In the lower half of the gun-metal tube are placed a magnetic needle, *b*, and a plumb-bob, *c*, each independent of the other and each swung over a gimbal, *d*. Above the needle and plumb-bob, respectively, is fixed a small electric lamp, *e*, and all are held in position and pressed by a spiral spring, *g*, attached to the bottom screwed plug, *h*. In the side of the tube, a series of small screws, *i*, are placed in a straight line parallel to the side, their ends projecting inside the tube about one-sixteenth inch. The cylindrical cases carrying the lamps and those carrying the needle and plumb-bob have a slot down the side, the projecting screws acting as guides for the slotted cases to slide into and keep them in position.

The top half of the tube contains a dry battery, *k*, and a clock, *j*, which has a spiral spring, *l*, attached to it. The spring presses against the top end piece *m* of the tube so that when the two halves of the tube are screwed together everything inside is held rigidly together and contact assured by means of the spiral springs at the top and bottom.

To the top end piece a ball-bearing swivel, *n*, is attached in order to lower the instrument on a wire, if necessary.

The cases, *p*, which carry the marine attachments for the magnetic needle and the plumb-bob are made of vulcanite, for insulating purposes, the compass attachment being made of brass, the outer ring of which is held in position by two brass screws on which the ring swings. On the face of each gimbal is a fixed pin point and round the edge is a recessed ring which holds the disk of sensitized photographic paper in place, the pin points holding them in position. The plumb-bob is made of gold attached to a fine silk thread swung from the center of a thin disk of plate glass, *q*, which fits into a recess in the top of the vulcanite case.

Both the magnetic needle and the plumb-bob swing immediately above (almost touching) the sensitized papers.

The clock has an extra wheel, *r*, to which is attached a copper projection *s* which at a certain set time makes connection with a copper spring, *t*, attached to the frame of the clock and completes an electric circuit, lighting up the lamps above the plumb-bob and the needle, and photographing a sharp shadow of each on the sensitized paper.

When the two photographs are developed, the dip and direction can be read off by making the pin pricks coincide.

The deflecting contrivance consists of a pilot wedge, a guide wedge, and a main deflecting wedge, and the method of procedure is as follows:

In the case of a Sullivan "B" hole ($2\frac{1}{8}$ inches diameter) a pilot wedge, Fig. 1 (*c*), is made of round iron, 2 inches in diameter, the length being 18 inches over all and the wedge face being about 6 inches long. The end opposite the wedge face is screwed to fit a piece of $1\frac{1}{2}$ inches (inside diameter) black piping. A $\frac{3}{4}$-inch hole is drilled in the face of the wedge and tapped, and a nick *a* is made with a chisel on the top of the wedge, along

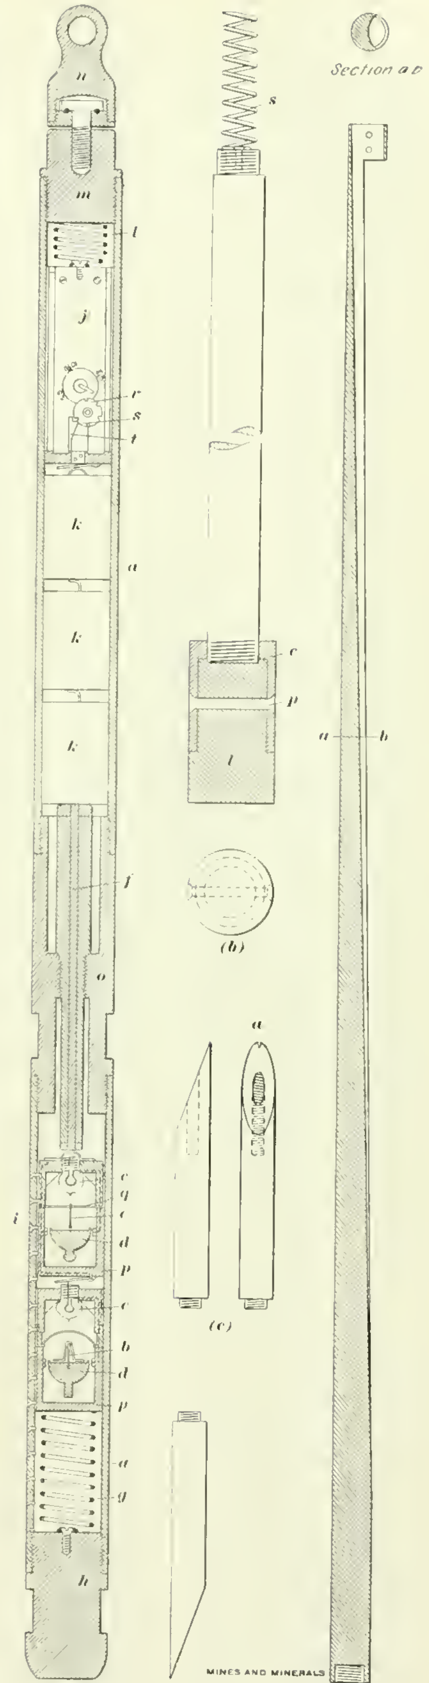

Fig. 1

its longitudinal axis. This nick is for surveying purposes, as will be explained later on. This wedge is screwed into a piece of $1\frac{1}{2}$-inch piping about 3 feet long, the piping being jagged at the end opposite to where the wedge is screwed into it. The bore hole is then filled with water and the pilot wedge and piping are dropped down the hole, wedge face upwards. The main rods are then lowered to find out whether the pilot wedge and pipe are resting on the bottom of the hole. If not, the wedge has to be lifted, by means of the tapped hole referred to above, and again dropped, until it is found that the wedge, and pipe are resting on a solid bottom, or at any rate are fast and rigid somewhere near the bottom of the hole.

The position of the wedge is surveyed with Mr. A. Payne-Gallwey's invention, Fig. 1 (*b*), which consists, for a "B" hole, of a brass rod, about $1\frac{1}{8}$ inches in diameter and 3 feet long, screwed at both ends. To one end is fixed a spiral spring, *s*, similar to that fixed to the bottom plug of the surveying instrument. To the other end a brass cup, *c*, 2 inches in diameter is screwed, having a $\frac{1}{4}$-inch diameter brass pin, *p*, riveted through across the diameter of the cup. This cup is filled with lead, *l*, which projects about 1 inch beyond the edge of the cup and is turned to the same diameter (2 inches). The end of the rod with the spiral spring is screwed into the bottom of the instrument, in place of the bottom plug.

The survey is made as follows:

The relative position of the pin points on the gimbals to the guide inside the case of the surveying instrument being known, the position is marked on the outside of the case and the line continued along the brass rod, cup, and projecting lead. The top end of the instrument is screwed into a brass tube 10 feet long and that again screwed on to the end of the drill rods.

The whole arrangement is lowered down the hole until the lead is resting on the top of the wedge, which, with its chisel cut, makes an impression on the lead, a photo of the magnetic needle being taken at the same time. On raising the rods, a disk with the impression is sawn off, and the direction of the wedge calculated.

The guide wedge, Fig. 1 (*d*), is an exact counterpart of the pilot wedge, and the butt end of this is screwed into the butt end or bottom of the main deflecting wedge.

The main deflecting wedge, Fig. 1 (*e*), is made out of a solid piece of 2-inch diameter round steel about 7 feet long. The bottom end is drilled and tapped to receive the butt end of the guide wedge. The top end is drilled with a $1\frac{3}{4}$-inch bit for 2 inches deep, thus leaving a ring of metal $\frac{1}{8}$ inch thick. The solid portion of the 7-foot length is then planed, commencing from the underside of the aforementioned metal ring down to about 1 foot from the bottom, in such a manner that a wedge is formed with a concave face with a radius of 1 inch and having a thickness of $\frac{1}{8}$ inch at the top and 2 inches at the bottom end. (See section *a-b*, Fig. 1.)

For surveying purposes a chisel cut is made in the top of the ring, along its diameter, coincident with the longitudinal center line of the wedge, as shown in section *a-b*, Fig. 1.

The direction of the face of the

Fig. 2. Plan Showing Deflected Bore Hole

pilot wedge now being known from the survey, the guide wedge is screwed into the main deflecting wedge in such a way that when the faces of the pilot, and guide wedges are together, the main deflecting wedge is facing in any predetermined direction.

The end of a "C" rod ($1\frac{5}{8}$ inches in diameter) is now placed into the metal ring at the top of the main deflecting wedge and riveted thereto with two $\frac{1}{4}$-inch copper rivets. To the other end of the "C" rod is attached a 10-foot length of "B" rod ($1\frac{7}{8}$ inches in diameter), on the top end of which is screwed a ball-bearing swivel, and the main drill rods are connected to the top of the swivel. The whole contrivance is then lowered down the hole, and, as soon as the point of the guide wedge touches the face of the pilot wedge, the swivel allows the guide wedge, and with it the deflecting wedge, to revolve until the faces of the guide and pilot are coincident, the top one sliding on the bottom one until they jam. If the weight of the rods is not sufficient to shear the rivets, hydraulic pressure is put on the piston of the drilling machine and the copper rivets sheared off, leaving the main deflecting wedge in position at the bottom of the hole.

At first it was necessary to drill the deflected hole with a smaller bit, but a means was devised whereby the deflected hole can be kept the same size as the original hole.

When the deflecting wedge has been set, the "C" hole is only drilled to a depth of about 12 feet below the top of the deflecting wedge, after which the rods are withdrawn and the taper tap is then lowered and screwed into the guide ring at the top of the main deflecting wedge, which is pulled out of the hole by this means; after which, the pilot wedge, together with the bottom pipe connected to it, is also raised.

A piece of round iron about 1 inch in diameter, and in this case about 13 feet long, the bottom end of which has been bent about $\frac{1}{4}$ inch out of the straight, is fastened to the end of the main rods with two copper rivets, and lowered down the hole until the bottom end of the round iron is level with the top of the new hole which has been drilled by the "C" bit. The rods are then lowered very gently and twisted around at the same time so as to humor the bent end of the round end to the new hole. Once the operator thinks this has been done the rods are further lowered until the bottom end of the round iron rests on the bottom of the new hole. When this has been effected, the copper rivets are sheared off in the same way as explained above, and the main rods withdrawn, leaving the iron rod at the bottom of the new hole.

A fairly liquid mixture of Portland cement is now made and put into a piece of piping of a length sufficient to carry the required amount of cement to fill up both the old and the new holes to about 1 foot above the top of the iron rod. The bottom end of the pipe is burred on the inside so as to hold a blank flange, made of thin insertion, the same diameter as the inside of the pipe. The pipe is then filled with a liquid cement and a similar insertion flange fixed on the top, but having a flap valve cut into it. The pipe is then fastened on to the end of the main rods and lowered down the hole until the bottom of it is about 1 foot from the top of the iron rod. Water is then pumped down the center of the drill rods, the pressure opening the insertion flap valve downwards and forcing the cement together with the bottom insertion flange, out of the pipe, and thus filling both old and new holes with cement up to the requisite height.

This cement is allowed to harden for two or three days, after which, drilling with a "B" bit (the same size with which the original hole is drilled) is commenced, and the cement is drilled away until the top of the iron rod enters the hole in the bit and acts as a guide, pulling the bit and rods over from the old hole into the new. Drilling is continued to some depth below the bottom of the iron rod; when once the core breaks, the iron rod, together with the core, which has broken off underneath it, is drawn out of the hole in the core barrel in the usual manner.

Pipe Ore, Secondary Limonite

In Volume 10, second series of the Missouri Bureau of Geology and Mines, H. A. Buehler, Director, it is stated that there are three forms of secondary limonite. These are hard boulder and tabular ore; stalactitic or pipe ore; and soft granular or ocherous ore. By secondary limonite is meant a deposit of iron obtained through the oxidation and hydration of marcasite and pyrite. Deposits of secondary limonite are of frequent occurrence and are widely distributed throughout the Ozark Plateau.

The stalactitic iron ore comprises so large a part of the secondary limonite that the term "pipe ore" is used freely in referring to it. In many instances the deposits are composed largely of pipe ore which, as a rule, is associated with both boulder and tabular ores, and in some instances with ocher. Pipe ore occurs chiefly in the upper portion of the deposits, giving place to ocher and tabular ores below. Except where exposed by erosion it is usually imbedded in red clay.

The pipes vary in size, from one-twentieth of an inch to 6 inches in diameter, and from a few inches to several feet in length. They are usually one-quarter of an inch in diameter and 6 or 8 inches long, their length being governed by the size of the opening in which they were formed. The pipes are usually nearly circular in cross-section and for the most part nearly uniform; some, however, show tapered or enlarged ends. Sometimes they branch, forming two or more pipes which may unite again and form a single pipe; or they may occur as single individuals or more often in parallel aggregates forming bundles. Occasionally pipes have confused criss-cross or twisted structure, the pipes being frequently twinned. The parallel arrangement is the more common, notably in the smaller pipes, or the wire pipes which have a diameter of one-tenth of an inch, or less. The wire pipes, when in massive bundles, have coalesced so firmly in instances as to form one solid mass, while in other instances they are so loosely cemented, that when exposed to the air the whole mass crumbles to a heap of individual pipes.

In cross-section the pipes exhibit a simple concentric banding or both radial and banded structure. Concentric banding is due to alternating light and dark rings of limonite encircling a closed center, the outer surface being relatively smooth and without crystal, botryoidal, or other pseudomorphous forms.

The following is the average analysis of shipments of pipe ore from ten mines: Iron, 55.27; silica, 7.56; phosphorus, .082; manganese, .138; moisture, 4.77.

Manufacture of Acid Phosphate

*By Strauss L. Lloyd**

At Port Inglis, Levy County, Fla., the Dunnellon Phosphate Co. has installed a plant for the manufacture of acid phosphate from the crude phosphate ore derived from their several mining plants. It is well known that phosphates, even when finely ground, are but slowly assimilated by plants; they are used, therefore, almost exclusively for making superphosphate, the process consisting in treating the dressed ore with sulphuric acid. Calcium carbonate, a common impurity in phosphate ore, consumes sulphuric acid in this treatment to form calcium sulphate. Two other impurities in phosphate ore, ferric oxide and alumina are objectionable, because they form insoluble phosphates, so that the proportion of soluble phosphates in the prepared superphosphate is diminished by their presence. The crude phosphates should be as free as possible from iron and alumina, (not contain more than 3 per cent.), also from calcium carbonate. The material to be treated is ground to pass a sieve having 80 meshes per linear inch, and then is charged intermittently in 400-pound and 500-pound lots into a lead-lined wooden tank, provided with an agitator, where it is mixed with sulphuric acid, run in as required from an adjacent tank. The quantity of acid varies with the composition of the phosphate, from 1,300 to 1,800 pounds per ton of phosphate being the usual quantities. The mixer is built above a brick chamber known as the "pit" or "den," and into this the semifluid mass, after it has been agitated for several minutes, is discharged through a chute. The temperature of the mass in the pit rapidly rises to 110° C., and CO_2, HCl, and HF gases are evolved before solidification sets in. The gases drawn off through flues are passed through a scrubber, a necessary process on account of the objectionable hydrochloric acid gas and the still more objectionable hydrogen fluoride gas. When the pit is nearly full, one of the sides, which is of wood and removable, is taken down and the product dug out and passed through a disintegrator, which reduces it to a powder. The proportion of sulphuric acid used in making a superphosphate is generally as large as it is possible to use and not impair the dryness of the finished product.

The value of the superphosphate depends on its content of phosphoric acid soluble in water. An ordinary superphosphate will contain from 20 to 30 per cent. of soluble phosphate, 40 to 49 per cent. of calcium sulphate, and 2 to 3 per cent. of insoluble. This the Dunnellon company contemplates will be a great saving of freight, as the product from their acid phosphate plant is used entirely for foreign export. No attempt has ever been made, by this company, to produce the "double superphosphate" to further save carriage and transportation charges.

*[illegible]

The minerals known to exist in paying quantities in Uruguay are as follows: Agates, amethysts, antimony, asbestos, asphalt, boracite, coal, chalcedony, copper, chrome iron, dolomite, graphite, iron, lead, magnesium, manganese, manganese hornblende, mica, ocher, onyx, peat, platinum, radioactive galena and blende, rock crystals, silver, talc, tin, red and green porphyry, sandstone of all colors, granite, limestone, marly lime schist suitable for cement manufacture, more than 300 varieties of marble, including pure white, red, and pink; red and yellow quartz in great quantities, very hard roofing slate infiltrated with silica, grindstone, lithographic stone, white clay, plaster, kaolin, oilstones, flint, water stones, tourmaline, jasper in many colors, topaz, and sulphur.

North Mt. Lyell Mine Fire

A Disastrous Fire in a Tasmanian Metal Mine—Methods Employed in Rescue Work

On October 12, 1912, a fire in the N. Mt. Lyell Mine, Tasmania, caused the death of 42 of 102 men in the mine.

The fire originated in the pump house on the 700-foot level, close to and on the east side of the main shaft, where it is believed there was a break in the electric motor that drives the pump, and which caused the insulation to fire and ignite the timbers. The fire was discovered at 10:45 A. M., but no special heed seems to have been given to it until 12:10 P. M., when the men rushed to the shaft which was the only exit. The one other exit provided was an engine winze that several days previous had become blocked by a cave and which at the time of the fire had not been opened. The usual number of miners were breaking ore on the 400-, 500-, 700-, 850-, 1,000-, and 1,100-foot levels when the smoke acompanying the conflagration gradually filled the shaft and levels, but was considered to be due to some unimportant cause, hence but a few of the men left the mine, and when the increasing smoke caused a large number to rush to the shaft it was too late.

The fire was not expected to spread, as with few exceptions the mine was wet, but in the incomplete combustion of the timber, carbon monoxide was generated, and the men not realizing this danger, lost their lives. This gas in the small proportion of 1 per cent. does not effect the burning of a candle, but poisons men quickly. The first symptom is the sudden failure of leg power, and the man who falls can never rise by himself, but drifts rapidly and painlessly to unconsciousness and death. If he is only unconscious when found he can be restored by fresh air or oxygen as a rule, and those gassed seem to suffer no ill effects after a day or two of rest.

As soon as the fire got under headway it carried the deadly carbon monoxide throughout the mine. In a metal mine such as the North Mt. Lyell, no special system of ventilation is provided, natural ventilation being depended upon; hence with changing weather and temperature the fresh air may be going into the mine through some of the various passages and the bad air out of the shaft, or the reverse. What direction the smoke took is not clear, but it rapidly filled all the workings both above and below the 700-foot level, while at the same time smoke poured forth from the mouth of the shaft. The heat from the fire soon made the main shaft an upcast through which a steady volume of smoke poured to the surface, but there were eddies which kept constantly changing. At one place the smoke is said to have changed its direction of movement about every 2 hours.

The rescuers directed their endeavors to keeping the main shaft open; to breaking through the engine winze that had closed between the 500- and 600-foot level; and to reaching the 1,000-foot level where it was known 50 men were alive but shut off. The Marine Board, of Devonport, supplied a diving outfit which arrived by special train, and as there were several expert divers among the company employes it was of great service for penetrating the gases in the inspection of the landings at the 500- and 700-foot levels.

Little evidence of fire was observed by the diver at the 500-foot landing, while the climax came by the shaft becoming damaged by heat, steam, or some other cause, at about 500 feet down so the cage could no longer pass this point.

Meantime the work on the engine winze had progressed until a rough passage had been forced to the 700-foot level. There were 60 feet of chain ladders passing through a mass of timber debris to the 600-foot level and then 100 feet of vertical ladders to the 700-foot level. There was a flow of water down the winze and this was caught by a penthouse or shaft sinker's roof and poured down over the ladders, to insure a draft, but it made ladder climbing difficult for the men weakened by gas. . Explorers proceeded to the 700-foot level and along toward the main shaft, but the fumes compelled them to retreat and the task of getting the weakened men up the ladders was very great. Communication was established with the 50 men at the 1,000-foot level by P. Peasnell, an employe, who talked with and got supplies to them. In the meanwhile strenuous efforts were made to repair the shaft so as to send the cage down to the 1,000-foot level and bring the men up through the smoke. This was given up, as the movement of the cage affected the ventilation of the mine elsewhere. Men again descended the engine winze and found the air quite good and clear on the 100-foot level to the main shaft. Chickens were lowered to the 850-foot level on the cage by the air winze and after 5 minutes were hauled up none the worse. Two men then went down to this level and reported the air good in the shaft, but bad in the level. The chickens were then lowered to the 1,000-foot level for 5 minutes, and on hauling them up they were found on their sides. Two men were quickly sent down with Draeger helmets to explore the 850-foot level and break through to the 1,000-foot level if possible. At the 850-foot level the explorers could not proceed far, but conversed with those on the 1,000-foot level. The exploring party then returned to the surface and other men went down to fix a canvas brattice at the 700-foot and 850-foot levels in order to turn all the fresh air down to the 1,000-foot level, and on Wednesday the imprisoned men reached the bottom of the engine winze and were drawn to the surface. As soon as the 1,000-foot level was clear of men, two men with Draeger helmets were sent down with others to the 850-foot level. Chickens were also taken, and by their use the drive was tested by men without helmets to the main shaft. Beyond the main shaft the chicken lost the use of its legs and the explorers halted. At this point the helmet men arrived back at the engine winze and reported 10 men dead in the stope, where conditions were most favorable, and the possibility of any man surviving there seemed too remote to warrant the evident risk to life, that the attempt to reach beyond this point would involve, so the explorers were withdrawn and arrangements started to attack the fire.

The engine winze was covered at the 700-foot level and the sides bratticed between it and the main shaft, while the main brattice was opened, but retained for emergency. The firemen were now able to reach the original source of the fire, and found it almost burned out at the pump house, but further examination showed the flames had extended to a rise farther in, and it was supposed the fire was quenched on about the 18th of October. This was a mistake; and after battling with it 9 days and the gases continuing to increase owing to the fire having gotten a foothold in a caved abandoned stope it was decided to fill the mine with water. Conditions of the mine at last report were not encouraging, and much regret is manifested because the bodies were not removed prior to flooding the mine, which will consume a long time and it will take a longer time to pump it out.

Hartwell Couder, M. A., A. R. S. M., in his account of the accident says: "* * * * A few points stand out clearly.

"In the first place, however wet a mine may be, it is not safe from fire. Some organization should exist in all mines of any size to cope with an outbreak. If helmets can be procured the men should be trained to their use. The work of the helmets was much discounted because the miners were not accustomed to helmets and the firemen did not know the mine. It is unsafe to rely on ventilation as a safeguard in rescue work, even if there are several sources of supply. Too many eddying air-currents are set up; for instance, at one place the smoke came up a rise and proceeded a short distance along the level and then went down a winze.

"These eddy currents were a great source of danger in the rescue work. Miners should be taught the danger of carbon monoxide. In this fire the carbon monoxide fumes were very deadly, and if the proportion of the gas had remained the same to the end, probably many of the rescuers would have perished. Their courage was not to be restrained, but it might have proved fatal not only to themselves but to the progress of the main work.

"The small animal test was only slightly used. Where used, it proved valuable, and it is the only known indicator for carbon monoxide."

Those men on the 1,000-foot level owe their lives to one man who had a knowledge of the flow of liquids. The men directed the compressed air directly at the approaching smoke which advanced steadily. Men commenced to fall when one of their leaders requested them to come close to the wall of the stope and face it while he directed the air against the wall. This gave a current of good air that followed the wall and resulted in saving the lives of 50 men. This man deserves many medals.

There is one lesson to be drawn from this disaster by the management of every mining company, viz., in mining it is always the unexpected that happens, consequently no risk should be permitted that involves the lives of men. In metal mines, fires when once fairly under way are more difficult and expensive to extinguish than fires in coal mines. There are two or three exceptions to this rule where coal mine fires have been allowed to burn for years until they have got beyond control, such as the Midlothian colliery, in Virginia; and Summit Hill and Carbondale fires in Pennsylvania.

Metal miners should be instructed in the laws of ventilation and mine gases, and the large mines should have trained helmet crews and fire-fighting apparatus always ready for instant use.

At an underground fire in the Bunker Hill mine, Idaho, in October, one man was killed, and to suppress the outbreak the No. 4 car of the United States Bureau of Mines was called on. The object lesson produced by the sight of these men entering the smoke stirred the miners to such a degree that a request was made for instructions in the use of the helmet. The last information received was to the effect that No. 5 car of the Bureau of Mines would be sent to Wallace for this purpose.

For the details of this disaster we are indebted to the very comprehensive articles in the *Australian Mining Standard* of October 17, 24, 31, 1912.

Driving a Tunnel in Japan

*By William L. Saunders**

The Japanese people have given many evidences of their progressiveness, but nothing emphasizes their spirit of progress more than the work which they are now doing in building a double-track, wide-gauge electric railway between Osaka and Nara. Osaka has been cal ed the Pittsburg of Japan. It is the commercial metropolis with 1,000,000, inhabitants, covering an area of more than 8 square miles, intersected from east to west by the river Yodo and with numerous canals running through it. Osaka is admirably situated for a manufacturing city. Its principal trade is with China. On arriving a Osaka one is impressed by its industrial activities as illustrated by the large number of chimneys. Old Osaka has left its monument in the great Castle, built by Taiko Hideyoshi in 1583. Little remains of the old Castle but the ruins and principally the walls of the moat These walls contain huge blocks of hard granite, some of them measuring 40 feet in length and 16 feet in height.

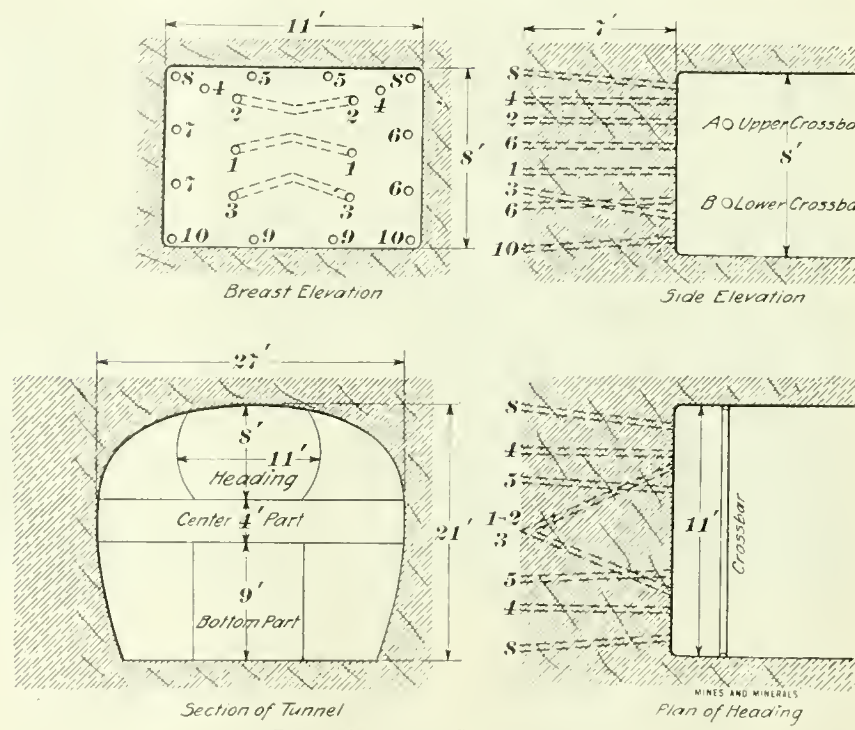

Fig. 1. Method of Driving Tunnel

From Osaka to Nara is from new to old Japan, for Nara is in every respect representative of what Japan used to be It was the ancient capital during seven reigns and until the seat of government was removed to Kyoto. At Nara is the largest statue of Buddha, built in the year 746.

* President of Ingersoll-Rand Co.

The railway now under construction is a short cut designed to reduce the time of travel and the mileage. The line runs through Mount Ikoma, which is about half-way between Osaka and Nara.

The contract for the construction of this tunnel was awarded to Obayashi Gumi, the engineering work being in charge of Dr. Eng. T. Oka. The tunnel work begins in the eastern end at Ikoma village, extending westwardly to Hineichi village, a distance of about 2 miles.

The finished dimensions of the complete tunnel are 22.2 feet in width by 19.35 feet in height. A cross-section of the tunnel is shown in Fig. 1. The heading, or upper bench, is driven ahead of the bottom or lower bench. Between the heading and bottom bench there is a central bench. To the right and left of the heading and lower bench are sections that are mined by the use of stoping drills, and the center bench is removed in the same way.

The heading, shown in elevation, is 8 feet high and 11 feet wide; the center bench is 4 feet high and 27 feet wide; and the bottom bench is 9 feet high and 8 feet wide.

In the heading a cross-bar 5 inches in diameter and 10 feet in length is fixed horizontally across the tunnel as shown in the plan. Jack-screws, in each end of this bar, serve to adjust and to fix it rigidly against the walls. Three water Leyner drills are mounted on this bar at A, Fig. 1, and the upper holes are drilled. Then the bar is lowered to B and the lower holes are drilled.

Because of the use of these light-weight drills, which do not kick hard against their mounting, it is possible to employ the cross-bar in place of the columns. Columns with arms are mainly used in America because drills of the percussion type require an absolutely rigid mounting. It is obvious that the use of the horizontal bar facilitates handling the drills and makes it possible to set up after a blast quicker than by the use of columns. The cross-bar with the drills mounted is handled by a gang of men, who climb up over the muck, place the bar in position and drill the holes while the muckers are at work below them.

The center, or cut holes, are drilled to a depth of 8 feet, all the other holes being 7 feet in depth. Blasting is done by time fuse, which is admitted nowadays to be the best practice. Gelatine dynamite is placed in the bottom of the hole next the primer, over it is placed more gelatine dynamite and then 60 per cent. dynamite. Clay is used for tamping. Where the rock is hard, from 22 to 26 holes are drilled in the heading, but in softer rock this number is reduced to 16 holes in some cases and in others as low as 12 holes. The rock in Mount Ikoma is granite, usually hard, especially in the east end. Progress in this tunnel has averaged over 10 feet of heading per day. Records have been made of 20 feet in 24 hours, single heading. This was on the west side where the rock is of moderate hardness. It usually requires 5 hours to drill 20 holes, 6 feet, to 7 feet deep. The work of loading, firing, and taking out the rock consumes about 3 hours, or a total shift of 8 hours. The work is done by the miners in 6-hour shifts, working day and night. One superintendent is in charge of each heading, with three drillers and three helpers.

Wooden mine cars having a capacity 30 cubic feet, are hauled by an electric locomotive in trains of 10 over a 25-pound rail track, having a 30-inch gauge.

For ventilation, 50-horsepower Roots blowers exhaust through a 20-inch stack. Ingersoll-Rand air compressors of 115 horsepower each furnish the compressed air at 100 pounds pressure, the air being conducted to the heading through a 5-inch pipe.

The holes drilled are usually about 2 inches in diameter and the progress of the drills is from 7 to 12 inches of hole per minute. Although water is fed into the bottom of the hole the discharge of the cuttings is really effected by compressed air which is forced in with the water, the minimum amount of water being used and only for the purpose of laying the dust.

Power at the portals of the tunnel is transmitted electrically a distance of 16 miles at 3,500 volts. The tunnel is lighted by 16-candlepower electric lamps.

Up to May 31, 1912, an advance was made in the east end of 2,127 feet, and in the west end 1,917 feet, or a total progress of 4,044 feet. The tunnel is to be lined with brick about 1,000 feet being already completed.

Shaft Sinking Device

Where shafts follow the dip of the ore and hoisting is done by buckets, an ingenious contrivance for tipping the bucket was planned by Mr. Harris, of the Harris Pyrite Co., in Ontario, as seen by Figs. 1 and 2. Stout lugs a are attached to each side of the bucket b. These lugs travel on skids until they come to rest in a notch a, Fig. 2, above the grizzly on which the ore is to be dumped. As the lugs are set below the center of the bucket, lowering causes the bucket to dump. The bucket is then raised a few feet and when lowered, the lugs catch a pair of curved arms b, which, when inverted by lowering the bucket, completely cover up the notches and allow the bucket to proceed down the shaft. It will be noted that the head-frame must be within sight of the man at the hoist. Skids at the Harris mine are on an angle of 72 degrees and should not be steeper for successful operation. Mr. Harris states that the reason for the safety bar which prevents the buckets from turning back and discharging down the shaft, is in case a bucket is sent up when nearly empty and loaded on one side; but if the buckets are loaded one-quarter full or more, no care need be taken to have the load even.

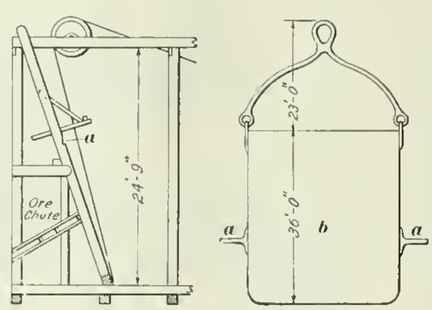

FIG. 1

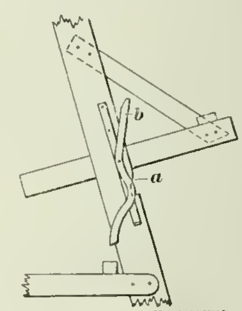

FIG. 2

Fire Assay Reducer

It is stated by C. A. Rose that according to the formula

$$FeS + 4\,PbO = Pb + FeO + SO_3$$

1 gram of iron sulphide should reduce 9.4 grams of lead. In practice 9 grams is obtained. Following charge is used: Ore, 5 AT; PbO, 80 g.; $HNaCO_3$, 20 g.; K_2CO_3, 10 g.; FeS, 3 g. The use of FeS prevents boiling and saves from 15 to 20 minutes in time of fusion.

Phosphate Ore Dressing

Loss of Soft Ores—Separating the Ores from Clays, Etc., and Process of Roasting or Drying

*By Strauss L. Lloyd**

THAT there is considerable loss of phosphate in mining is well known. Practically all the deposits contain, with other material, more or less phosphate in a soft or pulverulent condition. Under present methods of mining and treatment this "soft" phosphate is necessarily lost in the process of washing, being carried to the dump along with the sand, clay, and other constituents of the matrix. The amount of phosphate thus discarded may be expected to vary with different deposits and under different conditions. After reaching the dump there is also more or less mechanical separation so that samples taken from one part may be found much richer in phosphate than from some other part of the same dump. Samples taken at random from phosphate dumps in the hard-rock region gave the following analyses: Total phosphoric acid, 9.99 to 12.14; which is equivalent to tricalcium phosphate, 21.81 to 26.50. In another case, a sample of floats from the dumps in the land-pebble section gave as follows: Total phosphoric acid, 11.47; equivalent to tricalcium phosphate, 25.04. In still another analysis made of the plate-phosphate ore, it was as follows: Silica, 58.95 to 60.10; iron and alumina, 11.70 to 11.20; calcium phosphate, 26.80 to 27.92. It was estimated in this particular case that approximately 4 tons of material was excavated and washed in order to obtain 1 ton of the high-grade rock phosphate (77 per cent.). From this it is evident that of the material taken from the pit three-fourths, carrying about 27 per cent. calcium phosphate, goes into the dump, while one-fourth, carrying 77 per cent. calcium phosphate, is saved; thus of the total phosphate ore taken from the pit, in this instance at least, one-half goes into the dump.

From these data it is apparent that a large amount of phosphate ore is being lost annually in this section and that any economical methods of reclaiming this waste or of utilizing the floats, if such can be devised, are clearly of the greatest importance to the phosphate industry, and ultimately to the agricultural interest of the whole country.

With the extension of agriculture necessary to support increased population, together with the progressive exhaustion of the new and naturally rich soils, there arise increased demands upon the phosphate supply. At present this demand is coming mostly from the older countries of Europe, and the phosphate now produced is largely exported. The time is not far distant, however, when an equally strong demand will come from the exhausted soils of our own country. The hydraulic method of stripping the overburden and then mining the phosphate rock was described in Mr. Barr's article on phosphate mining in Florida.† In many places dredging for phosphate rock is practiced and in Fig. 1 is shown a steam dipper dredge which loads skips that are hauled up an incline and delivered to the top of the washer. The phosphate ore carried from the pits is dumped upon grizzlies where it is sized. That which passes through the bars of the grizzlies is ready for sizing, the "separator," or trommel, but that which is too large to pass through the bars is broken by hand with pick or axe and made to pass through the bars of the grizzly. The ore passing into the "separator" is sized for the first set of double log washers where it receives its first treatment for the removal of the clay which adheres to phosphate material. That part of the ore which is too large to pass through the perforations of the revolving screen, passes out the lower end and falls into a roll-jaw

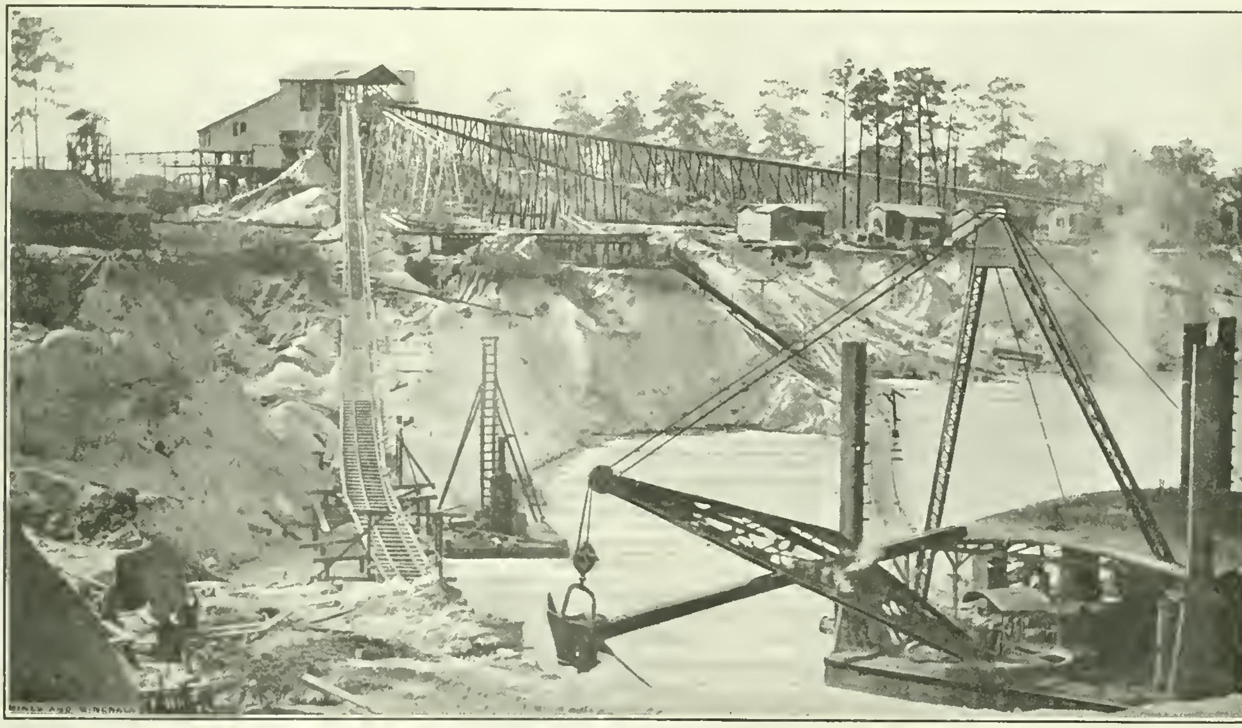

FIG. 1 DREDGING PHOSPHATE ROCK IN FLORIDA

*Chemist and Mining Engineer, Inverness, Fla.

†Florida Phosphate Practice, MINES AND MINERALS, December, 1912.

crusher and after being crushed it falls through a chute into the first set of log washers where it is washed with the ore which has been sized by the revolving screen. In the log washer shown in Fig. 3, one end of the washer log revolves in a gudgeon placed below the water in the box containing the ore to be washed; the other end works in journals. The log, which is driven by gear-wheels, works the ore toward the head of the box and discharges it into the second washer which may have either a single or a double log. In the majority of cases it is a single log. Water is introduced at the upper end of the box, while the ore is fed at the lower end; the clean water thus meets the ore and when it becomes dirty it flows out at the lower end, carrying with it the clay in suspension. There is no general standard for these log washers. The box is about 4 feet deep at one end and 2 feet at the other, according to the length of the logs, which vary from 16 feet to 30 feet and are pitched at an angle sufficient to give a rise of $1\frac{1}{4}$ inches to the foot. The dirty water from the washers generally flows away in sluices, but where the fall is not sufficient a centrifugal pump of some type is used to assist in its removal.

After the log washers have removed most of the clayey matter, the ore passes through a chute into a trommel with an internal spray, which eliminates the remaining clay and the smaller portions of the sand from the ore. These screens have jackets ranging from one-eighth inch to one-sixteenth inch, and are commonly known as "rinsers." The ore after passing the "rinser," falls through a chute on to a slowly revolving table where boys and old men pick out the "sand rock" and other foreign matter not removed by the log washers and screens. The ore after hand-sorting is automatically pushed through the center of the table by a large brush or scraper into a chute leading to a car under the table, in which it is carried to the drying shed, where it is kiln dried before being loaded into the railway box cars for transportation.

Fig. 2. Phosphate Mill of Florida Mining Co.

To reduce the moisture to the required 3 per cent. the producers of land-pebble phosphates use mechanical dryers entirely. While there are several kinds of these dryers, all are of the rotary cylinder type; that is, heated air and gases of combustion are made to pass through the cylinder from a furnace. The wet phosphate ore is fed automatically into the cylinder and by means of shelving riveted to the sides of the cylinder is gradually worked from the cold to the hot end, being repeatedly showered through the hot gases in its passage until discharged. After leaving the cylinder, the ore is carried by an elevator to the storage bin. The fuel is coal, wood, or crude petroleum.

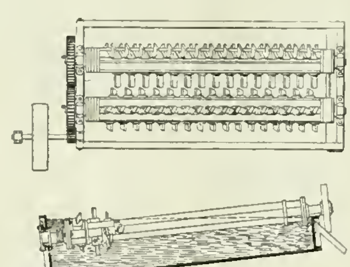

Fig. 3

The excess of moisture in the hard rock in this section of Florida during the early years of mining was removed entirely by kiln burning, a process still in use by many operators. For this purpose the phosphate ore is placed on ricks of wood. The wood is then fired, and the phosphate partly smothering the flames permits slow burning, and by the gradual spread of heat, the phosphate becomes more or less uniformly dried. More recently, with the growing scarcity of wood in the hard-rock section, several large producers have installed mechanical dryers similar to those used by the land pebble miners. In a number of instances the mechanical dryers are in a different part of the country, and away from the actual mining operations.

The disposition of the heat delivered to a blast furnace is a matter of interest always. Not very much work has been done on this problem of late years. Gruner, Schintz, Lowthian Bell, and others, did considerable investigation on the heat consumption of iron blast furnaces in the '60s and '70s. Their work is classic, but very much out of date. For western conditions in water-jacket furnaces recent work indicates that the heat furnished a pyritic furnace by coke and pyrites is absorbed in doing the following work: Expulsion of CO_2 in limestone, 16 per cent.; expulsion of water, 3.2 per cent.; heat absorbed by jacket water, 23.9 per cent.; by slag, 30 per cent.; by matte, 1.9 per cent.; by flue dust, 3 per cent.; by escaping gases, 10 per cent.; by water in blast, 7.2 per cent.; radiation, 6.7 per cent.

Practical Cyaniding—Part 6

Cleaning Zinc Boxes—Acid Treatment.—Drying and Roasting Gold Slime—Melting Precipitate—Tube Mills

By John Randall*

THE cleaning out of the zinc boxes when begun is required to be carried forwards without delay and the value of the material handled makes it necessary that good equipment should be used for the purpose.

The acid tank required is a circular wooden tank 5 to 7 feet in diameter by 4 feet deep and does not need a lead lining. Its top is placed below the zinc box or precipitation floor, and is covered by a stationary hood connecting with a flue. In this flue should be placed a nozzle for a jet of steam in order to create a strong draft to remove the fumes arising from the tank. In the side of the hood is an upward sliding door large enough to admit a man. In the bottom of the tank and near one side is an outlet formed of a piece of lead pipe to which on the outside is attached a piece of rubber hose. When the outlet is not in use the free end of the hose is kept above the level of the top of the tank. The tank bottom is three-fourths inch lower on the outlet side than the opposite side. Inside the tank the outlet is preferably closed by means of a wooden plug, the upper end of the plug reaching above the top of the tank for convenience in handling. This tank should also be provided near the top with an overflow pipe or launder leading to the vacuum filter or filter press, as the case may be.

The vacuum filter shown in Fig. 2 is not so convenient as a filter press for this work, but is inexpensive and is adequate for a small plant. It is constructed of steel, from 3 to 4 feet in diameter, with the part *a* above the filter bed *c* $1\frac{1}{2}$ to 2 feet in height. If it is operated by a wet vacuum pump the gauge glass at the side may be omitted and the chamber *b* below the filter bed made lower. The filter cloth that covers the filter bed is calked around the sides by a rope as shown in the plan, care being observed to fit the calking rope into the recess around the tank so as to form a perfectly tight joint and not allow connection with the vacuum chamber *b*. The calking rope cannot be depended upon to make a tight joint against the side of the tank and it will be seen that if there is any leak a portion of the clean-up may be lost. The perforated filter planks cover the radial iron supports *e* and they are covered by cocoa matting *m*. Over this matting is placed a filter cloth *w* of 8-ounce duck, and above this may be placed a thickness of muslin, the duck and muslin being secured by the calking rope. The muslin is intended to be taken up and

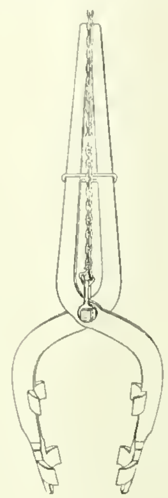

Fig. 1

washed or burned when necessary to recover the gold without disturbing the canvas. This vacuum filter is placed with its top a little below the level of the bottom outlet of the acid tank and within reach of the outlet hose.

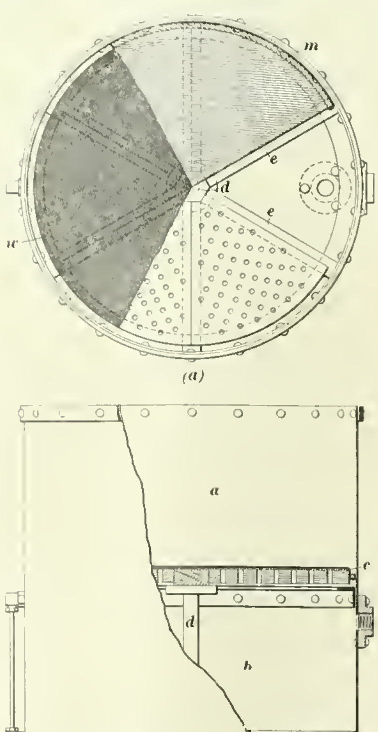

Fig. 2. Vacuum Filter

Simply constructed filter presses with round plates 18 inches to 2 feet in diameter are preferable to the vacuum filter for mills having a daily capacity of 100 tons or over. The type known as the recess frame press, having no distance frames, is good on account of its simplicity. It should be supplied with a "dummy plate" or solid plate to slip in at any point between the other plates when it is desirable to use only a part of the press. The cast-iron plates of the press may be kept painted as a protection against the acid liquor. In place of the vacuum filter is a tub in which is placed the suction of the filter pump.

Drying pans, 2 ft. × 2 ft., or 2 ft. × $2\frac{1}{2}$ ft., and 6 inches deep are made of heavy sheet steel or cast iron, with suitable hooks provided for handling the pans when hot. Cast-iron muffles can be had of the right size to accommodate two such pans. The muffle furnace is made of brick, and the iron work for the furnace is purchased from the manufacturers, who usually furnish drawings for the brickwork.

If the melting is to be done by coke, a wind furnace combined with the muffle furnace is used. The latest practice favors liquid fuel for melting, it being more convenient, besides the heat is always under perfect control. Liquid fuel compares favorably with coke in cost, as a large amount of the heat from coke is used on the furnace instead of the bullion.

The melting room should be provided with one or more conical pouring molds large enough at least to hold the contents of a No. 125 crucible, and also rectangular molds for bullion. A bullion mold having the inside dimensions $6\frac{1}{2}$ in. × $3\frac{1}{4}$ in. × $3\frac{1}{4}$ in. will hold 500 ounces of gold or a little more than half that amount of silver. Another convenient sized mold is 9 in. × $3\frac{3}{4}$ in. × $3\frac{3}{4}$ in. and holds 1,000 ounces of gold. Either mold will turn out a very attractive gold bar if filled only one-third to one-half full.

The form of crucible tongs shown in Fig. 1 is used for raising the crucibles from the furnace. Before using the tongs they should be carefully fitted to the crucible on which they are to be used. When the tongs are in use an attendant raises or lowers them by means of a pair of blocks, but they should be moderately

*Boulder, Colo. Part 1 appeared in August Mines and Minerals.

heated before attempting to pick up a hot crucible.

A few days previous to the clean-up the zinc is allowed to run down in the boxes, little or no fresh zinc being added. The solution is shut off from one box, the excess of solution siphoned to the sump by means of a piece of hose, and its gold slime launder connected with the acid tank, and beginning at the upper end of the box, as soon as the first two compartments are ready, the slime plug is pulled from the first compartment to allow the slimy liquid to run into the acid tank. The operator then puts on a pair of rubber gloves reaching to the elbows and raises a quantity of zinc, gently rubbing and squeezing it between his hands while an attendant sprays the zinc with a stream of water from a ¾-inch hose. The "gem" nozzle, used for sprinkling lawns, is good for washing zinc as the stream can be conveniently regulated. The water running from the zinc will at first appear inky, but will clear in a few seconds. The zinc as soon as washed is piled upon the second compartment. Short zinc may be rubbed through the screen at the bottom of the compartment, or, to save time, transferred to the acid tank in a tub. The screen at the bottom of the compartment is pulled up and washed and the compartment is washed perfectly clean with the hose, after which the screen and plug are replaced, and operations are begun on the second compartment, the washed zinc being removed to and packed in the first. These operations are repeated upon the other compartments until the box is finished. As soon as a compartment can be made ready it should be filled with cyanide solution, as the zinc oxidizes rapidly in contact with the air, sometimes generating a considerable amount of heat. If the zinc begins to heat before a compartment is ready for solution it may be cooled by dashing a bucketful of solution over it. Plenty of fresh zinc should be on hand for repacking the boxes, and the first box is generally put in operation before beginning work on the next. Quite an amount of short zinc may be returned to the boxes, but zinc that is quite fragile and easily rubbed to small particles is of little value for precipitation and is best sent to the acid tank. This matter is of necessity left to the judgment of the operator. When the acid tank is filled it will overflow into the vacuum filter and the pump must be started.

The water in the acid tank is siphoned to the vacuum filter or filter press until but from 8 to 16 inches in depth, according to the size of the clean-up, is left. If a filter press is in use, only three plates are needed for this operation, the remainder being kept clean until after the acid treatment is finished. After the steam draft is started in the acid-tank flue, about 25 pounds of commercial sulphuric acid is poured into the acid tank and the hood door closed. The seething mass is occasionally stirred with a wooden paddle about 4 inches wide and long enough to reach across the tank. While the acid treatment is going on the filter tank or press is cleaned and the small amount of product returned to the acid tank. Fresh acid is added from time to time according to the amount of short zinc in the clean-up. When the addition of a quart of acid does not cause further effervescence, and exploration with the paddle fails to disclose but very little zinc, the operation may be presumed to be complete. From 1 to 2 hours, with occasional stirring, may now be allowed for the dissolution of the remainder of the zinc. The tank should be explored with the paddle to see that no crusts of zinc have formed on the bottom, and then filled with hot water, or cold water may be run in and heated by steam, the contents being occasionally stirred while the tank is filling. Some prefer to allow about 12 hours for the gold slime to subside and then siphon off the acid liquor, filling the tank again with water for a wash. Others allow 2 hours for the greater part of the slime to settle, then siphon the acid liquor to the vacuum tank or filter press. The acid tank is then half filled with water, and the mixture thoroughly stirred, after which the plug on the inside of the acid tank is carefully raised, and the material sent to the filter, an attendant controlling the flow by means of the plug and stirring the slime to keep it in suspension. An 8-mesh screen has previously been placed on the outlet of the acid tank (over the filter tank) to intercept nails, gravel, or other undesirable material that often finds its way into the zinc boxes but should be kept out of the pump. After the liquid is out of the acid tank, a stream of water from the hose is turned in, the sides washed down, and finally a man goes inside the tank with the hose and cleans up the bottom. He then transfers the hose to the tub at the suction of the filter press pump until all the slime is in the press. Water is now pumped through the press to wash the cakes until the effluent from the press contains little or no acid, when compressed air, if available, is sent through the press for 10 minutes to dry the cakes. If the vacuum filter is used the cake can be washed by spraying water upon it. Some mills have a settling tank of a capacity of about 10 tons to which all the waste liquors from the clean-up are sent, a little gold subsiding in the bottom. As some iron salts are a solvent for gold, the acid liquor usually contains about $1.50 per ton of gold in solution.

To dry and roast the gold slime, the roasting pans are made ready by spreading paper over their bottoms and sides and then the slime cake is dumped into them. The paper in burning forms a film of carbon next the iron and prevents the cake sticking and also protects the iron. The muffle should be at a low red heat, the pans shoved in and the muffle door partly closed. When the greater part of the cake is at a low red heat it may be withdrawn from the muffle, cooled and weighed, the weight of the pans being previously known.

The fluxes used in melting the precipitate into bullion will vary considerably, different ores and different methods of extraction yielding precipitates that vary widely. The question can best be decided by running a few trial melts in 10-gram crucibles, assaying the slag. The quantity of flux required varies greatly, the office of the flux being to slag off the impurities in the precipitate, the metal itself not requiring a flux; therefore a precipitate yielding 60 per cent. bullion will require only half as much flux as a precipitate yielding only 20 per cent. bullion. A fluid slag must be secured or it will contain shot or prills of metal. A flux composed of equal parts of bicarbonate of soda and borax glass, with a little silica added if necessary to protect the crucible, generally answers every purpose, and the amount of flux used need never exceed the weight of the roasted precipitate, and may often be very much less. The flux is spread evenly over the top of the precipitate, the pan is set on the cement floor of the melting room, and the cake cut into half-inch pieces by means of a square-pointed shovel. This shovel is used in charging the crucibles and consists of an ordinary square-pointed shovel with the sides turned up. The cake may be cut in this manner with but very little dusting if care is used.

The crucible is filled level full, as the charge will settle. If the liquid fuel is used it is convenient to refill the crucible as the charge settles, but the refilling must be done before the top becomes fluid. By this means the crucible can be made to hold about 50 per cent. more than if not refilled. After the fusion is fluid it may be stirred with a plumbago stirrer or a green pole, and then left in the furnace for 10 to 15 minutes provided the heat is under control, when it is ready to pour.

The pouring mold is coated on the inside with lime whitewash or a clay wash to prevent the slag sticking, then made perfectly dry, and placed with its top on a level with the charging door of the furnace. The melt is poured in a steady stream in the center of the mold, which is the best way to avoid metal prills in the slag. After the slag has chilled, the button is detached and if there is any matte adhering to the button it must be cut off with a chisel.

The buttons are placed in a crucible with a little borax glass, and melted niter is added in small portions at a time in order to oxidize base metals as well as any remaining matte. On account of the convenience in cleaning the bar, it is best to have the slag of such a composition that it will dissolve in hot water. The potash from the niter is generally sufficient to form such a slag. Just previous to pouring, the melt is stirred with a graphite rod, heated before plunging it into the molten metal. The bullion mold should be warmed, rubbed on the inside with wax and then heated. It is then brought to the edge of the furnace, carefully leveled and the metal poured. As soon as the gold is set and while yet very hot, it is dumped into a small tub of water. If the bullion is tolerably fine and the slag right, the water will clean the bar perfectly and no scrubbing or treatment with acid is necessary. The bar is next sampled and weighed. A convenient method of sampling, and one that generally answers every requirement at the mill, is by means of a drill, making a hole about one-fourth inch deep in the top of the bar half way from the middle to the end and also in the bottom the same distance from the other end. No drillings from the bar should be put in the sample until after the entire cutting edge of the drill has penetrated the metal, as the drillings from the surface might contain a little slag.

In Clark's gold-refining method adopted in Rhodesia the gold slime is first treated with dilute acid to dissolve the zinc and such materials as can be converted into sulphates. If sodium hydroxide or sodium carbonate is present, as it usually is, hydrochloric acid is used to form calcium chloride, without dissolving much zinc. This solution is filtered or decanted. If the calcium compounds are treated with sulphuric acid, the bulk of the precipitates will be increased and in a measure interfere with subsequent operations. The slime is dried until it is almost free from moisture and is then wetted slightly with a solution obtained by dissolving niter cake in sulphuric acid. Afterwards a solution of sulphuric acid and water, made up of equal parts, is added. The proportions should be one part of liquid to five parts of slime, and to the mixture a small quantity of niter cake should be added. The fusion of such a mixture must be gradual to evaporate the moisture and then to prevent frothing. The temperature should be gradually raised to a visible red, at which heat the material is fused; it is afterwards allowed to cool. If a moist, but not sloppy, mixture of slime, sulphuric acid, and niter cake is fused, the time will be shortened and less frothing will occur. When cold, the mass should have a reddish-brown color and should be free from black patches. In the first fusion, cyanides, ferrocyanides, sulphides, and volatile compounds are eliminated, and sulphates formed; in the second fusion, more niter cake is added and the gold is collected in a form which may be dealt with mechanically. The second fusion is performed at a visible red heat, the object being to maintain the sulphates of silver and base metals without decomposing them; the niter cake accomplishes this at a higher temperature than would be possible without it.

To ascertain whether the fusion is complete, that is, if the gold has run together, an iron rod is thrust into the hot mass. If the cake on the rod appears white to greenish white between the patches of gold, the action is complete; if on cooling it appears as a brown mass, the gold has not properly run together. When fusion is complete, the melted material is ladled out and poured on a clean, cold iron plate and when cold it is broken into lumps.

To lixiviate it, the soluble portion of the fused mass is placed in wooden tubs and steam blown in until all solubles have been dissolved. The solubility of silver sulphate varies with the amount of sulphuric acid and other salts present, therefore the vat must have sufficient capacity to hold all the liquid required for the solution of silver sulphate; for instance, for each one-half ounce of silver one-fourth gallon of solution will be required. When the silver has been taken in solution there will remain gold, lead sulphate, calcium sulphate, and probably some other oxides and sulphates.

As the gold is now freed from sulphate of silver, it can be amalgamated and the insolubles eliminated, thus doing away with the necessity of fluxing and slagging them from the gold. If it is desired to remove the lead sulphate it is done previous to amalgamation, and after the silver has been removed, by adding a solution of sodium carbonate until the washings come away alkaline. The reaction is expressed by the equation

$$PbSO_4 + Na_2CO_3 = PbCO_3 + Na_2SO_4$$

If dilute acid is added until the solution coming away is slightly acid, the lead nitrate can be washed out with water. The gold amalgam can now be retorted. If small quantities of impurities are in the retort gold, they may be eliminated by placing the gold in a clay crucible, and heating, adding a small quantity of chlorate of potash and a little common salt. When the latter has melted and run through the porous cake of retorted gold, small pieces of dry niter cake should be added and, when frothing has ceased, a little borax poured in. This treatment will remove every trace of base metals and even small quantities of silver.

The following method of treating the gold precipitate was introduced into South Africa by Mr. Tavener:

The gold slime from the zinc boxes is sent to the clean-up tank, where it is washed and sent to the filter press. The fine zinc in the tank is collected and kept separate from the filter-press cakes, although both are dried for 15 minutes in pans placed in an oven. The slime cake is rubbed through a 4-mesh sieve, then weighed and mixed with the proper flux in about the following proportions:

Materials	Parts by Weight
Gold slime, partly dried	100
Litharge, PbO	50
Assay slag	$12\frac{1}{2}$
Sawdust	1
Slag previously used	$12\frac{1}{2}$

The proportions of litharge must be varied to agree with the amount of the gold present, so that the base bullion produced will carry 8 to 10 per cent. of gold. After the gold slime has been mixed with flux it is shoveled into a small reverberatory furnace. The fine zinc which was partly dried is then mixed with flux in about the following proportions:

Materials	Parts by Weight
Fine zinc	100
Litharge, PbO	125
Mixed slag	25

This mixture is charged in the furnace above the slime, and on top of this, litharge and some easily

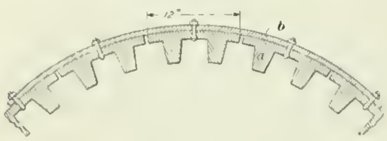

Fig. 3

fusible slag. The fire is then lighted, and after 2 hours the heat is raised and maintained at a high temperature. The charge is stirred and sawdust added for a reducer until the slag gives a clean sample, when it is run off into pots. Lime is thrown over the remaining slag with the object of making a pasty slag, which is then removed and kept for the next smelting.

The lead bullion is tapped into molds in the usual way. To dispose of the lead, the bullion is reduced in a large bone-ash cupel over which a stream of air plays, thus oxidizing the lead to litharge for future use. Part of the lead is absorbed by the bone ash as in cupeling. When the gold has partly cooled, it is drawn from the furnace and broken in pieces suitable for refining in a small crucible. This method has the advantage over the acid treatment that it permits mill sweepings and other materials carrying gold to be treated in the furnace.

Zinc can be removed from gold slime quite as completely by distillation as by the acid process. Enough carbon must be mixed with the dried precipitate to reduce the zinc oxide to metallic zinc, in which form it may be recovered for future use. The best results are obtained by quickly raising the heat above 2,100° F., although it requires 2,372° F. to remove the last of the zinc. All gold and silver volatilized in retorting is recovered when the zinc, as fume, is used over for precipitation. Clevenger, who advocates this process for treating gold precipitates, states that the material in the retort has the same appearance after as before distillation and that it can be poured like sand without any sticking.

The electric refining process is practiced at a plant where the copper and gold are deposited from a cyanide solution on a lead cathode. To refine the deposited metal, the cathode is removed from the precipitating tank, and placed in a wooden frame with cotton cloth sides but closed bottom. It is then suspended as an anode in a tank containing dilute sulphuric acid. The cathode in this refining tank is also lead, and when the current flows the copper is dissolved from the anode and precipitates on the cathode, where it slimes and falls to the bottom of the tank. The gold which is released as the copper is dissolved falls to the bottom of the frame that contains the anode and is lifted out when the anode has been cleaned by electrolysis. The gold slime is removed and dried, then melted and poured into molds.

The advantages of this system are that it obviates the necessity of scraping the cathode and separates the copper and gold without trouble.

The copper is recovered in cement form and in this case in sufficient quantity to pay the expense of refining the gold. The compartments in the precipitating tank hold five anodes and six cathodes, which are spaced 4 inches apart and are connected in series. The current strength is 5 amperes per square foot of anode surface, with an average resistance in the box of 8 volts, including the copper sliming on the cathode.

Cyanide Mill Machinery

The preliminary crushing of ore for the cyanide process does not differ from the methods used in other processes, but the increasing prevalence of fine grinding requires a somewhat extended discussion of the tube mill which is best used when all sliming is desired.

The tube mill is an iron cylinder varying from 16 to 22 feet in length and from 3 feet 6 inches to 5 feet in diameter. The larger diameter is better because of the greater ease with which repairs are made. At first it was assumed that Danish pebbles were the only ones suitable for tube mills, until it was found that pieces of hard ore worked fully as well and were cheaper. A mill 22 ft. ×5 ft. with $4\frac{1}{2}$-inch feed aperture, kept over one-half full of pebbles, utilizes about 3 tons daily. Tubes are lined with blocks of quartz bedded in cement; also with manganese steel, and a cast-iron and quartz combination lining.

The El Oro tube mill lining is composed of grooved iron plates a, Fig. 3, bolted, as shown, to the shell b, of the tube mill. Quartz stones placed in the mill automatically fill the grooves. In case one stone wears from the groove another replaces it, thus preserving the metal from wear. The internal appearance of the El Oro mill is shown in Fig. 4.

The life of tube-mill linings varies with the material to be ground, but where comparisons have been made, it has been found that 3,000 pounds of white cast iron, $1\frac{1}{8}$ inches thick, lasted 3 months; silex lining, $2\frac{1}{2}$ inches thick, lasted 4 months; while El Oro lining, weighing 13,700 pounds, lasted 10 months. Silex or chert lining lasts much better than cast iron, and further prevents the charge of pebbles from slipping and wearing the pebbles flat. Silex lining is laid in hydraulic cement, and after it is in place the interior of the tube is subjected to steam for 24 hours. It requires about 50 hours to reline, dry, and steam a tube mill before it can be placed in commission, although it is probable that with the aid of quick-setting cement this time could be decreased.

Before the tube mill was generally accepted as a recrusher, a large number of experiments were made to compare it with other machines. Table 1, made by Banks, in Waihi,

Table 1

Size of Screen	Material Passing Before Milling Per Cent.	Material Passing After Milling Per Cent.
30	5.32	.03
− 30+ 40	9.77	.12
− 40+ 60	15.94	1.13
− 60+100	13.96	7.43
−100+150	12.72	18.42
−150	42.72	72.87

furnishes a fair index of tube-mill capacity. A large proportion of the 72.87 per cent. of the tube mill product is less than 200 mesh. Chilean mills have been suggested in the place of tube mills. The Huntington mill is probably better than the Chilean

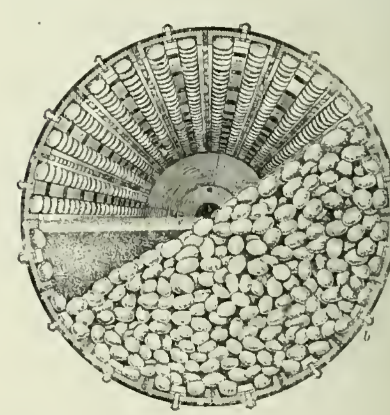

Fig. 4. Interior of Tube Mill

mill, although both have been proved inferior to the tube mill. The capacities of these mills are given in Table 2. In this table the starting power for the mill is given. Its actual running requires about 45 horsepower.

TABLE 2. COMPARISON OF MILLS

Type of Mill	Size Feet	Power Required Horse-power	Ore Crushed Tons Per Hour
Huntington mill	6	8	1.75

The Formation of Diamonds

*By Leonard Keene Hirshberg**

Dr. Orville A. Derby, of the Brazilian Bureau of Minerals and Mines, in Rio de Janeiro, has just finished an investigation into Nature's method of generating diamonds. From his studies he has evolved this law, namely: "Diamond crystals have been formed suspended in a medium sufficiently mobile or susceptible to solution, to permit an all around, free development."

Two Germans, Fersmann and Goldsmidt, have also studied the formation of diamonds in nature, and from their work Doctor Derby concludes that the extreme delicacy of the saturation point for carbon of the solution from which the material of the diamond crystals was derived, resulted so that the growth and reabsorbtion alternated in the development period of the great majority of brilliants in a way quite different from those of any other minerals.

Complete crystals of primary origin in certain rocks, are naturally formed in a mother liquid susceptible of dissolving the mineral. In rocks already consolidated, space for such crystals could only be gained through displacement of granules by the force of crystalline growth, or through the removal of solutions of the rock which occupied the space to be taken up by the crystal in the process of its formation. Such mineralizing agents as sulphur, carbon (in gas form), fluorine, and boron all have such solvent power.

No exact character of the molds left by dislodgment of diamond crystals from their parent rock (called kimberlite) has been accurately given, but judging from the idea that these are formed in place or floated up from some preexisting rock, they should be as sharply outlined as the mineral itself.

A number of nodules examined in the Newlands mine showed only a single diamond-bearing one. The others were garnets and diopsides. The one nodule had a flake about 3 inches long, and showed five diamonds, on the fractured faces. Six others were obtained by crushing detached fragments. Thus the whole layer (or flake) contained several dozen diamond crystals and the original nodule from which it was

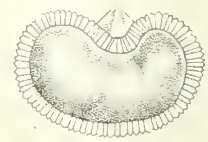

FIG. 1

broken—about the size of a 3-year-old child's head—must have contained hundreds.

The diamonds were embedded in the diopside, a yellowish green crystal made up of calcium, magnesium, and iron, or between this mineral and garnet. The granules of the garnet were covered with a thin, dark crust similar in appearance to the well-known kelyphite rim found on the mineral in many other rocks, but apparently of a somewhat different character.

The accompanying Fig. 1 will give an idea not only of kelyphite, but of the relation of a diamond crystal to its nearby granule of garnet.

Professor Friedlander, the Prussian scientist, in 1898, proved experimentally that the diamond could be produced artificially by introducing solid carbon into the fused volcanic minerals called chrysolite without any artificial pressure and at a temperature far below what had been hitherto considered indispensable. The fact that diamonds were also produced by Mosso and others in the electric furnace is beside the point.

Doctor Derby in speculating on the genesis of the diamond is thus able to "put aside the formidable ancient bugbear of extraordinary pressure and heat." From this he evolves the thoughtful theory that the diamond is a secondary daughter mineral crystallized out of a solution of carbon, which is also able to dissolve parts of the rock which also opens its spaces to the diamond crystals. He maintains from experimental and geological discoveries that the diamond occurs in the form of isolated and whole crystals closely embedded in rocks which occur in dykes, and which are composed of meteor-like, volcanic chrysolite.

This rock, wherever diamonds have been discovered in it, contains evidence of having been fractured after it was consolidated. The fracture was so complete that a free circulation of subterranean solutions could take place and produce a very advanced stage of alteration in all the volcanic mineral parts. The only portions that were perfectly fresh were the unfractured garnet sections, free from chrysolite.

The solutions and carbon gases that filtered into the fractures and fissures, says Doctor Derby, became locked up in the secondary minerals. These, the solutions of rock and carbon, also if they were fractured, attacked the enclosed garnet sections, which made a changed crust of secondary minerals. After the alteration of the garnet, the dissolved carbon formed crystals in the shape of diamonds attached to the secondary crusts, or a variety of carbon known as graphite.

Combating Ankylostomiasis in Italian Sulphur Mines

It appeared from observations made during the first half of 1910, at the Busca mine, where lime is strewn on the floor of the workings, and in that of Formignano, where sea salt mixed with $1\frac{1}{2}$ per cent. of iron sulphate is similarly used, that the infection if not retrograding, was at any rate making very little advance. It was, however, decided to make certain, by microscopic examination of the dejecta of all the workmen at both mines. The 29 men found to be infected were sent for further examination at the Cesena hospital, where the dictum was confirmed for 21 cases, 14 from the Formignano and 7 from the Busca mine. This proportion of 5.2 per cent. compares favorably with the 38 per cent. recorded before prophylactic measures were taken.

These results tend to show inferiority of the sea salt distribution as compared with that of lime, since the proportion of cases is 6.9 per cent. for Formignano against 3.5 for Busca. Moreover, the use of lime, which costs appreciably less, is not accompanied by the slimy mud due to the melting of salt, as to which the pushers have so frequently complained, on account of the roadway being rendered slippery. For all these reasons, the Trezza Albani Co., which owns both the mines, had decided in future to use only lime for strewing on the floor of the workings and also for disinfecting portable conveniences. It has moreover decided to have an examination of all the workmen made at least once a year, as well as one, at the Cesena hospital, of each new hand taken on.

Lake Superior and Cuban Iron Ores

Companies Controlling the Deposits—Description of Mining and Handling Methods in Cuba

By Day Allen Willey

THE largest iron-ore deposits in the United States so far as discovered, are in the states of Michigan, Minnesota, and Wisconsin. These deposits differ somewhat in analysis even in the same range and in the same mine; however, as a rule they may be classed as Bessemer ores. The Menominee Range in Michigan includes the Crystal Falls, Metropolitan, Iron River, and Florence areas. The Marquette Range in Michigan, includes the Republic and Swanzy areas; the Vermilion and Mesabi ranges are in Minnesota, and the Penokee-Gogebic Range is in Michigan and Wisconsin.

These districts produce about 75 per cent. of the iron ore in the United States. There has been a natural yearly increase in production in these ranges to comport with the annual increase in the consumption of pig iron. The United States Steel Corporation leased a large section of the ore beds on a royalty basis, which called for mining 750,000 tons the first year, to be increased until the annual output showed 8,250,000 tons. The corporation was to pay a running scale of prices, which increased from year to year. Thus, while the ore taken in 1907 cost $1.65 per ton, delivered at the Lake Superior ports, it must pay an increase amounting to 3.4 cents, per ton during the next year, a further increase of the same amount on the tonnage of 1909, and so on until 1917, when it is expected to mine at least 8,250,000 tons, which, according to its agreement, will cost it $1.99 per ton delivered at the shipping docks. To give a further idea of the terms of the lease, the following table shows the output price per ton, and total cost to the company yearly for a series of years:

Year	Annual Output	Rate Per Ton	Total Cost
1907	750,000	$1.65	$1,237,500
1910	3,000,000	1.75	5,250,000
1915	6,750,000	1.92	12,960,000
1917	8,250,000	1.99	16,417,500

This price is based on the understanding that all ore mined shall contain at least 59 per cent. of iron.

In addition to the mining of the beds leased by the United States Steel Corporation, several independent companies have depended on the Superior ranges, for raw material. There are no less than six independent owners who control iron ore beds estimated to contain from 25,000,000 tons to 75,000,000 tons each. They include the Jones & Laughlin Co., 50,000,000 tons; Lackawanna Steel Co., 75,000,000; Republic Iron & Steel Co., 30,000,000 tons; Rogers, Brown & Co., 50,000,000 tons; and Cleveland-Cliffs Iron Co., the same quantity. Including the smaller mines, the interests outside of the Steel Corporation control fully 500,000,000 tons of the ore known to exist in the northwest ranges out of 2,500,000,000 tons, the corporation about 80 per cent. with its latest acquisition.

These figures give an idea of the great tonnage of ore extracted from the ranges, and have caused engineers to make investigations as to the available remaining supply containing a sufficient percentage of iron to make it available as a basis for steel. The opinions have differed, one estimate being made that in 20 years the supply of ore which might be called merchantable will not be sufficient for the demand, at the present rate of mining.

This report has led to inquiry as to other sources of iron ore, and attention has been directed to the beds of Eastern Cuba which have been opened long enough to prove that the ore is of a high quality for steel making.

Two investigations of these deposits have been made by engineers of the Pennsylvania Steel Co. and its auxiliary company the Maryland Steel Co. The latter obtains from the present mines, the bulk of its iron ore for the manufacture of 400,000 tons of steel rails annually, in addition to the other forms of steel products. The second investigation made by the engineers was far more exhaustive and the borings and tests covered a much greater area of territory.

Fig. 1. Arrangement for Loading Ore into Steamers

Fig. 2. Ore Storage Bins at Daiquiri, Cuba

One ore body is on the summit of a gently rolling plateau, roughly speaking 10 miles long and 4 miles wide, with its principal axis lying northeast and southwest. Its elevation is about 1,600 feet at the northwestern extremity, which is nearest to Nipe Bay, and rises toward the southwest, to an elevation of 2,200 to 2,300 feet, with one peak reaching to 2,600 feet, and another to 3,200 feet. The surface of the plateau is almost entirely covered by a growth of pine lumber of medium size and averaging some 40 trees to the acre. There is little or no undergrowth other than ferns, and, except for a few islands, or "keys," of dense tropical forest, occurring in places where the ground is very moist, and where a certain amount of rich soil has collected, the entire plateau for 25,000 acres or more is open pine country.

The deposit of iron ore covers

practically the entire plateau. On the immediate surface, where it has been exposed to the weather, the ore is in the form of particles like bird shot, this being slightly superior in iron contents to the earthy ore beneath, although the difference will generally not exceed 1 to 2 per cent. The blanket of ore covers the plateau, and follows out on the points to the extremity of the gentle slope, stopping where the declivity becomes very abrupt, usually at an elevation of 1,600 feet. The slopes of the two peaks mentioned are also bare of ore.

At an early stage in the exploration it was apparent that a large body of ore existed. At certain plains, borings were made only 50 feet apart, to determine the topography of the underlying rock, with a view to the most economical working of the ore body; but the greater part of the later borings were spaced 1,000 feet apart. In this manner 18,500 acres were prospected and over 53,000,000 tons were calculated as available. The earlier pits and borings reached a depth of 5 to 17 feet, the bottom generally in ore.

No attempt was made to cover every acre of the ground, as a very large tonnage was already sufficiently assured.

The bed rock is serpentine, partly decomposed, and in some places so soft that the auger will enter. This rock outcrops in a few places, and in others the ore reaches a depth of 40 feet or more, but, in general, the depth is reasonably uniform. An open cut made in the claim shows a fair average depth of 15 feet over 15,525 acres, which, at 20 cubic feet to the ton, gives 605,000,000 tons. The engineers of the company consider it not improbable that when every acre of the ore ground has been explored, this figure may be exceeded, and regard it as certain that not less than 500,000,000 tons of ore, accessible for economical mining, exists on the plateau.

The ore is generally a limonite, varying from dark red to yellow in color. The latter color is found at greater depth, but there is no difference in chemical analysis. Some analyses indicate the existence of hematite with limonite. About 5 per cent. of the borings are in material below 27 per cent. in iron and high in silica or alumina, or both. This can be avoided in mining.

Fig. 3. Cuban Iron Ore Mine

Physically the ore presents some noteworthy peculiarities. One grade of the ore is the agglomeration of the shot-like particles, caused by the action of water and sun. These occurrences while local, will aggregate several million tons. Another grade is the shot ore, which while forming a large total tonnage could not be mined separately, as it varies from an inch to as much as a foot in thickness on the surface. The third grade which forms the great bulk of the deposit, is an earth ore, dark red, through light red to yellow in color.

It is evident in dressing this Mayari deposit it presents new features, both mechanical and metallurgical. Its soft nature and blanket form permit the use of steam shovels for excavation, but its tenacity, amounting almost to stickiness, has made it necessary to design a new form of car for its transportation, as it will not tip from any old form of dump car. The high percentage of water in the ore makes some sort of drying process indispensable preliminary to shipment, to avoid paying freight and duty on water.

The finely divided, almost dust-like, condition of the dried ore requires that this drying process shall go a step further and produce an agglomerated product in the form of clinker and bricks, to make it suitable for use in the furnace. The alumina content produces an unusual blast furnace slag and one which demands careful and intelligent operation. The chromium present, going into the pig iron, must be largely eliminated from the steel, and the characteristic behavior of the small remaining quantity of chromium in combination with varying percentages of carbon require to be studied in detail.

The experiments with the drying and clinkering plant and with the elimination of chromium in the steel-making process have been carried on at the Steelton plants of the Pennsylvania Steel Co., and are not available for publication.

The ore is mined by steam shovels and loaded into 50-ton cars. These are lowered over double-track inclines as shown in Fig. 3 to a yard $2\frac{1}{2}$ miles distant. Two separate inclines are connected by 4,000 feet of level track. The inclines are laid with 90-pound steel rails and operated by "barney" cars, running on a narrow-gauge track of 60-pound rails, inside the main track. The two barneys to which the main cable is attached are connected by a tail-rope running around a sheave at the base of the incline. Two cars can be lowered at one time, over a maximum grade of 25 per cent., and simultaneously two empty cars may be raised on the other track. The weight of the loaded cars is sufficient to raise the empties, but winding engines are installed at the head of each incline to provide for rapid starting and better control. The main hoisting ropes, $2\frac{1}{2}$ inches in diameter, are attached to the barneys, and pass around the drums of the winding engines in the usual manner. The smaller tail-rope, connecting the rear ends of the two barneys, is for convenience in manipulating them and acts also as a sort of balance.

At the foot of the incline the barney drops into a pit, and the loaded cars, run out over it to the yard track, while the empties, to be hoisted on the next trip, are fed by gravity past the barney pit, to be picked up by the barney as it comes from the pit on its up trip.

From the foot of the upper incline to the head of the lower, a locomotive shifts the cars over the 4,000 feet of intervening level track; but at the foot of the lower incline no locomotive is required, as by an ingenious arrangement of yard tracks, the loaded cars, from either incline track, run off to the same yard track, where they are coupled into a train, while the empties in the yard feed in by gravity to either incline track. The inclines have a capacity of 6,000 to 8,000 tons in 10 hours, and are so arranged that the size of the rope may, when necessary, be increased to carry three cars, thereby increasing the capacity 50 per cent.

From the foot of the lower incline there is a railroad 13 miles long, with a maximum gradient of one-half of 1 per cent., all grades favorable to the traffic and a maximum curvature of 6 degrees, the ore is carried in 30-car trains over this railroad to the terminal town of Felton, on Cagimaya Bay. The railroad, is laid with hardwood ties and 90-pound rails, and heavily ballasted. All bridges, except a trestle across the narrow estuary which separates Cagimaya Key from the mainland, are of steel; culverts are of concrete and drains of cast-iron pipe.

At Felton, the tidewater island terminus, the ore is dried and stockpiled for shipment. The ore cars open on one side, and cranes lift the entire car body off the trucks by the other side, so that the bottom of the car may, if necessary, be raised to a vertical position, and the ore will slide out into a long trough. From this trough it is lifted by a 15-ton grab bucket, operated from a bridge or gantry crane, and served directly to the drying plant.

The product of this plant is carried by an electric transfer car to the storage for clinkered ore. This is located with its main axis parallel to the shore line, and as close thereto, as conditions permit. The transfer car deposits the dried ore in another trough from which a second bridge with a 15-ton grab bucket lifts it for storage in a stock pile, or, by means of an extension boom reaching out over the water, loads it from the pile into steamers lying along the water front close to the island.

A dredged channel 3,000 feet long, 200 feet wide, and 28 feet deep allows vessels to reach the shore line of the island, where a dredged basin gives shore frontage and admits of turning the vessels.

As the process of drying the ore requires a large amount of coal, all of which must be brought from the American coast, provision for coal discharge and storage is made along the 1,000 feet of deep-water front. The coal is discharged by unloading machines on a bridge similar to the ore bridge and stored in a pile near the shore and in continuation of the ore pile. The cranes, bridges, and unloading devices are electrically operated, and an electric power and lighting plant, together with machine, blacksmith, boiler, and carpenter shops, foundry and terminal railroad yards, form part of the installation at the Felton terminal.

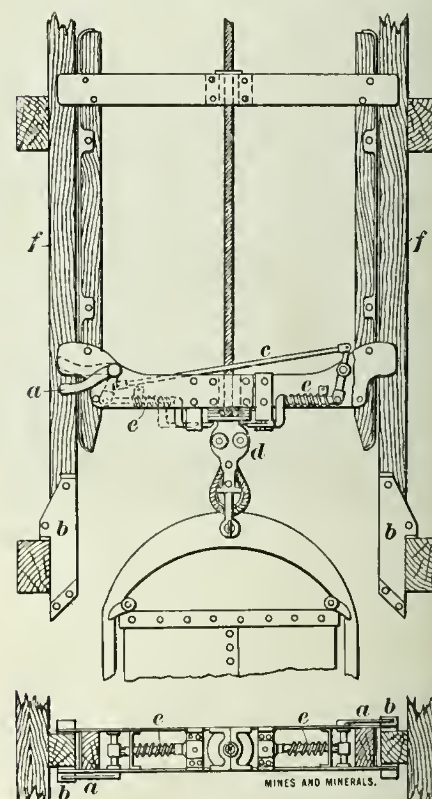
What, if any, portion of the Mayari ores will become available for other eastern steel makers is a matter for the future. Whatever tonnage comes to the United States will strengthen by so much the position of the iron industry on the eastern seaboard. That section has seen the disadvantage of even its partial dependence upon lake ores increased in recent years by the declining iron content of these ores and the increasing proportion of Mesabi ores with their higher moisture. The costs are accentuated by the long rail haul. The Mayari deposit and the knowledge that it is of very large extent, have brought out the suggestion in some quarters, that Cuban ores and Virginia and West Virginia fuel will soon be assembled on the lower Chesapeake Bay. Newport News, as the terminal of the Chesapeake & Ohio Railroad, and Lambert Point, across the bay, the terminal of the Norfolk & Western, or some point at which both roads could be utilized, would afford an advantageous rate on coal, in case by-product coke ovens were erected at the seaboard, or on coke, if it should be regarded more economical to produce the coke at the mines.

Russian Gold

The production of gold in Russia in 1911 is estimated at 2,326 poods or 83,975 pounds. The largest yields come from the Ural and from Siberia. Heretofore, the gold production has been limited almost exclusively to the washing process, but it is now the intention to attempt the smelting process for the gold ores from veins, since the former method has shown a large decrease of gold production on account of the exhaustion of the beds. The gold production in 1911 in East Siberia was 3,610 pounds less than in the preceding year, which may, however, mostly be due to the want of workmen. In the Lena district, in the river basins of the Olekma and the Witin, 95 per cent. of last year's find was obtained through sand washeries. No doubt it will be in the Ural Mountains where the smelting process will be used first, because the placers there have been exhausted through many years exploitation.

Berry Safety Catch

The use of crossheads in shafts has been condemned by a large number of mining men, but in several countries where inquiries have been made into their use, the consensus of opinion has been that the danger was lessened by the use of a crosshead, provided it was equipped with a safety appliance to prevent t hanging up in the shaft. In the Transvaal, the Berry safety catch, shown herewith, according to E. T. Cooki l, Inspector of Mines, Ontario, Can., has given satisfaction, in preventing the crossheads of sinking buckets hanging in the shaft. The levers a, in descending, strike on the stops b, and by means of the connecting-rod c operate both levers. When the cross-head is raised from the stops by rope clamp d the tension on the springs e is released and the crosshead rides freely between the guides f which also center the bucket in the shaft.



Berry Safety Catch

NEW MINING MACHINERY

Storage Battery Electric Locomotive

Ten storage-battery electric haulage locomotives are being used by Holbrook, Cabot & Rolins Corporation, New York, who are executing a contract on one of the sections of the New York Aqueduct now being built to convey the Catskill water supply into the city. These locomotives are used for transporting excavated material on cars to the shafts which have been sunk approximately a mile apart for expeditious tunnel driving. The material is then hoisted to the surface. The locomotives are of somewhat different design to the twelve locomotives Smith, Hauser, Locher & Co. are employing for putting through another section of the tunnel.

These are the pioneer storage-battery locomotives built for underground haulage. The new locomotives have a 4-ton rating and are coupled up to four cars to form the usual train. Tunnel locomotives impelled by storage batteries are designed for short distance hauls at moderate speeds, where it is not feasible to install an overhead trolley system. The latter system is employed to better advantage in most cases; but where local conditions demand the storage-battery type, it has proved an excellent substitute.

In the case of the New York Aqueduct tunnel, trolley locomotives were impossible because the tunnel headings would not permit their entrance, and the storage-battery haulage locomotives, manufactured by the General Electric Co., have proved efficient and economical for this work and permitted laying the tracks without the filling necessary when hauling by mules.

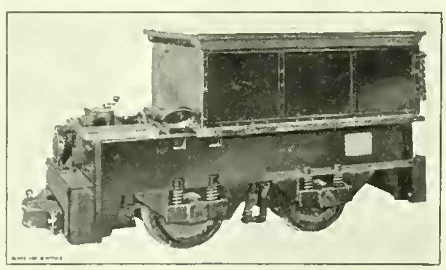
The locomotives are built to conform to the following specifications: Diameter of wheels, 20 inches; wheel base, 34 inches; total weight, 8,000 pounds; length over all, 7 feet 10½ inches; height over batteries, 49¾ inches; track gauge, 34 inches; speed at maximum tractive effort, 3½ minutes per hour.

The batteries have 44 cells, have a 5-hour discharge capacity, and to facilitate removal, the battery trays are provided with rollers. The locomotives are equipped with an ampere-hour meter, headlight, and gong.

The frame consists of two steel channel sides and steel-plate ends. A seat for the operator is provided in front and couplers suitable to the cars in use are attached at both ends. Cast-steel pedestals, which carry the journal boxes, are bolted to the lower web of the channel side frames.

The cast-steel journal boxes are fitted with roller bearings, which assure efficient mechanical transmission of power and consequent economy in battery current consumption. The weight of the car is supported from the journal boxes by two coiled springs.

The wheels are pressed on and keyed to the axles, which are case-hardened at the journals, so that there is practically no wear either on the roller bearings or the axles.



Storage Battery Locomotive

The motors are of the automobile type, designed to operate from batteries, and to effect the maximum possible economy in the use of battery current. They have large overload capacity and operate with practically sparkless commutation. High efficiency is obtained by designing the motors with a small air gap; and by running the iron at low densities, the speed and torque are steeper than in the ordinary series motor, thereby tending to limit the overload which can be thrown on the batteries. The armature shaft rotates in ball bearings, which reduces the friction losses, and makes the bearing wear practically negligible. The motors are compact, readily accessible for inspection and repair, dust and moisture proof, and are mounted in cast-steel suspension cradles, one side being supported on the axle bearings and the other side spring-suspended from the locomotive frame, in accordance with standard locomotive compensator practice.

The motors drive the axles through double reduction gearing, an intermediate shaft, carrying the intermediate gearing. As slow speed service is ordinarily required of a storage-battery locomotive, the use of double reduction gearing permits such speeds without rheostatic losses; and, due to the large gear reduction from armature shaft to wheel tread, very high tractive efforts are obtained at comparatively small current inputs to the motors.

The storage batteries have plates with high ampere-hour efficiency; the cells being grouped in four or more trays mounted on top of the locomotive frame in a sheet-iron case with wooden base and cover.

Trade Notices

Coal Briquetting.—The Roberts & Schaefer Co., of Chicago, has recently reorganized its coal briquetting department, which will henceforth be in charge of Mr. Charles L. Wright, formerly of the Fuel Testing Division of the Bureau of Mines, where he had large opportunities for investigations into the briquetting of coals and lignites. The company has acquired an operating plant and is prepared to make briquetting tests for prospective clients. It has also secured the exclusive United States rights for the manufacture and sale of a briquetting press of unusual merit.

Pump Catalog.—A finely illustrated catalog of 58 pages has been issued by the Goyne Steam Pump Co., of Ashland, Pa. In this is described the extensive line of heavy mine pumps for which this firm is well known. These pumps are the outgrowth of experience since 1881 in some of the most difficult work in the anthracite regions of Pennsylvania, and the firm is prepared to build mine pumps both small and large for any conditions.

New Electric Installations.—The Colorado Fuel and Iron Co., Denver, Colo., is installing additional apparatus for equipping its mine at Pictou, Colo., with electric drive. This includes a 500-kilowatt rotary converter, motors, and switchboard apparatus. For operating its coal mine, at Carron City, Colo., electrical hoist apparatus consisting of a 125-horsepower motor-generator set, 250-horsepower motor, air compressor and switchboard, is being added to the power-house equipment. The Calumet & Hecla Mining Co., Calumet, Mich., is installing sixty-five motors, of 40-horsepower capacity each, for equipping its mines and smelters with electric drive. The St. Joseph Lead Co., Bonne Terre, Mo., is adding to its power plant at the Leadwood mines a 1,000-kilowatt alternating-current generator, and in the power plant of the Bonne Terre mines a new 1,250 kv-a. Curtis turbogenerator is being installed. All the above equipment is made by the General Electric Co.

Manager of Atlanta Office.—The H. W. Johns-Manville Co. announces the appointment of Mr. C. S. Berry as manager of its Atlanta, Ga., office, located at 31½ South Broad Street. A stock of roofings, packings, pipe coverings, and other J-M asbestos, magnesia, and electrical products is carried at this address.

A Bird Man's Eye View.—The bird's-eye view of a manufacturing plant, drawn from the imagination or an architect's set of plans, is common in advertising literature. The bird man's eye view, showing things as they are and not as the manufacturer would like to have them, is the latest move toward truthfulness in advertising.

Previous composite pictures of the Hawthorne Works, of the Western Electric Co., had not been satisfactory because so many obstacles to obtaining a true perspective were presented by the immensity of the complex of buildings, and the idea of obtaining an aeroplane picture was suggested by the proximity of the grounds of the Chicago Aero Club, at Cicero, where some of the world's greatest flights have been made. Five flights were necessary to secure an acceptable picture. The aviator and the photographer rose to a height of 2,500 feet and the aeroplane was permitted to glide down to 1,000 feet at a speed of 45 miles an hour. Between heights of 1,500 and 1,000 feet the picture was taken. Experts who have seen the result declare it to be the most remarkable photograph ever taken. A reproduction of the photo was published as a supplement to the *Western Electric News* for December.

Chain Stokers.—The Illinois Stoker Co. has issued a handsome and useful pamphlet on "Chain Stokers." In this are incorporated the proximate analyses of coals from every state in the United States. Also an efficiency based on evaporation from and at 212° F. Naturally this table is entirely theoretical but it shows what might be done, if, etc.; however, it will be interesting to those who would like to see how close their boilers are coming to theory.

Catalogs Received

Albany Lubricating Co., 708-710 Washington St., New York City. The Soothsayer, 5 pages; "Some Don'ts" for buyers of Lubricants.

De Laval Steam Turbine Co., Trenton, N. J. De Laval Steam Turbines Velocity Stage Type, 47 pages.

Green Fuel Economizer Co., Mattewan, N. Y. Best Proportions of Boiler and Economizer Surface, 24 pages.

Strong, Carlisle & Hammond Co., Cleveland, Ohio. Strong Steam Traps, 16 pages.

Illinois Stoker Co., Alton, Ill. Chain Grate Stokers, 51 pages.

The C. F. Pease Co., 166 West Adams Street, Chicago, Ill. Everything for Blueprinting, 32 pages.

General Electric Co., Schenectady, N. Y. Bulletin No. A4039, Direct-Current Motor-Starting and Speed-Regulating Rheostats and Panels, 35 pages; Bulletin No. A4040, Contractors for Industrial Service, 10 pages; Bulletin No. 4993, Type Ri Single-Phase Motors, 15 pages.

National Tube Co., Pittsburg, Pa. "National" Pipe, 3 pages.

Increase in Platinum Production

California and Oregon produced all the platinum which was mined in the United States in 1911, and this, as shown by Waldemar Lindgren, of the United States Geological Survey, in an advance chapter from "Mineral Resources" for 1911 was $8,631 greater in value than the output for 1910. The following is a statement of production in troy ounces and the values for the two years. In 1910, California produced 337 ounces valued at $8,386 and Oregon 53 ounces valued at $1,121; in 1911, California produced 511 ounces, valued at $14,873, and Oregon 117 ounces valued at $3,265.

The average price paid for platinum in 1911 was $28.87 an ounce, compared with $24.38 in 1910, the higher price undoubtedly resulting in an increased production.

Importations in 1911 of crude platinum sands resulted in an estimated refined product of 27,500 ounces, nearly four times the domestic production. An additional amount was derived from imported ores and mattes, so that the total quantity of refined platinum produced in domestic refineries is estimated by Mr. Lindgren at approximately 29,140 fine ounces, of which about 940 ounces, valued at $40,890, was derived from domestic sources of various kinds—platinum sands, copper and gold bullion, etc. The corresponding estimate for 1910 was 773 ounces, valued at $25,277.

The platinum imported and entered for consumption in the United States in 1911, including ores and manufactured products, was valued at $4,866,207, an increase over the 1910 figures of $1,212,543. The exports amounted to only $8,139.

The world's production of platinum in 1911 was 314,323 troy ounces, compared with 286,952 ounces in 1910.

Mr. Lindgren's report of platinum contains an interesting discussion of the platinum-bearing minerals, the uses of the metal, its sources in the United States, and the possibility of new discoveries. It also contains notes on the other platinum metals such as iridium and palladium.

Chloral Hydrate as a Solvent

Attention may be drawn to the extraordinary solvent powers of chloral hydrate. It has long been used for microscopic purposes to render objects transparent, but its solvent power may also be utilized in many other ways. For example, in toxicological investigations for the detection of alkaloids a 60-per-cent. solution of chloral hydrate dissolves all alkaloids and their salts, even the usually insoluble tannates. Resins, gum-resins, and balsams are almost all soluble, and in case of gum-resins a quantitative separation of the constituents may easily be effected, because by adding alcohol to the chloral solution the gum is precipitated while the resin is thrown out by adding water. Fats, oils, and waxes show variations of solubility which may serve for their partial differentiation. Vegetable coloring matters are dissolved by chloral-hydrate solutions, with the exception of indigo; and the presence of indigo in litmus, which is stated to be very common, may be thereby detected. In the investigation of blood-coloring matter, starch, gelatin, and proteids, the solvent action of chloral hydrate may also find useful application.

Mines and Minerals

Vol. XXXIII.—No. 7. FEBRUARY, 1913—SCRANTON, PA. Price, 25 Cents

PUBLISHED MONTHLY AT SCRANTON, PA.
ESTABLISHED 1881
INTERNATIONAL TEXTBOOK CO., PUBLISHERS

SUBSCRIPTION RATES

Single Copies .... 25 cents
Yearly Subscription, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines ... $2.00
To Canada 2.50
To all other countries 3.00

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us.

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

MINING engineers, who, without collegiate education, have obtained prominence in the profession by reason of natural ability, broad experience, and hard study, are unanimous in stating that their successes would have been easier and more quickly attained if they had had the benefit of a first-class course in a technical school or college.

THE demand for rational laws regulating the working of coal mines is always caused by the necessity of measures to conserve the health and safety of the mine workers. The mine worker who opposes any measure calculated to ensure careful and constant inspection of mines, and the impartial enforcement of the law, is not only his own enemy, but is opposing the best interests of his fellow workman.

MEN who have received degrees as mining engineers from good technical schools, and who have not been successful, should not be considered examples of the value of the education given them. No engineering course makes an engineer of a man. It simply gives him a good foundation on which to build a successful and practical experience. If the possessor of such a foundation does not build a first-class superstructure on it, the fault lies either in his lack of industry or the fact that his mental attributes do not fit him for the profession.

A Suggestion to State Mine Inspectors

SOME years ago this journal advocated a national convention of State Mine Inspectors as a preliminary step toward uniformity of State Mine Laws and State Mine Inspectors' Reports. This resulted later in the formation of the Mine Inspectors Institute of the United States of America. It has been in existence for several years and has been productive of much good.

It can greatly increase its usefulness if, as an organization, it will use its influence to bring about a uniformity of mine laws and of annual reports. To make possible the latter it will also be necessary to establish a uniform fiscal year. With such uniformity, it will be easy to make comparisons of results in the various states and to compile national statistics, and make deductions of greater accuracy than is now possible.

As a model for tabulated reports, those of the mine inspectors of Pennsylvania can be commended in the highest degree. If, for some states, these reports are too comprehensive, a part might be eliminated. But the more important ones can be adopted to advantage. If best results are to be secured, every state should insist on reports as complete as those of Pennsylvania.

With a uniformity of mine laws and rules, coal miners from one state migrating to another will find that the conditions in the mines to which they go are practically the same as in the mines from which they came. This will mean that, in a large measure, they will be free from the troubles and dangers incident to more or less different conditions existing in the mines or in the laws and mine rules.

Another feature in which uniformity will be of great advantage is in the matter of danger signals. In the Bituminous Mine Code of Pennsylvania there is a provision that danger signals in all mines must be uniform and of a design approved by the Chief of the Department of Mines. Chief Roderick, of Pennsylvania, has approved of a danger signal which was illustrated and described in our issue of December last. This signal is simple but conspicuous. Its meaning is readily understood by non-English speaking workmen after it is once explained to them. A description of it is as follows:

"Its size is 30 in. × 10 in. with an oval in the center 14 inches long and 10 inches wide. The color inside the oval is red and outside the oval black. In the red oval the word 'Danger' appears in white letters, as large as possible consistent with the preservation of the contrast of colors."

Every mine worker in the bituminous mines of Pennsylvania will be familiar with this danger signal in the near future. If the same design is used in other states, the miner from Pennsylvania locating in such states will know what it means, and, conversely, this will be the case with miners coming to Pennsylvania from other fields.

Modern methods of travel have minimized distances; State boundaries, except in a legal sense, are obsolete. An earnest effort should, therefore, be made to have the conditions attached to our coal-mining industry as nearly uniform as possible. The Mine Inspectors Institute is composed of men who realize this fact, and it is hoped that it will, as a representative body, use its influence to bring about this uniformity.

Stray Electric Currents in Coal Mines

According to information furnished by Professor Norwood there is a new element of danger in coal mines where electricity is used, not heretofore suspected. We have been advocating the use of copper needles and copper tipped tamping bars to prevent sparking and premature explosions, now we find that if stray electric currents are running through the coal, copper needles are dangerous and will cause explosion.

As we understand conditions, permissible explosives can only be fired by detonators, but there seems to be danger of stray electric currents coming in contact with the caps and causing detonation before things are ready. Danger from this source can be minimized by placing the cap in the center of the cartridge using only wooden sticks for tamping and not using two kinds of explosives in the same shot hole. The attention of our readers is called to the article of Professor Norwood, who is Chief Inspector of Mines for Kentucky.

The Selection of State Mine Inspectors

The most important function of a rational coal mine law is to provide for the maximum protection to the health and safety of the mine workers. A secondary function is to provide for the safety of the mine property.

Violations of the mine law by operators or mine officials must be prosecuted by the Mine Inspector, or he fails in his duty. Violations of the mine law by mine workers, whereby they endanger the lives and health of either themselves or their fellow workers, must also be prosecuted with equal vigor.

A competent Mine Inspector must be a man thoroughly conversant with all conditions existing in mines. He must possess a thorough knowledge of the technicalities of mining and he must have had extensive practical experience. In addition he must be a man possessing both physical and moral courage and a mental temperament that will always ensure the use of good judgment and the avoidance of hasty and ill-advised action.

Such men are procurable, but they cannot do their full duty unless their entire time is devoted to the actual work of an Inspector. If they do their duty impartially they are bound to offend those whom they prosecute for breaches of the mine law. Every man, whether operator, official, or mine worker, whom he offends, no matter how just his case may be, becomes his enemy. That it human nature. Every enemy he makes in doing his duty exerts more or less influence over others.

It is evident that if inspection is to be properly performed, competent Inspectors must be obtained. They must be free from any influence that will tend to detract from the full exercise of the powers vested in them.

There is only one way in which competent Inspectors free from bias or outside influences can be secured. That way is provided in the proposed new or codified Anthracite Mine Law of Pennsylvania.

This proposed article in the mine law provides for the appointment by the Governor of an examining board to consist of five miners in actual practice and four mining engineers. This board is to examine candidates in a thorough manner both in writing and orally. All candidates passing both the written and oral examinations with a percentage of 90, or more, are to be certified to the Governor who shall appoint to the office or offices the one or more candidates having passed with the best records. The records of the written examinations and stenographic reports of the oral examinations are to be filed in the Department of Mines at Harrisburg. While this plan of selecting inspectors is a great improvement on the present plan of electing them, it can be further improved by a slight change in the make-up of the Examining Board. In our opinion, an examining board composed of two mining engineers, two qualified mine foremen, and five miners, will be better. This puts on the board, in the persons of the mine foremen, representatives more familiar with *all* the details of mining than the others. At the same time it gives the miners a majority of the board.

Men selected in this manner are under obligations to no one. They know that enemies made by enforcing the law cannot affect their reappointment. They can feel secure in their positions and can reasonably expect reappointment if they do their full duty and keep so well abreast of progress in mining matters as to pass the examination necessary for reappointment. If some one else shows greater proficiency and superior qualifications, naturally that man will succeed to the office.

The man who opposes the above rational plan and advocates the election of State Mine Inspectors from among those who hold certificates of competency as mine foremen, is, either through lack of consideration of the duties of an Inspector, or designedly, doing an injury to the mine workers.

In the first place every man who can pass the technical examination necessary to secure a mine foreman's certificate is not competent to be a State Mine Inspector. In fact some men holding certificates of competency as mine foremen are not capable of being mine foremen. There is something more than practical experience and technical ability necessary.

In the second place, out of about 172,000 mine workers in the anthracite regions only about 35,000 are certified miners.

All of these are not voters, and no one of common sense will admit that all who are voters have ability to select a competent mine inspector. But assuming they are, they are but 35,000 voters in a voting population of 135,000 in the counties forming the anthracite regions. This leaves 100,000 voters incompetent to judge as to whether the candidates for mine inspectors are competent or not. This is no reflection on the general intelligence of the 100,000 voters. It means simply that as most of them are of avocations varying from farm laborers to business and professional men; they are not familiar with mining conditions.

Under the present law, the State Mine Inspectors in the anthracite regions are elected. This provision of the law, bad as it is, is not as bad as the one now proposed which makes every man holding a mine foreman's certificate eligible as a candidate for election.

Even as the law now stands, Inspectors in office, who have been diligent in enforcing the mine laws, cannot be reelected. The men whom they have prosecuted can bring enough influence to bear to defeat them either at the primaries or the general election.

We have in the past condemned the election of State Mine Inspectors as a vicious plan, and have shown that if an Inspector wants to succeed himself in office he must neglect his official duties to electioneer before the primaries, and continue to do so till after the general election. In fact he must be electioneering more or less all the time. He must be a "trimmer" at all times. He must not offend the mine officials or they will defeat him at election time. He must not prosecute mine workers for violations of the law or they and their friends will defeat him at the polls. In fact, if he wants reelection the less he does as an Inspector the better for himself.

A good Inspector should be kept in office as long as he is physically able to perform the duties. Each year of service adds to his ability as an Inspector. Constant changes in the Inspectorship mean a handicap to the main object of the mine laws, viz., the protection of the health and safety of the mine workers.

The mine worker who advocates the election of State Mine Inspectors by popular vote is either misled by designing men, or has formed his opinion on the matter without considering the subject from all sides. It is the duty of every intelligent mine worker and mine official to use his influence to correct this wrong. Every man in the state of Pennsylvania who possesses enough humanity to earnestly desire that the coal mines of the state shall be made as safe as possible should use his influence to help the enactment of the measure providing for the selection of candidates for State Mine Inspectors by special, rigid, examinations, and the appointment of the most competent men by the Governor.

Electrical Knowledge for Mine Foremen

An OLD mine foreman said to a young mine electrician who happened to have graduated from school and was starting to work: "George, you do be a bright fellow, now tell us, how many volts do there be in an ampere?" This question was told to another foreman who was acquainted with the first, the second laughed heartily and said, "That's a good one on him, that's good. Of course, why the amperes are in the volts."

It is knowledge such as this which has caused the frequent arrangement for mine management that the mine electrician should be responsible to an electrical engineer or electrical district foreman, and not to the mine foreman, except indirectly. This has often been a cause of friction. For the mine electrician realizes that he cannot be discharged by the mine foreman, when responsible to some other official. The electrician knows that his knowledge of electricity is superior to that of the mine foreman. What he does not realize is that it is superior knowledge on a minor point. A little knowledge here becomes a dangerous thing, for inattention to the desires of the foreman is likely to develop on the part of the electrician, with the consequent hampering of the man who is responsible for the output of the mine and who knows what should be accomplished.

The Bituminous Mine Law of Pennsylvania prevents this difficulty, for it is distinctly stated in the law that the "mine electrician * * * shall be subject to the authority of the mine foreman." In the Anthracite Law under the general rules it is stated that "the owner * * * of a mine * * * shall place the underground workings thereof and all that is related to the same, under the charge and daily supervision of a competent person who shall be called Mine Foreman." Therefore, in Pennsylvania at least, this divided authority is prohibited by law. In other states where conditions have seemed to render necessary this division of authority and it is not forbidden by law, there is a remedy without having recourse to the law. It is to demand of a mine foreman, as the demand is made in other directions, that he have a certain knowledge of electricity, if he is to obtain his results by its use. A foreman is not required to be a skilled machinist, but it is demanded that he make intelligent use of steam and machinery. So too it might be required that he have sufficient knowledge of electrical machinery that an electrician can be entrusted to his care.

Under any conditions, however, a mine foreman must have full charge over a mine, if he is to be held responsible for the result. Good management cannot be obtained when there is a dual authority and one-half of that authority is absent a greater or less portion of the time, as will happen when a mine electrician is responsible to an electrical engineer.

The Coal Miner

THE competent coal miner is a mechanic, just as is the competent carpenter and machinist. There are "wood butchers" who call themselves carpenters and there are similar incompetent men who call themselves coal miners. To be a competent coal miner a man must learn the trade. He must learn how to break down the coal in the safest and most economical manner, and this means the learning of numerous important details. He must know how and when to set props, how to recognize and guard against danger to himself and his laborer, and numerous other important mechanical and cautionary operations.

Such being the case, and coal mining, especially in the anthracite seams, being a dangerous occupation, there is much to be said in favor of a rational miners' examination law.

Such a law, if enacted, should provide for the employment as miners of only such men as have learned the trade, and who have shown by an examination that they are competent mechanics. Three years is generally considered the length of apprenticeship in other mechanical trades. There is no reason why the same apprenticeship term should not apply to miners. As there is no discrimination in other trades on account of the country or locality in which a mechanic learned his trade, there should be no such discrimination in any coal field.

The present miners' examination law for the anthracite regions is a failure. It has put in the mines, as miners, thousands of men who never learned the trade. These men are inefficient and add to the natural dangers of the mine. Legally they are miners, actually the are not.

If the miners' examination section of the proposed codified and revised anthracite mine law is to be of salutary effect in conserving the "health and safety of the mine employes, and the protection and preservation of the mine property," it should provide that each applicant for a miner's certificate shall be over 21 years of age, and shall have had at least 3 years' experience as a miner's laborer, or at such other work inside of coal mines as would enable him to learn his trade as a coal miner. There should be no restriction as to where he learned his trade, as long as he proves to the examining board that he has learned it. Naturally, he should also prove his familiarity with safety lamps and the use of explosives, and that he has sufficient knowledge of the English language to understand the instructions given by the mine officials.

Such a law will be in entire harmony with the object of the general mine law. It will prevent incompetent men, who are not only inefficient, but who are in a measure a menace to the safety of their fellow workers, posing as miners, and will compel them to learn the trade if they desire to become miners. It will also encourage actual miners from other regions, and other countries, to seek work in the anthracite mines, instead of excluding them as is now the case.

Under present conditions no competent English, Welsh, Scotch, or German miner will seek work in a region where he is compelled to serve 2 years in a laboring capacity under a man who is not as competent as he is, and who in many instances is more illiterate and of less natural intelligence.

Thirty years ago the steam plant at the average American coal mine consisted of primitive cylindrical boilers and none of the efficient and economical appliances usually found at large steam plants used in other industries. Today the reverse is the case. Coal mine managers recognize the value of boilers and appliances that increase efficiency and economy in fuel and labor.

COAL MINING & PREPARATION

Cleaning Coke-Oven Gas

Method of Condensing and Separating By-Products Method of Manufacture of Sulphate of Ammonia

By Sydney F. Walker

THE successful operation of a by-product coke-oven plant depends upon the thoroughness with which the gas is cleaned. The by-product coke oven, practically a large retort containing coal, is subjected to external heat in order to drive off the volatile matter in the coal. The process is merely one of distillation in which the gaseous part of the coal is separated from the fixed carbon which remains in the retort with the ash and is termed coke. The gas as it leaves the retort is hot and contains a number of substances which may be removed either by condensation or by absorption, the principal ones being tar, ammonia, and hydrogen sulphide. Ammonia is converted into sulphate of ammonia which finds an increasing market in the United Kingdom; and as the quantity increases the demand and price seems to increase. At the Bargoed colliery there is a by-product coke-oven plant similar to the Cwintillery plant shown in Fig. 1, which has been so successful in cleaning the gas that a large quantity of it is used in generating electric power by the aid of gas engines.

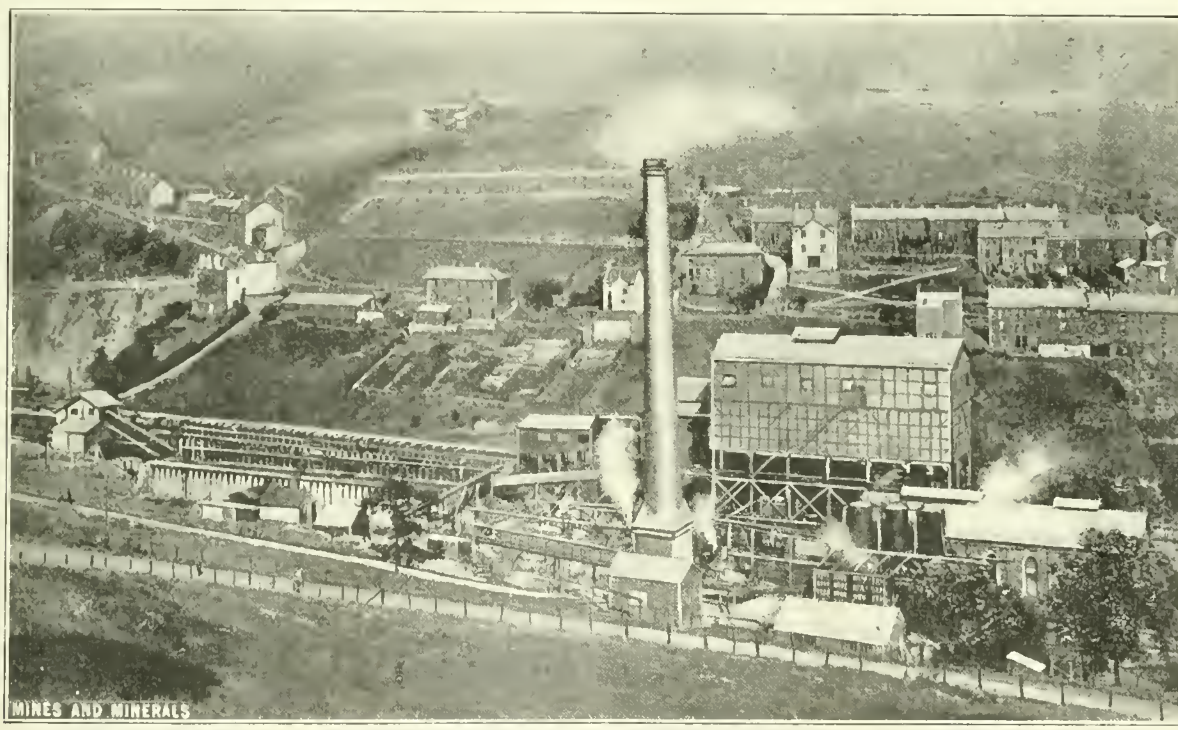

Fig. 1. Cwintillery By-product Coke Plant, Showing Washery and Storage Bunker

The first process in the treatment of gas from the coke ovens is to pass it through a condenser which may be horizontal or vertical. One of the common horizontal forms shown in Fig. 2 consists of cast-iron pipes coupled end to end, with return bends placed in a zigzag manner so that the gas may pass in at *a* and out at *b*. Fig. 3 shows one kind of vertical pipe condenser, the cooling pipes being arranged vertically, the lower ends of the pipes being fitted into partitioned boxes, or headers, of larger area than the pipes through which water circulates. The gas is kept in motion by an exhauster, which is usually of the Connersville blower type rather than a fan, particularly when the gas is impure.

Lowering the temperature of the gas causes a considerable portion of the water vapor to precipitate; also, a considerable portion of the tarry matter, and a certain quantity of the dust. The tar, water, and dust are led into receptacles provided for them. After the condensers come the scrubbers, which are used to remove the ammonia vapor from the gas. Water has a great absorptive power for ammonia, and the different types of scrubbers, seal, tower, or rotary, are based on this fact. Fig. 4 shows the more common form of tower scrubber. It consists of a cylinder *a* containing perforated partitions on which coke or shavings are placed loosely. The water or weak ammonia liquor enters through pipe *b* and works downwards while the gas enters through pipe *c* and travels upwards and out the pipe *d*. The water in trickling downwards absorbs ammonia and flows out at *e*.

The quantity of ammonia that any volume of water will dissolve, depends entirely upon its temperature, and directly upon the pressure to which it is exposed. The lower the temperature of the water, the larger the quantity of ammonia it will dissolve. Two operations take place in the scrubber, viz., the absorption of ammonia from the gas by the water, and the deposit of more of the tarry matter upon the substances contained in the scrubber. In some scrubbers, what are practically gratings of wood, are employed, and the tar is deposited upon them. In other scrubbers, coke and sawdust are employed; the tar is deposited upon the surface and in the pores of the coke, and on the sawdust. In all cases the wood grids or boards, and the coke or sawdust require renewing when saturated with tar.

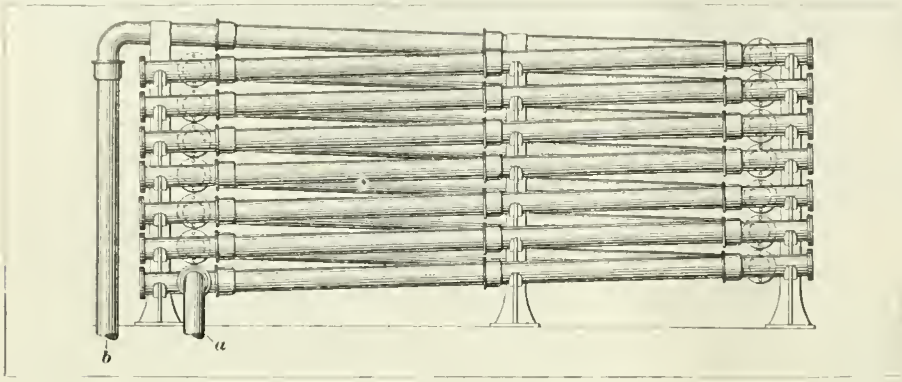

Fig. 2. Horizontal Pipe Condenser

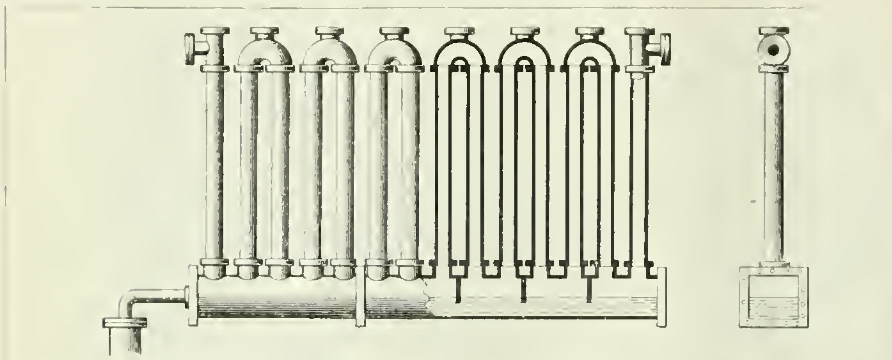

Fig. 3. Vertical Pipe Condenser

To remove the ammonia from the ammonical liquor obtained in the scrubber it is treated with sulphuric acid and converted into sulphate of ammonia. There are various ways for bringing about the reaction, the common method, however, is to pass ammonia gas upwards through a chamber or tower, where it is exposed to a fine spray of sulphuric acid. The resulting products are sulphate of ammonia, which falls to the bottom, water vapor, and sometimes other gases. The quantity of ammonia that water can hold in solution, varies inversely with its temperature; and consequently when it is required to drive off the ammonia from the water all that is required is to raise its temperature. At about 60° F., a gallon of water can dissolve nearly 6 pounds of gaseous ammonia; at 80° F. the possible quantity is reduced to about 4⅓ pounds; at 100° F. it is only 3⅓ pounds, and so on.

At Bargoed the ammoniacal liquor is drained from the scrubbers, and from the gas coolers, into a tank provided for them. It is pumped from the drainage tank into another tank above the ammonia still, into which it then passes. The ammoniacal-liquor still shown in Fig. 5 consists of a number of trays, over which the ammonia liquor passes from above downwards, the liquor forming a water seal in each tray. Steam enters at the bottom of the still, and passes up through the ammonia liquor on the trays, thus heating it, and causing the ammonia gas, and any sulphuretted hydrogen gas that remains, to evaporate. Some of the ammonia liquor which contains ammonium salts in solution, is passed through the lime still to the ammonia still. The ammonium salts break up in the presence of lime, when aided by heat, and the liquor is kept passing through the lime still, to ensure the thorough change of all ammonium salts. The ammonia passes into the still, and the remainder of the salts combine with the lime, to form other products, that need not be entered into here. The ammonia gas passes from the still into the saturator shown to the right of the lime still, where it is made to double through a solution of sulphuric acid. Sulphate of ammonia is formed, and falls into the receptacle provided for it below the saturator, from which it is driven out by the steam ejector shown, and delivered on to the draining table still further to the right, from whence it passes to the centrifugal drier, and thence to the bucket conveyer which delivers it to the sulphate storeroom. The carbonic acid and steam, and any sulphuretted hydrogen that has come over from the ammonia still, are carried off by the waste gas pipe, shown above the sulphuric acid, to condensers similar to those employed for cooling the gas as it comes from the coke ovens. The sulphuretted hydrogen is carried from the condensers to the sulphur ovens where it is burned with that coming from the gas purification plant.

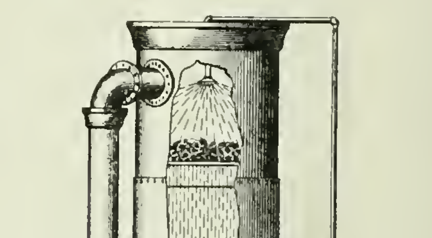

Fig. 4. Gas Scrubber

Perhaps one of the most interesting and economic portions of the Bargoed recovery plant, is that by which the sulphuretted hydrogen is removed from the gas, and made to furnish the sulphuric acid required to form the sulphate of ammonia. In this particular case, it happens that the amount of sulphur recovered from the sulphuretted hydrogen is just sufficient to make the required quantity of sulphuric acid. The reaction of sulphuretted hydrogen upon the hydrated oxide of iron is the basis for the ammonium sulphate process, but it appears to be uncertain whether the chemical reaction which takes place results in the formation of a sulphide of iron and free sulphur or merely a higher sulphide of iron. In any case, however, the sulphur is removed from the sulphuretted hydrogen, and is absorbed by the hydrated oxide of iron. The apparatus in which the action takes place consists of a number of boxes, in which are wooden grids, having the hydrated oxide of iron spread over them. The boxes are closed by iron lids with water seals; and the gas to be purified is forced through them. At Bargoed, two sets of iron oxide purifying boxes are employed, one set being used at a time. The purification can only be carried on until a certain proportion of sulphur has been taken up by the hydrated oxide; then the oxide has to be exposed to atmospheric air, with the result that the iron sulphide is converted into iron oxide, and the sulphur is deposited free amongst the oxide. The oxide is used over and over again, until a certain percentage, at Bargoed it is stated to be 60 per cent., of sulphur is deposited. The oxide and sulphur are then burnt together in a furnace specially arranged for the purpose, the sulphur being converted during the process into sulphurous acid, then sulphuric acid, after which it is deposited in the usual lead chambers. The purified iron oxide is used over again for further purification of the gas. From the oxide purifier, the gas passes on to a gas holder arranged to store 300,000 cubic feet, any tar or dust remaining in it being taken out by rotary washers, on the way.

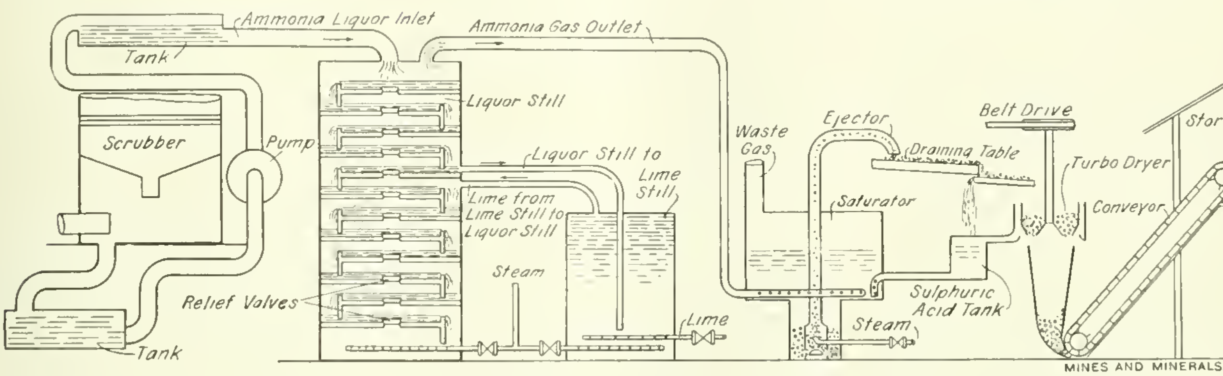

Fig. 5. Diagram Showing Sequence of Operations in Sulphate of Ammonia Plant

The Manufacture of Coke

Comparison of the Costs of Beehive and By-Product Ovens Economies by Saving By-Products

*By F. E. Lucas**

THE following is abstracted from a paper presented by F. E. Lucas, superintendent of the Coke Oven Department of the Dominion Iron and Steel Co., at the Cleveland, Ohio, 1912, meeting of the American Institute of Mining Engineers.

In selecting a by-product oven, the considerations should be simplicity in design; accessibility for inspection and repairs; such arrangement for combustion chambers and flues as will furnish a uniform temperature to all parts of the oven; and a by-product plant that will turn the gas out free from tar and with only traces of the ammonia.

The advantages of the by-product oven are its higher yield of coke over other ovens, and the economic factors which save the by-products and gas. The ammonium sulphate recovered finds a ready market, and the demand for this product as a fertilizer must always increase as the population of the country increases, and the farm and garden lands require more fertilization.

The tar finds a ready market, and this also is bound to increase. The value of tar by-products is rising as the demand increases. It would make a book in itself to describe the many products made from tar, all the way from pitch to drugs and perfumes. But we will consider the main products alone, viz., pitch, creosote oils, and light oils. For road making, roofing, and briqueting there will always be a market for the pitch. With the exhaustion of our timber lands in sight, we must either do something to conserve them or find a substitute. Railroad companies and mine owners will find it to their advantage to creosote all railroad ties and pit timbers as well as bridge and pier timbers. The lighter oils will be used in internal-combustion engines.

Probably the greatest waste the country has ever seen, or ever will see, has been going on for all the years we have been making coke in beehive ovens and burning the gas out in the air. Making coke in by-product ovens, and utilizing the gas by the most economical means, will revolutionize the production of power. It has already been done, most notably in Germany; and we must come to it sooner or later. The sooner we arrive at that point the better for the industries of the country, and the more we shall have done toward conserving our coal resources.

A modern by-product oven, run at a reasonable capacity, will give 50 per cent. or more of surplus gas from a coal of about 28 per cent. volatile content. The surplus gas is the gas over and above the quantity needed to keep the oven up to the required temperature. This surplus gas should run from 450 to 500 British thermal units per cubic foot. The quantity of surplus gas is approximately 5,000 cubic feet; hence, $5,000 \times 450 = 2,250,000$ British thermal units per ton of coal carbonized is available for the production of power = 93.750 British thermal units per hour. The builders of gas engines tell us we can get 1 horsepower on a heat consumption of 11,000 British thermal units. On that basis, we find 8.5 horsepower

*Sydney, N. S.

per hour from the surplus gas from 1 ton of coal.

The surplus gas can also be used for illuminating purposes. This is done at some plants in this country and at a great many in Germany. By installing two collecting mains on top of the ovens, the rich gas, given off during the earlier hours of the coking time, can be collected in one main, and the leaner gas in the second. By this means gas of 650 to 750 British thermal units, or from 16 to 19 candlepower, can be derived direct from the ovens without enriching. The lean gas is still of sufficiently high calorific value for heating the ovens. Gas from the by-product ovens can be piped for hundreds of miles if necessary. Again, the gas may be used for steam raising or for heating all manner of furnaces; or in conjunction with steel works, can be used in a steel furnace instead of producer gas. The recent investigations by Professor Bone have shown how by flameless combustion we can get 95 per cent. of efficiency out of the gas we burn.

In any of the above ways the gas can be used with great economy; but I believe the production of power from gas engines opens up the largest field.

In the year 1911 there was produced in America approximately 29,338,000 tons of coke, of which approximately 21,448,000 tons was produced in beehive ovens. I do not know the figures for the average volatile content of the coal that went to make this coke; but, assuming a fairly low volatile coal of say about 24 per cent., to produce 21,000,000 tons of coke in by-product ovens would take about 26,000,000 tons of such coal. Allowing the small amount of 4,000 cubic feet of surplus gas per ton of coal, and 15 pounds of ammonium sulphate, and 7 gallons of tar, and allowing the surplus gas to furnish only 400 British thermal units per cubic foot we find that we would have 26,000,000 × 4,000 = 104,000,000,000 cubic feet of gas per year; this at 400 British thermal units per cubic foot = 41,600,000,000,000 British thermal units; reduced to hours = 4,748,858,447 British thermal units, at 11,000 British thermal units per horsepower = 431,714 horsepower. Or allowing the value of 10 cents per 1,000 cubic feet, for the gas, we have the sum of $10,400,000. Of ammonium sulphate we have 174,107 gross tons at a value of approximately $60 per ton = $10,446,420. Of tar we have 182,000,000 gallons, worth at 2 cents per gallon, $3,640,000. Total value of gas, ammonia, and tar, $24,486,420.

I do not doubt that the coal from which the coke was made would have given better results than I have shown here, but even at these conservative figures we can see what a loss there has been.

The above amount is 7 per cent. on about $350,000,000, a sum which would build by-product ovens enough to carbonize 125,000,000 tons of coal yearly. Besides this loss, there has been the loss of the coal burned in the beehive oven. Allowing 64 per cent. as a fair yield for the beehive and 78 per cent. for the by-product ovens, there would be a loss exceeding 6,000,000 tons of coal. This at $1 per ton added to the other loss gives us a grand total of over $30,000,000 lost in one year. It seems to me that this is well worth "getting after." Much can be done if we approach this subject in the same manner, and give it the same study and attention as has been given in past years to questions pertaining to mining and metallurgy.

COMPARISONS BETWEEN BEEHIVE AND BY-PRODUCT OVENS

Beehive.—

Ordinary type, 12.5 feet in diameter.

Cost from $700 to $1,200 per oven.

Produces 4 net tons of coke in 48 hours, equal to 2 net tons in 24 hours.

Yield of coke from coal, 60 per cent.

By-products and surplus gas, none.

By-Product Ovens.—

Oven charge, 9 tons.

Coking time, 24 hours.

(Ovens may be larger or smaller than this, but 9 tons would probably be about the average charge for the modern type of oven.)

Coke produced on 70 per cent. yield, equals 6.3 tons of coke per oven in 24 hours.

By-Products.—

Ammonium sulphate, 22 pounds per net ton of coal = 31 pounds per net ton of coke. Value, 2.25 cents per pound above cost of manufacture = 70 cents per ton of coke made.

Tar, 8.5 gallons per ton of coal = 10.7 gallons per ton of coke, at 2 cents per gallon = 21 cents per ton of coke.

Surplus gas, 5,000 cubic feet per ton of coal = 7,143 cubic feet per ton of coke, at 10 cents per 1,000 cubic feet = 71 cents per ton of coke.

The total value of by-products as above is, ammonium sulphate, $.70; tar, $.21; gas, $.71. Total, $1.62 per ton of coke. Add to the above the difference between 60 per cent. yield in beehive ovens and 70 per cent. in by-product ovens on the same coal. Taking coal at $1.50 per ton: Coal per ton of coke produced in beehive oven, = $2.50; coal per ton of coke produced in by-product oven = $2.14. Balance in favor of by-product oven, $.36. So that the total saving in coal and by-products equals $1.62 plus $.36 = $1.98 per ton of coke made, = $12.47 per oven in 24 hours = $4,551.55 per oven per year. Or for by-products alone, without saving in coal, $3,723 per oven per year.

For a plant of 100 ovens, the saving equals $455,155 per year. Cost of 100-oven plant complete is approximately $1,000,000. A 100-oven plant of above capacity will produce 630 tons of coke per day = 229,950 tons per year, working on 24 hours coking time.

If benzol is recovered it will further add to the income from by-products.

Coal Mine Employes in the United States

According to statistics compiled by the United States Geological Survey, the total number of employes at coal mines in the United States in 1911, was 722,335, of whom 172,585 were employed in the anthracite regions of Pennsylvania, and 549,750 in the bituminous and lignite mines of the country.

The anthracite miners averaged 246 working days during the year, as against 211 days for the bituminous and lignite miners. The average annual production for each employe was 524 tons in the anthracite mines and 738 tons in the bituminous and lignite mines. The average daily production for each employe was 2.13 short tons in the anthracite mines and 3.5 short tons in the bituminous and lignite mines.

Dr. J. H. Haldane has designed a portable apparatus for the analysis of mine air and the determination of the percentage of firedamp in any return air. The apparatus is arranged so as to burn the firedamp in a closed tube by means of a platinum wire, heated by means of a bichromate cell, and then measure the decrease in the volume of the air. The determinations are quickly and simply made.

The Proposed Anthracite Mine Law

A Review and Criticism of the Act Proposed by the Subcommittee of the Commission to Revise and Codify the Law

By Rufus J. Foster, Mining Engineer

A CAREFUL study of the Act proposed by the subcommittee, and which at this writing is being considered by the full Commission, shows a proposed law containing many excellent features, as well as some omissions, and some provisions that are in part at least impracticable. These faults are, I am confident, not due to lack of ability or of conscientious work on the part of the members of the subcommittee. When the scope of the proposed law, and its length are considered, it is not surprising to find some points meriting adverse criticism.

In commending the general features of the proposed act, and in criticizing some of the details, the writer's opinions are based on the fact that the law should be, what its title calls for, "An Act to Provide for the Health and Safety of Persons Employed in and about the Anthracite Mines of the Commonwealth of Pennsylvania, and for the Protection and Preservation of the Property Connected Therewith." The man who advocates provisions in such a law which are for political purposes, or for purposes other than those stated specifically in the title of the act, no matter whether he is mine worker, mine official, or mine owner, is untrue to the best interests of both employes and employer.

Inasmuch as this review to be of greatest value must be as brief as is consistent with clearness, each point adversely criticized is treated in as few words, and with as little argument as possible.

In this connection, it is but fair to state, that, before writing this, the author had an opportunity to read the criticisms of the operators' committee. These criticisms and suggested improvements he found in practically every instance to be betterments tending to make the various sections either more specific in their requirements, or to modify the sections so as to make their enforcement practical wherever possible. Naturally, in many of the opinions here expressed, there will be a similarity with those expressed by that committee. However, as the gentlemen composing the operators' committee do not possess, or claim to possess, a monopoly of mining knowledge, or good mining sense, the writer claims the right to express his opinions, based on nearly 40 years of experience in and study of coal mining, regardless of whether such opinions agree or disagree with those of others.

In Section 1, Article 2, the definition of the term "mine" can be improved. As it stands in the report, the workings in each seam at a colliery working more than one seam would constitute a separate mine, as far as the provisions of the law are concerned, even if all the coal produced is hoisted from one shaft or slope.

In the same section the use of the unbonneted Davy lamp by fire bosses is prohibited. The section will be all right if the word unbonnetted is omitted and the requirement be limited to safety lamps approved by the Chief of the Department of Mines.

The definition of the term "mining engineer" needs considerable modification. As proposed, it describes a mine surveyor, and the experience requirement is unnecessarily long. A better definition, though incomplete, broad enough for the purpose of the act would be—the term mining engineer means any person who is competent to accurately survey and plot the inside workings of a mine and the surface topography, and to construct geological cross-sections, and who has had at least 3 years practical experience at such work. To require the young man who is not a graduate of a school of mines or similar institution to have had 10 years experience, and the graduate 5 years experience, will work a hardship on many bright, careful, and thoroughly competent young men. The fact that a man is a graduate of a school of mines is not by any means infallible proof that he is the more competent or careful man. His course in such school merely means that he can learn the practical work quicker and more easily, if he wants to, and experience has shown in many cases that he doesn't want to. This is by no means the fault of the school.

In Article 3, defining the duties of superintendents, there are a number of points in which improvements can be made.

In Section 6 the word "signals" is used when "signs" is meant. In Section 7, the locality at which copies of the General and Special Rules shall be posted is not specifically stated. The addition of the words "near the main entrance of the mine" will remedy this. In Section 8, the superintendent is limited to the use of the telephone or telegraph in notifying the State Mine Inspector of accidents. As occasions may arise where a special messenger will be quicker, he should have the right to use such means. In Section 13 a self-recording thermometer is required at every mine. This we think is unnecessary. The self-recording barometer provision is all right; but the thermometer will serve no practical purpose and will entail on the mine foreman an additional duty without any compensating benefit, but which will lessen the time at his disposal for more important duties to both his employer and subordinate employes.

As all working mine maps in the anthracite region are made on a scale of 100 feet per inch, there is no necessity of the provision of the old law being changed, particularly when mine maps on a scale of 100 feet per inch are more intelligible and easier read than those made on a smaller scale.

The provision requiring a duplicate print of the mine map in the mine foreman's office should be changed to read a "true copy" of the mine map, so that either a blueprint, a brown print or a tracing will meet the requirement.

The requirement that the superintendent shall under certain conditions extend the workings on the Inspector's map should be changed to require him to have this work done. It is not the duty of the superintendent to do the actual surveying and mapping.

In Article 6, which defines the duties of a mine foreman, Section 1, which provides for the employment of certificated foremen, should be so modified, that the one mine foreman may have charge of several detached openings at the same colliery, if each of those openings employing 20 or more men is under the supervision of a properly qualified assistant mine foreman.

That section requiring daily inspection of every working place during working hours by the foreman or an assistant foreman should be modified by the insertion of the words "whenever it is practicable to do so." The reason for this suggested modification is that something unusual, and possibly dangerous, may occur in one section of a mine requiring the attention of the foreman and all his assistants, and thereby prevent strict compliance with the law. Inasmuch as the fire boss *must* make a daily examination, and his report of his inspection must be examined and countersigned by the mine foreman, this should be considered a sufficient compliance with the law, when such unusual occurrences happen. The provision that the mine foreman shall instruct the miner as to when, where, and how to set timber, and in blasting the coal, should be eliminated. The law requires that the miner shall hold a certificate of competency secured by passing an examination to show "that he is competent to do the work of the miner without endangering his own life or the lives of others." If a man passes such an examination it must be assumed that he knows his business, and he should assume the full responsibility for his own acts. Naturally, if a mine foreman sees a miner doing any work improperly, it is his duty to correct him, but he cannot, in addition to his numerous other duties act as an instructor to the miners, and in many cases his doing so would be resented.

The section providing for biweekly measurements of the ventilating currents will be more easily understood if the words "inside breast" and "outside breast" are more specifically denoted as "inside working breast" and "outside working breast."

In Section 6, of Article 6, which directs that the mine foreman shall see that all stoppings between gangways and airways are properly built, reference is made to Article 15. This is a typographical error and should read Article 14. The section providing that the mine foreman or a competent other person shall each day examine the shafts, slopes, traveling ways, signal apparatus, etc., should be modified to read each *working* day. As it now stands, it will require such examinations every day of the year regardless of whether the mine is in operation or not.

Sections 12 and 13, of Article 6, require the mine foreman and assistant foremen to make a daily report, in ink, stating the general condition of the working places visited by them. As in all mines where fire bosses are employed, this duty is performed by them as directed by law, there is no necessity for the work being duplicated and additional duties placed on the foremen, that will take time that should be devoted to more important details. These sections should be modified so as to apply only to mines where fire bosses are not employed. Sections 15 and 16 use the word signal for sign. It should be modified to read "signal, or sign," thus making its meaning clearer.

Section 17 of the same article should be modified to permit the use of lime or cement mortar in building stoppings, as in many instances lime mortar is equally as good as cement mortar, and while the kind of stoppings required by this section are suitable in the Wyoming and Lackawanna regions, they are not always practicable in the thick and heavy pitching seams of the Hazleton and Schuylkill regions. Therefore the section should be modified so as to require such stoppings where the use of the designated material is practicable.

Section 18, of Article 6, requires that any accumulation of explosive or noxious gas in the worked-out or abandoned section of a mine shall be removed as soon as possible after its discovery, if practicable. It then orders that no person shall be allowed in that portion of the mine until such gases are removed or rendered harmless. This should be modified to read "No person excepting those employed in the removal of the gas shall be allowed, etc., etc."

Section 26, which provides for the withdrawal of all the men in case of an accident to the fan whereby ventilation is seriously interrupted, should apply to the mine or portion of the mine, instead of to the whole mine. In some cases the ventilation of the entire mine is not furnished by one fan, and many cases arise in which the interference with the air-current in one section of the mine does not affect the other section in any way whatever. Under such circumstances it is unjust to both men and officials to require the men in the unaffected sections to quit work.

Section 27 of the same article requires that the mine foreman and assistant mine foreman shall measure the bits of the miners' drills to see that they cut a hole at least $\frac{1}{8}$ of an inch larger than the diameter of the cartridge. Article 24, Section 3, under the title "Duties of the Miner," provides that no miner shall force a tight cartridge into any hole. To comply with this rule it is incumbent on the miner to see that his drill is of the right size, and therefore the section in Article 6 is unnecessary and unjustly places responsibility on the mine foreman and his assistants that should be borne by the miner.

In Section 30, the words "or any other" occur in such a way that they seem confusing and unnecessary. This is probably a clerical or typographical error. In Article 7 defining the duties of the fire boss there are several instances in which the intent of the law can be made clearer by the use of additional words.

As a criticism, I claim that the fire boss, while required to use a safety lamp for testing purposes, should not be prohibited from having an approved storage-battery electric light to use in lighting him through sections of the mine where examinations are not necessary, and also to enable him to more closely observe the character of the roof and sides as regards danger from falls.

Section 4, of this article, should not only require the fire boss to report to the mine foreman or his assistant the dangerous condition of any place in which men are working, but he should be required to instruct the men to make the place safe, or if necessary send them out until the place is made safe.

In general, Article 9 regulating the selection of State Mine Inspectors, is one that I heartily approve, though some minor changes will improve it. Its adoption will effectually remove the selection of Inspectors from politics and will ensure the selection of capable men of a high technical and moral standard. I have consistently advocated this system for years, so will not repeat arguments in its favor. I am of the opinion, however, that that portion of Section 3, requiring the candidates to have had at least 6 months experience as a fire boss, should be eliminated. Many miners, who never served a day as a fire boss, are as conversant with, and have had as much experience in gas, as most fire bosses, and they should not be discriminated against.

In Article 14, Section 4, the provision for walls separating the inlet and return airways, where such walls are required, should be modified the same as suggested for Section 17 of Article 6, and for the same reasons.

In Section 7 of the same article, an improvement can be made by a more definite statement as to what constitutes a "main door," and it should also be modified to permit of a self-acting door without an attendant, when such automatic or self-acting door is approved by the Inspector of the district. There are a number of such doors in successful use in mines in the anthracite regions as well as in many bituminous fields.

Section 1, of Article 15, should be modified so that, in addition to signaling apparatus, the tops and bottoms of slopes should be connected with telephones or speaking tubes.

The section providing for safety gates controlled by the cages, at the heads of shafts should be modified so as to permit gates raised or lowered by other means, at shafts where the coal is not landed at the shaft head, as is the case at many mines. Safety gates should be required, but their control should be made practicable.

In the case of the coupling chain attached to the wire rope at hoisting shafts, either iron or steel chain should be allowed, as it is a well-known fact that a good iron chain is, for the purpose intended, better than a steel chain.

The section providing for the examination of ropes used for hoisting should be so modified as to place the responsibility for the examination of ropes on inside slopes, planes, and shafts, on the mine foreman, and not on the outside foreman. The latter should, of course, be responsible for the ropes under his charge,

Section 3, of Article 17, is all right as far as shafts are concerned, but in many cases it is impracticable to construct a passageway such as described from one side of the bottom of a slope to the other. Therefore the word slope should be eliminated from the section.

The requirement of fireproofing the sides, roof, and bottom of mine openings for a distance of 50 feet or more from the surface, should be modified so as to apply to permanent openings and not to every outlet to the surface, as the latter are often only temporary openings, and should be exempted in the same way as are cave-ins.

Section 8, of Article 17, which provides that the top of each shaft and also of each slope or any intermediate lift thereof shall be securely fenced off, is impracticable as far as slopes are concerned, and the requirement as to slopes should be eliminated.

In that portion of the proposed law regulating the use of electricity in mines, there are a number of instances in which an opinion as to what is safe and practical and what is unsafe or impractical, should be obtained from an able and experienced electrical engineer, or better still a committee consisting of an able electrical engineer, a certified and thoroughly competent mine foreman, and one of the State Mine Inspectors.

Article 22, of the proposed law, is not only unnecessary, but opens a way for frequent and annoying interferences with the mine foreman in his duty to his employer, and to the state as set forth in the mine law. In the first place, the state requires a mine foreman to show through a rigid examination that he knows very much more regarding the safe conduct of mine workings than is required of the miner. Therefore, under no circumstances should he be placed in a position subordinate to the miner. In the second place, the law provides for more thorough inspections by fire bosses, mine foremen, and State Inspectors, than a committee of two miners can make. If such inspections are not made, or if dangerous or unhealthy conditions are not remedied, any individual miner or any group of miners can lodge a complaint with the State Inspector, and if the complaint is well grounded, redress or punishment for the violation of the law will follow.

In Article 24, defining the duties of the miner, Rule 24, of Article 12, of the present mine law is omitted, and this omission is a serious mistake. This is the rule requiring the miner to report to the foreman any dangerous condition he may notice in the mine. This omission was probably an oversight on the part of the subcommittee. Another rule should be added prohibiting the miner leaving his working place in an unsafe condition without reporting it to the foreman or assistant foreman. Neither should he be permitted to leave his laborer in the working place when he leaves for the day. Neither should laborers be allowed to work in said place unless the miner is present, and neither miners or laborers should be allowed to unnecessarily be on haulage roads or be allowed to enter idle or abandoned workings without receiving permission from the foreman, the assistant foreman, or the fire boss.

Article 26, of the proposed law, which provides for Rescue and First-Aid Corps, contains some details which are inconsistent with the practice originated by the anthracite companies, and which has been developed to such a high degree of efficiency that it has won world-wide commendation. There are also some requirements, particularly in the number of helmets, which in the case of the establishment of a central station are in excess of the number that will ever be required.

Article 27, providing for ambulances and stretchers, is not exactly what it should be. The provision that when 90 per cent. of the employes live within a radius of one-half mile from the principal entrance of the mine, an ambulance is not to be required, should be stricken out. There should be an ambulance ready for service at each mine.

Sections 3 and 6, of Article 30, are so worded that they prohibit the use of actylene mine lamps. This is a mistake that should be remedied. Section 1, of Article 33, providing for fireproof building in the mine, should be modified to permit the use of any incombustible material approved by the district mine inspector.

In the interest of safety the General Rules proposed can be improved or made more practical as follows:

By an addition to Rule 6 prohibiting the use of any explosive, detonator, cap, squib, or fuse, in the mine, except on the written approval of the superintendent.

By the insertion of a rule prohibiting the use of mixed explosives.

A Union Cut in Wages

The American Fuel Co. and the Rocky Mountain Fuel Co., operating in the northern Colorado coal field, are cutting prices, the former being a union and the latter a non-union mine. The American company's employes agree to cut their wages in half if the national organization will pay them strike benefits to make up the loss. It is stated that the national organization will do this to prevent monopoly of the coal business by the Rocky Mountain Fuel Co. It looks as if the union was trying to create a monopoly of the labor business and coal business as well.

Stray Electric Currents

Three Instances Where Shots in Mines Were Prematurely Exploded by Electric Currents

*By C. J. Norwood**

I HAVE NO formal paper to present, nor even a formal statement to make. But some interesting information has come to me that may be of interest to you gentlemen.

I have been interested, as a mine inspector for the state, in the effort to get an explosive to replace black powder in our coal mines. If we are to get a safer powder, it must do as good work as black powder, it must be as readily handled, and it must cost practically no more. Some months ago a new powder, a loose, granular powder, came to my attention. It may be handled like black powder; that is, made into cartridges and fired by a fuse, a squib, or by electricity. After having made some investigations, I witnessed some tests intended to determine the question of safety in handling it, including a friction test much more severe than may be expected in the charging of a shot hole. I then witnessed a number of tests made with it in shooting coal in one of the mines of the St. Bernard Mining Co., at Earlington. Standing but a short distance away from the face, I watched the shots as they broke the coal, a thing that would have been impossible in the case of black powder, and noted the very short and fleeting flame made by each shot, the excellent coal produced, and the practically clear atmosphere left after shooting. The ultimate cost per pound figured out to be about the same as black powder. I was favorably impressed with all I had learned and had seen, and felt that a thorough, practical test, such as would be given by the exclusive use of the powder in a mine for 30 days or more, would be justified. The St. Bernard Mining Co. undertook such a test, setting aside two of its mines, representing two different seams (No. 9 and No. 11), for the purpose. In each mine the coal is undercut by "air puncher" machines, and the holes are drilled by rotary drills making 1,600 revolutions per minute, the usual depth of a hole being $4\frac{1}{2}$ feet. Firing is done with squibs. The main haulage is by electric motor.

Frank D. Rash, vice-president of the company, advised that the work proceeded satisfactorily until on August 9 two premature shots occurred in one of the mines in the No. 11 seam, in different rooms, and about 30 minutes apart. In the first room several holes had been drilled. The shooter had loaded the lower left rib hole, using a copper needle, had tamped it, and withdrawn the needle. Another hole was then loaded with the same needle. After an interval of a few minutes the needle was inserted into the first hole, to clear it for firing with a squib, when the shot went off while the shooter was holding the needle, heaving the coal down in good fashion. The shooter was at the side of the hole, within about 18 inches of the face, but was not hurt; he simply felt the jar. Six other men were in the room, near the face, but no one was hurt. In the second room the top hole on the left rib had been loaded, a copper needle being used. The squib failed to fire the powder and the needle was inserted to clear the hole. When the needle reached the powder, the latter went off, heaving out the coal. The shooter, who was inserting the needle, had his arm jarred, but was not injured. The men thought they could account for the premature shots in ordinary ways, and went on with their work, but on August 28 a third premature shot occurred, this time in a room neck. In this case the shooter held the cartridge (about 12 inches long) in his left hand, inserted his copper needle into it about 4 to 6 inches, then placed it in the lower right rib hole and pushed it until near the bottom of the hole, when it exploded, throwing the coal out about 3 feet. The shooter's hand was badly lacerated, and he was severely but not dangerously burned. The driller, about 10 feet away, was not hurt. Upon the occurrence of this third premature shot, Mr. Rash at once stopped all use of the powder and put the case up to the manufacturers.

You gentlemen will observe that conditions were uniquely favorable for an intelligent investigation of the causes of the premature explosions, as the men still lived, all but one uninjured, to tell precisely what had happened. Had black powder been used not a man would have lived to tell the tale, and the usual explanation would have been accepted. I wish to bring to your attention certain important facts developed in the investigation undertaken by the manufacturers to account for the premature explosions of their powder. The facts developed are of interest without regard to the particular powder. Therefore, I will not undertake to tell of all the tests to which the powder was submitted while the manufacturers were seeking an explanation of the explosions. It is sufficient to say that they satisfied themselves that the explosions were not due to any chemical reaction in the powder, or to a spark caused by "sulphur," or to any fire in the hole, or to friction, and so on. Finally, it was thought that in some way electricity might have exploded the powder, and Prof. H. B. Dates, of the Case School of Applied Science, Cleveland, Ohio, was called upon to assist in the investigation. Professor Dates visited the mine and, with the proper instruments, made tests to ascertain whether there were any stray currents or other electrical conditions in the places where the premature explosions occurred that might have been concerned in the latter. I have a copy of his report. He found stray electric currents, in the coal, and in at least one instance of sufficient intensity, under the proper combination of conditions, to have ignited the powder, or even black powder.

In order that you may be able to understand the readings reported to him, I will say that the coal, which is 6 to 7 feet thick, has two thin dirt bands, one about 18 or 20 inches below the roof and one about 2 feet above the floor. It also carries some thin, irregularly placed, horizontal "sulphur" bands, usually only a few inches in length. You will recall that the haulage is electric. Also that a copper needle was always in evidence; that the first and second explosions occurred while such a needle was being inserted into the holes, and that in the third case the cartridge was on a copper needle, part of the needle of course coming in contact with the coal. The rails are used as the return for the current. The compressed-air pipe, to which is attached the wire-wrapped hose for the punchers and drills, was reported by Professor Dates to be bonded to the rails. Tests were made in several rooms, including those in which the premature shots occurred, also at the face of one of the entries, and were conducted on two days. Readings of potential were obtained many times on both days between points on the coal and the floor, and between

*Remarks made before the Kentucky Mining Institute, December 9, 1912, by C. J. Norwood, Chief Inspector of Mines.

the air pipe and the coal. Also, in several instances readings were obtained between points in shot holes and the floor. In all cases cited here a high resistance instrument was used. Points on the floor and air pipe were positive to those on the coal.

Maximum potential readings obtained in rooms 6 and 7 (faces about 200 feet in from the entry) on entry East 18 were as follows:

	Volts
Between floor and upper dirt band	.75
Between floor and lower dirt band	.50
Between floor and sulphur band	1.20
Between floor and point in shot hole	.50

When the tests were made these rooms were "beyond the point to which the locomotive runs and outside the direct path to the power house, except in so far as the rails in entry E 18 influence the path of the return currents."

In room 13 on entry W 18 (face about 10 feet in from entry), "potential readings could be obtained at practically all points on the face of the coal and on the side walls of the room." The following are "typical of those obtained on both days, and repeated many times on both days," between the air pipe and points on the coal seam:

	Volts
Approximately 2 inches below roof	.5
Approximately 2 inches above upper dirt band	2.0
On upper dirt band	2.0
Approximately 2 inches below upper dirt band	1.0
Midway between upper and lower dirt bands	1.8
Approximately 2 inches above lower dirt band	2.0
On lower dirt band	2.0
Approximately 2 inches below lower dirt band	.8
Approximately 2 inches above floor	1.3
On floor at foot of coal face	1.0

Potential readings of similar value were also obtained in room 14 of entry W 18, and at the face of the entry; also between points near the rear of shot holes and the floor at those places.

Professor Dates observes: "Rooms 13 and 14 are in a more or less direct line from the end of the locomotive run to the power house, and the rails in W 18 are so situated as to aid the currents to take a return path through this part of the mine."

He also says: "At times very high readings were observed. The conditions producing these high readings were temporary and evidently of short duration, as evidenced by the fact that such values were obtained only over very limited periods of time, often not exceeding a few seconds." For room 13, W 18, he reports that "a reading of 25 volts was observed between air pipe and lower dirt seam; several of 12 volts and one of 10 volts between floor and lower dirt seam." The variation in the values of potential differences from time to time between the floor and coal are "according to the position of the locomotive and the operation of other apparatus."

Here we have demonstration of the fact that a difference as high as 25 volts may occur. Was that sufficient to fire the powder? And if such voltage is sufficient to fire this powder, will it fire black powder also?

This question was at once taken up by Mr. W. C. Waddell, electrical engineer, with the cooperation of Professor Dates, in the latter's laboratory, and some interesting results were obtained. It was demonstrated that it was impossible to fire either the powder under investigation or black powder by an electric spark with so low as 10 volts unless the current exceeded .25 ampere; but that "with a low amperage and a fairly high voltage, 15 to 30 volts, the 'spark' becomes an 'arc,' by means of which either the powder in question or black powder may easily be fired." It was concluded, after considering all the results obtained in the experiments, with different combinations of voltage and amperage, that "a fair average" of the current required to fire the powder under investigation would be 25 volts and .30 ampere; and to fire black powder it would be 25 volts and .35 ampere. Mr. Waddell "found that with a high resistance in the current there must have been at least .30 ampere present to get a reading of 25 volts," a reading that was obtained in the No. 11 mine.

As the results of this investigation were new to me, I have brought the matter to your attention thinking that it may be new to you. I understand that the Pittsburg Testing Station is interested in the matter also. It seems to me well worth your consideration, especially those of you who have electricity in your mines. We know that men have been killed while loading or needling out shot holes; we know about "premature" shots with black powder, but as a rule we have not known just what caused them—the man has not been here to give information. We have made the same guesses for "electrified" mines as have served for those not using electricity. But it appears that in mines that are "electrified" stray currents may occur in the coal seam, and that it is possible for such a current to fire black powder. With the rapid growth in the use of electricity in mines there appears to be an increase of danger that some of us have not thought of; we should consider this, and be on the lookout for stray currents in the coal that may be sufficient to explode black powder.

Obituary

PROF. R. SAMPSON

Prof. R. Sampson, of the School of Mines at Washington State College, was run down by a passenger train in December, while crossing the Northern Pacific tracks near the College campus, at Pullman, Wash. Professor Sampson was a graduate of Massachusetts Institute of Technology and specialized in ore dressing. He was highly respected and liked by all who knew him, and by his death the Insitution loses a valuable instructor.

DR. FRANK L. MCKEE

Dr. Frank L. McKee died in Wilkes-Barre, January 13, after being operated on for appendicitis. Doctor McKee, once Colonel of the 9th Regiment, N. G. P., was a resident of Plymouth. He received a gold medal for his work at the Johnstown flood; he saw service in the Spanish-American war; and in late years has been active in promoting first-aid work among the miners of the Parrish, Lehigh and Wilkes-Barre, and the Susquehanna coal companies. He had many friends among company officials and coal miners.

MARTIN MCLAUGHLIN

Martin McLaughlin, State Mine Inspector for the Sixteenth Anthracite District of Pennsylvania, died at his home in Shamokin, Pa., on December 22, 1912, aged 55 years. Mr. McLaughlin was born and raised in the anthracite region and received his early education in the public schools of Ashland. He worked in various capacities around the mines, from slate picker to miner, and by study, integrity, and natural intelligence advanced successively to the positions of fire boss, assistant foreman, foreman, and State Mine Inspector. In the latter position he served the state most efficiently for almost 7 years.

MAJOR EMIL C. WAGNER

Major Emil C. Wagner, Assistant Superintendent of the Girard Estate, in charge of the lands in Schuylkill and Columbia counties of Pa., died at his residence in Girardville, Pa., on December 16, 1912, in the 67th year of his age. Major Wagner was born in Geissen, Germany, on May 29, 1846, and came to America with his parents who located in Philadelphia in 1849. In 1869 he became Assistant Superintendent of the Girard Estate. In this position Major Wagner was identified in a prominent manner with the coal-mining interests of the Mahanoy region. He was, respectively, a captain and a major of the Eighth Regiment, National Guard of Pa., and was a director of the State Hospital at Fountain Springs near Ashland. Major Wagner was twice married. His first wife was Miss Margaret H. Kerr, of Philadelphia, to whom two children were born, Charles W. Wagner, of Pottsville, Division Engineer for the Hudson Coal Co., and Christina, wife of John S. Barnhart, of Girardville. His second wife and widow was Miss Laura E. Ulmer, of Pottsville. Major Wagner was a man of lovable character and most genial disposition.

Personals

W. C. Rogers has been appointed manager of the Reliance Coal and Coke Co., with headquarters at Third and Walnut Streets, Cincinnati, Ohio.

William J. Jones, ex-mine inspector of New York state, has been appointed Inspector of Explosives in the Department of State Fire Marshal, with headquarters at Akron, N. Y.

Charles T. Main, engineer, 201 Devonshire Street, Boston, has been awarded the contract for the engineering work in connection with the development of the Big Falls of the Missouri River, near Great Falls, Mont., and Thompson Falls, on Clark's Fork, of the Columbia River.

H. C. Hoover has been elected a member of the board of trustees of Leland Stanford University.

Arthur J. Hoskin, mining engineer, of Denver, Colo., is at present in Dahlonega, Ga., where he is going to start an operation to treat Georgia gold ores, after which he will return to Denver.

Mr. Davidson, Secretary Alabama Operators Association, has prepared and had printed "Safety Pamphlet" No. 2 for the use of the association.

Dr. Henry M. Payne, formerly mining and metallurgical expert for Stephen T. Williams and staff, incorporated, 50 Church Street, New York City, is now chief of staff. Stephen T. Williams, the pioneer efficiency engineer, established this business in 1879.

J. P. Hutchins was recently engaged in examination work on mines for the Cabinet of the Czar of Russia, in consultation with the engineers of the cabinet.

E. J. Haddock has resigned his position with the Montgomery Coal Washing and Mfg. Co., Inc., Birmingham, Ala., to accept the position of chief engineer of the I. L. Smith Co. and Smith & Post Co., Milwaukee, Wis.

R. B. Brinsmade recently returned to his office in Puebla City, Mex., after a protracted visit in the northern part of Puebla State on mine-examination work.

P. J. Friel, of Buck Mountain, near Mahanoy City, Pa., has been appointed State Mine Inspector for the Sixteenth Anthracite District of Pennsylvania, vice Martin McLaughlin, deceased. Mr. Friel previous to his appointment was in charge of the Lehigh Valley Coal Co.'s operations at Buck Mountain. He will serve the unexpired 3 years of the late Inspector McLaughlin's term.

The Governor of Illinois has appointed as members of the Illinois Mine Rescue Station Commission, Thomas Moses, general superintendent of the Bunsen Coal Co., as one of the operators, in place of the late W. W. Taylor, and J. M. Zimmerman, representing the United Mine Workers of America, in place of Charles Krallman, recently resigned.

The Governor of Illinois has appointed the Mining Investigation Commission consisting of the following members: H. H. Stoek, J. A. Holmes, J. E. Williams, Richard Newsam, G. W. Traer, Thos. Jeremiah, Benj. Williams, Geo. McArtor, Wm. Hall. This Commission was authorized by the last session of the Illinois legislature and was given power and authority to investigate methods and conditions of mining coal in the state of Illinois with special reference to the safety of human lives and property, and the conservation of the coal deposits.

Robert Morris, of Greensburg, Pa., for many years chief engineer of the Keystone Coal and Coke Co., in charge of mines in central and western Pennsylvania, is a candidate for appointment as a mining engineer member of the Bituminous Mine Inspectors Examining Board. He is especially fitted for the appointment because of his ability and wide experience as to the needs and requirements for safety in the mines of the entire district.

I. A. Boucher, general manager of the Logan Coal Co., that operates a number of mines in the central Pennsylvania district, is spending considerable time in West Virginia in the organization of the Decota Coal Co., to operate mines on the Coal and Coke Railroad. He is associated in this new enterprise with William J. Faux, of Philadelphia, and others identified with the Logan Coal Co.

J. W. Preston, of Johnstown, operating mines at Hollsopple, Somerset County, has organized the Lydalia Coal Co., to operate the Anspach mine on the Listonburg Branch of the B. & O. Railroad. This mine was formerly operated by the Anspach Coal Co. It consists of a lease of about 500 acres of the C′ coal. The mine is equipped with electricity for haulage and for the purpose of mining coal, and is capable of an output of 500 tons per day.

Jacob Swives, one of the pioneer coal operators of Philipsburg, Pa., and Charles E. Sharpless, of Cresson, have organized the Benscreek Coal Mining Co., and have taken a lease of 300 acres from the Cambria Mining and Mfg. Co., on the Benscreek Branch of the Pennsylvania Railroad. The coal bed leased is what is known as the "B" Rider, found at an interval of about 15 feet above the "B" or Miller seam, and runs from 3 to 5 feet in thickness. As far as known, this is the only locality in the county where this seam is found of commercial thickness and quality.

Hon. Timothy L. Woodruff, of New York, president of the Pneumelectric Machine Co., with John L. Wagner, vice-president of the same concern, visited the mines of the Berwind-White Coal Mining Co., at Windber, in December, for the purpose of inspecting the mines and seeing in operation some of the 180 or more Pneumelectric mining machines in use by the Berwind-White Co. in the Windber district.

The following men have received the degree of Mining Engineer from the Massachusetts Institute of Technology: Reuben Bermudez, Jr., Honduras, C. A.; John Leighton Bray, Boston, Mass.; Robert Sayre Cox, Terre Haute, Ind.; Frank Henry Curtis, East Weymouth, Mass.; Harold Beukman Davis, Lancaster, N. Y.; Leslie Burton Duke, Wellesley Hills, Mass.; Christopher Fallon, Wayne, Pa.; Harold Robert Leslie Fox, Jamaica, W. I.; Leslie Hall Goodwin, Allston, Mass.; Edmund Lewis Homan, Marblehead, Mass.; James Henry Morley, C. E., Swarthmore, Pa.; Stalker Elijah Reed, Hudson, N. H.; Wellesley Joseph Seligman, Brookline, Mass.; Harold Harris Sharp, A. B., Melrose, Mass.; Frank Elijah Starr, Fitchburg, Mass.; Walter Howell Triplett, B. S., Bangor, Me.; Paul McIntosh Tyler, Hyde Park, Mass.; Ralph Edward Vining, South Weymouth, Mass.; Robert Everett Whipple, Beverly, Mass.; Oscar Karl Wiessner, Lawrence, Mass.; Clarence Richardson Woodward, Wellesley Hills, Mass.

Difficulties in Mine Surveying

Examples Showing How Difficult Emergencies Have Been Met by a Resourceful Surveyor

By H. G. Henderson

THE work of the mine surveyor is not at all times plain sailing, and the practical value of a skilled man is demonstrated by the way in which he can overcome unexpected and awkward difficulties. For this reason it may be stated that technical training is worth about 80 per cent. of a man's value as a surveyor, the other 20 per cent. being made up by his originality and resource in overcoming such difficulties. To illustrate what is meant by the above remark, it will be interesting to describe some special difficulties which have been met with in survey work, and the way they were overcome.

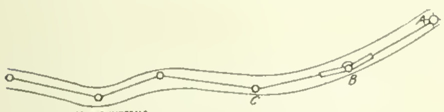

FIG. 1

There are occasions when a surveyor is called upon to make surveys at a moment's notice; and it is quite likely that when such emergencies arise no suitable instruments can be obtained without considerable delay; in such cases a method of approximate survey, which has been tested in practice with satisfactory results, may be of interest.

The surveyor on a large group of mines in the Western States had ridden over to one of the smaller mines from his office for the purpose of inspection only, and found himself at this mine, 2 or 3 days' ride from his office where he had left his instruments, and faced with a difficulty of an urgent nature. He found that owing to the bad air in the adit drive, it would be necessary to at once sink an air-shaft from the surface to the back of the end. As he had no time to send for his instruments he made a rough survey with a 2-foot rule and tape in the following manner.

The level had been driven with five bends or turns, as shown in Fig. 1, and at each turn the surveyor drove a 6-inch nail into the center of the tram sleepers, and also placed a peg at the mouth of the adit. He then took his 2-foot rule which was jointed at the middle, and marked at the bend in degrees, and placed in it three pins as sights, one at each end and one in the center. He then proceeded to point B at the angle of the first bend from the mouth of the adit, and from the head of the nail at that point he sighted to A in one direction, and then on to a light held behind a nail at C. In this way he was able to read the angle CBA with a considerable degree of accuracy, and to proceed in the same way at successive stations to the end. When this was done he came out of the pit to the peg at A and started in a like manner to survey on the ground up the hill, or rather he repeated his angles in the same direction as the adit, taking care to allow for the slope of the ground. In this way he reproduced on the surface the position of the end underneath, and the shaft was sunk at this point, and "holed" to a few feet from the end.

It often happens in preparing a surface survey of a mining property, that while it is possible to take offsets of one side of a stream or road, it is impossible to get anything like an accurate measurement at the other side. Such cases of difficulty occur when a bank is overgrown or steep, preventing the assistant from getting accurately into place. For this reason it may be of interest to give a typical instance where on a mining property there occurred a stream which it was important to take in on the plan. The survey was conducted from the road bordering one boundary of the property under survey, and the surveyor, who was pressed for time, found himself on one side of the stream and unable to approach it except in one or two places on account of the marshy ground. Fig 3 shows diagrammatically the disposition of the ground at this point. It was impossible, owing to the marsh, to approach within 15 or 20 feet from the road. It was, however, noticed that by making a detour it was possible to get into a field on the other side of the stream without difficulty, and the following method was adopted both as a means of saving time, and fixing accurately the course of the stream. From the stations A and B at the ends of the line 21 of the survey conducted along the road, observations were taken to a pole fixed at D. In a similar manner observations were taken at the ends of line 22 on the road survey to a second pole fixed at E, and in this way the positions of points D and E were determined on the plan. Crossing over the stream to the line DE thus found, the surveyor was able to take his offsets of the stream in the usual way, as shown by the dotted lines on the sketch. This method, besides overcoming the frequently occurring difficulty of inaccessibility, is interesting as demonstrating one of the means of saving time which are so important to the practical surveyor.

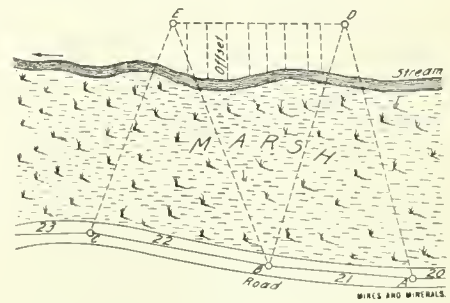

FIG. 3

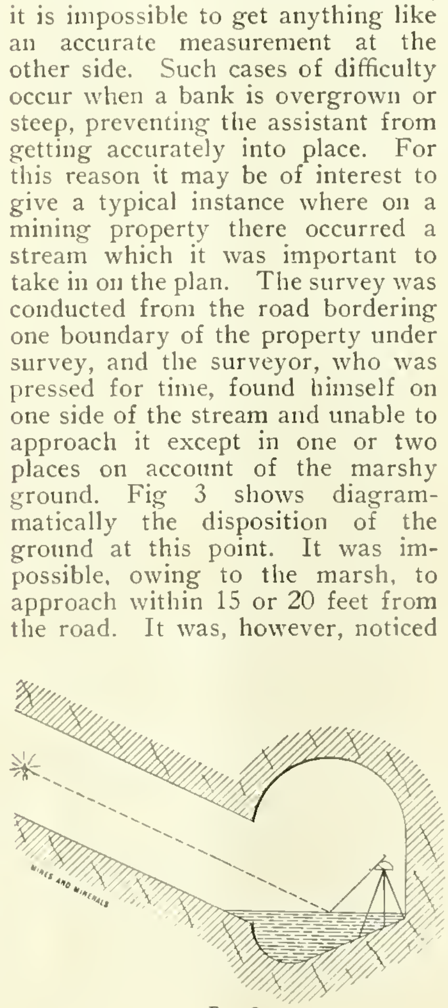

FIG. 2

In underground survey work the difficulties of narrow and tortuous passages are sometimes further increased by the presence of water in the workings. On one occasion the surveyor, in the course of his underground work, found himself very nearly up to his waist in water in the bottom level of the mine, and owing to the increasing depth of the water near the shaft he found it impossible to approach a position which he wished to obtain. The state of affairs can be understood by reference to Fig 2. It was important to take the angle of the inclination of the shaft, but owing to the presence of water, the surveyor was unable to bring his instrument into a position suitable for taking this inclination. As, however, "necessity is the mother of invention," the surveyor utilized the surface of the water as a reflecting mirror. He sent a miner some distance up the shaft with a candle as indicated in the sketch, and the light from this candle was, of course, reflected from the surface of the water enabling the surveyor by shifting the position of his instrument, to read with the utmost accuracy the angle by the reflection of the ray of light from the surface of the water when this was still. This angle of reflection was, of course, equal to the angle of inclination or "dip" of the shaft, and in this way the surveyor obtained his reading without further trouble.

The surveyor in metalliferous mines often has great difficulty in getting from a higher to a lower level, owing to the narrow and twisted rises and winzes between the two levels. He is very fortunate if he succeeds in getting a straight sight fore and back with his theodolite. In numerous cases where, for such reasons, it is not possible to see one or both ways, the following method has been adopted.

In Fig. 4, it will be observed that while it is possible to take observations from the theodolite at the point *A* to the stand at the point *B*, it is impossible, owing to the hanging wall, to take a back sight from *B* to *A*, inasmuch as the head of the stand at *B* although set as low as possible is not visible from the lower level. In the method adopted in such an instance, a plumb-line was hung from the stand *B* and a light held behind it. A piece of greased paper was interposed between the light and the plumb-line, because the diffusion of the light obtained caused the plumb-line to show up more plainly against the illuminated surface of the greased paper. The foresight was observed from the point *A* and the distance measured to the plumb-line. The height of the stand above the point on the plumb-line to which the sight was taken was also measured. As the surveyor knew that he could not take a backsight of *A* from the point above, he, before unclamping his theodolite, had a candle fixed by means of a lump of clay to the foot-wall near the ladders, and in the line of sight at the point *D*. He then proceeded to the stand *B*, and took a backsight to the candle at *D*. This was, of course, equivalent to sighting to the last station *A* owing to the fact that the candle had been placed in line with the telescope when this was at *A*. This method is of advantage in tortuous passages as it gives great flexibility of operation. Instead of using greased paper to show up the plumb-line it is better to use ordinary tracing paper, as it is not so liable to catch fire from the candle as is the former.

The above examples may be taken as sufficiently indicative of the troubles to be met with to demonstrate that originality is occasionally necessary, and therefore the surveyor should seek to cultivate it.

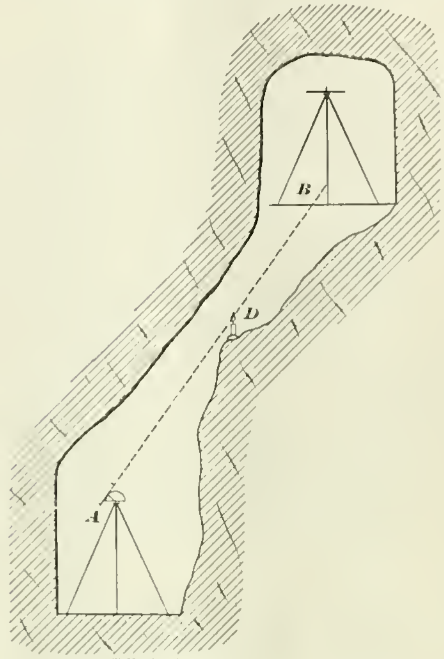

Fig. 4

Book Review

Explosives, a synoptic and critical treatment of the literature of the subject as gathered from various sources by Dr. H. Brunswig. Translated and annotated by Charles E. Monroe and Alton L. Kibler. This book, printed by John Wiley & Sons, New York, contains 350 pages with illustrations wherever necessary. In it will be found facts, recorded in the literature of the explosives, that have been applied and arranged by Doctor Brunswig according to the physical-chemical methods of the subject. It is to the diligent use of these physical-chemical methods that we owe the lasting worth of the classical experiments of Berthelot and Abel. Of more recent writings, Doctor Brunswig says Van-T Hoff, le Chatelier and Nernst hold prominent places. The difficulty in reviewing a book of this kind lies in the fact that nearly every paragraph contains matter which dovetails in the next paragraph and so on through succeeding paragraphs to the end.

If one takes any particular point in reviewing he can do the entire work, but if he attempts to follow out lines of reasoning his review becomes too prosaical. The only attempt, therefore, is to give a general impression of the book through the table of contents and from reading paragraphs here and there.

The book is divided into 10 chapters: Chapter 1 being General Behavior of Explosive Systems; the next on the Velocity of Explosive Reactions; Chapter 3, treats of Explosive Pressure, in which we are informed that the brisance of an explosive reaction is one which causes the surrounding inert substances to lose their form entirely and become fragmentary. Further the brisance is judged from the size and extent of compression and shattered region caused by the explosion; Chapter 4 deals with Temperature of Explosions; Chapter 5, Gases from Explosive Reactions; Chapter 6 treats of Explosions by Influence; Chapter 7, Flame of an Explosion; Chapter 8 treats of the Peculiarities of Particular Explosives, such as Physical Changes in Explosives, Igniters, Fuses, and Detonators; also of the Mercury Fulminate; Chapter 9 treats of Propellants, such as black powder, and smokeless powder; Chapter 10, on Blasting Explosives, a number of which are analyzed; and finally on Hints on Handling, Application, and Destruction of Explosives.

Some of these chapters have as many as ten subdivisions, others have but one. In this book, theoretical and mathematical discussions have been omitted, giving development of our knowledge of explosive processes and forcing them more and more into the narrow field of exact chemistry of explosives; or, in other words, the physical-chemical science which deals with the velocities of chemical reactions and chemical equilibria at very high temperatures and pressures.

Business Prospects Year Book for 1913, edited by Joseph Davies and C. P. Hailey. Published by The Business Statistics Co., Ltd., Cardiff, Wales, $2.50, or 10 shillings net. This is the seventh year for this forecast of the business situation to be published. In this book the statistics of fourteen subjects are compiled in a concise form and from them conclusions are drawn as to what will happen to coal, iron, copper, tin, cotton, etc., the best recommendation of the book is the heading on the title page; whether we agree or differ with the conclusions, the facts and estimates given cannot fail to be of interest to every business man.

Some Features of Mine Disasters

Gas and Coal Dust Explosions—Explosives—Electricity—Lighting Apparatus—Mine Fires, Etc.

*By George S. Rice**

As a result of the investigation of mine explosions and mine fires by the engineers of the Bureau of Mines, the following features have been noticed:

Gas Explosions.—At a number of mines where disasters have occurred the operators had considered the mines non-gaseous, and accordingly had not taken sufficient precautions to insure ventilation at the face. Usually the mines had ample fan capacity, but investigation showed that at the face there was insufficient current, largely because of leaky stoppings. In some mines too much reliance was placed on line brattices to conduct the air-current to the face. In some mines rooms had been turned ahead of the last break-through, so that when a fall of roof had knocked down the brattice, or curtains, or the doors on the roadways had been carelessly left open for greater convenience in haulage, there was no circulation of air, with the result that gas had collected and been ignited by an open light or the flame from a shot of black powder or dynamite.

Several disasters were caused by the mine foremen allowing miners with naked lamps to enter districts containing gas, or by the fire boss endeavoring to "brush" or fan out a pocket of gas by using a coat or canvas sheet and thus throwing the inflammable gas upon an open light. In the majority of American mines there is very little inflammable gas (methane chiefly) under ordinary conditions, but at a time of low barometer, or when there has been a large fall of roof, or through encountering a fault or crevice containing gas, dangerous conditions arise suddenly between the time when the mine is inspected in the early morning and when the miner enters the working place. Many such disasters have occurred in so-called "non-gaseous mines" in which open lights were used. When a mine is considered gaseous, safety lamps are generally used, and many other precautions are taken. The absence of gas for days or weeks lulls suspicion and causes relaxation of effort on the part of the foreman. The remedy would appear to be a greater extension of the use of safety lamps.

Coal-Dust Explosions.—In practically all the bituminous coal mines in which disastrous coal-dust explosions have occurred, the engineers of the bureau have observed that no attention was paid to the accumulations of dry coal dust in the inner workings. In some mines near the shaft or on the main roads artificial watering had been done, which satisfied the casual visitor that the conditions were safe; but the inner workings contained vast amounts of inflammable coal dust, which, when ignited by a small explosion of gas or a blown-out shot, or other cause, had initiated an explosion that traversed not only these inner workings but also more or less of the outer roadways which had been more or less dampened by sprinkling.

Even where an explosion has been stopped before it reached the mouth of the mine, the afterdamp gases have smothered the miners throughout a much larger area than that traversed by the explosion. None of the mines in which large dust explosions have occurred had prior to the disaster employed systematic humidifying with steam.

Improper Handling of Explosives. In many mines examined by the mining engineers explosives were carelessly handled. In certain instances the operators supposed that they had admirable shot-firing and inspection systems, but examination at the face disclosed that there had been many blown-out shots. In some cases it was found that detonators and explosives had been kept in the same box, and that shot firers had carried detonators in the same sack with the explosives. Where firing had been done with a battery it was found that many batteries were of the ordinary dry-cell type without any safeguards. In one accident during the year the state mine inspector reported that a shot firer was killed by putting a dry-cell battery in the same sack with detonators and explosives.

The use of permissible explosives that passed the tests of the bureau has much decreased the dangers of igniting gas and dust, but it has been found that they have not been used in some mines according to the methods prescribed by the bureau; that is, they have not been properly tamped, or the charge limit has been exceeded.

In many cases the miner has been permitted to have too large a quantity of explosives in his possession. In some states he is permitted to have 25 pounds or more of black powder.

The method of bringing explosives into the mine and the method of storing them is bad at many mines. Stringent regulations on this subject should be made by state authorities. In some districts kegs of powder or other explosives belonging to the miners are left exposed in their respective working places instead of being placed in tight boxes with locks.

Accidents From Electricity.—Several disasters have been attributed to electric arcs from grounds or short circuits igniting coal dust or gas. Trolley haulage should not be permitted in entries in which there is one-half per cent. or more of inflammable gas.

In a large number of mines using electrical machinery it has been found that the installation was very imperfect, particularly as regards insulation. The use of electricity in coal mines is constantly extending, and an increasing number of accidents have been attributed to its use; hence greater care should be exercised in insulation. It would be desirable if every coal-mining state had an electrical engineer on its inspection staff.

Lighting and Accidents.—In all but two of the mines in which large disastrous explosions have occurred during the past few years, open lights have been used. In many of these mines there was more or less inflammable gas, generally not in noticeable quantities, but sufficient to produce dangerous conditions under certain circumstances. On the other hand, the mines that have been considered and acknowledged by the operators to be gaseous have generally been free from explosions, although one small disaster was attributed to the imperfect condition of a safety lamp. Safety lamps give a poorer light and are especially unsatisfactory for examination of the roof and floor, but their use tends to produce discipline and care in other directions. Where used, however, they must be inspected daily by some competent

*Chief Mining Engineer, U. S. Bureau of Mines. Abstracted from advance sheets of the Second Annual Report of the Director.

person. Portable electric lamps give much better light and are being adopted to some extent in the Pennsylvania anthracite field. Different types of electric lights for use by miners are now under investigation by the bureau at Pittsburg. If the safety conditions are to be improved, it seems probable that the use of these electric lamps will be widely extended, and will much lessen the danger of explosions and mine fires that attends the use of open lights.

Ventilation.—As already mentioned, there is great need for improvement in mine ventilation, especially at the face where the miner works. Mine foremen are sometimes too easily satisfied with sending down large volumes of air into the mine and disregard the fact that it does not reach the face in sufficient quantity to sweep away gases that may accumulate there, either the firedamp from the coal or poisonous gases from the powder used in bringing down the coal. Generally the fan equipment at coal mines is sufficient, but in many of these mines the underground system of ventilation in the more remote parts of the mines is not as efficient as it should be. It is usually easy enough to have good air along the main entries and haulage roads and manways, where the men travel, but it is more difficult, though just as important, to have good air at the places where the men work.

Mine Fires.—Some disastrous mine fires have occurred during the past few years through gross carelessness in handling open lights, or from short circuits of electric currents due to improper insulation, or from underground power plants. These have been the causes of fires in certain metal mines investigated, as well as in coal mines. One bad fire, which occasioned loss of life, was caused by setting fire to oil used for lubrication. Such instances are due both to the use of open lights and to the arrangements for storing the oil or other inflammable material. There has been a great disregard of danger in the employment of wood for underground engine houses, pump rooms, and stables, which are especially liable to fires. But in some districts, following disastrous mine fires, as in Illinois and in the anthracite fields of Pennsylvania, many drastic improvements have been made. Similar precautions against mine fires should be taken and facilities for fighting such fires should be introduced in mines throughout the country, without awaiting the occurrence of additional mine disasters. A preliminary report on mine fires, by G. S. Rice, has been prepared for publication as a technical paper (No. 24); and another, by J. W. Paul, has been prepared for publication as a miners' circular (No. 10).

Escape Arrangements.—Many of the mines in this country have inadequate facilities for escape in case of fire or explosion. These should always be in duplicate, and either escape way should provide adequate means of exit from the mine. Few mines have sufficient provision in the way of fire-fighting equipment in and about the exit ways. The state of Illinois has passed some excellent laws and regulations for fire fighting, but unfortunately very few of the mining states have even fundamental regulations requiring such improvements.

Refuge Chambers.—Most victims of explosion disasters have been overcome by afterdamp and not by violence or burning, but some miners have escaped from disasters by bratticing themselves off in inner workings. These facts show that had refuge chambers been provided many of the miners that were lost might have been saved. Chambers of simple type are easy to make, and the several engineers of the bureau advise that all mines provide them. Even if nothing more than several mine rooms or chambers of ordinary size in different parts of the mine were utilized, these could have tight-fitting doors in duplicate, a supply of drinking water in sealed bottles, a limited quantity of food in cans, a supply of first-aid equipment, a few fire extinguishers, and, if practicable, a protected telephone. Such rooms would prove useful under many conditions arising in the daily routine of mining operations, and would prove a good investment even though no large disasters occurred. Rescue parties would naturally aim to reach these rescue chambers promptly before making a random search throughout the mine; and in time of trouble, when ordinary escape ways were blocked by poisonous gases or rock falls, men in the mines would endeavor to reach these safety chambers. Where the mines are not deep, special holes might be bored from the surface down into such chambers, through which holes fresh air might be forced when needed below and through which telephone lines could be run to the surface.

While thus calling attention to the advantages of such rescue chambers, the bureau has not urged their installation as equal in importance to precautionary measures looking to the prevention of mine disasters. But interest in them increases as it is realized that mine disasters may still occur notwithstanding all precautions, though, let it be hoped, at increasingly less frequent intervals.

Falls of Roof Coal.—By far the largest annual loss of lives in mines is caused by falls of roof and coal; this is true of metal mines as well as coal mines. The underlying cause of this large loss, which in the calendar year 1910 was 1,310 lives, and in 1911, 1,321 lives, is being sought by the mining engineers of this bureau. Though the immediate cause is lack of sufficient timber, the mining system seems also at fault, in view of the much smaller loss of life per thousand employed in the mines of Europe. Closely connected with this question is the reckless use of explosives, which shatters the roof, and the lack of sufficient direct supervision of the working faces by the mine foremen. The use of less timber and fewer mine foremen but more powder in American coal mines, as compared with those in European countries, meets the American demand for cheaper coal, but at heavy cost in the loss of human life and waste of fuel resources.

These facts need not be considered as a basis of criticism of either the miner or the mine owner, but they indicate an urgent need for recasting the economic conditions under which the coal-mining industry is now being operated.

Meanwhile the Bureau of Mines is beginning a careful examination into the nature and means of preventing accidents from these and other miscellaneous causes.

Cerium Igniters

Cerium alloys possess the property of emitting sparks when struck, and this property has been made use of in an igniter. The alloy used is composed of cerium and iron and the spark produced by a rubbing contact with a steel wheel ignites a wick saturated with gasoline. This application of a metal which heretofore has had no commercial use is quite an advance. The same idea has also been used in a device for lighting gas. The apparatus has a holder with a cerium-iron alloy which rubs on a steel file and emits a spark sufficient to ignite gas.

Prize Contest

With the idea of stimulating interest in practical mining questions, and at the same time drawing out ideas from our readers who constitute a large portion of America's most progressive mining men of all classes, we offer the following prizes:

For the best answer to each of the following questions, we will give any books on mining or the sciences related thereto, now in print, to the value of $3.

For the second best answer, similar books to the value of $2 will be given.

Both prizes for answers to the same questions will not be awarded to any one person.

CONDITIONS

1. Competitors must be subscribers to MINES AND MINERALS.

2. The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

3. Answers must be written in ink on one side of the paper only.

4. "Competition Contest" must be written on the envelope in which the answers are sent to us.

5. One person may compete in all the questions.

6. Our decision as to the merits of the answers shall be final.

7. Answers must be mailed to us not later than one month after publication of the question.

8. The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes, and to mention the numbers of the questions when so doing.

9. In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.

10. Employes of the International Textbook Company, or of MINES AND MINERALS, are not eligible to enter this contest.

Questions for Prizes

9. There is a tract of land containing 840 acres in a nearly square plot, in which at a depth of 630 feet there is 4 feet of clean coking coal lying practically horizontal. The floor of the seam is so soft it creeps; the slate roof rock next to the coal is from 2 to 4 feet thick and liable to fall unless pulled down. It is desired to know what system should be followed when mining the coal and the advantages of the system advocated, using a sketch.

10. What quantity of air in cubic feet per minute will be obtained with a 2-inch water gauge, when a fan 24 feet in diameter makes 90 revolutions per minute under the following conditions: Diameter of the central orifice of intake 12 feet, area of the discharge, 60 square feet; length of the blades, 9 feet; length of the airway, 3,600 feet; area of the airway, 60 square feet.

11. From a coal shaft 650 feet deep, it is desired to hoist 1,200 tons of coal in 8 hours. The engine is 20 in.×36 in. first motion and is run so as to give an average speed of 1,600 feet per minute. What steam pressure will be required and what weight of coal should a car contain?

12. The following data of an underground survey being given, find the course and distance from *A* to *E* and give the area of the figure enclosed:

From *A* to *B* 35° 18′, 448 feet; from *B* to *C* 106° 20′, 565 feet; from *C* to *D* 190° 36′, 368 feet; from *D* to *E* 160° 31′, 433 feet.

NOTICE TO PRIZE CONTESTANTS

It is especially important that Condition 2 of this contest be observed. A number of contestants have failed to do this. Be as original as possible, writing so that others not knowing the subject can learn from your answers. Be careful in copying the answers you send us; leaving out decimal points might count against you when there is a large number of contestants and the work otherwise correct.

Answers for Which Prizes Have Been Awarded

QUES. 1. *Calculation of Size of Fan Required for a Given Circulation.* What size and type of fan would you employ for the circulation of a volume of 160,000 cubic feet of air per minute against a water gauge of 2 inches? Show method of arriving at size.

ANS.—To produce 160,000 cubic feet of air per minute with a 2-inch water gauge, a double intake centrifugal fan should be used. The inner diameter of this fan is obtained by the following formula,

$$d = .023\sqrt{Q}$$
$$d = .023 \times 400 = 9.2 \text{ feet}$$

The breadth of a double intake fan equals five-eighths times the inner diameter, or by formula,

$$b = \tfrac{5}{8}d = \tfrac{5}{8} \times 9.2 \text{ feet} = 5 \text{ feet } 9 \text{ inches}$$

The relation of the inner diameter to the outer diameter is exprcssed by formula

$$m = \sqrt[3]{\frac{\sqrt{a}\,Q}{m^2}\left[c + \left(\frac{3{,}000}{x}\right)^3\right]} + 1$$

in which $m = \dfrac{d_1}{d} = \dfrac{\text{outer diameter}}{\text{inner diameter}}$

a = sectional area of fan drift, in square feet where power is measured;

Q = quantity of air in circulation in feet per minute;

m = number of revolutions per minute, assumed 100;

c = fan constant, 4;

$x = \sqrt[3]{\dfrac{Q^2}{p}}$. Velocity assumed 1,200 feet per minute.

Since the velocity assumed is 1,200 feet per minute the area equals

$$\frac{160{,}000}{1{,}200} = 133\tfrac{1}{3} \text{ square feet} = a.$$

$$m = \sqrt[3]{\frac{\sqrt{a}\,Q}{m^2}\left[c + \left(\frac{3{,}000}{x}\right)^3\right]} + 1$$

$$x = \sqrt[3]{\frac{Q^2}{p}} = \sqrt[3]{\frac{160{,}000^2}{10.4}} = 1{,}350.23$$

Substituting,

$$m=\sqrt[3]{\frac{133\frac{1}{3}\times 160,000}{(100)^2}\times\sqrt{\left[4+\left(\frac{3,000}{1,350.23}\right)^3\right]}+1}$$

Solving, $m=2$

Therefore the outer diameter equals twice the inner diameter which is 9.2 feet, or the outer diameter equal 18.4 feet.

Ques. 2. *Diffusion of Mine Gases.* (*a*) Why does marsh gas CH_4 diffuse more rapidly into the air-current than carbonic acid gas CO_2. (*b*) In a close place, where the ventilation is poor, is there any limit to the diffusion of marsh gas into the atmosphere.

Ans. (*a*) *Diffusion.*—All fluids which do not act chemically on each other, especially air and gases of different densities, where in proximity, tend to diffuse into each other; that is to say, their molecules pass freely among each other, and tend to form a complete intermixing of the two gases. This property is called diffusion, and is caused by lack of equilibrium between the molecular vibrations of the two masses; so that the molecules of the two masses tend to thoroughly intermingle.

Rate of Diffusion.—The relative rates of velocities of the diffusion of the gases into each other are as the inverse ratio of the square roots of their densities or specific gravities.

In determining the rates of diffusion, air is taken as the standard unit (1), the relative rates of diffusion of the different gases can be found by dividing 1 by the square root of the density of the different gases. Thus,

$$\frac{1}{\sqrt{\text{density or specific gravity of gas}}}$$

The density, or specific gravity, of marsh gas is .5590.

Then, $\frac{1}{\sqrt{.5590}}=\frac{1}{.7477}=1.3375$, say 1.340 velocity of diffusion, taking air as 1.

The density or specific gravity of carbonic acid gas is 1.5291.

Then, $\frac{1}{\sqrt{1.5291}}=\frac{1}{1.2366}=.8087$, say .810, velocity of diffusion, taking air as 1.

From this we see that 1,340 volumes of marsh gas will diffuse in the same time as 810 volumes of carbonic acid gas.

(*b*) *Limit of Diffusion.*—The diffusion of gases takes place more rapidly in a moving current than in still air. The diffusion of gases continues to take place until the moisture of gases is uniform, or complete saturation takes place. The action of the gases rising from the floor to the roof, if a feeder is on the floor, helps a diffusion of the lighter gases very much. On the other hand, with a feeder located in the roof, giving off the same gases, the gases would tend to accumulate along the roof, and if the air-current is at all sluggish at this point, the diffusion of the gases will be comparatively slow.

It often happens that a feeder in the roof or other high point of the workings gives off gas more rapidly than diffusion can take place, where the air-current is sluggish. This results in the accumulation of a body of pure marsh gas at this point.

In like manner we often have an accumulation of a large body of carbonic acid gas, or blackdamp, near the floor or other low place in the mine workings, when the air-current is sluggish and where the carbonic acid gas is formed quicker than diffusion takes place.

La Salle, Ill.

Ques. 3. *Distance Between Centers.*—(*a*) Given a gangway driven due north and chambers turned on a course N 75° W so that there will be 50 feet between centers, what is the distance on the gangway between center lines?

(*b*) If the course of the gangway is changed to N 20° W 20 feet inside of the center line of a chamber, what will be the distance on the course of the gangway between the center lines of the chambers?

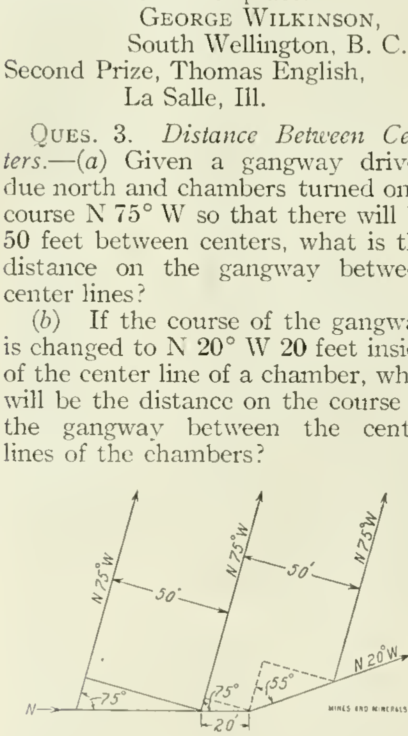

Fig. 1

Ans.—(*a*) Since the course of the gangway is due north, and the course of the chamber is N 75° W, the included angle between the course of the gangway and that of the chamber is 75 degrees. The distance between centers is always measured at right angles to the course of the chambers; hence we have a right triangle formed, with the length 50 feet as the side opposite, and the angle 75 degrees as the included angle, while the distance on the gangway between centers corresponds to the hypotenuse whose length is required.

From the solution of right triangles:

$$\text{Hypotenuse}=\frac{\text{side opposite}}{\text{sine included angle}}.$$

Hence, by the same rule: Distance on gangway

$$=\frac{\text{distance between centers}}{\text{sine of included angle}}$$

Or, distance along gangway between center lines $=\frac{50}{\text{sine }75°}=\frac{50}{.96593}=51.76$ feet. Ans.

General rule:

$$\frac{\text{distance between centers}}{\text{sine of included angle}}=\text{distance along gangway}$$

(*b*) Since the gangway has advanced 20 feet on the old course, it has advanced $20\times\text{sine }75°$, or 19.32 feet of the required 50 feet between centers. (See Fig. 1.) There still remains $50-19.32=30.68$ feet between centers which is to be attained by the new course of the gangway. As the new course of the gangway is N 20° W, the included angle between the course of the chamber and the course of the gangway is now 55°. Then, by the general rule given in answer to Ques. 3 (*a*), the distance between centers along the gangway, from where the gangway changes its course to the center line of the next chamber is $\frac{30.68}{\text{sine }55°}=\frac{30.68}{.81915}=37.45$ feet.

For all succeeding chambers the distance between centers measured along the gangway will be $\frac{50}{\text{sine }55°}=\frac{50}{.81915}=61.04$ feet.

Second Prize, W. F. Evans,
Franklin Furnace, N. J.

Ques. 4. *Size of Pumps.*—If a mine is making 4,000 gallons of water an hour and the shaft is 260 feet deep, what is the size of a plunger pump which will be necessary to take care of this water? What is the size of a centrifugal pump?

Ans.—Assuming that there is a sump large enough to hold 24 hours water at the bottom of this shaft, namely 96,000 gallons, and the water is to be pumped in 8 hours of each day, then $\frac{96,000}{8\times 60}=200$ gallons per minute. To this must be added one-fourth for slip of water past the piston of the pump, making $200\times\frac{5}{4}=250$ gallons per minute.

If a duplex double-acting pump that makes 15 double strokes per minute is used at a speed of pumping of 60 feet per minute; then, $\frac{250\times 231}{2\times 60\times 12}$ $=40.1$ square inches will be the area of each water cylinder and $d=\sqrt{\frac{40}{.7854}}$ $=5$ inches, as the diameter of each water cylinder.

Allow 40 per cent. of the power for frictional losses, and a mean effective steam pressure of 60 pounds per square inch, the pump being located at the bottom of the shaft; the diameter of each steam cylinder is

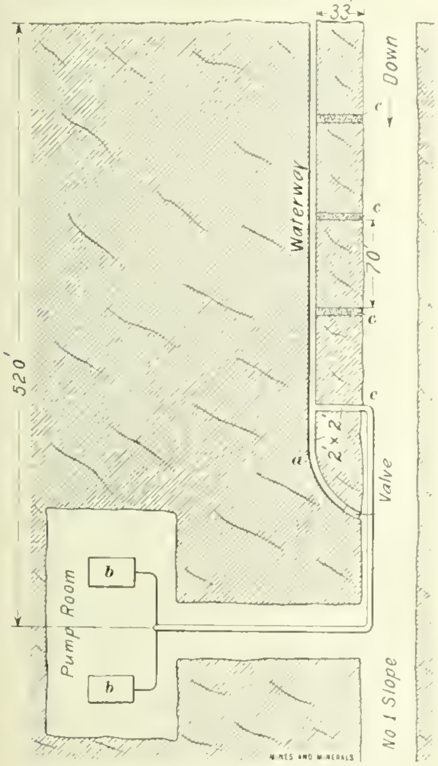

Fig. 1. Plan of Pumping Arrangement

$$d=3.76\sqrt{\frac{G\,h}{2(p\,S)}}=3.76\times\frac{250\times 270}{2\times 60\times 60}$$

$=9$, or in practice, 10 inches as diameter of steam piston. In the above formula,

d = diameter of cylinder;
G = gallons per minute;
h = head, in feet;
p = steam pressure, per square inch;
S = piston speed of pump, feet.

Then the size of duplex, double-acting pump is as follows: Steam cylinder 10 in.$\times$24 in.; water cylinder 5 in $\times$24 in.

Centrifugal pumps are not adapted to pump against this head, they are sometimes rated for 35 to 40 and 100 feet, but it is seldom they are able to give results, even at this; in fact they are not equal, nor near so, to the rough usage of the mine that the plunger pump is.

Crockett, Cal.

Pumping Through Coal

Written for Mines and Minerals

At Storrs No. 1 mine belonging to the D. L. & W. R. R. Co., near Scranton, Pa., trouble was experienced in the maintenance of a column pipe for the pumps at the foot of No. 1 slope. A 10-inch cast-iron pipe was used, and the water here being exceptionally acidulous, the pipes were quickly corroded as shown in Fig. 2, and also from time to time became blocked with sediment and iron precipitate. H. E. Harris, assistant superintendent for the district in which Storrs mine is located, conceived the idea of doing away with the pipe on the slope where it was in the way, and in its place driving a small hole through the pillar at one side of the slope and using this as a pipe as shown in plan, Fig. 1.

The slope is 520 feet long with a dip of 12 degrees. The head on the pumps is 93 feet and the thickness of the coal bed at this point between 7 and 8 feet.

To make this hole, cross-cuts were driven from the slope into the pillar a distance of 33 feet, and about 70 feet apart. To drive these cross-cuts, which are about 2 feet square, a special set of tools was made. In the coal face a number of holes were drilled with the small auger and then the coal was picked out with the small picks. The hole for the water was driven at right angles to the cross-cuts and in the same manner. The lower end of the waterway *c* was curved to the slope so that it can be completely drained. The pipe from pumps *b* is led into the first cross-cut *c*. Where the cross-cuts meet the waterway they are closed with brick and concrete; and outside of this they are completely filled and concreted tight, with the result that there has been no leakage. In the bottom cross-cut and in one cross-cut near the top, valves have been placed so that it will be possible to enter the waterway to clean it, if it should become blocked with "yellow boy" or sediment.

Fig. 2. Showing Corrosion of Pipe

This waterway has been in operation for several months and has worked very satisfactorily. It took 8 months for the miner to drive this hole, but it is expected that the maintenance cost of the old pipe, which amounted to about $1,500 a year, will be eliminated. The speed of the pumps has been reduced from 37 to 19 strokes and the water is now pumped out in 14 hours. Fig. 3 shows the water discharging at the upper cross-cut into the water tunnel leading from the mine.

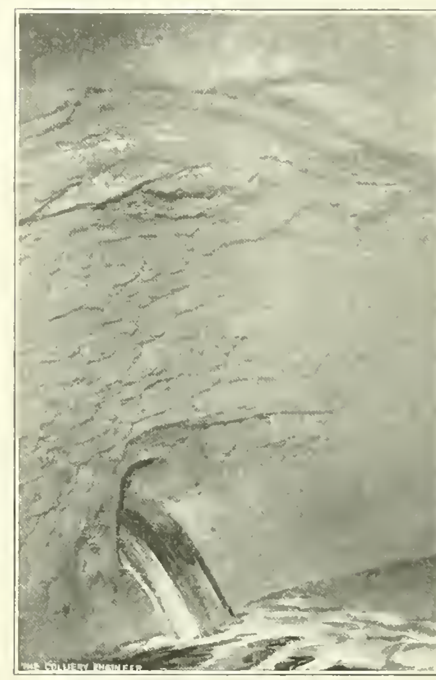

Fig. 3. Discharge from Pump

World's Gold Production 1912

The world's production of gold during 1912 was $5,500,000 greater than in 1911, the total having been $465,000,000, according to a preliminary estimate prepared by George E. Roberts, director of the mint. Gold production in the United States amounted to $91,685,168, compared with $96,890,000 in 1911. California led with $19,988,486; Colorado was second with $18,791,710; Alaska third with $17,398,946; Nevada fourth with $13,331,680, and South Dakota fifth with $7,795,680.

Notes on Mines and Mining

Reports on Conditions and Other Matters of Interest in Various Coal Fields

By Special Correspondents

COLORADO. Mr. Edwin Thomas, formerly chief inspector for the Stag Cañon Fuel Co., at Dawson, N. Mex., accepted the superintendency of the Weaver mine of the Victor-American Fuel Coal Co., at Gibson, N. Mex., assuming his duties there December 1, 1912.

Joseph Smith, who has been general superintendent for the past 3 years over the properties of the Stag Cañon Fuel Co., at Dawson, N. Mex., leaves there January 1 to take charge of his own coal-mining interests near Trinidad, Colo. Wm. McDermott, formerly with the Victor-American Fuel Co. as division superintendent of their Trinidad division, has accepted the position left vacant by Mr. Smith's resignation. Mr. McDermott's successor has not yet been appointed.

Pottsville, Pa.

The Board of City Trusts of the Girard Estate has awarded to Baird Snyder, Jr., of Pottsville, Pa., the lease of a tract of 300 acres of coal land, north of Shenandoah. The tract contains approximately 8,000,000 tons of coal and the operation will be one of the largest ever opened in the region. There were ten bidders for the lease, among them being some of the largest coal companies.

Mr. Snyder will organize a company under the laws of the state of Pennsylvania, with a capital stock of $500,000. All the stock has been sold. Mr. Snyder will be the president and general manager of the company. The product will be handled by Weston, Dodson & Co.

Johnstown, Pa.

After a great deal of opposition on the part of Mayor Joseph Cauffiel, of Johnstown, Pa., the Johnstown & Stonycreek Railroad Co. have completed their line to the mines of the Valley Smokeless Coal Co., affording this concern an outlet for their product over the Pennsylvania Railroad, in addition to their present connection over the B. & O. R. R. With this new outlet and in anticipation of good car supply, the development of the B seam of coal on this property, in addition to the C′ which is now being worked, is being pushed as rapidly as possible.

There has been considerable activity in the purchase of coal lands in the Blacklick district of Cambria and Indiana counties during the past year. During the months of August and September the Manor Real Estate and Trust Co., of Philadelphia, a subsidiary concern of the Pennsylvania Railroad Co., purchased upwards of 10,000 acres of coal land, at a cost of $1,250,000. This land adjoins the property of the Ebensburg Coal Co., who have recently built the new town of Colver, whose output is shipped over the New York Central lines by way of the Blacklick & Yellow Creek Railway. As this entire acreage adjoins, or was tributary to, the Blacklick & Yellow Creek Railroad, it is said this purchase was made on the part of the Pennsylvania Railroad Co. interests to assure them the freight. The property is said to contain two seams of coal, the "B" and the "D" or Moshannon seam, of excellent thickness and quality, although, on account of the great depth of the coal measures below the surface, requiring expensive shaft operations, the property may not be developed at an early date. Its acquisition by the Pennsylvania interests will mean over $100,000,000 in coal freight alone to that system. During the past month title to 2,311 acres in the Ebensburg district of Cambria County, at a cost of $291,714, has been taken in the name of Benjamin W. Carskaddon, manager of the above-named real estate company, which will add considerably more to the amount of freight assured the Pennsylvania Railroad system. It is said the Ebensburg Coal Co., in the interest of the New York Central Railroad, are negotiating at the present time for the purchase of 3,000 acres more in the same district, which is the last acreage of any size or importance in the district not in holding concerns.

A case of unusual interest to the mining fraternity of the state was that of the Calvin heirs against the Henrietta Coal Mining Co., tried in the courts of Cambria County during November and December. It was the longest case of record in Cambria County, occupying the time of the Court for 3 weeks, and was a case without precedent in the state. It involved the question of skilful and economical mining and the percentage of coal that should have been recovered in the "B" or Miller seam. The plaintiffs in the case were the Calvin heirs, who leased to the Henrietta Coal Mining Co. the "B" seam of coal in a tract of land containing 433 acres. The lease was made in the year 1895 for a period of 10 years, at 8 cents per ton, with the provision that at the end of that period the lease could be renewed on terms satisfactory to both parties. At the end of the 10-year period negotiations were entered into for a renewal of the lease, and at the end of 2 years and 8 months, upon their failure to agree on satisfactory terms, the coal company ceased their operations on the property of the plaintiffs. It was claimed by the plaintiffs that a certain acreage of coal had been worked out or lost to them by unskilful mining and that in the mining the company should have accounted to them for a great deal more coal than was paid for. The engineers for the plaintiffs made careful surveys of the area worked over, taking hundreds of measurements of the thickness of the workable coal in the seam. From samples of coal taken from the different parts of the mine the specific gravity was determined in order to ascertain the weight of the coal per cubic foot, and from this information a calculation was made of the total quantity of coal which should have been in this area originally. Fifteen per cent. for loss in mining was deducted and a claim made for the difference between this result and the tonnage upon which royalty had been paid the plaintiffs. The engineer for the defendants also took hundreds of measurements and made calculations as to the recovery of coal, claiming that an 80-per-cent. recovery, or 20-per-cent. loss, would be a fair recovery in the mining of that coal at the time in which the mining was done, during the period from 1895 to 1907. The questions at issue were, first, the percentage of coal which should have been recovered in this seam, the thickness of merchantable coal, and the weight per cubic foot of the coal. There was considerable difference of opinion as to what constituted bony coal, and the testimony of a great many witnesses was heard on that point, witnesses for the defendants claiming that coal exceeding 9 per cent., in ash and $1\frac{1}{2}$ per cent. in sulphur would be considered bony and not merchantable "B" seam coal. Most of the mining engineers, mine superintendents, and mine inspectors of the district were concerned in the case on one side or the other, and much technical evidence was offered to substantiate the claims of both sides. The recovery of coal in the "B" seam, as testified to by various witnesses, ranged from 77 to 91 per cent. The total claim of the plaintiffs was a little over $23,000, while a verdict was secured for $16,100. The plaintiffs were represented by Evans & Evans, attorneys at law, Ebensburg, who were assisted in the preparation of the case by Andrew B. Crichton, mining engineer, Johnstown, Pa., while the defendants were represented by O. H. Hewitt, Kittle and Shettig, assisted by Joseph S. Sillyman & Co., engineers, Altoona, Pa. Both sides have asked for a new trial, and the progress of this case through the higher courts will be watched with interest by those interested in mining in this community, if it is appealed.

Oklahoma

Recently in the Oklahoma field, the old stockholders of the Folsom-Morris Coal Mining Co., at Midway, transferred their holdings to the new Folsom-Morris Coal Mining Co. The company owns 1,920 acres of coal land at Midway, and is capitalized at $500,000. On December 1 the new company took over the holdings of the Western Coal and Mining Co., at Lehigh, which comprise 7,200 acres of coal land adjoining the other tract. The general office will be maintained at Lehigh.

The area now controlled by the company has four working mines, all worked by shafts of about 200 feet depth. The daily capacity of the different mines ranges from 200 tons to 500 tons. About 700 men are employed all told. The coal is the Lehigh or McAlester bed and varies in thickness from 3 feet 10 inches to 4 feet 6 inches. It is of good quality.

Mining machines in the Oklahoma coal field are used only in a very limited number. In 1909 there were 34 machines of various types used; in 1910 the number dropped to 13; in 1911 it increased to 26, and during the past year a number of machines have been added. In 1911 the amount of coal mined by machines in the state amounted to less than 3 per cent. of the total production. This year will show an increased tonnage as well as some increase in the percentage.

The use of the machines is showing good results especially in the thinner coal beds. As an example of the work which is being done, Mine No. 6 of the Oklahoma Coal Co., at Dewar, may be taken. In this mine are three machines of the continuous-cutter type. During the months of June and July these three machines maintained an average tonnage per day per machine of nearly 100 tons of mine-run coal. The coal averages about 3 feet, and the cutting is done in the coal. Each machine is operated by a runner and helper, and the rate for cutting is 18 cents per ton, and the average daily earnings for the two were $9. The price paid for loading coal after the machine is 62.5 cents, and the average daily wages made by each man were $5.54. The total cost of cutting and loading was 80.5 cents per ton, being a difference of only 3 cents between this method and the solid shooting rate of 83.5 cents. The profit to the operator is in the greater percentage of lump coal. This coal when mined by the ordinary mining methods of the state produced lump, 35 per cent.; nut, 30 per cent.; slack, 35 per cent. The machine-mined coal averages 60 per cent. lump, over a 2-inch screen; nut, 20 per cent.; slack, 20 per cent.

Seattle

A party of coal miners under the direction of R. Y. Williams, mining engineer of the United States Bureau of Mines, returned on the last trip of the steamer "Yukon," from the Controller Bay coal field, of Alaska. Mr. Williams and his party have been in the coal field for several months, and were engaged in getting out a large sample of coal to be tested by the United States Navy on one of the battleships.

The party had great difficulty in landing at Katalla, and lost their first barge containing instruments and supplies. The Alaskan coast at this place is comparatively open and is storm-swept for the greater part of the autumn and winter months.

The party spent the greater part of the time in mining coal from the Cunningham coal claims. Most of the work was done on Trout Creek, in one of the drifts opened by Clarence Cunningham prior to 1906. The coal beds at this particular point are considerably broken and the Bureau of Mines party had considerable trouble in getting the coal out, due to the broken condition of the strata.

About 855 tons of coal have been mined and are now on the side of the trail near the mouth of the drift awaiting transportation to tidewater. It is the intention to get this coal down to Stillwater during the coming winter. Horses will be used to drag sleds down Stillwater Creek.

The grade of coal on this property is very good, but badly crushed. Coal of a similar quality taken from the MacDonald mine in the western part of the field proved equal to the best semibituminous coal of West Virginia.

Mr. Williams and his party experienced considerable trouble in getting out of the alleged harbor at Controller Bay. They were taken to Wigham Island, with the intention of having one of the passing steamers call for them, but the storms were so severe and so continuous that it was impossible to get to them for 2 weeks.

Mr. Williams speaks very highly of the miners, most of whom were engaged in Seattle. They are accustomed to western conditions and knew what to expect in the northern country. They had a very stormy season and many discomforts but he states that they did splendidly.

The Issaquah and Superior Coal Mining Co., Ltd., a Canadian and German company, are engaged in opening the old Issaquah coal mine, in King County, Wash. Mr. J. Raymond Watkins, a recent arrival from the coal fields of South Wales, is superintendent in charge. The intention is to open the mine on bed No. 5 and drive a rock tunnel to the underlying and overlying beds. Issaquah mine was at one time a big producer, but about 10 years ago, a preglacial erosion was struck as the lower gangway was being driven east, and in this manner the mine became flooded. The No. 4 bed was always popular on the coal market and it is the intention of the present company to get to this bed and ship principally from it.

The coal markets in the Northwest are very good at present, due perhaps to several causes. One of the principal factors is that several of the mines are having labor troubles which have cut down their capacities considerably, and some of the mines on Vancouver Island are closed entirely. California fuel oil is still a big factor in the fuel supply of the Pacific Coast and will continue to be for many years. But the West is developing so rapidly and new industries are coming in so fast that the prospects for a good coal market are bright.

Utah

The following statement in regard to the mining industry of Utah has been issued by J. E. Pettit, state mine inspector:

We close the fiscal year, November 30, 1912, with the largest increase of coal and coke for any one year in the history of the state.

The output of coal increased 586,885 tons or 23.46 per cent.

The coke production increased 134,988 tons or 63.56 per cent.

The hydrocarbons decreased 3,393.69 tons or 9.1 per cent.

The most important reason given for the large increase in coal has been the demand for coke.

In the manufacture of coke 603,446 tons of coal were used during the past year against 365,822 tons for 1911.

The increase in the use of coal in the state for the past year is also noticeable. The amount used in 1911 was 2,124,500 tons and in 1912, 2,466,745 tons, while exports to neighboring states increased from 418,671 tons to 463,349 tons in the same period of time.

The distribution of coke provides some interesting figures. The Nevada smelters received 31,563 tons, against 335 tons in 1911. The Montana smelters increased their order from 86,714 tons to 135,865 tons. Idaho used 894 tons, while Utah increased her tonnage from 123,752 tons in 1911 to 176,426 tons in 1912.

The decrease in the hydrocarbon product is due to peculiar eastern conditions by which the market for this product is governed. The marketing of this product seems to be intermittent, one month the mines are working to full capacity, the next month the forces are reduced.

There have been no labor troubles during the past year. The wages of those employed in and around the mines and coke plants remained practically the same as last year, and from close observation, we are convinced that a good feeling exists between employer and employed.

The selling price of coal remained the same as in 1911; however, the market price for the hydrocarbon product is somewhat lower.

Three new coal properties, viz., the Willow Creek mine, operated by the Utah Fuel Co., the Panther Cañon or Cameron mine, operated by the Castle Gate Coal Co., and the Neslen mine, operated by the American Fuel Co. have been added to the list of coal shippers during the past year.

The Storrs mine, being developed and equipped by the Spring Cañon Coal Co., will be shipping coal by February 1. A railroad 4½ miles in length has been built to the mine, connecting with the main line of the Denver & Rio Grande Railroad Co., one-half mile west of Helper.

A new contrivance (for the Western States) in handling coal from the mine to the tipple is being installed at this mine. The coal outcrops on a bluff several hundred feet above the bed of the cañon. On account of the cañon grade being too steep to build the railroad to within 3,600 feet of the opening, it was decided to transport the coal this distance by an aerial tramway, which is in course of erection, and the company expects it to be in operation by February 1, 1913.

No serious shortage of cars has been reported during the year, except in the latter part of September and October. It has been impossible for the State Mine Inspector to visit all of the coal and hydrocarbon mines of the state as required by law, owing to the increase of new mines and the development of the old producing mines and their scattered condition. All of the large operating mines have been visited. Those which were not visited are mines in Iron and Uintah counties and which are in operation a few months in the winter season, only.

During the past 60 days, Mr. G. B. Smith has been employed as deputy state mine inspector.

The coal production for 1912 was 3,088,356 tons, or an increase of 586,885 tons.

Coke production for the year was 347,356 tons, an increase of 134,988 tons.

Hydrocarbon production was 33,656.31 tons, which is a decrease of 3,393.69 tons.

The amount of explosives used: 351,505 pounds of black powder and 395,218 pounds of giant and permissible powders, a total of 746,723 pounds, or 1 pound of powder used for every 4.13 tons of coal mined.

The number of men employed in and around the coal and hydrocarbon mines and coke plants during the year was 4,063, or an increase of 265 men over 1911. The average days worked by the regular producing mines was 280 days.

Average amount of coal produced per man (including miners, day men, and outside men, but not including coke workers) was 770 tons.

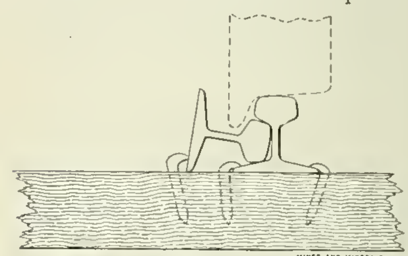
There were 6 mine foremen's certificates issued, and 3 fire boss's certificates.

There were 160 accidents in and around the coal and hydrocarbon mines during the past year. Eighteen resulted fatally, 31 serious, and 111 non-serious. Two of the fatal accidents occurred outside of the mines, one in an open rock cut, and one in an engine house.

As a result of the fatal accidents, there are seven widows and eighteen fatherless children.

Track Extension With Rails on Side

Instead of using short pieces of rails to extend the track as a chamber or gangway advances, the arrangement shown in the accompanying sketch can be used. This is to lay a rail on its side so that the head of the rail lies against the web of the rail which is permanently in place, and drive a spike on the outside against the bottom of the rail so that it will not slide out. Then as the car travels on the track it passes from one rail to the other, the wheel will run first on the tread and then on the flange as it drops into the groove formed by the web and head of the rail. The drop from



Arrangement of Rails

one rail to the other is not enough to make any difference in the running of a car. As the track advances, the rail, which lies on its side, is merely shoved forward, ties of course being laid beneath it. The plan cannot be used where an electric locomotive must pull a car away from a face and where it would be expected to travel on the loose rail, for the motor would then lose the return connections.

Use of Coke-Oven Gas

The entire gas supply of Mulheim-on-the-Ruhr, Germany, and of Barmen, about 40 miles distant, is obtained from two coke-oven plants. The installation consists of 50 Koppers, horizontal, regenerator ovens, each capable of taking from 8 to 10 tons for a charge; the time of carbonization is 24 hours and only the richer portion of the gas, that evolved from the second to the twelfth hour, which is about 50 per cent. of the yield, is used for distribution. During this period one oven will produce 70,600 cubic feet of gas of a calorific value well over 600 British thermal units per cubic foot with the average composition—CO_2, 1.2; CO, 6.8; H, 49.5; CH_4, 38.3, and N, 4.2 per cent. A yield of 65 to 69 per cent. of large coke, 5 to 6 per cent. of tar, and 1.3 to 1.5 per cent. of ammonium sulphate is obtained. The gas costs 17 cents per 1,000 cubic feet, and is sold for 70 cents per 1,000 cubic feet.

Answers to Examination Questions

Questions Asked at the Examination for State Mine Inspector, Colorado, 1911

(Continued from January issue)

Ques. 18.—Name six essential features of a good safety lamp.

Ans.—The qualities that make a lamp the best for testing for gas are not altogether those that render it desirable for general use in gaseous mines. For the latter purpose six of the essential features, are: (1) giving of ample light in all directions, which is attained by the use of a glass globe surrounding the flame; (2) failure to pass the flame through the gauze and thus ignite the gas outside the lamp when held in a strong current of air; which is brought about by the use of a bonnet; (3) a lock that cannot be opened by unauthorized persons or in an unsafe place, usually of the magnetic type requiring the application of a strong magnet to open the fastenings; (4) freedom from smoking, which is accomplished through providing a good draft; (5) ability to relight the lamp, usually done by the use of a percussion igniter as in the Wolfe lamp; (6) freedom from explosions inside the lamp, obtained by the use of a bonnet, by multiple gauzes, etc. To these might be added light weight and consequent portability; simplicity of construction with attendant easy cleaning; materials of good quality and strength, with resultant long life and low cost of upkeep, etc.

Ques. 19.—What thickness of steel plate is required in the shell of a cylindrical boiler 60 inches in diameter, for a safe working pressure of 100 pounds per square inch, the tensile strain on the boiler plate not to exceed 8,000 pounds per square inch, and no allowance to be made for joints?

Ans.—The formula generally used for this purpose is: Thickness in inches $= \frac{\text{working pressure}}{\text{safe load}} \times \text{radius}$ of boiler $= \frac{100}{8{,}000} \times \frac{60}{2} = \frac{3}{8}$ inch. In this formula, the working pressure and safe load (tensile strain) are expressed in pounds per square inch, and the radius of the boiler is given in inches.

Ques. 20.—Explain briefly the difference between natural and artificial ventilation.

Ans.—Natural ventilation is produced by what are known as natural agencies, or causes that exist in nature without the application of artificial means. Some of these natural agencies producing a circulation of air are water falling down a shaft dragging the air with it; air blowing down a windsail or funnel placed at the top of the air-shaft; and, chiefly, the difference between underground and surface temperatures by means of which one column of air is heated and consequently expanded and made lighter than another connected column, so that, in the effort to secure an equilibrium or balance in weight, an upward motion of the lighter air column is produced. Artificial ventilation is brought about through the agency of some mechanical means, such as a furnace, air compressor, fan, etc. Artificial ventilation, particularly

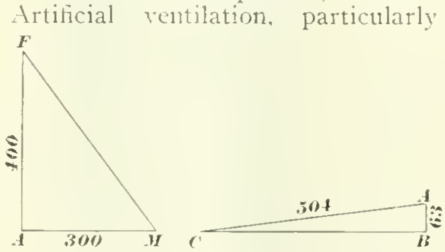


Fig. 1

when produced by a good fan, is to be preferred to natural ventilation, as it can be made independent of changes in the weather, etc., which always affect natural ventilation.

Ques. 21.—An entry runs west 100 feet, thence north 135 feet, thence west 140 feet, thence north 165 feet, thence west 160 feet. What is the length of a straight line from start to face?

Ans.—The sum of the northings is $135 + 165 = 300$ feet. The sum of the westings is $100 + 140 + 160 = 400$ feet. Hence the face of the entry is 400 feet west and 300 feet north of the starting point. This is shown in the triangle, Fig. 1, in which the unknown line MF is the required distance from mouth to face. As this is a right-angled triangle we have

$$MF = \sqrt{MA^2 + FA^2} = \sqrt{300^2 + 400^2} = \sqrt{90{,}000 + 160{,}000} = \sqrt{250{,}000} = 500 \text{ feet}$$

Ques. 22.—What, in your opinion is the reason that there are more explosions in the winter months than at any other time of the year?

Ans.—It is questionable if there are more explosions at one season of the year than the other, as methane, blown-out shots, mine fires, poor electrical connections, etc., are as abundant or as apt to occur in July as in January, and any one or all of these may produce an explosion.

On the other hand, explosions occurring in the winter months are commonly, almost universally, much wider spread and more disastrous than those happening in the warm months. This is due to the fact that in the winter the coal dust on the floor, roof, and ribs of a mine is much dryer than in summer; and this dry coal dust is the chief, if not the only, means by which an otherwise local explosion, affecting but a small part of the mine and endangering but a few men, is carried throughout the entire workings, frequently killing all the workers. During the winter months the temperature of the outside air is lower than that of the mine. As the temperature of the air rises, either by natural or artificial means, its ability to absorb moisture increases very rapidly. Hence, during the winter months, the cold outside air enters the mine, is heated to the prevailing mine temperature, and thus has its capacity for moisture increased. This moisture it gathers from the dust, leaving it dry and in the best possible shape to extend and thus render very disastrous what, in the summer, would otherwise be a minor and local explosion. In the summer, the reverse is the case, and the air enters the mine at a higher temperature, is cooled, and frequently deposits moisture, often making the roads muddy, and wet dust cannot be gathered up and thus propagate an explosive wave.

Ques. 23.—What is the rubbing surface per square foot of section for an airway 7 feet high, 11 feet wide, and 4,672 feet long?

Ans.—The perimeter, or distance around the outside of this airway is $7 + 7 + 11 + 11 = 36$ feet, and the rubbing surface is $36 \times 4{,}672 = 168{,}192$ square feet. The cross-section, or area, of the airway is $7 \times 11 = 77$ square feet. The rubbing surface per square foot of section (or area) is $168{,}192 \div 77 = 2{,}184.31$ square feet.

Ques. 24.—What are the duties of a mine inspector in the state of Colorado?

Ans.—These are plainly stated in the state laws relating to coal mines, a copy of which may be obtained by application to the Chief Coal

Mine Inspector, State Capitol Building, Denver.

Ques. 25.—If there are 60,000 cubic feet of air passing in a single airway, and this current is divided into 9 splits, each split having the same size area as the original current, how much additional air will be obtained?

Ans.—When the power remains constant the quantity of air circulated is proportional to the number of splits; hence the total quantity in circulation will be 60,-$000 \times 9 = 540{,}000$ cubic feet. The increase in the amount will be 540,-$000 - 60{,}000 = 480{,}000$ cubic feet. This assumes that the nine splits radiate out from the foot of the shaft like the spokes of a wheel, which is manifestly improbable.

Ques. 26.—A Guibal fan is 20 feet in diameter with 8-foot blades making 50 revolutions per minute. What quantity of air would you expect to be put in circulation, the modulus of the fan being .75, the deduction for center being 100?

Ans.—The total area of the fan is $20^2 \times .7854 = 314.16$ square feet. The available area, the central opening having an area of 100 square feet, is $314.16 - 100 = 214.16$. As the blades are 8 feet wide the volume of air displaced at each revolution is theoretically $214.16 \times 8 = 1{,}713.28$ cubic feet. As the efficiency of the fan is 75 per cent. the actual volume discharged or put in circulation, is $1{,}713.28 \times .75 = 1{,}284.96$ cubic feet per revolution. As the fan makes 50 revolutions per minute, the total volume of air circulated is 1,284.96 $\times 50 = 64{,}248$ cubic feet per minute.

Ques. 27.—How would you lay out your works so as to insure the least damage in case of an explosion?

Ans.—If the mine is not dusty although gaseous, the effects of a gas explosion may be limited in extent if the mine is divided into a series of districts or panels, the workings of which are not connected and each of which is ventilated by a separate split of air. If the mine is dusty, the panel or district system is also to be recommended, with stone dust or water barriers at the mouth of each panel of sufficient width that the burning dust of a "dust explosion" may be extinguished before the explosive wave reaches the main haulageway and adjacent panels.

Ques. 28.—Under what conditions may afterdamp become explosive?

Ans.—In the case of what is known as a dust explosion, if not sufficient air is present to burn the coal dust to CO_2 a considerable volume of CO may be formed; or, in event of a simple gas explosion, more or less methane, CH_4, may remain unburned. In either case it is possible, when the proper amount of air is mixed with the gases named, that an explosive mixture may be produced.

Ques. 29.—What are the duties of the State Inspector of Coal Mines of Colorado in regard to loss of life or serious personal injury at any coal mine in the state?

Ans.—See answer to Ques. 24.

Ques. 30.—If the quantity of air in the downcast shaft weighs 1,800 pounds, the depth of the shaft being 300 feet, and the difference of the weight of air in the two shafts is 250 pounds, what will be the length of the motive column, assuming that the shafts are of the same size and depth?

Ans.—As the depth of the shaft is 300 feet and the total weight of air in it is 1,800 pounds, each layer of air 1 foot thick weighs 1,-$800 \div 300 = 6$ pounds. As the difference in the weight of the air in the two shafts is 250 pounds and each foot in depth weighs 6 pounds, the length of the motive column producing this weight or pressure is $250 \div 6 = 41.66 +$ ft. = 41 feet 8 inches.

Ques. 31.—In a mine giving off 2,500 cubic feet of marsh gas per minute, the volume of air entering the intake opening is 4,500,000 cubic feet per hour; what is the percentage of gas in the return current? Would you consider this percentage of gas dangerous?

Ans.—If 2,500 cubic feet of gas are given off each minute, 2,-$500 \times 60 = 150{,}000$ are given off each hour. The volume of the return current, neglecting any increase in volume due to increase in temperature, will be that of the intake air and that of the gas combined, or $4{,}500{,}000 + 150{,}000 = 4{,}650{,}000$ cubic feet. The percentage of gas in this firedamp mixture will be 150,-$000 \times 100 \div 4{,}650{,}000 = 3.23$ per cent. and this is the percentage in the return air-current. This amount of gas will not in itself explode, but indicates a very dangerous condition in a dry and dusty mine, as a much lower percentage of marsh gas will communicate the flame of a blown-out or windy shot to the dust with the probability of producing an extensive and disastrous explosion.

Ques. 32.—Explain how you would determine the safe working load for a seasoned hemlock mine prop 10 inches square and 10 feet long, assuming the crushing load per square inch is 5,300 pounds.

Ans.—The area of the cross-section of this post is $10 \times 10 = 100$ square inches. The total weight that will crush the post is equal to the crushing load per square inch multiplied by the number of square inches in the cross-section or 5,-$300 \times 100 = 530{,}000$ pounds or 530,-$000 \div 2{,}000 = 265$ tons. As the load supported by a mine post is not a moving one, a factor of safety of 3 is probably ample; that is, the safe working load may be considered to be one-third of the crushing load or $265 \div 3 = 88\frac{1}{3}$, say, 90 tons.

Ques. 33.—Two drill holes 1 mile apart are put down to a seam of coal. The depth of the first is 634 feet and that of the second 850 feet; the surface of the former is 25 feet above the top of the latter. What is the inclination of the coal seam between the two points, measured in inches per yard?

Ans.—The depths of the two holes must be reduced to a common level or datum as the top of one is 25 feet above that of the other. The depth to the coal is in the one hole 850 feet and in the other $634 - 25 = 609$ feet when both holes are measured from a common level. The difference in level is $850 - 609 = 241$ feet $= 241 \times 12 = 2{,}882$ inches. One mile contains $5{,}280 \div 3 = 1{,}760$ yards. As the distance between the bore holes is 1,760 yards and the total difference in elevation of the coal at the bottoms of the holes is 2,882 inches, the inclination of the seam is $2{,}882 \div 1{,}760 = 1.64$ inches per yard. It should be noted that this is only the average inclination, and while actual mining operations in undisturbed regions may show but little variation from this, in regions that are at all mountainous or disturbed, the seam is very apt to show a grade much more or less than this at points between the two drill holes.

Ques. 34.—What constitutes firedamp; and what gaseous mixtures does it include?

Ans.—Damp is a term brought to America from England where it was used to mean a state or condition of the mine air wherein it differed from outside air. Various "damps" were recognized, as blackdamp, whitedamp, stinkdamp, chokedamp, firedamp, etc., each indicating a different condition of the atmosphere. Firedamp originally meant a condition of the mine air in which the flame of a candle might cause an explosion, apparently of the air itself. It is recognized more clearly now that these damps are ordinary air containing variable amounts of different gases given off from the workings. Unfortunately, careless usage has brought it about that both the pure gas and its mixture with air are now known as damps. Thus, strictly, firedamp is a mixture of methane, marsh gas, or CH_4, with air, but the term is as often applied to the pure gas as given off, say, by a feeder. Likewise, firedamp, includes in its meaning any mixture of air with an explosive gas, such as CO (carbon monoxide), H_2S (sulphuretted hydrogen), and the like, although these mixtures from their poisonous nature were early recognized as being different from firedamp, and were called whitedamp and stinkdamp, respectively.

Ques. 35.—In what time can an engine of 40 effective horsepower pump 4,000 cubic feet of water from a depth of 360 feet?

Ans.—A horsepower is equal to 33,000 pounds raised 1 foot high in 1 minute. As the engine is of 40 horsepower, it is capable of raising $40 \times 33{,}000 = 1{,}320{,}000$ pounds 1 foot high in 1 minute. At 62.5 pounds per cubic foot, 4,000 cubic feet of water weighs $4{,}000 \times 62.5 = 250{,}000$ pounds. But this is raised 360 feet, so the work involved in pumping is equal to raising $250{,}000 \times 360 = 90{,}000{,}000$ pounds 1 foot high. As the pump is capable of raising 1,320,000 pounds in 1 minute, it will require $90{,}000{,}000 \div 1{,}320{,}000 = 68.18$ minutes to raise 4,000 cubic feet of water 360 feet.

Ques. 36.—What will be the difference in the strength of two pitch-pine timbers each 9 feet long and supported at both ends, the one being 10 in. × 10 in. and the other 8 in. × 12 in., placed on edge?

Ans.—For the same span the strength of beams is proportional to bh^2, in which b is the breadth and h the depth or height. For the first beam, where both b and h are equal to 10, this expression becomes $10 \times 10^2 = 1{,}000$. For the second beam, $b = 8$ and $h = 12$, and $bh^2 = 8 \times 12^2 = 1{,}152$. That is, the strengths of the two beams are to each other as 1,000 : 1,152, or for every 1,000 pounds carried by the first beam, the second will carry 1,152.

Ques. 37.—How would you open a 30-foot coal seam pitching at an angle of 45 degrees with a lift of 300 feet, to get a sufficient supply of air to the face of the entry and rooms, the seam being very gaseous? State where and how you would place the fan, the property being opened by a tunnel, all the workings being above water level.

Ans.—A pair of tunnels would be necessary to open the seam. The lower one, I, Fig. 2, connecting with the main entry, E, being used for haulage and the upper one, R, connecting with the air-course, A, being the return and at the mouth of which the fan is placed. These rock tunnels should be driven with sufficient grade to insure proper drainage. When the coal is reached, entries, E, and air-courses, A, are driven each way with a slight rising gradient; and they are connected the one with the other as often as the amount of gas given off makes it necessary. In very gaseous seams it might be advisable to carry a line of brattice along one side of the entry to insure a supply of fresh air at the face.

The room necks are about 6 ft. × 9 ft. and are driven up on the floor of the seam for a distance of 20 feet to 25 feet when they are widened out to full room width; at the point of widening out a battery, k, of heavy timbers is built through an opening in which the coal is run by way of the chute, a, into the cars on the entry. The room neck is usually divided into two parts by a brattice, one of which constitutes the loading chute, a, and the other and much smaller one, n, is a manway to give access to the battery. In the middle of the pillar between the room necks a narrow manway, m, is driven in for from 15 to 20 feet, or a little more, and branches b b, are turned off in both directions and continued until they intersect the rooms on either side. From these points the manways, which are also airways, are carried up along each rib as shown. The miner works out the full thickness of the seam, standing upon the loose coal behind and beneath him and which is retained in place by the battery, k, and the timbered sides of the manways, m m. In very gaseous mines each room may have a separate split of air by connecting the manway, m, near the lower part of the room, with the main return, A, by a separate cross-cut, d. In this case the breakthroughs, c, between the rooms are not necessary, as the air enters from the main entry, E, passes up through the entire length of the manway, m m m, around the face and into the main return by way of the cross-cut, d. If the rooms are ventilated in pairs, or groups of three, four, or more, these breakthroughs between the rooms are, of course, necessary.

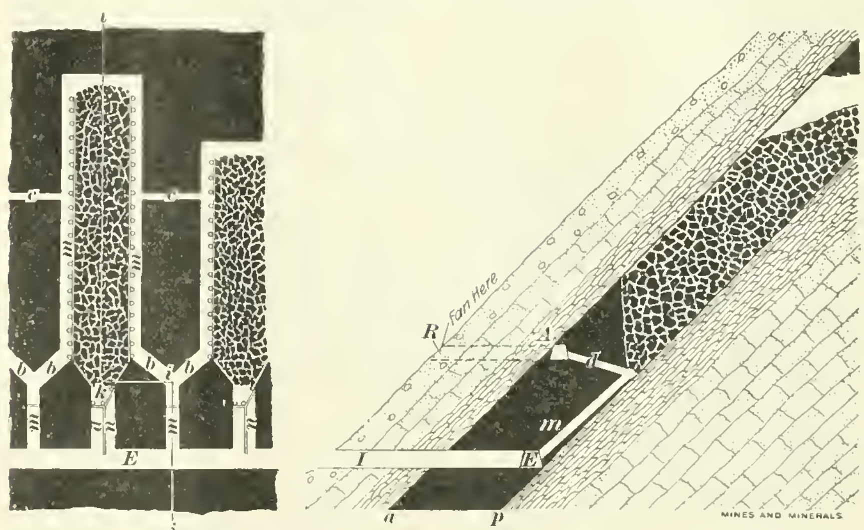

Fig. 2

The fan should be placed on the hillside at the mouth of the tunnel, R. How it should be placed will depend entirely upon local conditions of surface configuration, building material available, etc. The section is taken on the lines lk-ij.

(To be continued)

Depth of Oil Wells

The depth of Colonel Drake's oil well, at Titusville, Pa., the first in the state, was $69\frac{1}{2}$ feet, and from it 25 barrels of oil were pumped in 1 day. His derrick was 34 feet high and his drill rope manila. In California, in the Coalinga oil field, the wells are over 4,000 feet deep, the derricks 82 feet high, and the ropes coming into general use are steel of six strands of 19 wires each.

The Letter Box

Readers are invited to ask or answer any question pertaining to mining, or to express their views on mining subjects in this department. All communications must be accompanied by the name and address of the writer—not necessarily for publication. The editors are not responsible for views expressed by correspondents.

Coal Dust and Steam

Editor Mines and Minerals:

SIR:—I have just read Mr. Reynolds' article on "Coal Dust and Steam." If he had explained the principle of this it would have made the matter simpler for those to whom the idea is new.

Many years ago when I first worked in a coal mine as a mining engineer, a young man who was about as new to the mines as I was, asked me the question:

"Mr. Hooper, what makes the mine sweat in the summer and get dry in the winter?"

The answer explains the whole question.

In summer the air condenses and gives off moisture to the mine so that everything is thoroughly dampened.

In winter the cold air going in expands and drinks up the moisture like a sponge, taking up, in a large mine, many thousands of gallons per day, particularly from the dust, the gob and everywhere.

My object in writing this is that the principle being well understood, the remedy would also be easier.

The air should in winter or at any other time, be at a higher temperature, than that of the mine. This could be brought about by use of steam pipe.

The steam fed to this hot air, is taken up and the condensation deposits the moisture where needed.

This matter is simple and we have much to thank Mr. Reynolds and men like him for, for leading the way to a better understanding of this matter. J. DE B. HOOPER

Dixie Springs, Ala.

To Remove Marsh Gas

Editor Mines and Minerals:

SIR:—For the benefit of the readers of MINES AND MINERALS I am sending details of my proposed method of removing marsh gas from entry and room headings and would like to have their opinions.

As marsh gas accumulates near the roof because of slow diffusion, the plan is to place a perforated pipe near the face at the roof and attach it to another pipe that continues to a miniature exhaust fan placed on the return beyond all the working places. This fan is to exhaust through a 4-inch pipe, but as the quantity of gas to be exhausted is not large the friction will not prevent the proper working of this fan, if calculations are made relative to the size of the pipes.

It is not practicable to brattice all working places and even if it were the gas would be on the return in some cases in so large quantities as to cause an explosion, where with this system it would be possible to eliminate the gas so as to use open lights. T. J. GANNON

Oklahoma City, Okla.

Dangers of Acetylene Lamps

Editor Mines and Minerals:

SIR:—I have read with interest the articles on page 254 of your December issue regarding the use of acetylene gas lamps, and for the benefit of your readers I desire to give you my experience.

The acetylene lamp is admittedly a very convenient thing for a miner on account of the brilliant light it gives. But something more is needed by the miner in addition to a bright light. You cannot tell anything about the condition of a roof by simply looking at it. You must sound the roof to know its condition. The carbide light on account of its brightness has been taken up by many miners who do not realize the danger that there is in its use. It deceives the miner because it consumes so very little oxygen. The officials of this company realize the danger attached to the use of this lamp and have discouraged as much as possible the use of same.

To verify our belief in the dangers attendant upon the use of this lamp, we made a short time ago an experiment with the assistance of our helmet crew. The crew was sent into an abandoned piece of workings where there was a large accumulation of blackdamp. They entered this place with three lights, an electric hand light, an acetylene lamp, and an ordinary pit lamp filled with lard oil. The pit lamp became extinguished before going but 5 feet into this place and more than one effort was made to keep it lighted. The carbide light was not affected at all.

The men went into this place a distance of 500 feet, and for practice worked on stoppings, cleaned away some rock, and did a little timbering. This work lasted 2 hours and at the end of this time, the acetylene lamp was still burning. This convinced us that this lamp was a very dangerous thing, as the condition of the light and the manner in which it is affected is about the only caution that the miner has of the presence of blackdamp or CO_2.

In going through the mine, I have often seen instances where men have emptied partly exhausted carbide on the roadway and I have ignited same and watched it burn for some time. It is such things as this which cause mine fires that cannot be accounted for. I have seen men with as much as 5 pounds of carbide at one time in a box at the face and in a large mine where there are about 300 men daily, and especially if the mine is damp, I consider it a very dangerous practice.

I wish that some of the many crews of helmet teams in the country at the present time would try the carbide lamp in CO_2 and verify the experiment which I made.

D. H. SOMERVILLE

Gibson, N. Mex.

Combustion of Gas and Dust

Editor Mines and Minerals:

SIR:—The first part of Dr. J. C. Haldane's work entitled "The Investigation of Mine Air," is written by Dr. Otto Brunck, Professor in the Royal Saxon Mining College, Freiberg. On page 21 Doctor Brunck says: "It (carbonic oxide, or CO) also forms a constituent of the afterdamp produced by an explosion of firedamp, when the percentage of methane exceeds 9.5, because then the proportion of air no longer suffices for the complete combustion of the methane."

Doctor Brunck does not give the reactions involved in the two cases but they may be assumed to be, $CH_4+2O_2=CO_2+2H_2O$ (for complete combustion), and $2CH_4+3O_2=2CO+4H_2O$ (for incomplete combustion).

On page 35 of "Ventilation in Mines," by Robert Wabner, E. M., of Tarnowitz, Silesia, it is stated: "Now, Doctor Brookman of Bochum, has shown that the product of the imperfect combustion of methane is ethylene (olefiant gas, or C_2H_4), and not carbon monoxide (CO). Consequently the coal dust is the sole cause of the formation of CO and of the poisonous and dangerous character of the afterdamp."

From this view point, the reactions may be assumed to be, $CH_4+2O_2=CO_2+2H_2O$ (for complete combustion), and $2CH_4+O_2=C_2H_4+2H_2O$ (for incomplete combustion).

This would appear rather an important and interesting difference and I would very much like to know which statement is to be relied upon. Wabner's work was published in 1903, and Haldane's in 1905.

Francis G Welles

Waste in Mining

A number of prominent mining men were asked to answer two questions relative to the statement of Dr. J. A. Holmes, in Bulletin 47, Bureau of Mines, that "During the the past year (1911) in producing 500,000,000 tons of coal, there were wasted, or left underground in such condition that it probably will not be recovered in the future, 250,000,000 tons of coal." The questions were as follows:

1. Does the waste occur in your field?
2. Do you know from observation where such waste occurs, and if so, where?

The replies received are well worth reading and digesting.

Mr. John Laing writes: "The only district in West Virginia where we have coal left underground and where there is a possibility that it will not be recovered without great expense, is in the mines of Marshall and Ohio counties. They have a system of mining there where they claim it is impossible to draw pillars successfully because the overlying stratum is so strong that it will not break, but simply brings on a squeeze each time they attempt to draw the pillars, regardless of the method used. With this exception I know of no other district in West Virginia where coal is being promiscuously left in the ground because of any crude methods.

John Laing, Chief Dept. Mines

Note.—Marshall and Ohio counties produced but 1.39 per cent. of the total quantity of coal mined in West Virginia. If any of the readers of Mines and Minerals can formulate a plan to decrease the waste in Marshall and Ohio counties of West Virginia it surely will be appreciated.

Next month there will be a letter from a noted coal man telling of the waste in Indiana and Illinois and suggesting a remedy.—Editor.

Chemical Interpolation of Anthracite

A Method of Rapidly Determining the Composition of Commercial Anthracite

By M. S. Hachita *

Anthracite as shipped to market may properly be called "commercial coal." This fuel consists of normal coal which is free from impurities, and a small amount of refuse or inferior grade of fuel. The latter may be divided into two classes: slate and bone.

If, however, the amount of refuse in the prepared product exceeds the allowable limits, due to improper working conditions of the machinery, etc., it is detected by the coal inspector, whose sole duty is to inspect every railroad car of coal loaded for the market. In testing a car of coal, the

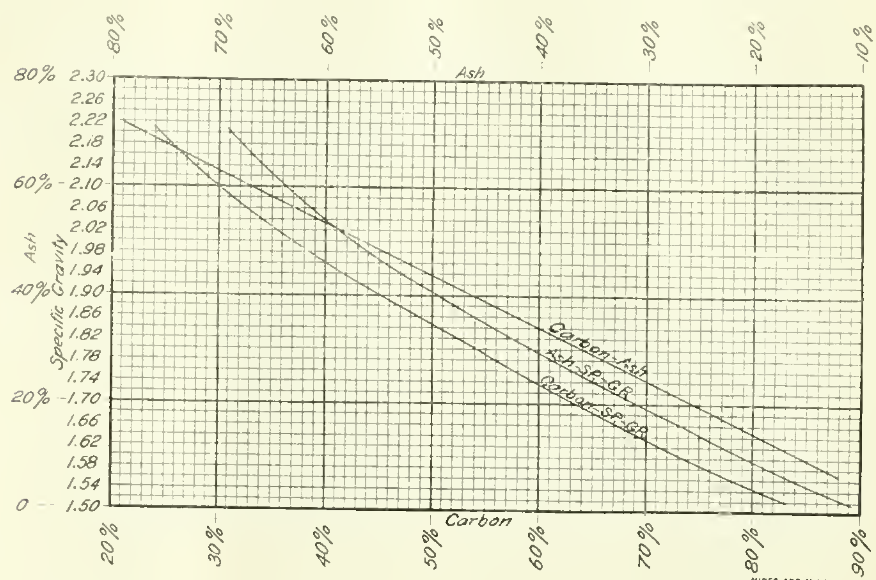

Fig. 1

The commercial anthracite coal therefore consists of normal coal, slate, and bone. The presence of such impurities in the commodity is unintentional on the operator's part, in fact, the companies spare no expense in the attempt to keep their output free from the undesirable materials. Slate and bone occur in the seams of coal in bands the thickness of which varies from that of paper up to many inches. In mining, the refuse comes down with the coal. The preparation of the coal for market begins at the face of the workings; in that the laborer, when loading a car, picks out as much of the slate and bone as time permits. Mine picking is by no means perfect on account of the poor light and surrounding darkness. When a car is thus loaded it is brought to the surface and dumped into the breaker where the raw coal undergoes many processes of mechanical preparation.

inspector takes three samples of 50 pounds each, one at the middle and one at each of the extreme ends of the car. The result of the three tests is averaged, and if the figures show greater than that allowed, the car is condemned and has to go through the process of preparation again. This method of sampling applies only to the prepared sizes; that is, chestnut coal and larger. For pea coal a $6\frac{1}{4}$-pound sample is taken from all over the car; and for buckwheat coal, the size of a sample is 2 pounds taken the same way as in the case of pea coal. The quantity of a sample of buckwheat No. 2 and No. 3, is proportionately smaller. Every car of coal shipped is carefully inspected and reported to the main office with the car number, the size of coal, the tonnage and the percentage of impurities it contains.

To make a chemical test of every car of coal shipped, entails extra work, which under the present market condition is prohibitive, although the majority of the large producers

* Paper read at the December, 1912, meeting of the Lackawanna Chemical Society, by M. S. Hachita, chemist for Lehigh Valley Coal Co., Wilkes-Barre, Pa.

maintain laboratories where the coal is analyzed along certain lines.

In connection with the present method of coal inspection, it has occurred to me that there is some chemical relation between normal coal and the commercial product, for varying amounts of refuse in the latter. Experience has shown that the composition of normal coal for a given colliery is practically constant for at least 6 months or longer, depending upon the proportion of coal mined in each seam; and the same may be said in regard to the composition of slate and bone. When results of such analyses are available it is an easy matter to interpolate the composition of a given commercial coal. The interpolated figures are sufficiently accurate for commercial purposes. To obtain a normal coal it is advisable to use either pea or buckwheat coal, as the particles in the small sizes are more uniform and representative. Daily samples of buckwheat or pea must be taken for at least a month, and the accumulated sample reduced to about 25 pounds by quartering, then the sample is picked by a coal inspector according to the established standard, and divided into three parts; namely, normal coal, average slate, and average bone. Analyses made of these materials would form the basis for the interpolation of commercial products. A method I herewith propose is as follows: Let

C_c = percentage of carbon in the normal coal;

C_b = percentage of carbon in the average bone;

C_s = percentage of carbon in the average slate;

A_c = percentage of ash in the normal coal;

A_b = percentage of ash in the average bone;

A_s = percentage of ash in the average slate;

B = percentage of bone in the commercial coal;

S = percentage of slate in the commercial coal.

Then $100-(B+S)$ = percentage of normal coal in commercial coal (1).

Total carbon in commercial coal $=[100-(B+S)]C_c+BC_b+SC_s$ (2).

Total ash in commercial coal $=[100-(B+S)]A_c+BA_b+SA_s$ (3).

Taking $C_c=85.2$; $C_b=53.6$; $C_s=19.1$; $A_c=9.3$; $A_b=40.7$; $A_s=73.5$; when B and S each equals zero, the (1) becomes 100 per cent.; (2) becomes 85.2 per cent. of carbon and (3) becomes 9.3 per cent. of ash. If $B=3$ and $S=2$, (1) becomes $100-(3+2)=95$ per cent. of normal coal; (2) becomes $95\times.852+3\times.536+2\times.191 = 80.94+1.608+.382 = 82.93$ per cent. of carbon; (3) becomes, $95\times.093+3\times.407+2\times.735 = 8.835+1.221+1.470 = 11.526$ per cent. of ash.

Any other combination of slate and bone with normal coal can be calculated in the same way. Table 1 is constructed by the equations 1, 2, and 3. The figures in the top row give the percentages of slate and those in column 1 give the bone. The table is calculated up to 15 per cent. of slate and bone. The use of such a table as this is familiar to you, and I therefore omit an explanation of it.

Table 1. Showing Percentages of Fixed Carbon and Ash of Commercial Coal Having Various Combinations of Impurities

A car of coal was condemned some time ago on account of the slate it contained. A representative sample was taken from the car and tested for slate and bone and the table was applied according to the percentage of these materials Then the slate and bone were mixed with the coal. This sample was analyzed and the result of the analysis compared with that of the table figures. The comparison was as follows:

By the table: Carbon 72.81; ash; 21.86.

Table 2. Normal Coal

	Moisture	Volatile	Carbon	Ash	Specific Gravity
Northern anthracite field	1.46	3.84	85.07	9.63	1.486
Eastern middle anthracite field	1.83	2.89	84.84	10.44	1.589
Western middle anthracite field	1.51	3.32	84.56	10.61	1.527
Southern anthracite field	1.01	5.44	79.76	13.79	1.468
Average	1.45	3.87	83.56	11.12	1.518
Average Bone					
Northern anthracite field	.78	5.13	51.92	42.17	1.813

Western middle anthracite field	1.12	4.63	53.48	40.77	1.801
Southern anthracite field	1.22	5.75	53.74	32.29	1.746
Average	1.10	4.96	53.85	40.36	1.802
Average Slate					
Northern anthracite field	.94	6.33	22.91	69.82	2.231
Eastern middle anthracite field	1.15	5.28	24.28	69.29	2.225
Western middle anthracite field	.91	5.67	24.20	69.22	2.222
Southern anthracite field	.79	6.08	24.83	68.30	2.152
Average	.95	5.84	24.06	69.15	2.208

By analysis: Carbon 73.09; ash 21.54.

From this comparison it will readily be seen that the table figures are only .28 per cent. too small for carbon and .32 per cent. too large for the ash. These errors are not too large, and are within the error allowed in the commercial analyses of fuel. Having the percentage of slate and bone, with the aid of the Table 1 we can properly interpolate the chemical composition of any given car of coal shipped. It frequently happens that a coal dealer complains about a shipment of a car or two on account of the appearance of the coal. In such cases it is not practicable to send a representative to a distant point to examine and take a sample of coal. Such a step, if taken, shows the weakness of the shipper's position. On the other hand the use of the table as I have suggested will enable the operator to convince the dealer without sending anybody and the business can be transacted more quickly.

The composition of normal coal differs in different collieries and in different fields. Table 2 gives the average composition of normal coal, bone, and slate in the different fields.

Dividing each element in the slate and bone by the corresponding element in the normal coal in Table 2, gives the figures shown in Table 3 in which it will be noted that all bone, except one, contains less moisture and a larger amount of volatile matter than the normal coal, and the same is true with the slate, while the carbon in the bone varies from 61 to 67 per cent. of the carbon in the coal and that in slate from 27 to 31 per cent. of the coal. Ash in the bone varies from 2.85 to 4.28, or an average of 3.60 times that in the coal, while in the slate it varies from 4.95 to 7.25 or an average of 6.20 times that in the coal. The similar variations in the specific gravity will also be noted. The quality of heat produced by the carbon in the slate and bone is undoubtedly the same as that produced by the carbon in the coal, but whether or not the volatile matter in the refuse, especially in the slate has any heating value has not been investigated.

From the average values of the analysis of the normal coal and refuse a chart, Fig. 1, is constructed. The lines connecting the carbon-ash loci show that they are practically in the same straight line. In other words the percentage of carbon in a given fuel varies inversely as ash. Generally speaking, the higher the specific gravity of the material the greater the ash percentage; but the lines connecting the loci show that this is not in a straight line but forms a curve. The chart also shows that the specific gravity increases more rapidly as the percentage of the ash becomes higher. Carbonization of anthracite can also be determined by the specific gravity of a given material. The lines of loci show that this also is not in straight line; but that it is similar to the ash specific-gravity loci. In this curve it will be noted that the increase of specific gravity is more rapid as the percentage of carbon becomes less and less. To obtain percentage of the refuse in the steam sizes, especially the rice and barley coal, it is almost impossible to get an accurate figure. The reason is that the particles composing the material are so small that it is hard to draw lines between the normal coal and bone, and the bone and slate. In such cases a determination of specific gravity is made of the fuel. When such data are available, the chemical composition of coal can be obtained diagrammatically. For instance, if a given fuel has a specific gravity of 1.58, from the carbon-specific gravity curve on the diagram the carbon content of the coal is 75.5 per cent. and from the ash-specific gravity curve the ash is 18.5 per cent. The use of this diagram is not limited to the steam sizes, and can be used for the larger coal if so desired.

Table 3. Bone

	Moisture	Volatile	Carbon	Ash	Specific Gravity
Northern anthracite field	.54	1.34	.61	4.38	1.22

The Mine Foreman

*By Thomas Turner**

The company operating a mine has certain interests that must be taken care of by the foreman and fire boss, and this can only be done successfully, with each one working for the same great interest. We must not, however, forget that the workingmen have certain rights and privileges, that can only be taken care of when the bosses consult each other on matters pertaining to their labor, and consider the man worthy of his rights.

Having never been a mine foreman, perhaps I am not able to judge what is called a model boss, but as we all have our own opinion, perhaps you will allow me to express in a few words some traits of character that a foreman should have.

The foreman I consider as a general over his staff, his orders should be given when he knows they are right, in firmness and kindness, expecting nothing else but obedience, and treating his men with such kindness that they will stand ready to do his bidding. Social enjoyment has become the fad of the day, and Mr. Boss, if you have to be out late at night, and have perhaps indulged in such dissipation that causes you to feel a little out of humor in the morning, please remember the fire boss and give him that good morning that he likes to hear. Think of his entering the mine at 2.30 o'clock, coming in contact with gas, bad roofs, squeezes, and many other things that fill the thoughtful man's mind, and you will agree with me that this, above any other time, is the wrong time to show that you are in an ill temper and perhaps want to take it out of him. One of the best ways to bring your assistants in close touch with you is to let them know that you appreciate their work when it is well done.

I think it is wrong for a foreman to think that his plans and ideas are the only ones that are right without consulting his assistants. A few years ago I worked as a fire boss for a mine foreman, and as usual I made suggestions that I thought were for the saving of labor for the men, and also for the benefit of the company, and he told me, if not directly, then indirectly, that he was paid for thinking and I for working. What do you think was my attitude toward him in respect to giving my opinion? Of course I did not give it, after that, and, just because we did not consult, it was detrimental to the interest of

* Fire Boss, Alden Coal Co., Alden, Pa. Abstract from a paper read before the Nanticoke, Pa., Mining Institute under title of "The Mine Foreman and His Relation to His Assistants."

both the men and the company. This foreman never had the good-will and cooperation of his assistants. His work as a foreman was not a success, and after a very short time another foreman came to the mines where I was fire boss. A very hard problem, was up to us in the nature of a mine trouble. The very first day that man came into the mine he called me and another assistant back from some men we had working, and said: "Now men, I have come here not only to boss but to work hand in hand with you, and what I know I want you to know. Every opinion or suggestion you may have, do not be afraid to tell it to me. I am sure it will be considered. Let us work in harmony and we will get through this trouble all right." What was the outcome of that conference? We were successful in that, what I called the most difficult mine trouble that I met in all my mine experience. Was it all that was accomplished through that little conference? Oh, no, our relations continued of the most pleasant kind, and we worked together in harmony. His interest in the mines became my interest and I always felt that there was nothing too much for me to do for him.

Do not understand me to mean that a mine foreman, in order to have the good-will of his assistants, must be lenient with their mistakes. Oh, no, he should be firm and determined in his correction of mistakes made by his men and always ready to enforce discipline.

A mine foreman should have a certain amount of executive ability and have a good knowledge of how to handle men, and also when he has a good man, try and keep him, for every good man strengthens your organization. There are a great many good men that would never make good foremen. It seems as though a good mine foreman has to be made to order. Consequently there are some holding positions today who are not filling them as they should be filled. They are of a nervous disposition and their judgment is led astray by their ill temper. They do not think they are bosses unless they are swearing at, bulldozing, or discharging someone all the time. Such foremen may have able corps of assistants who could help them, if they were of a different disposition, but as they are ignored by the foremen, the latter always has more trouble than is necessary.

I well know that the foreman who is willing to take the grievances of his men as they come to him, in a spirit of respect for their rights, is the man who will have their good will, and harmony will exist. He will be able to handle his men better and give better service to his employer. When men approach their foreman on a question of price, it is not always the disappointment of not getting the dollars and cents, but sometimes in not receiving a kind word and manly treatment of which they are deserving. I am glad that we have so many superintendents and foremen who have charge of our mines, who are willing at all times to consider the workmen's needs and treat them as men, but I have known some mine foremen, and I am sorry to say there are some holding positions today, that act as if they were very far above their fellow men, and will not give them the consideration that every man should have when he comes to talk business.

With an experience of about 25 years as fire boss, I ought to be able to judge what kind of a man should fill this position. I do not hesitate for a moment to say that a fire boss ought to be a temperance man, for a man that drinks and keeps late hours is not a fit man to examine miners' places, and protect their lives and the company's property or interests.

The fire boss, to a certain extent is the keeper of his brother's life. Therefore we must be faithful in the making of our examinations, knowing that our neglect can bring accident or death to our fellow workmen and great loss to the company that employs us. A fire boss ought to be a man who stands ready to receive orders from his foreman and carry them into execution. The foreman's interest should be his interest. He should be a man who would go into extreme danger if need be to protect life and property. A fire boss should be such a man as will study the needs of his brother. I think that if we practice the maxim "Do unto others as you would have them do unto you," even in our mine work we would meet with more success. Every man whether he be the most experienced miner or the common laborer, is worthy of your respect and courtesy If he is ignorant, then let us help educate him; if experienced, let us appreciate his knowledge. We should so treat men that they will respect us, and so understand our fair dealings with them that they will be willing to do anything for us, knowing that we are fair between man and master. A fire boss should be a man who has had broad mining experience, one who has done nearly all kinds of work in the mines or had charge of such work, so that he has gained a practical experience, which will give him the proper judgment to enable him to direct his men and give orders and insist that they be carried out. Misjudgment on the part of the fire boss in giving orders has in the past been the cause of a number of accidents, and especially has this been so in cases where gas has been found and air splits have been changed and interfered with. The man that is not practical in his position, is thoughtless in regard to the danger of making any change in the air split of his section.

No change should ever be made in an air split in the mines while the men are at work, unless it is a case of extreme necessity; maybe a mine fire, cave or such causes, and only then after informing the men in that section of the change. An assistant foreman should be free at all times to consult with his foreman, to bring about the best results in his section and to assure the very best protection to his men.

He should not think that he has gained so much knowledge about the mine that he need not consult the foreman or bring matters of importance to his attention. A good foreman is always ready to consult with his assistants to bring about the best results for the men and company. My brother fire boss, experience has taught me that our position is one of very sacred trust and no man that goes into the mine has an equal responsibility with you, not even the mine foreman, for he is obliged to take your word and report.

Don't be a conceited fire boss, because your foreman has taken you from a breast, or from a position as driver boss, and given you charge of a section of men. Don't feel that you are the superintendent or an officer of the company, but feel that you have still much to learn. Then your fellow men, seeing your attitude, will be open and friendly with you and you will be able to learn many valuable things from them. On the other hand, if your promotion fills you with pride and raises you far above the men you have just left, your success will not be assured, for these men will be against your interests, and your foreman will not be able to advance you very fast in your mine education, for you will not have the same spirit toward him.

In the great business of mining, the organization of each mine should be in harmony and working together, that the most careful protection may come to each man and boy's life and the property and rights of the company.

Mining Societies and Institutes

American Mining Congress—Coal Mining Institute of America, Canadian Mining Institute, and Others

THE fifteenth annual session of the American Mining Congress opened, at Spokane, Wash., on November 25, President Samuel A. Taylor presiding.

Mr. Graham B. Dennis, of Spokane, called the meeting to order, and Mr. R. Isinger, president of the Spokane Chamber of Commerce, made the address of welcome, after which President Taylor was introduced. Then followed the responses to the address of welcome. Delegates were there from Peru to Alaska, and each in turn manifested a desire to partake of the good things that Spokane had prepared for them.

The reception to the President was given Monday evening in the quarters of the Spokane Club. President Taylor at this time gave the annual address.

The work of the congress began in earnest on Tuesday morning, at which time several papers were read and a number of speeches were made. The paper prepared by Henry S. Graves, Chief Forester, and read by Mr. Silcox, a member of the forestry department, was the spark that kindled a brief but intense fire. Mr. Graves in his paper asked that specific examples be given wherein the forestry department as now operated had been a detriment to the progress of mining in the West. There were examples a plenty. Men from Alaska and Idaho related specific instances where they had been handicapped greatly by the operation of the department.

Alaska had many representatives at this congress and also many friends who never saw the northland, but as each pioneer recited his experiences of the North and the hardships placed upon him by the bureaucratic enthusiasts of the East, there was much evidence of indignation among the members present. The much discussed, but little understood, question of Alaska coal had the floor for a considerable space of time. There was strong feeling among the members of the congress that something should be done whereby justice could be meted out to those that had acted in good faith, and the following resolution was passed: "We urgently recommend that Congress pass an act immediately authorizing all claimants to Alaska coal lands, whose claims were filed prior to November 12, 1906, to maintain action in the United States courts, with right of appeal to circuit and supreme courts of the country, so that any judgment finally rendered shall be conclusive of the rights of the parties, thereby canceling such claims as may be adjudged invalid and requiring the immediate issuance of patents to such claims as may be adjudged valid."

American Mining Congress at Spokane

In speaking of conservation, David Ross, Commissioner of Labor of Illinois, said in a speech that was to the point, that his own state of Illinois had enough coal to supply the entire United States for the next thousand years, and that there was no need for this great cry of conservation, and that the present generation should in some manner get the benefit of the great storehouse that had been laid away in the past ages. He advocated the opening of the Alaska coal mines so that the people of that territory could now get the benefit of their resources.

Alaskan railroads received some attention and it was voted that Congress be asked to aid in the building of one or two trunk lines in the territory, so that the enormous freight rates now being demanded could be materially reduced.

While Alaska received a great deal of attention there were other important matters that created more or less discussion. W. R. Allen, Lieutenant-Governor of Montana, made a lengthy speech in favor of a "Blue-Sky" law. He was in favor of each state having a department whereby any investor could secure reliable data relative to any mining venture, in which shares were advertised for sale. Others made speeches along the same line and for a time it appeared that the congress was in favor of such legislation, until J. D. Decker, Congressman-elect from Joplin, Mo., arose, stated the fact that he was from that state, the mention of which provoked many smiles, then said that he could not see any virtue in such a law and called attention to a great many defects and shortcomings that such a law would necessarily have. It was decided to appoint a committee and let this committee draft such a law as they thought would cover the question to the best interests of all concerned. The report of this committee will be submitted to the congress at a later date.

Compensation was another subject that was given considerable attention.

John Wallace, State Industrial Insurance Commissioner of the state of Washington, gave in some detail the working of the compensation law of that state. The congress was made up mainly of operators rather than employes, but the sentiment of the congress was greatly in favor of such a law as the state of Washington now has, and went on record to that effect. Mr. Wallace stated that the law as now operating in Washington has a few defects, but these he hopes will be remedied at the next meeting of the legislature.

The congress went on record against the reduction of tariff on lead and zinc.

The following officers were elected to hold for the ensuing year: D. W. Brunton, of Denver, for president; Hennon Jennings, of Washington, D. C., for first vice-president; E. A. Montgomery, of Los Angeles, second vice-president; Carl Scholz, of Chicago, as third vice-president, and J. F. Callbreath, secretary.

Spokane offered to build a temple at a cost of not less than $500,000 for a permanent home for the American Mining Congress; the offer was accepted with thanks, but it was decided to hear from other cities before final action was taken. There were many present who thought the headquarters should be at Washington, D. C.

The committee at Spokane had provided for the entertainment of the visitors, among other things, a mining camp scene which was intended to portray the conditions of pioneer days. Thursday night was ladies' night and at this performance there were to be seen the original camp scenes, and life where there was much drinking and gambling games of all kinds were to be seen. The scenic effects were realistic and "Taylor Gulch" was a very popular place. Friday night was "for men only" and it was here the lid of Spokane, which by the way is a closed town, was pried up a little, and in the opinion of some the lid was entirely removed. There was a great variety of stunts that night, and among them was one dance that many of the good people of Spokane objected to. It is certain, however, that this matter got out of the hands of the local committee and the performers overstepped the limit. It is regrettable that they should have done so, for it marred what would otherwise have been a very instructive and enjoyable entertainment.

On Sunday a party of about 250 members of the congress visited the mining camps of the Cœur d'Alene and examined the underground workings of some of the more important mines. The visitors were treated with the novel feature of listening to a band playing down in one of the mines. After the visits to the various mines an athletic program was given in which the employes of several of the mines took part. At the conclusion of the athletic program the members of the congress returned to Spokane and from there scattered to their several homes.

COAL MINING INSTITUTE OF AMERICA

The Coal Mining Institute of America held its annual session in Pittsburg, December 18 and 19, in the School of Mines building of the Pittsburg University. This meeting was largely attended, but as it came in a busy season of the year, and the soft coal business was particularly a busy one in December, many who would have gladly attended were unable to do so.

Retiring President A. W. Calloway, manager of the Rochester & Pittsburg Coal and Iron Co., could only afford sufficient time to read his address and then hasten to take a train.

W. R. Calverley, superintendent Berwind-White Co., spent one evening at the Fort Pitt Hotel and left early the next day to visit one of the numerous mines in his charge.

George K. Krebs, Somerset, Pa., general superintendent of the Reading Iron Co.'s bituminous mines, spent part of one day at the meeting and then vanished.

William Seddon, Brownsville, who was the Institute's first secretary when it started, 27 years ago, contributed a history of the Coal Mining Institute of America. Messrs. F. Z. Schellenberg, Rufus J. Foster, and Thomas K. Adams, and some of the earlier members of the Institute, also added to the history of the Institute with appropriate remarks.

The following papers were read at the meeting: "Clinkering of Coal Ash," E. B. Wilson, Scranton, Pa.; "Roof Action," R. D. Hall, New York; "Welfare, at the H. C. Frick Coke Co.," by Thomas W. Dawson, assistant chief engineer. Mr. Dawson illustrated his address by the use of the stereopticon, making it unusually interesting. Prof. H. D. Palister, of the Pennsylvania State College, read a paper by Dr. W. R. Crane, who is studying the Alaska coal measures of the Bering River coal field, Alaska.

In the evening the annual Institute dinner and social session was held at the Fort Pitt Hotel. At the dinner Thomas K. Adams spoke on the "State Inspection of Mines"; John W. Boileau, on "The Future of the Coal Industry in Western Pennsylvania"; W. H. Glasgow spoke on "The Welfare of the Miner is the Welfare of Industry"; J. C. Johnston, editor of *Coal and Coke Operator*, spoke on "Evolutionary Revolution in the Coal Trade"; R. J. Foster, manager of Mines and Minerals, spoke on "The Necessity of the Operators in the Bituminous Fields cooperating with the Operators in the Anthracite Fields to prevent politics entering into the construction of state mine laws." He showed the necessity of having the Governor appoint the mine inspectors in the anthracite field as is done in the bituminous fields, drawing a comparison of the workings of the two systems prevailing in the two coal fields of Pennsylvania. J. H. Callbreath, secretary of the American Mining Institute, spoke forcefully against the present system of conservation of public lands; W. D. Affelder, general manager Bulger Block Coal Co., delivered an address on "Rib Drawing by Machinery." This precipitated a debate which lasted for some time, the various members participating in the discussion and endeavoring to disapprove the ideas advanced by Mr. Affelder. Al C. Fieldner, chemist in the Coal Laboratory of the Pittsburg Testing Station, United States Bureau of Mines, read a paper on "Accuracy and Limitation of Coal Analyses." This was an excellent paper and will appear in Mines and Minerals.

At the business session the following were elected officers for the ensuing year: President, W. E. Fohl, Consulting Mine Engineer, Pittsburg; First Vice-President, Jesse K. Johnston, Charleroi, Pa.; Second Vice-President, Thomas D. Furnis, Punxsutawney, Pa.; Third Vice-President, George K. Krebs, Somerset, Pa.; Secretary and Treasurer, Charles L. Fay, Wilkes-Barre, Pa.; Executive Board, H. Hinterleiter, Clearfield; Samuel C. Taylor, Pittsburg; A. P. Cameron, Irwin, Pa.; F. W. Cunningham, Charleroi, Pa.; Auditors, C. L. Clark, New Alexandria, and R. M. Husler, Indiana, Pa. R. Dawson Hall, New York, was reelected Editor of the *Proceedings*.

At noon the Institute members were guests of the University of Pittsburg at a luncheon in Hotel Shenley. After luncheon, E. B. Guenther, East Pittsburg, Pa., read a paper on "Gas Producers from the Standpoint of Mining Men." E. B. Wilson, who in his paper on the "Clinkering of Coal Ash," made the statement that "pyrite was not the cause of coal clinkering," took exceptions to Mr. Guenther's statement that "pyrite causes clinkering in gas producers."

R. D. Hall thought that this would be a good time to settle the question. He stated that some metallurgists agreed with Mr. Wilson, and others did not, naming a Mr. Liddell who he said he had consulted in the matter, not knowing anything of it himself.

G. R. Delamater, Philadelphia, read a paper on "Improved Coal Washing Conditions," after which the meeting adjourned, to meet probably in Wilkes-Barre next summer. Taken as a whole the meeting was a most successful one, the membership having increased to 800, some twenty-five or thirty members having joined at this meeting.

CANADIAN MINING INSTITUTE

The Annual Meeting of the Canadian Mining Institute will be held in Ottawa on March 5, 6, and 7, 1913. The Institute's headquarters will be the Chateau Laurier. Since the hotel accommodation is limited it is important that members should make early application for reservations either to the Secretary, H. Mortimer Lamb, Room 3, Windsor Hotel, Montreal, or direct to the manager of the Chateau Laurier, at Ottawa.

Among the papers already promised for the meeting are the following: "Mining Methods as at Present Employed in the Yukon," by Dr. H. M. Payne, of New York; "The Evolution of Gold Metallurgy," by R. B. Lamb, Toronto; "Grinding Analyses and Their Application to Cyanidation, Classification, Etc.," by John W. Bell, McGill University, Montreal; "Some Notes on the Geology of the Pearl Lake Section of the Porcupine District," by H. G. Skavlem, Aura Lake, Ont.; "Monel Metal," by Dr. W. Campbell, Columbia University, New York; "Recent Metallurgical Developments," by Dr. Alfred Stansfield, McGill University, Montreal; "The Steel Industry of Nova Scotia," by Thos. Cantley, New Glasgow, N. S.; "The Iron Resources of Quebec," by Prof. E. Dulieux, Ecole Polytechnique, Montreal; "The Agglomeration of Iron Ores," by N. V. Hansell, New York; "Prospecting the Iron Sands of Natashkwan, Que., with the Empire Drill," by G. C. Mackenzie, Department of Mines, Ottawa; "Mica Mining in Canada," by Hugh de Schmid, Department of Mines, Ottawa; "Mica Manufacturing and Marketing," by S. O. Fillion, Ottawa; "The Origin of Graphite," by John Stansfield, McGill University, Montreal; "The Clay Resources of Western Canada," by Dr. Heinrich Ries, Cornell University Ithaca, N. Y.; "The Utilization of Exhaust Steam," by J. M. Gordon, Montreal; "State Aid to Mining in Australasia," by H. Mortimer-Lamb, Montreal; "The Evolution of Mining and Milling," by J. J. Penhale, Sherbrooke; "The Use of Rescue Apparatus in Metal Mines," by H. E. Bertling, Toronto; "Gold and Placer Mining," by W. J. Dick, Ottawa; "The Best Methods of Mining Coal under Various Conditions," by Alex. Sharp, Vancouver; "Core Drilling," by H. P. Moore, Toronto.

ROCKY MOUNTAIN COAL MINING INSTITUTE

A local chapter of the Rocky Mountain Coal Mining Institute was organized in Trinidad, Colo., December 28, by those members of the organization whose homes are in southern Colorado. James S. Thompson, division superintendent of the Colorado Fuel and Iron Co., was chosen as president; F. P. Bayles, vice-president; and Ben Snodgrass, superintendent of the Del Agua mine of the Victor-American Fuel Co., secretary-treasurer. The following executive committee was elected: J. S. Thompson, F. P. Bayles, B. W. Snodgrass, J. E. McLaughlin, M. O. Danford. The first regular meeting was called for January 25, 1913. Meetings are to be held every three months. The founding of this chapter is in accordance with plans made by the Rocky Mountain Coal Mining Institute, which was organized at Denver last November, provision being made to have local chapters of the institute organized in the various mining districts of the state in order that the members in these districts should be able to meet as often and as conveniently as possible to discuss mining problems.

OLD FREIBERGERS

On Friday evening, December 20, at the Hofbrau-Haus, Broadway and Thirtieth Street, New York City, a number of old students of the Freiberg Bergakademie sat down to dinner. This meeting was called for the purpose of forming an association in America to be known as the "Old Freibergers in America." After the dinner a business meeting was held and the following officers were elected: President, R. W. Raymond, Freiberg, 1861; Vice-President, Gardner F. Williams, Freiberg, 1868; and Secretary-Treasurer, C. L. Bryden, Freiberg, 1907.

It was decided to hold two meetings a year, one on March 25, the anniversary of the founding of the Akademie, March 25, 1765, and the other on the 20th of December, this to be the annual meeting. The following members were present: Dr. R. W. Raymond, 1861; Gardner F. Williams, 1868; P. J. Oettinger, 1867; Stuart M. Buck, 1868; T. Waln Morgan Draper, 1876; Baron Alfred von der Ropp, 1882; Franklin Guiterman, 1877; F. G. Corning, 1879; R. Boice, 1908; Albert Meyer, 1908; R. M. Payne, 1909; Dr. E. E. Lungwitz, 1886; F. H. Sistermans, 1885; Geo. M. M. Godly, 1900; Walter V. Rohlffs, 1903; H. H. Knox, 1886; H. A. Wilkens, 1889; and C. L. Bryden, 1907. All old Freibergers who have not already done so, are requested to send in their names to the Secretary, C. L. Bryden, 1015 Myrtle Street, Scranton, Pa.

The second annual Northwest Mining Convention will be held in Spokane, February 19 to 21, inclusive. Invitations will be sent to the American Institute of Mining Engineers, the electrical and chemical engineers' organizations, the societies of civil and mechanical engineers and others. Negotiations looking toward reduced railroad rates will at once be taken up. The Pacific northwestern states and the western Canadian provinces constitute the territory to be represented.

From information received from T. J. Barr, secretary of the Kentucky Mining Institute, a state First-Aid Contest will be held in Lexington next May. A number of teams are pledged to enter the contest which insures its being a success. The Goodman Mfg. Co., Chicago, Ill., has offered a silver cup as first prize.

On December 19, 1912, the Pittsburg Coal Co.'s Relief Department of River Coal, held their annual banquet and smoker at the Monongahela House, Pittsburg. During the banquet a negro quartette kept things lively, and at the end of the session Mr. Wilson and Mr. Wachung delivered speeches. After the banquet the company visited the theater. Mr. G. W. Schluederberg, of the Pittsburg Coal Co., presided.

Walter R. Calverley, general superintendent of the Berwind-White Coal Co., will deliver an address on "Some of the Phases of Bituminous Coal Mining," before the Yale Mining Society in New Haven, Conn. Mr. Calverley's experience is such that he is able to talk interestingly and instructively on any phase of soft-coal mining.

The U. S. Bureau of Mines

Some Good Things It Has Accomplished, as Shown in Its Second Annual Report

In his Second Annual Report as Director, Doctor Holmes truly states that the work of the Bureau of Mines has not been continued long enough to make possible any accurate measure of the benefits to come from it. He does, however, mention some of the apparent benefits, and in calling attention to them he does not claim for the Bureau all the credit, but says: "In this connection large credit is to be given to many private individuals—engineers, operators, and miners—and to many State Mine Inspectors who have aided in bringing about these results." While several of the larger coal-mining companies had inaugurated the use of explosives with a shorter and cooler flame than black powder before the organization of the Bureau, there is no doubt that its work hastened a more general adoption of what are styled "permissible explosives," until in the year 1911 the consumption was more than 13,000,000 pounds, and this amount was largely increased in 1912. The work of the Bureau in investigating explosives has been recognized by all intelligent mining men as of great value. The Bureau has also accomplished considerable good in its investigations of mine explosions, both as regards to the prevention of gas explosions, and also to limiting the extent of those due to sudden outbursts of gas or sudden appearances of gas due to causes not controlled by reasonable precautions. It has also been instrumental, through the cooperation of mine officials, in having adopted certain precautions that lessen the dangers incident to the use of electricity in gaseous and dusty mines. This has not only been of distinct benefit to the mine workers, but has also been of value in making the use of a most convenient method of transmitting power in mines practically as safe as any other. The investigations of the Bureau in connection with accidents from falls of roof and of coal and from failure of mine equipment, have been too few and too incomplete to warrant Doctor Holmes claiming any extended beneficial results; but safety recommendations of the Bureau, based on preliminary examinations, are being more widely adopted than was the case in the past. In regard to the matter of mine fires and mine rescue work we quote from Doctor Holmes' report:

"The investigations of mine fires have resulted in making clear many of the contributory causes of such fires and have shown the proper equipment and methods for preventing and fighting fires. Especial attention has been given to the analysis of the atmosphere of fire areas as an aid in determining whether an area has been so sealed that outside air can not reach the fire, which, in such event, will be smothered. The findings of the bureau in this respect are proving of service to operators and to State Mine Inspectors.

"The mine-rescue work, including both investigations and general demonstration and educational work, has been carried on in connection with the operations of the mine-rescue cars and mine-rescue stations and has already yielded worthy results. Some new methods have been adopted, and in the first-aid and the rescue methods several thousand miners have been given training that will prove useful to them and to their fellow miners in time of minor accidents or of great mine disasters.

"In connection with such rescue work, some 20 lives have been saved by employes of the Bureau of Mines, and several additional lives have been saved by miners trained by the bureau through the operation of the mine-rescue cars and stations. Meanwhile, the general demonstrations and illustrated lectures given by the employes of the bureau in connection with the work of the cars have been attended by more that 200,000 miners in different parts of the country, and some 2,000 miners have been granted certificates as fully trained in mine-rescue and first-aid work.

"Another important part of the movement for greater safety in mines to which the bureau has contributed largely is the organization of private mine-rescue stations, equipped and maintained at the coal mines by the larger operators. More than 1,500 sets of artificial breathing apparatus have been purchased and are now in use at such stations, and in addition a half dozen of the larger coal companies have equipped and are operating special mine-rescue cars for use at the groups of mines under their management. One of the states has equipped and is now operating three mine-rescue stations and three mine-rescue cars."

The investigation of certain diseases to which mine workers are more or less subject, especially "miners' asthma," or as the report calls it "miners' consumption," has been undertaken in cooperation with the Public Health Service, and it is hoped that these investigations will lead to immediate improvement in the conditions responsible for the diseases.

Doctor Holmes also shows in a comparative table a marked improvement in the fatalities in American coal mines in the five calendar years ending December 31, 1911. This table shows the figures to be as follows:

Production, Number of Men Employed, and Number of Men Killed in and About the Coal Mines of the United States in the Calendar Years 1907 to 1911, Inclusive*

Year	Production (Short Tons)†	Number Employed†	Production (Short Tons)‡	Number Employed‡	Number Killed: Total	Number Killed: Per 1,000 Employed	Number Killed: Per 1,000,000 Short Tons Mined	Production Per Death (Short Tons)
1907....	480,363,424	680,492	461,406,000	655,418	3,197	4.88	6.93	144,000
1908....	415,842,698	690,438	404,933,000	672,794	2,449	3.64	6.05	165,000
1909....	460,814,616	666,555	460,761,000	666,523	2,668	4.00	5.79	173,000
1910.....	501,596,378	725,030	501,596,000	725,030	2,840	3.92	5.66	177,000

* The figures for production and number of men employed are from "Mineral Resources of the United States," E. W. Parker, U. S. Geological Survey, except for the number of men employed in 1911, which were compiled by the Bureau of Mines.

† These figures represent the total production and the total number of employes in the entire coal-mining industry of the United States.

‡ These figures represent the production and the number of men employed in those states in which records of fatal accidents are in existence. The figures are directly comparable with the number of men killed as given in the fifth column and are those on which the mortality rates given herewith are based. It will be noted that the portion of the industry not represented in the rates for 1907-1909 is extremely small and that in 1910-11 the entire industry is covered.

In another line, the Bureau has been of service to the Government in the preparation of specifications under which the coal used for governmental purposes is purchased. This work has not been of value to the Government only. It has been made available to large purchasers of fuel generally. In regard to the utilization of inferior fuels, the report says:

"The utilization of fuels that have heretofore been considered waste products because of their being low grade and containing an excessively high proportion of ash has been much aided through the Government's investigations in connection with the use of the gas producer for low-grade fuels.

"In its preliminary investigation into the subject of waste of resources in the mining of coal and other mineral products, the bureau has already contributed to an awakening of public interest and an awakening of many of the mine operators of the country to the importance of a thorough examination into this subject. It is hoped that this examination can be made, for it will, if made, point the way toward more efficient and less wasteful methods of mining, handling, and utilizing the more important mineral resources of the country."

Among the features of the work of the Bureau during the fiscal year ended June 30, 1912, Doctor Holmes says: "The investigations conducted by the bureau during the fiscal year, 1912, like those of the preceding year, were devoted chiefly toward the prevention of large coal-mine disasters." Every mine in the United States at which an explosion or fire of any note occurred, was visited by one or more engineers connected with the Bureau, who, in cooperation with or with the approval of the state or mine officials, investigated the cause of the disaster and rendered such aid as was possible.

To facilitate its investigations of mine disasters and to demonstrate the use of mine-rescue apparatus and approved methods of rendering first aid to the injured, the bureau maintains six mine-rescue stations and seven mine-rescue cars in those of the larger coal fields in which mine disasters are most likely to occur. The stations are at Pittsburg, Pa.; Urbana, Ill.; Knoxville, Tenn.; Seattle, Wash.; McAlester, Okla.; and Birmingham, Ala. The cars were distributed as follows:

Car 1, in the anthracite fields, with headquarters at Wilkes-Barre, Pa. Car 2, in the coal fields of New Mexico, Colorado, and Utah, with headquarters at Trinidad, Colo., and Salt Lake City, Utah. Car 3, in the coal fields of western Kentucky, Indiana, and Illinois, with headquarters at Evansville, Ind. Car 4, in the coal fields of Wyoming, northern Colorado, and Utah, with headquarters at Rock Springs, Wyo. Car 5, in the coal fields of Montana and Washington, with headquarters at Billings, Mont., and Seattle, Wash. Car 6, in the coal fields of western Pennsylvania and northern West Virginia, with headquarters at Pittsburg. Car 7, in the coal fields of southern West Virginia, western Virginia, eastern Kentucky, and eastern Tennessee, with headquarters at Huntington, W. Va.

So many miners have desired to receive training in mine-rescue and first-aid methods that the present training facilities are inadequate. By reason of insufficient supplies and equipment, these facilities were not operated during the year at more than 50 per cent. of their maximum possible effectiveness.

Nearly 65,000 persons (mainly miners) visited the safety cars and stations; more than 36,000 miners attended the mine-safety lectures; more than 10,000 miners took partial training in rescue or first-aid work; and about 1,000 certificates were issued to miners showing proficiency in such work. Miners and operators in all coal fields have taken active interest in the demonstration work of the bureau, and many operators have organized and equipped mine-rescue corps at their own mines at their own expense.

The foregoing brief summary of the report is necessarily abridged to the relation of matters of most general interest to our readers. The complete report, which will shortly be published, contains very much of interest and value.

Keeping Snow Off the Tracks

Last winter when the thermometer was 12 degrees below zero and 14 inches of snow lay on the ground, it became necessary to make use of a "bullgine" at the mine No. 1 of the Johnston City Coal Co., at Johnston City, Ill. The "bullgine" consisted of two yoke of oxen. The country at the time was so covered with snow that the railroad was hampered and unable to move the cars about the tipple. So resort was at first had to horses, but they could not do the work. With the oxen it was possible to move the cars and keep up the output of the mine, which amounted to about 3,000 tons a day.

An Illinois Substitute for a Locomotive

In this connection, the description of a mining wrinkle which is used to keep the tracks at a colliery free from ice, is not out of place. In winter the tracks leading from the loading chutes often get so covered with ice that instead of the cars moving by gravity, power must be used to move them. But if a steam pipe is laid alongside the rail and kept warm with a little steam the track can be kept free from ice and the cars will run as usual. An inch or an inch and a half pipe serves for this purpose. It is fastened to the ties close to the rail, but care is taken that it is in such a position that the car wheel flanges will not break the pipe, and the pipe should not be fastened so tightly that it cannot expand when the steam is turned into it. Exhaust steam may be used to supply the heat, but live steam is preferable for the reason that the pipe then can be kept warm during the time that the engines are not running, such as at night when the temperature is the lowest. The pipe is laid alongside the rail as far as the empty and loaded cars usually stand on the delivery tracks.

Blasting Coal on to Pans

Written for Mines and Minerals

A new method of mining coal is being attempted by the D. L. & W. R. R. Co. under the direction of Col. R. A. Phillips, general manager of the Coal Mining Department. This method is to first undercut the coal by machines and then to blow the coal down on to pans or scows which have been placed in the undercut. These pans are then pulled out over the bottom and the coal dumped into the cars.

The method is still more or less in the experimental stage, but enough work has been done so that more machinery has been ordered and the value of the plan is proven.

The mine where this work is being done, is the Storrs No. 1, situated on the city line of Scranton. Fourteen places are now being worked by machines in the Clark seam, which varies from 30 to 50 inches in thickness. The seam is all clean coal so that all of it is sent to the breaker, no cleaning at the face being necessary. It is worked by the room-and-pillar method, as there are overlying seams. The car in use at this mine stands 4 feet 2 inches above the rail, so that it has been necessary, in order to get the car into the chambers, to cut 2 feet or more of bottom rock, the bottom being softer than the roof rock which is hard and strong, though the bottom is often so hard that jumpers must be used for drilling. It is to avoid this lifting of bottom that this method is being tried, for blasting and loading the rock is not only expensive but it causes a loss of production.

The rooms are being driven 27 feet wide, and after the machine undercut is finished, the fine coal is cleaned thoroughly from it with scrapers, and then pans, 6 feet wide by 8 feet long, are inserted into the cut. There are four pans to each cut, which leaves a distance of 1 foot between the pans when they are in position. The coal breaks easily and is blown down on to these pans, in large pieces.

The first pans were made of sheet iron with a 1-inch round iron frame. At the sides were placed 2-inch angle irons so that one edge pointed upwards. It was found that when the coal was blown down it split along the edge of the pans. The pans are now made out of quarter-inch boiler plate as shown in Fig. 1. The sides are turned up for 2 inches and the bottom of the pan is strengthened by flat bar iron. Three chains centering in a ring are fastened to the front of the pan and the pan is drawn along by a rope attached to the ring. There are spikes on the inside of the pan bottom to grip the coal in order that when the tractive force is applied, the pans will not be drawn from under the broken coal. A crab locomotive is used to pull the pans. It has been found that it takes a pull of 400 pounds to draw the pan full of coal over the bottom.

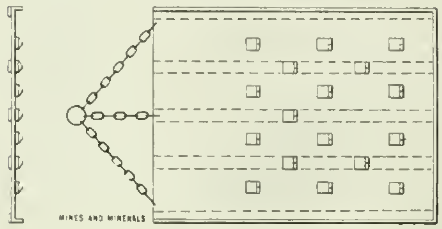

Fig. 1

The hardest part of getting the cut out is to draw out the first pan. In doing this, attachment is made to the coal as well as to the pan, the block of coal being drawn along also. The attachment is made by means of round iron bars 1 or 2 feet long with a link at the end, an inch hole being bored at an angle into the coal and into it the bar is inserted. As soon as one pan is drawn the rest are easily moved.

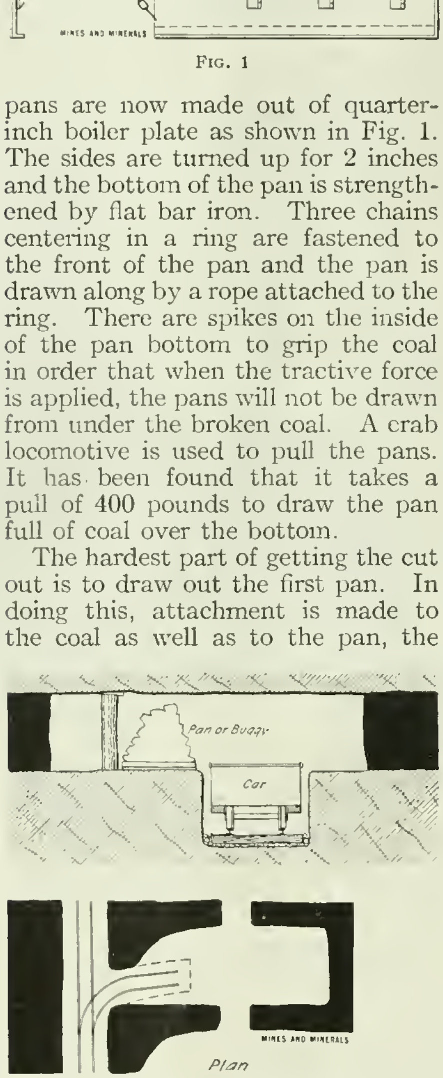

Fig. 2

The bottom rock at the mouth of the rooms is cut so deep that the edge of the bottom is level with the top of the car as shown in Fig. 2. This is done to facilitate the loading. Attempt is to be made to dump the coal directly from the pans to the car by means of a tipping platform, but this is not a proven success.

By the use of the pans, and under the most favorable circumstances, the cut in a room has been drawn in an hour and a half. It yields twelve cars. Three men, a miner and two laborers, are expected to clean two rooms in a day. In reckoning the number of men employed in getting out the cut, account must be taken of the motormen and rock men as well as the machine men and miners. But 20 men are expected to load about 85 cars per day, the cars having $2\frac{1}{2}$ tons capacity.

When the seam increases in thickness after the room has been started, it will not be possible to get a solid chunk of coal on a pan out of the chamber. In this case buggies are to be used. These buggies stand 2 feet from the rail and are 18 inches deep. The sides fall down so that the coal is easily loaded into the car. The usual style of buggy has one end open and the coal is dumped from it on to the bottom rock or into the bottom cut made for the car and then loaded by hand into the cars. This method has been improved upon by bringing the buggy alongside the car. As the bottom of the buggy is then on a level with the top of the car, it is a simple matter to drop one side of the buggy and tip the buggy, letting the coal fall into the mine car.

Ropes and pulleys are provided to pull the buggies back and forth, that they may not have to be pushed out by hand.

The pans can be used only under the special condition which exists here. The roof is strong, requiring few props; the bottom is so regular that the pan will slide upon it; and the coal is so clean that no sorting is done at the face.

Coal Trade of Natal

The Natal collieries during 1911 maintained the progress of 1910. The output was 2,394,238 tons of 2,240 pounds each, compared with 2,296,687 tons in 1910. The output of the coal mines was restricted in 1911, as in previous years, by the scarcity of railway rolling stock and native labor. Track improvements are in progress and rolling stock has been added, but it is hard to keep up with the increasing traffic.—*U. S. Consular Report.*

ORE MINING & METALLURGY

Sudbury Nickel-Copper Industry

Extent of the Deposits—Methods of Mining the Ore, Heap Roasting, and Smelting to Matte

By Reginald E. Hare *

FOR the past 10 years, the world's chief supply of nickel has come from the Sudbury mining district of Ontario, Can. Previous to this, New Caledonia produced most of the nickel and at present is the only important competitor of Sudbury. New Caledonia produces about one-third of the world's supply of nickel, while Sudbury produces two-thirds. The Sudbury ore deposits were originally worked for copper by the Canadian Copper Co. in 1887. Cars of picked ore were shipped to eastern refiners and the difficulty experienced in treating it for copper, led to the discovery of the nickel. There was no available method of separating this metal from the copper, and a period of experimentation followed. It was finally discovered that repeated melting of the copper-nickel-iron matte, obtained on smelting the ore with an alkaline sulphide, gives a satisfactory separation. It was then necessary to find a market for the large quantity of nickel available.

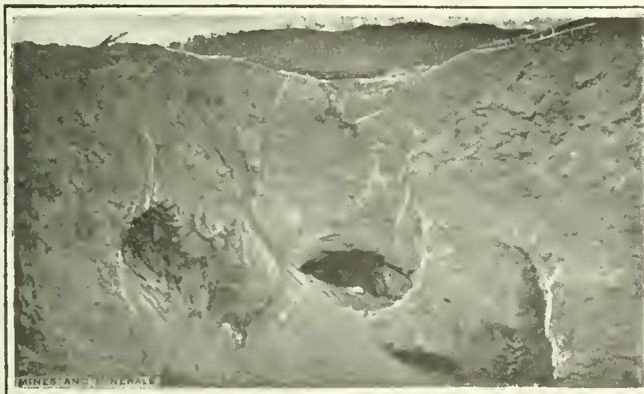

FIG. 1. OPEN PITS, CREIGHTON MINE

FIG. 2. SHAFT HOUSES, CREIGHTON MINE

Fortunately recognition about this time, 1890, of the valuable properties of nickel-steel placed the industry on a substantial basis, and the profit from nickel in the Sudbury ores soon became greater than that from the copper. The known ore reserves are very large and there are numerous promising properties which are yet undeveloped Increased yield in future years is therefore to be expected. Table 1 from the 1911 report of Thomas W. Gibson, Deputy Minister of Mines of Ontario, shows the growth of the industry in recent years.

The values given in this table are not for refined metal, but spot value of matte shipped. The metallic contents of the 32,607 tons of matte shipped in 1911, according to J. McLeish, of the Department of Mines, Canada, were, copper, 17,932,263 pounds and nickel, 34,098,744 pounds. Estimating nickel at 30 cents per pound, Mr. McLeish finds for the refined metal a total valuation of $10,229,623.

The matte value is the one considered in the Canadian reports because the refining is not done there. Of the 36,014,782 pounds of matte produced in 1911, there was exported to the United States 30,679,451 pounds and to Great Britain 5,335,331 pounds. The Canadian Copper Co. and the Mond Nickel Co. produce practically all the matte shipped at present.

The nickel mineral is pentlandite $(FeNi)S$ which occurs intimately associated with the sulphides, pyrrhotite and chalcopyrite, at or near the basic margin of a thick laccolithic rock which Dr. A. P. Coleman has described as "a great boat-shaped mass, 36.2 miles long, 16.6 miles wide and 1.25 miles thick." The basic lower and outer portion of this rock mass is a quartz-hypersthene-gabbro, or norite. There are several large deposits of sulphides occurring with the norite in such a way that some geologists believe the sulphides and norite to have been formed from the same magma.* The deposits, which yield about 3 per cent. nickel and 1.5 per cent. copper, occur in thick masses dipping toward the norite, and most of them have been developed from inclined shafts sunk in the foot-wall. From the shaft, levels are driven through the ore to the hanging wall; raises are then put through to the

Copper contents of matte	5,260	7,003	7,501	7,873	9,630	8,966
Spot value of nickel	$3,839,419	$2,270,442	$1,866,059	$2,790,798	$4,005,961	
Spot value of copper	$806,413	$1,020,913	$1,062,680	$1,122,219	$1,374,103	

NOTE.—For discussion of origin see *Mining World*, June 29, 1912.

surface and the ore mined by enlarging the opening from surface downwards, the system being, in mining parlance, "milling." Large open pits are thus formed as shown in the view of the Creighton mine, Fig. 1. When

Fig. 3. Rock House and Hoist, Copper Cliff Mine

Fig. 4. Wood Piled for Heap Roasting

a depth is reached, where it is necessary to provide protection for the men, the open-pit work is abandoned; a floor pillar is left and the mining continued by underground methods. In some mines the levels are protected by dry walls and mining carried on by a filling method similar to that of the Baltic copper mine. Conditions are not remarkably favorable for the dry-wall method, however, and ordinary drift sets are now being used in preference. The necessary quantity of waste rock suitable for walling is not broken in mining the ore.

At the Creighton mine, the largest nickel mine in the world, most of the ore has been taken from what is now an enormous open pit. In the pit the ore is being broken in benches by

Fig. 5. Heap of Ore Roasting at Copper Cliff

Fig. 6. Reverberatory Plant, Copper Cliff

drilling deep vertical holes and blasting with 40-per-cent. dynamite. Much of the ore breaks in large pieces and this is broken again by sand-blasting or by sledges. From the pit floor the broken ore is loaded into cars and trammed through the levels to the shafts in the foot-wall. On the surface the ore is crushed, screened, and sorted on traveling belts, and sent to be heap roasted, an operation preliminary to smelting. Fig. 2 shows the head-frames and rock houses at the Creighton mine and Fig. 3 the rock house and hoist at Copper Cliff mine.

The ore is brought to the roasting yard on railroad cars and spread over the cord-wood piles, shown in Fig. 4. Each heap consists of from 1,000 to 2,000 tons of ore. A layer of fine ore is spread on top of the heap to prevent free burning, and then the wood below is fired. The sulphides once ignited furnish the fuel for the partial oxidation of the iron, copper, and nickel, while a part of the sulphur is dissipated as sulphur dioxide SO_2. It requires about 4 months to roast a pile of 2,000 tons of ore to a product that contains about 12 per cent. sulphur. When this stage is reached the fire is quenched with water and the roasted ore is loaded by steam shovels into railroad cars and hauled to the smelter bins. Fig. 5 shows a heap of ore roasting.

The smelting plant of the Canadian Copper Co. at Copper Cliff, Ontario, produces annually about 7,000 tons copper and 15,000 tons of nickel in the form of a matte containing about 80 per cent. copper-nickel. There are five blast furnaces 4 feet by 17 feet at the tuyeres and 19 feet high from hearth plate to charging floor.

Recently, for the purpose of treating fine ore and flue dust, two modern reverberatory furnaces, shown in Fig. 6, 19 feet wide by 112 feet long, were built and put in operation.

From the stock bins, the roasted ore, quartz, scrap, raw ore, and coke are loaded into charging cars, and hauled to the blast furnaces by electric motors. The charging cars of the side roll-dump type, hold about 3,000 pounds of ore and are drawn in trains of 7 or 8. A common furnace charge is 3 cars of roasted ore, 1 car of raw ore, a few hundred pounds of quartz and enough coke to make from 11 to 12 per cent. by weight. Each furnace produces about 300 tons per day of matte averaging 22 to 23 per cent. copper-nickel. Experience has shown that it is most economical at this plant to produce a low-grade matte with consequent cleaner slag. From the forehearths the slag flows into 25-ton pots mounted on standard-gauge trucks and is hauled in trains to the dump. The matte which accumulates in the settlers or forehearths is tapped into 7-ton steel-plate ladles which are placed on trucks by a crane and hauled to the converter building.

Until recently there were ten stands of acid-lined converters in use, but during the past 2 years these have been replaced by five stands of basic-lined converters.

In the mattes treated, there is about 2 pounds of iron, to each pound of copper-nickel; and to oxidize this iron, 3,000 cubic feet of air per minute is blown through the molten material. To supply silica with which the iron oxide unites to form slag, quartz or other silicious material is dumped on top of the matte in the converter as required. It is stated that while the acid-lined converters required relining after bessemerizing 6 or 7 tons of matte, the basic-lined converters make from 3,000 to 4,000 tons before relining is necessary.

Starting with a charge of about 60 tons of furnace matte and 10 tons of quartz the blast is turned on for about 40 minutes. The converter is then turned down to skim the slag and more furnace matte and quartz are added. This process is repeated until about 70 tons of Bessemer matte containing about 80 per cent. nickel-copper is obtained. It is then poured into molds. The bessemerized matte is not refined in Canada, as the necessary raw materials are not cheaply assembled at Copper Cliff. The process of refining is to melt the matte with an alkaline sulphide and repeatedly remelt the nickel "bottom" thus obtained, with more alkaline sulphide. A comparatively clean separation is thus obtained. The refining is done at Constable Hook, N. J., where salt cake, oil, coal, and chemicals are readily obtained.

While the product of the Sudbury mines comes into the market chiefly in the form of metallic nickel and copper, another product seems likely to prove of great importance. This is the alloy of copper and nickel known as Monel metal, which contains the metals in nearly the same proportion as does the bessemerized matte, viz., copper from 28 to 30 per cent.; nickel from 70 to 60 per cent., and iron 2 per cent. and more. Monel metal besides being less costly than nickel has high tensile strength and non-corrosive properties, and can take its place in many cases. It has been used for numerous purposes such as propellers for war vessels, roofs for large buildings, steam turbine parts, motor-boat shafts, and as ropes for mine hoists and cableways. Constantan, an alloy composed of 60 per cent. copper and 40 per cent. nickel is said to be unaffected by changes in temperature.

Automatic Sand Sluicer

The principle involved in the reaction wheel has long been in use as a means of evenly distributing sand in cyanide tanks, but it remained for Edwin L. Oliver, of San Francisco, to make use of practically the same device for sluicing sand out of the tank after leaching was completed. In Fig. 1 is shown the reaction wheel suspended from a crawl. After cleaning sand out of one tank the sluicer may be readily removed to another. The large horizontal pipe which carries water to the wheel is pivoted so it can be revolved and the sluicer placed over another tank opposite; or it can be readily uncoupled and the sluicer moved to the next tank in the row. The excellent illustration shows the valve stems and hand wheels for raising the discharge valves in the bottom of the tank through which the sand flows out into launders. It also shows the straight walls cut in the sand by streams of water issuing from the wheel, a feature which indicates that the sand is free from slime, as it should be, and which is one of the reasons why such excellent recovery is accomplished at the North Star mill in Grass Valley, Cal.

Fig. 1. Automatic Sluicer for Sand Tanks

At this mill the average recovery has for several years been between 92 and 94 per cent. of the assay value of slime and sand, while the total recovery from the ore has averaged slightly better than 98 per cent. The value of the ore, going to the mill, in 1911 was \$10.75 per ton. By means of stamp-mill amalgamation 70 per cent. of this gold was recovered, the balance being treated by the cyanide process. The tailing from the cyanide treatment contained 24 cents in gold.

The apparatus will sluice out a 25-foot diameter tank, 8 feet deep, holding 120 tons of sand in from 1 to $1\frac{1}{2}$ hours without any attention, using for the purpose from 1 to $1\frac{1}{2}$ tons of water per ton of sand. The apparatus has been used successfully at the North Star mill; at the Trinity cyanide mill at Carrville, Cal., and also at the Empire mill in Grass Valley. This new wrinkle in sand sluicing will be appreciated by those who have been using hose and nozzle, revolving scrapers, and shovels for cleaning sand out of the tanks.

A Blow-Pipe Bead Without Platinum Wire

Since the price of platinum wire has doubled during the past year, the following method of forming beads in blow-pipe analysis will prove interesting.

To obtain a borax bead without the aid of a platinum wire, heat one end of a glass rod in an alcohol flame and then dip into a mixture consisting of two parts by weight of powdered borax and one part of litharge. The end of the rod is then heated again, whereby an easily fusible bead of lead borate is formed. This is cooled off slightly, dipped into the substance to be examined, heated again, and after thorough fusion cooled off. The bead will then show the characteristic color.

Kansas and Oklahoma Gas Fields

Conditions Affecting the Gas Supply—Description of Compressor Plants for Transporting Gas in Pipes

By Lucius L. Wittich

IN an effort to supply cities and towns in Missouri, Kansas, and Oklahoma with a sufficient quantity of natural gas to meet their requirements, the Kansas Natural Gas Co. and the Quapaw Gas Co. are extending their lines into new districts in Oklahoma and many new wells are being opened; yet even with these additions the production is on the wane and it is only a question of a few years, according to geologists and experts on natural gas, before the stores of natural gas will have been so seriously depleted that only the communities in the immediate gas zone can continue to draw their supply from this fuel. At present, pipe lines extend as far north as Kansas City and St. Joseph, Mo., and Topeka, Kans.; the Quapaw is a new company and produces a comparatively small volume of gas. The Kansas Natural Gas Co., the pioneer company in the field, is now producing less than 70,000,000 cubic feet of gas daily, compared with 150,000,000 cubic feet a few years ago. The company believes the extension of pipe lines and the construction of a large compressor station, in what is known as the Hogshooter district in Oklahoma, will add 30,000,000 cubic feet daily, thus bringing the total to about 100,000,000 cubic feet. The greatest estimate placed on the future production is 108,000,000 cubic feet, or 42,000,000 cubic feet less than the maximum of a few years ago.

In order that consumers might know the true conditions, the Kansas Natural Gas Co. has requested commercial organizations in the various communities using natural gas to visit the sources of supply. Joplin business men took advantage of this opportunity to inspect the fields and a tour of investigation was made late in the fall. The party was made up of representatives of the Joplin Commercial Club, the East Joplin Business Men's Club, the South Joplin Booster Club, the Villa Heights Commercial Club, several bankers and other business men and the writer, representing Mines and Minerals. From Joplin they went by rail to Cherryvale, Kans., one of the first cities in the gas belt. This place is on the extreme eastern boundary of the gas fields and procures its supply from the Iola-Portland Pipe Line Co., a small company furnishing gas to several cities and towns in the immediate vicinity. The chief source of supply comes from fields 40 miles distant although some gas is found not far from Cherryvale, Kans.

Fig. 1. Grabham Gas Compressing Station

From Cherryvale to Independence, Kans., the trip was made by trolley, and from Independence to Tulsa, Okla, a distance of 175 miles, the trip was made by automobile, the visitors stopping at Bartlesville, Okla., the first night out. In this trip the main compressor station in the Independence field, the newly constructed compressor station in the Hogshooter field, compressor stations of other gas companies, and innumerable wells were visited, A. B. MacBeth, of Independence, general manager of Kansas Natural Gas Co., being present to explain all details. J. T. Lynn, of Detroit, president of the Joplin Gas Co., a distributing concern which procures its supply from the Kansas Natural, and B. J. Crahan, general manager of the Joplin Gas Co., also were members of the party and explained many interesting and instructive details of the development.

At the central offices of the Kansas Natural Gas Co., at Independence, visitors were shown a large roller map, giving the location of all wells and pipe lines and other points of interest in connection with the procuring of natural gas, and Mr. MacBeth pointed out the proposed automobile route to be followed. He showed the location of the 673 active wells of his company, 235 of which are located in the Independence field. It was also explained that an open-air pressure of say 400 pounds meant a pressure of about 40 to 80 pounds when turned into a pipe line. The greatest number of new wells, it was pointed out, are of about 5,000,000 to 10,000,000 cubic feet flow daily and are located in the Osage Nation. Wilson County, Kans., which formerly produced 130,000,000 cubic feet daily, is now turning out barely 8,000,000 cubic feet. A great many wells are still flowing in this field, but their volume is greatly reduced. This field lies to the north of the Independence field and formerly was an important factor in the gas production. The gas from this field passes through the compressor station at Petrolia, Kans. Formerly a large compressor station was located at Scipio, Kans., but this was only a substation, handling gas that came from the Grabham station in the Independence field and aiding in pumping it on to Kansas City. This plant has been removed to the Hogshooter district at a heavy expense. Therefore, all of the gas with the exception of the 8,000,000 cubic feet that passes through the Petrolia station, goes through the Grabham station, which, in turn will likewise handle all of the new supply from the Oklahoma fields which will be pumped through from the Hogshooter station.

The first stop was at the Grabham station, 6 miles south of Independence, where $10,000 is yet to be spent in improvements in order that the plant may be better fitted to handle the greater volume of gas. The fact that the Kansas Natural Gas Co. went into the hands of receivers recently necessitated the procuring of a court order before the necessary funds could be appropriated for the construction of the needed improvements. The court granted the company the right to proceed with its work. The cost will be divided as follows:

	Total Cost	Already Expended
Hogshooter station	$145,000	$88,000
Hogshooter intake	56,000	33,000
Collinsville extension	68,000	4,500
Tulsa extension	63,000	160

Fig. 1, a view of the Grabham station, shows what the officials of the company claim to be the largest natural gas compressor station in the world. For this and other photographs in this article the writer is indebted to W. Moeller, Jr., engineer of the company and in charge of construction.

The plant is equipped with nine twin compressors, six of which have a horsepower of 1,100 each, while the remaining three have 1,350 horsepower each, making a total of 10,650 horsepower daily. The gas comes into the compressor station through two 16-inch mains, the average pressure for one being 35 pounds, for the other 25 pounds. The capacity of the compressor is greatly increased when the intake pressure is greater, but the rock pressure of the Kansas and Oklahoma fields is much less than that of the Eastern States where the rock in which the gas occurs is much harder and where the pressure is higher, retaining its strength for years after the average Kansas or Oklahoma well is exhausted. The outgoing pressure from the Grabham station ranges between 190 and 200 pounds. The compression of the gas causes great heat and it is necessary to run the gas in pipes through water in order to cool it before permitting it to pass into the distributing mains. Two large reservoirs have been constructed for this purpose, and in order that the water may not become heated from constant contact with the hot pipes, a spray system has been installed, the water being kept in constant circulation, while it passes continuously through spraying devices and is sent high into the air and thus cooled. Only the gas that goes to Kansas City, Topeka, and points in northern Kansas and Missouri passes through the Petrolia station. Joplin and many other cities and towns in eastern Kansas and western Missouri get their supply directly from the Grabham station.

One mile southeast of the Grabham station the visitors stopped at a well which Mr. MacBeth stated had a flow of 26,000,000 cubic feet daily 3 years ago when it was brought in. It also had a rock pressure of 350 pounds. He opened the cap and tested the volume and the pressure, showing that the former has dropped to 55 pounds. He said this was true of virtually all of the remaining 234 wells in the immediate Independence field. As the country is open prairie slightly rolling, the visitors were enabled to see to great distances in all directions. Many wells were visible. Another well, 6 miles southeast of Grabham, was visited. At this point both oil and gas are encountered in different wells, the former being sold to the Prairie Oil and Gas Co. The cap was removed from this well, which had a flow of 8,500,000 cubic feet and a pressure of 400 pounds. It was recently brought in and is considered one of the best in the field. When the cap was removed the noise of the escaping gas was deafening. It was stated that a few years would see this well's capacity materially reduced.

Many wells that had been capped were noted along the route. Residents of the immediate districts were inclined to believe that the company was deliberately withholding much of its gas supply in order to make it appear that the volume is decreasing, but the company maintains that the capped wells have been almost exhausted, and are being held in reserve in the hope that the pressure and the volume may increase. In connection with this, Erasmus Haworth, geologist of the state of Kansas, says it is possible for wells to recuperate. "The real explanation of the gradual decrease of the pressure," he observes in his Report on Kansas Oil and Gas, "may be the movement of water within the sandrock. Suppose we have a well drilled into a gas bubble in the sandrock, which bubble is entirely surrounded by water on all its borders; should the well be used lavishly gas would travel from different places in the pool to the foot of the well and escape more rapidly than the water could close in on the ever-decreasing bubble of gas, and in this way the gas pressure would be gradually decreased as the well became exhausted. If, however, the well should be closed for a period of weeks or months we would expect it to regain its pressure and ultimately reach the normal pressure when the well was first drilled."

Fig. 2. Hogshooter Gas Compressing Station

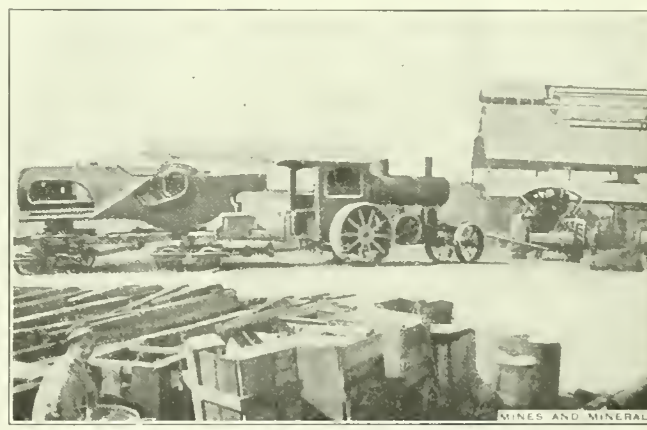

Fig. 3. Hauling Gas Engine Frames

The wells southeast of Grabham station feed into 10-inch mains which in turn feed into the 16-inch mains that lead to the compressor station. From this field an 18-inch line leads southward into Oklahoma.

A new field known as the California field is being opened in the northern part of Oklahoma. This district lies 12 miles south of the city of Coffeyville, Kans., which is within a mile of the state line. In this immediate district 36 wells are pouring their output into the 18-inch main that leads northward. The field, when at its maximum capacity a year ago, was producing about

4,000,000 cubic feet to the well daily. This volume has been decreased to an average of less than 1,000,000 cubic feet to the well. A small 600-horsepower compressor was recently removed from the Chanute, Kans., field and is now in operation at a point 5 miles north of the California field.

One mile west of the first well visited in the California field the visitors stopped at a well which had been drilled for gas, but which had encountered oil. Pipe lines had been connected with the mains of the Prairie Oil and Gas Co., and the output, which is small, is sold for 70 cents a barrel.

The Kansas Natural Gas Co. owns a comparatively small acreage, save where it has compressor stations. Prospecting for gas is common among the landowners of the district, and when they bring in a gasser they find no trouble in marketing their production at the rate of 3 cents per 1,000 cubic feet. The same company, likewise, procures leases from landowners and does its own drilling, the customary rate being $50 a year for a producing well brought in through this method, regardless of the volume or pressure. Conditions of course vary, the price paid for gas in some fields being only 2½ cents while in other regions as high as 3½ cents is paid. It is seldom necessary to shoot the wells, save where the pressure at the start is very weak. A nitroglycerine "go devil" is then utilized. It is necessary to shoot the oil wells more often than the gas in bringing in a producer.

Toward dusk of the first day of the tour the visitors passed through a region where countless scores of flambeau lights were blazing on every side, and as night came on the glare of the torches became more and more in evidence. Many of these burn day and night. Many residents of the outlying districts depend on the torches for the lighting of their houses, one or two big jets of flame, stationed near the dwelling, making the premises almost as light as day and making it unnecessary to have gas burners on the inside. Where prospecting rigs are at work two or three flambeaux are stationed, and it is seldom, indeed, that any effort is made to shut them off through the day. The waste of gas in this manner is undoubtedly heavy. The glare of these torches was to be seen in every direction until the tourists finally pulled into Bartlesville, Okla., for the night.

The Hogshooter district, 14 miles southeast of Bartlesville, was the first region visited on the following day. Work on construction of the big compressor station was advancing rapidly. Fig. 2 shows the progress that had been made at that time. Six twin compressors will be operated in this station. Formerly the plant was operated at Scipio, Kans., north of Petrolia. With the aid of the Scipio plant the Grabham station could have pumped 92,000,000 cubic feet daily; as the gas supply decreased the Grabham plant found it possible to handle, unaided, at least 70,000,000 cubic feet; hence the northern compressor station was removed to the Hogshooter area to

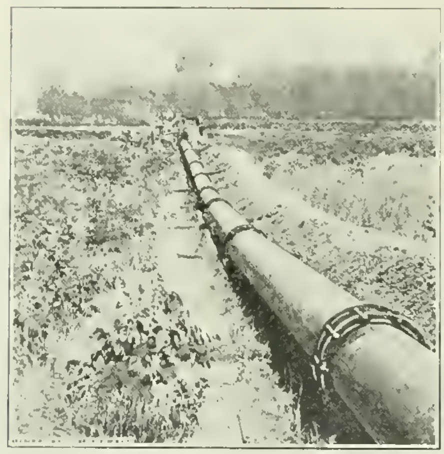

Fig. 4. Main Gas Pipe Line, Hogshooter Field

the south. The rebuilt station will handle gas from the Collinsville, Owasso, and Tulsa fields. In the Hogshooter field there are now about 100 wells; formerly there were 125 and the pressure and volume were much greater than at present. The gas is encountered in sandrock at a depth of 1,200 feet. The average rock pressure is 125 pounds. Toward the south the pressure increases, being 150 pounds at Collinsville, 480 pounds at Owasso, and 600 pounds at Tulsa. The natural flow took the gas to the Grabham station before the Hogshooter plant was built. About 20,000,000 cubic feet daily went from this field before the building of the new compressor station. The flow will be more than doubled by the new station.

The cost of moving the compressor station from Scipio will aggregate more than $50,000. Powerful traction engines were employed to haul heavy pieces of machinery from the nearest railroad point, the Dewey, Okla., spur, 11 miles distant, to the Hogshooter field. In order to get stone necessary in the construction of this plant the company operated its own stone quarry, a suitable formation being found near the site of the station. To move each of the main frames of the big gas engines, three traction engines were employed. The weight of each frame is 40 tons, Fig. 3 showing one of these enormous pieces of machinery being brought to the station. In all, 150 freight cars were filled with machinery. In moving the equipment from the Dewey spur, 50 teams, wagons, and drivers were employed in addition to the traction engines.

In order to make the capacity of the transporting system greater, parallel pipe lines are laid for some distance south. Two 16-inch lines run south of the Hogshooter station for a distance of about 12 miles, from which point only one main extends into the new fields (Fig. 4). The intake at the Hogshooter station is 16 inches in diameter. An 18-inch line extends some distance south, connecting with the two 16-inch mains.

The houses of the workmen at the Hogshooter station are substantially constructed of corrugated metal and cement. A small army of laborers is employed, and every reasonable care is taken to see that sanitary conditions are good.

The visitors went from the Hogshooter station to the new compressor plant of the Quapaw Gas Co., 1 mile to the north. Steam instead of gas engines are used to generate power at this plant, gas, of course, being used for fuel. The company is experiencing difficulty in procuring enough gas from the immediate vicinity to keep the plant running at full capacity. There are two steam compressors of 750 horsepower each, the capacity of the plant being 20,000,000 cubic feet daily when the intake pressure is 100 pounds or better.

Returning via the Hogshooter station the trip was continued southward. The plant of the Henry Oil and Gas Co. was passed some distance to the south. This is a small concern that supplies gas to the Bartlesville smelters. Scattered throughout the gas belt are a number of other similar plants supplying gas to the smelters at low rates. Gradually, however, the supply is being exhausted and the smelters are returning to the use of coal for fuel.

Further to the south the new Owasso field was reached and here the cap was removed from a well that had just been brought in and which was considered an exceptionally heavy producer. A test showed the pressure to be close to 500 pounds and the volume 10,500,000 cubic feet daily. Gas was encountered at a depth of 1,171 feet and the boring was continued to a depth of 1,185 feet. This well was

16 miles north of Tulsa, and throughout the remainder of the trip wells in the newly developed region were plentiful. To the south of the Arkansas River new fields are being opened, but these are so remotely located from the pipe lines of the Kansas Natural Gas Co., that for the present at least no effort will be made to extend lines into those districts.

Natural gas was first used commercially in Kansas in 1873. Prior to that time prospect drilling had been carried on for a number of years, the first systematic efforts dating back to 1870. Iola, Kans., was the first town to get natural gas for lighting, and it was found within 737 feet of the surface. Iola continues to have natural gas from wells near the city although the supply is limited. Paola, Kans., got gas as early as 1882 and it was found as near the surface as 300 feet.

The real development of the Kansas gas fields did not begin until about 1890, Neodesha being the first city to get its supply from the big fields of southern Kansas. Coffeyville was among the first cities to make use of natural gas from the southern Kansas fields.

In the vicinity of Muskogee, Okla., a few wells have been sunk into the Mississippian limestones and some gas and oil procured, but with these exceptions virtually all the oil and gas is confined to the coal measures, or Pennsylvanian series, overlying the Mississippian, judging from development in the Midcontinental field. Of all the horizons of the coal measures the most productive is that formed of the Cherokee shales, occurring at an average depth of 1,000 to 1,200 feet beneath the surface. Within the shales occur the sandstones, of much less lateral extent than the shales themselves. The sandstones grade into the shales in all directions, and it is from the sandstone that the bulk of the gas is procured, although gas is obtained in some instances from holes drilled into shales that showed no hint of sandrock, while, in some cases, near Bartlesville and other points in Oklahoma more noticeably than in Kansas, gas is in some places found in limestone.

As a rule the gas from both Kansas and Oklahoma is high in fuel value, although an occasional well produces a gas that is low in combustible constituents.

A wide difference is noted in the gas from different portions of the two states, but it is indicated that the variation in composition follows some regular order, related presumably to the geological structure.

Platinum and Allied Metals*

The production of platinum in the United States is increasing owing to the high prices paid for the metal. The production reported in 1911 was 628 troy ounces, an increase of 238 ounces compared with the output of 1910.

The entire output of crude platinum in the United States is recovered from placer mines in Oregon and California, which also produce gold. Of the California product, 488 ounces were recovered as a by-product in dredging operations in Butte, Yuba, Sacramento, and Calaveras counties, 205 ounces being derived from Butte County and saved in the dredging of gold-bearing gravels at Oroville. Smaller quantities were recovered from placer operations of various kinds in Calaveras, Del Norte, Humboldt, Placer, Siskiyou, and Trinity counties.

In Oregon the quantity recovered in 1911 was 117 ounces, having a reported value of $3,265. The ocean beaches in Coos and Curry counties yielded 50 ounces. The remainder came mainly from placer mines in Josephine County, near Kerby.

The production of refined platinum from crude metal derived from placers is calculated on the basis of a content of fine metal of 70 per cent. and, thus computed, 440 fine ounces is found to have been the output from domestic placers in 1911.

In 1911 crude platinum sand was imported into the United States to the amount of 34,412 ounces. Assuming a content of fine platinum of 80 per cent. we arrive at the approximate figure of 27,500 ounces of refined platinum produced in the United States in domestic refineries from foreign sands.

In calculating the production from bullion there is some difficulty because of some refineries like that of the United States Mint, the output of which is in large part derived from secondary sources—that is, from scrap platinum and from sweepings, etc., bought from jewelers and dentists. During 1910 private refineries also began the separation of platinum metals from gold bullion.

According to the best estimate that can be made, domestic refineries produced in 1911 about 1,200 fine ounces of platinum from bullion. It is not possible to differentiate between that derived from domestic and that from foreign ores. Probably not more than 500 ounces were obtained from bullion derived from domestic mines.

In conclusion, the total quantity of refined platinum produced in domestic refineries would be approximately 29,140 fine ounces, of which only about 940 ounces, valued at $40,890, were derived from domestic sources of various kinds. The corresponding estimate in 1910 was 773 ounces, valued at $25,277.

Most of the platinum recovered from mines is contained in the gold and copper bullion only in small quantities, and consequently it is in still smaller quantities in the original ores, which can therefore not be considered as platinum ores. During 1911 a shipment of material which may properly be classed as a copper-platinum-palladium ore was made from the New Rambler mine, in Wyoming. The quantity recovered was not large compared to the total production of refined platinum given above, but nevertheless the shipment constitutes a notable event.

The New Rambler mine is in the Medicine Bow Range about 32 miles west of Laramie. The deposit, which mainly contains oxidized copper ores and secondary covellite, is in dioritic rock of pre-Cambrian age. H. L. Wells and S. L. Penfield found sperrylite (arsenide of platinum) crystals in this ore in association with covellite and pyrite. The occurrence of platinum in the ore was first announced by Prof. Wilbur C. Knight. It is reported that the rich ores and concentrates shipped contained about .5 ounce of platinum and 1 ounce of palladium per ton. A secondary concentration of the platinum metals has doubtless been effected during the oxidation of the deposits. A specimen of covellite from the Rambler mine assayed 1.8 ounces per ton of platinum and 1.1 ounces of gold. A small quantity of palladium was also noticed in this sample. The gold is principally in the free state, but these metallic particles contain no platinum. Low-grade ore from the mine was found to contain .25 ounce of platinum and .03 ounce of gold, besides a trace of palladium.

The owners of the New Rambler mine have built an experimental mill with the capacity of 150 tons per day, and are experimenting on the problem of the utilization of the lower grade ores.

A platinum deposit discovered some years ago in southern Nevada east of Moapa consists of a dike of peridotite which contains copper

*Abstracted from advance chapters from "Mineral Resources of the United States."

minerals and carries a little platinum, as described in "Mineral Resources" for 1908.

The strong demand for platinum and the remarkable rise in quotations which began in 1910 continued throughout 1911. The year began with refined platinum quoted at about $29 per ounce. There was an almost uninterrupted increase in price until November and December, during which months the price had risen to $46 per ounce. At the end of December $48.50 was paid. The demand abated somewhat in the first months of 1912.

The apparent consumption is measured by the approximate production of refined metal in the United States, which was about 29,140 fine ounces, added to the imports of bars, manufactured metal, and manufactured products, amounting to approximately 91,600 fine ounces. The total apparent consumption was, therefore, 120,740 fine ounces, which is about one-half of the world's production of refined platinum. This estimate takes no account of the secondary platinum recovered from scrap.

THE PLATINUM METALS*

Six closely related metals are usually referred to as the "platinum group." They are platinum, iridium, osmium, ruthenium, rhodium, and palladium. According to their atomic weights, they fall into two groups, the first including ruthenium (101.7), rhodium (103), and palladium (107); the second group including osmium (191), iridium (193.1), and platinum (194.9). The atomic weight of gold (197.2) is close to that of platinum. In specific gravity the purified metals range as follows: Osmium, 22.48; iridium, 22.42; platinum, 21.48; ruthenium, 12.26; rhodium, 12.1; palladium, 11.4.

In fusibility the order is as follows: Osmium is the most refractory of the metals, melting considerably above 2,000° C.; ruthenium, iridium, and rhodium follow in order; the fusion point of iridium is from 2,150° to 2,250° C. At 1,100° C., iridium begins to oxidize to a purple oxide. The melting-point of platinum is 1,779° C. Palladium is the most fusible and melts at about 1,549° C., or at about the same temperature as wrought iron.

Platinum.—The mineral called platinum is really an alloy of platinum, iridium, rhodium, palladium, and often osmium, with varying amounts of iron, copper, and gold. It is usually found as small nuggets, scales, and rounded or irregular grains; its color is steel gray. The specific gravity of the crude platinum varies from 14 to 19. The percentage of platinum varies also within wide limits, but is generally from 70 to 85 per cent. The native platinum may be strongly magnetic or comparatively inert. The metal platinum is of grayish white color and is hard, malleable, and ductile.

Iridium.—Iridium is generally present in crude platinum sand in alloy with osmium, as iridosmine, or more rarely in alloy with platinum as native metal. In its manufacture from crude platinum it is obtained as a sponge, which is then melted with the addition of a little phosphorus. Melted iridium is a brilliant white, brittle metal. Owing to its hardness, which is 6.7 Mohs scale, it is used for pointing gold pens. The price varies and at this writing is quoted at $68 per ounce in New York City.

Osmium.—Osmium occurs generally as an alloy with iridium, in which the other metals of the group are very subordinate. The mineral called iridosmine forms hexagonal crystals or flattened grains and has a white color considerably lighter than that of platinum. It contains from 40 to 77 per cent. iridium and from 20 to 50 per cent. osmium.

The metal in refined state is bluish gray, hard, and brittle and oxidizes rather easily.

Palladium.—Palladium is a white metal, intermediate in color between platinum and silver. Its hardness is about equal to that of platinum. It is malleable, ductile, and sectile, and dissolves easily in nitric acid. Palladium is present in almost all varieties of crude platinum, but the analyses rarely show more than 2 per cent. In larger quantities it is present in some copper ores, but its state of combination is in doubt. Probably it is combined with arsenic, like sperrylite.

Rhodium.—Rhodium is a white metal of the color of aluminum. It is ductile and malleable at red heat. The metal occurs in crude platinum in quantities up to 4 per cent. Like palladium, it probably occurs in combination with arsenic in certain copper ores.

Ruthenium.—Ruthenium is a white, hard, and brittle metal, which is scarcely attacked by aqua regia. Like osmium, it oxidizes rather easily in the air. It is found to small extent in crude platinum, but mainly occurs to the extent of a small percentage in the mineral iridosmine.

Other Platinum Minerals.—Very few platinum minerals are known beyond those already mentioned. Sperrylite or arsenide of platinum ($PtAs_2$), with a little antimony and rhodium, occurs as small crystals of an isometric form and tin-white color in certain copper and nickel ores—for instance, at Sudbury, Ontario, and at the New Rambler mine, Wyoming. The minute crystals are embedded in pyrrhotite or covellite.

Laurite is an extremely rare sulphide of ruthenium with a minor amount of osmium. It is known only from the platinum washings of Borneo.

Palladium in quantities up to 10 per cent. also occurs in combination with gold. This mineral, called porpezite, has been described from Brazil, where it occurs in gold-bearing veins.

Platinum has been found in some varieties of tetrahedrite and bournonite. In minute quantities it occurs in some quartz veins, mainly of the so-called "high-temperature class," for instance, in northern Finland and in the gold-bearing veins of Beresowsk, Russia. Occasionally platinum is found in clay shales and in coal ashes, but so far not in recoverable quantities. Platinum is present in some meteorites and in the sun.

* The following paragraphs are in part taken from Kemp, J. F., "Geological Relations and Distribution of Platinum and Associated Metals": Bull. U.S. Geol. Survey, No. 193, 1902.

Determining Platinum

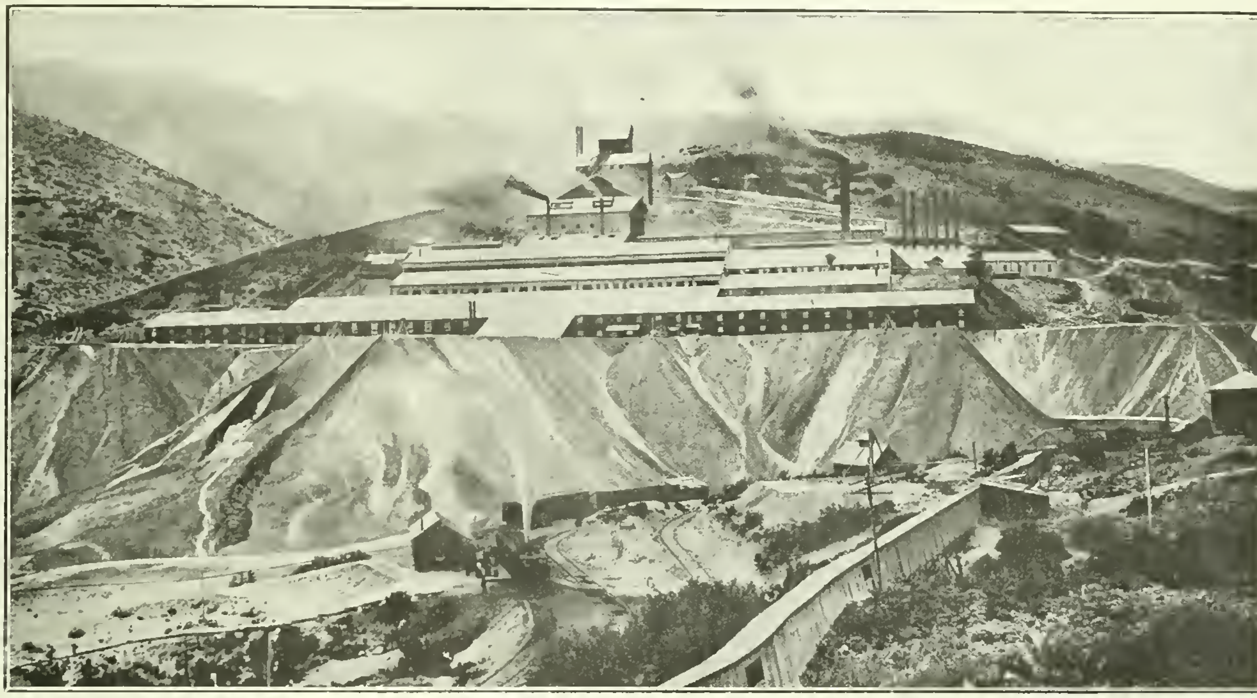
Small quantities of platinum pass into the nitric acid solution obtained in the regular course of assaying on parting gold from silver. To this solution a limited quantity of a very diluted solution of hydrogen suphide (1 part of the strong solution diluted with from 10 to 20 parts of water), sufficient to precipitate the platinum and three to five times as much silver, is added, and after standing for 3 or 4 hours, or preferably over night, the precipitate is collected and dried, the paper burnt off, and the residue wrapped in a piece of thin lead foil and cupeled. The resulting bead is parted in strong sulphuric acid, leaving the platinum usually in the form of sponge, which is washed, annealed, and weighed. The same method of concentrating in a precipitate of silver sulphide may be used for the determination of minute quantities of gold in high-grade silver. (F. P. Dewey, J. Ind. Eng. Chem., 1912, 4, 257-S, *Journal of the Society of Chemical Industry*, Vol. 31, 437.)

Practical Cyaniding—(Concluded)

Descriptions of Practice at Some Large Cyanide Mills in the United States and Mexico

*By John Randall**

THE Goldfield Consolidated mill treats daily 850 tons of complex sulphotelluride ore having the average value of $40 per ton, principally gold. After being delivered to the mill bins the ore is stamped in water to a four-mesh battery screen (.18 inch opening), the 100 stamps weighing 1,050 pounds each, the



GOLDEN GATE MILL, MERCUR

stamp duty being 8½ tons. The battery product sizes as shown in Table 1.

The material is next classified in two 7-foot spitzkasten, each taking the product of 50 stamps. The overflow from the spitzkasten goes to the concentrating department. The underflow goes to six 6-foot Chilean mills crushing to a 16-mesh screen. The product of these mills sizes as shown in Table 2.

The Chilean mills are of the L. C. Trent make and use Midvale forged steel for roller shells and dies. The steel consumed per ton of ore milled is .32 pound. The product of the Chilean mills joins the product of the tube mills and passes to cones and spitzkasten where a large amount of the water and a portion of the slime are separated in the overflow which goes

to the concentrating department. The coarse underflow goes to six Dorr classifiers, the sand product from which is fed to six tube mills, the tube mill product being returned to the classifiers in the usual manner. The slime product from the Dorr classifiers goes to the concentrating department. The final product of the grinding and crushing machinery as it reaches the concentration floor sizes as in Table 3. At the concentrator floor the pulp is dewatered in cones until it contains three to three and one-half parts of water to one part of ore by weight and is sent to 76 Deister No. 3 slime tables. The concentrate recovered on these tables amounts to 5½ per cent. of the ore by weight and contains 72 per cent. of the gold. The concentrate is then sent over amalgamating plates where 20 per cent. of the gold is recovered by amalgamation with mercury. The plate tailing is afterwards treated with cyanide

solution in a separate department of the mill and receives different treatment from the concentrator tailing which is also treated by cyanide.

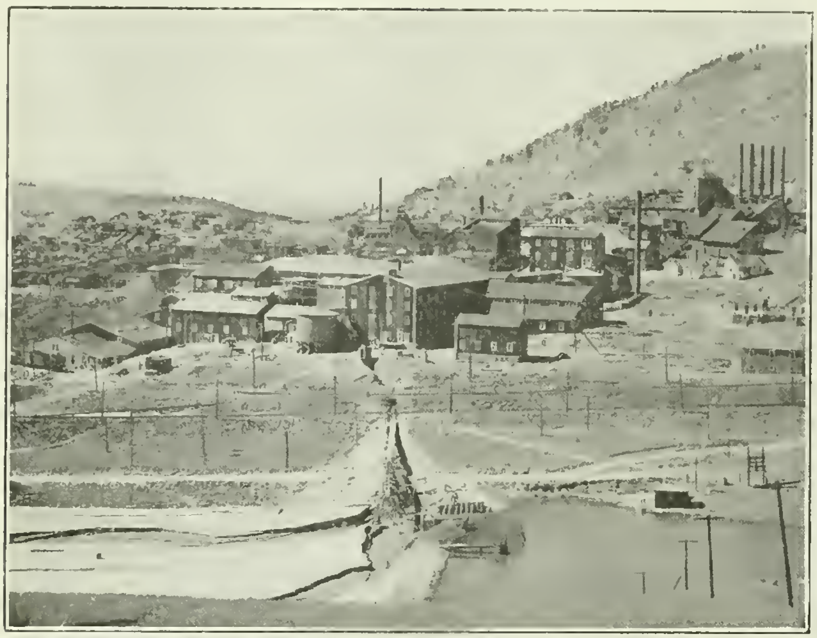
The tailing from the concentrators is dewatered in 29½-foot settlers to 40 per cent. moisture, milk of lime being added in the settlers. The pulp is next sent to a battery of ten Pachuca tanks operating in series, where it receives treatment with cyanide solution for the first time. These tanks are 15 feet in diameter by 45 feet in height. The solution has a strength of 1.2 pounds *KCN* per ton and protective alkalinity equivalent

* Boulder, Colo. Part 1 appeared in August, 1912, MINES AND MINERALS.

to .5 pound CaO. A small amount of lead acetate is fed into the Pachuca tanks. The pulp then passes to storage tanks equipped with mechanical stirrers to keep the coarser particles in suspension and thence goes to a Butters filter plant of 336 leaves. In the operation of the filter the pulp flows to the filter tanks by gravity through 16-inch pipe lines and the excess pulp flows to a sump in the same manner, thus considerably shortening the time required for a cycle of operations. The excess pulp in the sump is returned to the storage tanks by a centrifugal pump of moderate capacity but running continuously. Diffusion losses are obviated by using a fresh portion of barren solution for the wash at each cycle, the excess solution not being returned for use on the following cake but sent to the Pachuca tanks. A value of 30 cents gold is said to be dissolved from the cakes during washing, which cannot be gained by further agitation in the Pachucas, but it is probable that the most of this could be dissolved in the Pachuca tanks if they could be operated on the series-decantation principle with barren solution added to the last one and passing up the series. The extraction during the washing of the cake is found to be better by lengthening the time under a reduced vacuum. No wash water is used, the cake being dropped in solution, the excess solution decanted to the mill and the tailing sent to waste with a low content of moisture.

The cycle of operations for the Butters filter is as follows: Filling vats with pulp, 10 minutes; forming cake, 60 to 80 minutes; discharging excess pulp, 14 minutes; filling with wash solution, 10 minutes; washing, 85 to 100 minutes; decanting and discharging, 20 minutes. Total time, 3 hours 15 minutes to 3 hours 50 minutes.

The concentrate after passing the amalgamating plates is worth about $400 per ton gold. It is then dewatered, agitated for 8 hours with a weak sulphuric-acid solution, receives three water washes, and lime is added. It is then agitated in Pachuca tanks with a $4\frac{1}{2}$-pound cyanide solution, some sodium peroxide and Na_2O_2 lead acetate being added. The agitation is carried on in 8-hour intervals, the solution being decanted and fresh solution added between each interval. The concentrate then goes to a Kelly filter press.



Stratton's Independence Mill

The gold-bearing solutions leaving the filters are apparently clear but contain a small amount of very light flocculi, and in order to remove this they are passed through three clarifying filter presses having 60 frames 3 feet square. This improves precipitation and insures that the barren solution shall not contain more than 6 cents gold per ton. Zinc dust is used for the precipitant, by means of the regular Merrill equipment, four 30-frame, 4-foot, triangular, presses being used. The precipitate from the Merrill presses is briqueted with litharge, dried, run down in a small blast furnace, and the resulting lead bullion cupeled. The product from the zinc filter presses was once dried in a furnace and melted in Faber Du Faur tilting furnaces, previous to the introduction of the blast furnace. No acid is used in the treatment of precipitate. About equal weights of gold and silver are recovered, and the average percentage of extraction is $94\frac{1}{2}$. It is interesting to note that the extraction from the unroasted concentrate is a little better than 95 per cent.

The cost of cyaniding the concentrate is $5.85 per ton, 93 cents being for labor, $4.44 for supplies, mostly chemicals, and 48 cents for power. This cost when distributed over the entire ore tonnage is calculated as 38.1 cents per ton. The following analysis, by Mr. Hutchinson, the mill superintendent, gives the principal items of cost and the total cost per ton at this notable mill for the year 1911:

Crushing-conveying	$ .040
Stamping	.134
Chilean milling	.097
Tube milling	.177
Concentrating	.057
Agitating	.604
Water service	.098
Steam heating	.056
Filtering-discharging	.068
Precipitating	.074
Refining	.098
Other items	.510
Mill total	$2.013
Cyaniding concentrate	.381
Total	$2.394

Some of the elements of mill cost at Goldfield are high, notably water. In comparing the cost at this mill with that of other plants it must be borne in mind that the allowable milling cost depends upon the grade of the ore and the consequent gain to be derived from refinements in treatments giving a higher percentage of extraction.

The Goldfield Consolidated mill was described in Mines and Minerals, Vol. 32, p. 610. It treats $40 ore and is the most modern cyanide mill.

Mercer, Utah, is the oldest cyaniding district in the West. At first all the ore was oxidized and was treated without roasting but now the Golden Gate mill, the principal one in the district, roasts about one-third of its ore. This mill receives two kinds of ore, the more oxidized being termed "mixed ore" and the other "base." All the ore is crushed dry, the base ore being crushed to a $\frac{1}{4}$-mesh screen and afterwards roasted. It is necessary that the roasting be very carefully done, to avoid fritting which occurs at a low heat. The "mixed ore" is sent to a different part of the mill, put through a Gates crusher, thence through two sets of rolls, being screened between the two, and is separated finally into coarse and fine by means of a trommel covered with three-mesh screen wire. The oversize from this trommel is not recrushed but sent to the leaching vats. Some of these pieces are nearly 1 inch in diameter but the ore is soft and so porous that the solution penetrates it. After the vat is filled, a layer of lime is put on the top and the cyanide solution turned on from the bottom. Generally no attempt is made to drain the vat between successive applications of solution, as it tends to pack the ore and cause slime to settle on the filter. Sometimes a part of the vat charge is made up of roasted ore. The size passing through the meshes of the trommel contains a considerable amount of clayey material and this is loosened from the harder particles by being mixed with solution and passed through two modified log washers operated in tandem. These "mixer-separators" as they are termed, are set at an inclination of 1 inch to 1 foot, the action of the revolving blades being to work the coarse ore toward the upper end where it is discharged, while the fine ore and slime are washed to the lower end discharge, this going to the second washer where the operation is repeated. The following is a sizing from the coarse ore discharge of the No. 1 mixer-separator:

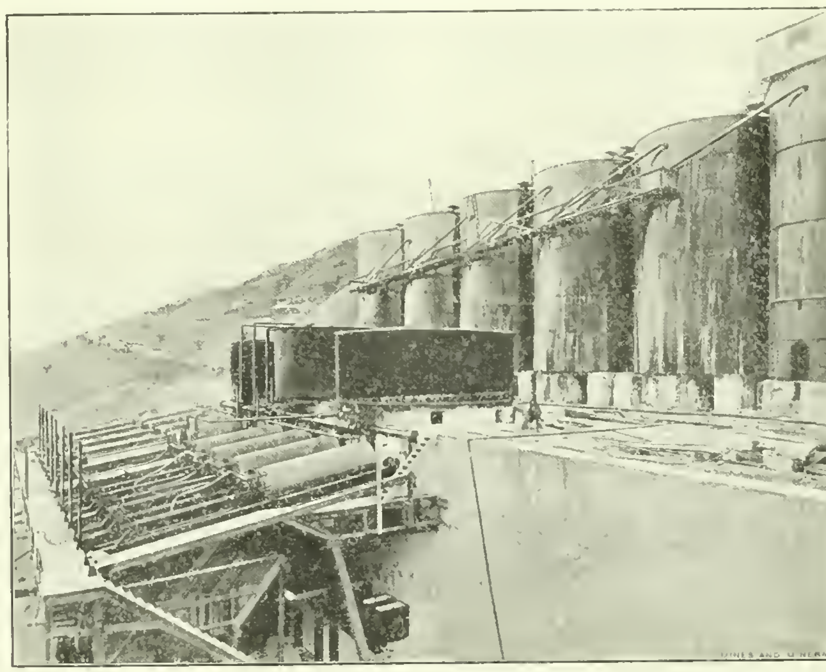
Mesh	Per Cent.
+ 4	37.8
− 4+ 8	33.5
− 8+18	10.7
−16	7.8
Slime	10.1
Loss	.1
	100.0

As this coarse sand contains 10.1 per cent. slime, it is afterwards classified. All the product from the mixer-separators is sent to Dorr classifiers, the granular material from the sand discharge end of the classifiers being distributed in solution to leaching vats. The slime is sent to thickeners and thence to a Moore filter plant without agitation, as extraction seems to occur as soon as the slimed ore can be separated in the classifiers. Lately the practice has been to send a portion of the roasted ore to the log washers and classifiers, as the dust from the roasted ore tends to make the slime cake more permeable. The strength of solution used is 1.8 pounds per ton and the cyanide consumption is stated at .7 pound per ton of ore. The value of the ore is below $3.50 per ton gold and the extraction 70 per cent. Some of the gold is insoluble and this has received a large amount of careful attention. The practice has been changed from time to time to meet new conditions. In 1911, 33 per cent. of the ore was roasted at a cost of 92 cents per ton, making the roasting cost 30.36 cents when distributed over the whole tonnage. The following is the mill cost per ton as compiled from the company's report for the year 1911:

Crushing	$ .1082
Roasting	.3036
Extraction	.5331
Precipitation	.0532
Refining	.0419
	$1.0400

During that year the mining cost was $1.29 per ton, milling $1.04, total $2.33. An average of $2.32 per ton was recovered from the ore, being for the year $55,696 in bullion. The operating loss of 1 cent per ton was turned into a small net profit by miscellaneous sources of income.

The ores of the Cripple Creek district, consisting of porphyry, andesitic breccia, phonolite, decomposed granite, and quartz, usually carry on the surface iron oxide, manganese oxide, and oxide of tellurium; below the water level the gold occurs in the minerals calaverite and sylvanite and is associated with more or less iron pyrite. The mineral fluorspar frequently occurs in the veins. While the surface ores contain free gold, they do not yield their gold in amalgamation, it usually being coated with oxide, or tellurium, or some substance that interferes with its extraction by this method. The extraction of gold from the surface ores by potassium cyanide presents no difficulties; but the treatment of telluride ores without subjecting them to a preliminary roast has been attended with the drawbacks of extremely fine grinding and prolonged percolation in the tanks (sometimes from 12 to 14 days) in order to secure a fair extraction. The ores are roasted to oxidize the tellurium, with the result that shot gold is formed, and this requires additional appliances for recovery, besides fine grinding. The present practice is to crush as coarse as possible in ball mills, that is, to a product which will roast satisfactorily. After roasting, fine crushing is carried on in Chilean mills, and, instead of amalgamation, blankets are employed to save the free gold. The sands are next separated from the slime and percolated with cyanide solution, while the slime is treated by vacuum or pressure filters.



Parral and Pachuca Tanks

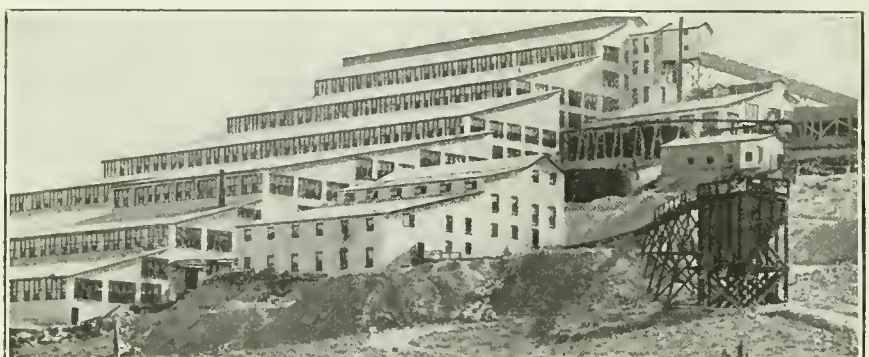
The first mill to treat Tonopah, Nev., ore was erected at Millers, 11 miles away from Tonopah, where an abundance of water for milling purposes was struck at a depth of 35 feet below the surface. The mill, while named the Desert, belongs to the Tonopah Mining Co., and treats an ore containing silver and gold in the proportion of 100 to 1, with a recovery of about 90 per cent. of both the silver and the gold. The ore is treated by stamping, amalgamating, concentrating, and cyaniding; Huntington mills are used for grinding the ore crushed by the stamps and the middling product from the concentrating tables.

The mill is capable of crushing 450 tons of ore per day through a 10-mesh screen, and regrinding the pulp in Huntington mills to a 30-mesh screen. From the crushers the ore is raised to classifiers, the sands going to the tables and the slime to the collecting tanks. The middlings from the tables are sent back to the Huntington mills and thence to the classifiers. The pulp from the classifiers is carried in a launder to collecting tanks 33 feet in diameter and 8 feet deep to the filter bottom, into which it is distributed by means of a revolving wet-pulp distributor.

The water and slime are discharged through curtained overflow gates and pass to the slime-treatment tanks. The sand remains in the collecting tanks and, after being drained by gravity and finally by vacuum, it is discharged by the tank excavator upon belt conveyers 20 inches wide and 90 feet long, located under the collecting tanks.

The belt conveyers under the collecting tanks discharge upon two inclined belt conveyers, which carry the sand to a long conveyer located above and between the two rows of sand-leaching tanks. This conveyer is 20 inches wide, 290 feet long, and is driven by an electric motor, at its discharge end. It is arranged with shafts and pulley wheels so as to drive the conveying belts under the tanks. There are 18 sand-leaching tanks 33 feet in diameter and $8\frac{1}{2}$ feet deep, each one being equipped with filter bottom and plug. The long belt conveyer discharges the sand by means of a tripper, upon a belt conveyer that is connected with the sand distributor, both being supported on a movable bridge. After the first treatment, the sand is discharged from the leaching tanks by the sand excavator upon 20-inch belt conveyers 307 feet long, which deliver the sand to cross-conveyers and back to the long conveyer, which feeds it as before to a sand distributor placed over one of the second set of treatment tanks. After the second leaching treatment the sand is discharged from the tanks by the excavator upon the belt conveyers 307 feet long, which are reversed in direction of motion, and discharge upon an inclined stacker conveyer. In order to move the excavator and sand distributor from one row of tanks to the other, a transfer table is provided. This table consists of a heavy framed platform car, which operates on rails placed at right angles to the excavator tracks. The transfer table is driven by a small electric motor belted and geared to one axle. The nominal capacity of the sand-handling system is 100 tons per hour.

The belt conveyers are driven by one 25-horsepower, three-phase, alternating-current, Westinghouse motor. The excavator is operated by one 10-horsepower motor; the sand distributor by one 5-horsepower and one 3-horsepower motor, and the transfer table by one 3-horsepower motor. One man is required on each shift to operate the sand-conveying machinery. To prevent the precipitation of silver as sulphide, 1 pound of lead acetate is added for 3 tons of sand in the tanks. The concentrate from the tables carries on an average 650 ounces of silver and 8 ounces of gold. To produce 1 ton of concentrate requires the milling of 100 tons of ore. Concentrate is shipped to the smelter.



GOLDFIELD CONSOLIDATED MILL

The wet crushing mills in the Black Hills of South Dakota use cyanide solutions in the stamp-mill mortar in place of water. The ore is crushed from 8-mesh to 20-mesh screen, and requires from 3 to 8 tons of solution per ton of ore crushed; however, although the ore is crushed coarse, about 35 per cent. is slime. The crushed ore passes to classifiers, the sand going to leaching vats and the slime to agitating tanks and Moore filters.

At the Homestake the ore is largely free milling and is crushed in water to 30 mesh, amalgamated, and the tailing sent to the cyanide plants. The sand and slime are separated by a system of cones of special construction run in series, the sand being washed by water as it passes down the series of cones until it is very clean, when it is sent to the sand vats and distributed by means of Butters distributors. The vats are filled with water before the distribution of sand begins, and during the filling an overflow is maintained around the entire circumference of the vat into a peripheral overflow launder. The No. 1 plant has 14 leaching vats, each 44 feet in diameter and holding a charge 9 feet in depth. Two of these vats are filled every 24-hour day, making a daily sand tonnage of 1,200 tons. The 14 vats thus provide for a 7-day cycle of operations. After the water is drained off, the standard solution, 2.8 pounds KCN per ton, is run on, and this treatment, with frequent drainings to admit air, is kept up for about 3 days. Owing to the large amount of water in the charge before the solution is run on, the effluent solution contains only about 2 pounds of cyanide per ton and is sent to the weak gold tank and after precipitation in Merrill presses is used as the weak solution for another ore charge. After treatment with standard solution the vats are leached with weak barren solution followed by water washes for the remainder of the allotted time. The effluent weak solution goes to a sump without precipitation, as it contains only about 40 cents gold per ton. It is then standardized to be used as the strong or standard solution on a succeeding charge of sand. The solution is thus enriched by passing through a second sand charge before it goes to the precipitating presses. The solution before precipitation contains about \$2 gold per ton. The residue is sluiced out with water from two lines of hose, the operation requiring 4 hours of time. At Deadwood, 4 miles below the mills, is the Homestake slime plant that treats the slime from 4,000 tons of ore per day. The entire treatment, dewatering, extraction, and washing, is done in Merrill presses. The Merrill zinc-dust precipitation method is also used. The slime coming into the plant has a head value of 90 cents per ton but a good profit is made in treating this low-grade material.

The Treadwell cyanide plant, at Douglas Island, Alaska, was built to treat the sulphide concentrate from the tailing of the free milling plants. The concentrate amounts to 1.8 per cent. of the ore, and the mills produce from 80 to 100 tons of this concentrate per day which contains a little over 3 ounces of gold per ton. The material is ground in Abbe tube mills until 98 per cent. will pass a 200-mesh screen, the sizing of the finished product being done in a Dorr classifier. It then has a preliminary treatment in Pachuca tanks with lime water, next it is agitated in Pachuca tanks with a 2-pound cyanide solution, after which it is washed in Kelly pressure filters. The solution goes to clarifying presses, thence to a Merrill zinc-dust precipitating plant. An extraction of 97 per cent. is obtained at a cost of a little under $2 per ton.

Cyanide practice in the Republic of Mexico is thoroughly modern, exceptionally good work being done in the treatment of silver ores. The milling plant of the Compania Beneficiadora de Pachuca consists of two mills. Both are here described, the old one being interesting on account of the manner in which it has been adapted to modern conditions, and the new one, known as the Santa Gertrudis, being a fair example of the best modern practice.

The Guadalupe mill consists of a converted patio plant, the old Chilean mills having been retained, tube mills added, and a cyanide plant substituted for the patio process. The ore for this plant is brought down from the mine by the Pachuca Railroad Co., on 1-ton flat-bottom cars drawn by Shay locomotives, a distance of $2\frac{1}{2}$ miles. The fine ore is hauled separately from the coarse ore, the screening being done by the mine sorting grizzlies. The coarse ore is put through a Blake crusher, mixed with the fine ore, and trammed by hand to mill bins and fed to 14 slow-speed Chilean mills modernized by putting on steel-tired mullers and driving them by electric motors. The mills retain the stone sills or crushing dies, and are equipped with $\frac{1}{2}$-inch mesh screens. The effluent pulp passes through four Dorr classifiers, the slime therefrom going to eight 15'×45' Pachuca tanks and the sand to three 5'×22' tube mills, each belt driven by a 100-horsepower motor. Each tube mill discharge is returned to the Dorr classifier by means of a 10"×54" Frenier pump. The slime from the classifiers is elevated to the Pachuca tanks by means of centrifugal pumps. The eight Pachuca tanks are operated continuously in series, the discharge from the last tank of the series being elevated by a short air lift to the two 15'×30' storage tanks supplying a 300-ton Moore filter plant. Precipitation is effected by zinc shavings, the precipitate being unusually clean, running 78 per cent. bullion. The bullion produced runs about 920 fine, of which 920 parts are silver.

The new mill near the Santa Gertrudis mine treats 850 metric tons (dry weight) of silver ore per day by all-sliming and cyanidation. The equipment consists of four gyratory crushers, sixty 1,550-pound stamps, 18 Dorr classifiers, 12 tube mills, 13 Dorr thickeners, and 28 Pachuca tanks, with 4 Merrill slime presses with Merrill zinc-dust precipitation. The silver extraction amounts to over 90 per cent. and the consumption of zinc dust is nine-tenths of 1 ounce for each ounce of bullion precipitated.

Efficiency in Mining

*W. J. Crocker**

The two main avenues of cost in all mining are labor and supplies; there are many subdivisions of these two, but in considering mining efficiency as a cost reducer, these two heads should be considered separately.

In the matter of labor, because the work is not constant or always under the eye of a foreman, as in a manufacturing plant, it is more necessary to obtain the good-will of the workman than in other industries. It is not always true that the cheapest labor is the most profitable. To illustrate: the writer knew a superintendent who was called upon to increase the average production of his men; he first ascertained that his superiors were willing to pay more than the scheduled rate of wages provided ore could be mined cheaper. He then went underground, selected a crowd of Austrian miners, stayed with that one crowd from morning till quitting time, when they went to the chute with a car of ore he followed them out, he was with them in their timbering operations, planned their holes for them, and saw that they performed a good day's work; they almost doubled their ordinary output for one day. Next day he took a crowd of Italians doing the same kind of work; he told them what the first crowd had accomplished, jollied them up, telling them Italians were as good workmen as Austrians, etc., followed the same method as in the preceding day, and obtained an even better day's work from them; next day it was a crowd of Finnish miners that had his attention; the fourth day he was back with the Austrians. He had a plain talk with them. They reasoned they would only be allowed to earn from $2.50 to $2.85 per 10-hour day as formerly; he promised them all they could make, set them a contract to be abided by for a year, basing the contract to allow them about $2.50 for the day's work as performed while he was with them, guaranteed them a minimum of $2.50 per day, and showed them they could earn over $4 per day if they worked; they made over $4 per day for a year, and in 3 months, when the miners gained confidence in him, they came to him asking for contracts which he gave. The result was the average tons per man per day were raised from 4.5 or 5 to over 7 and kept there for a year. The overhead charges, such as engineers, landers, trammers, motormen, surface labor, office force, etc., were all included in the 7 tons per man per day; all these got the same pay as formerly but had to speed up and meet the pace set by the miners underground. In this case the good-will of the miners meant increased production for all the mine, but only increased pay for the miners.

In another mine where 12 to 14 tons of coal per 24-hour day was being consumed, a new fireman was hired, who had fired lake and ocean going boats, and locomotives, as well as stationary boilers, and was an expert fireman. Where other men who had held that job quit because the work was too hard he had time for a smoke; an account of coal consumption showed that he used from 1,500 pounds to a ton less coal per shift than other men did; he asked for a raise, was told there was a set rate for firemen, he quit, the company hired another man and coal consumption again increased. In this case the company lost the difference between the cost of a ton of coal and a raise for the fireman because of a standard wage rate.

In the matter of supplies there are three big items, fuel, timber, and powder. In the previous instance fuel could have been saved; it also can often be saved by installing a telephone underground; many trips are made by men and boys coming up on the cage when a phone message would answer as well, thus saving the steam necessary to hoist a cage, and steam means money. Water draining to lower levels may be used to run a fan for ventilation purposes, saving compressed air, which also means money; and in getting well-ventilated working places miners can accomplish more work with less fatigue. Foremen and bosses should know just what is the cost of supplies handled by the men, and its direct bearing on the cost per ton produced. In some districts poles cost almost twice as much as split lagging, yet miners use poles where lagging would serve; if the boss knew the difference in cost he could prevent this waste. In the matter of powder, 40-per-cent. powder is often used where 30-per-

* Negaunee, Mich.

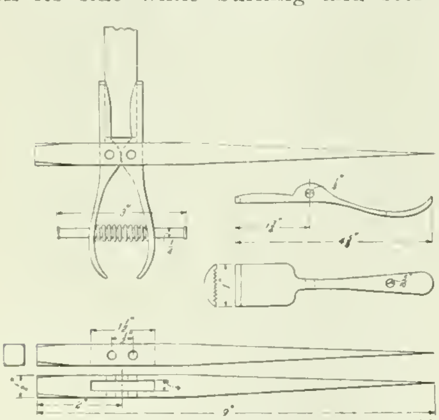
cent. would do the same work, sometimes even 20-per-cent. will serve; there is approximately a difference of seven-tenths of a cent per pound in price between 30-per-cent. and 40-per-cent., which could be saved in many places. Candles, too, can be saved; in many mines the men are given three or four candles for a shift's work; it makes a big difference whether they are given sixes or eights, if they are given four candles per shift, eight to the pound, then they use ½ pound per shift; if four candles, six to the pound, then they use ⅔ pound per shift, which makes a big difference in cost in a year.

There are various ways in which a practical miner with a knowledge of mining costs can apply his experience so as to create efficiency and lower the cost per ton for ore produced.

A Drift Candlestick

*By William J. Crocker**

It is a very common thing in mines where candles are used to see two 5-inch or 6-inch nails driven in the timbers to hold a candle. Many mine fires can be traced to this dangerous practice, candle grease and snoffs (short candle ends) dropping on the level close to the timbers as the candles burn through the nails. Occasionally a candle wick drops while burning and sets fire to the accumulation of grease and wicks at the bottom of the level, the fire thus spreading to the mine timbers; or because of the imperfect grip of the round smooth nails on the round smooth candle, the candle tilts over on its side while burning and sets



Drift Candlestick

the timbers afire higher up. After reading about a fire in a mine where 17 men lost their lives, from such cause, Captain Thomas Nicholas, of the Mohawk mine, Aurora, Minn., now superintendent of the Cascade Mining Co., Palmer, Mich., designed, and had made the drift candlestick as shown, which automatically puts

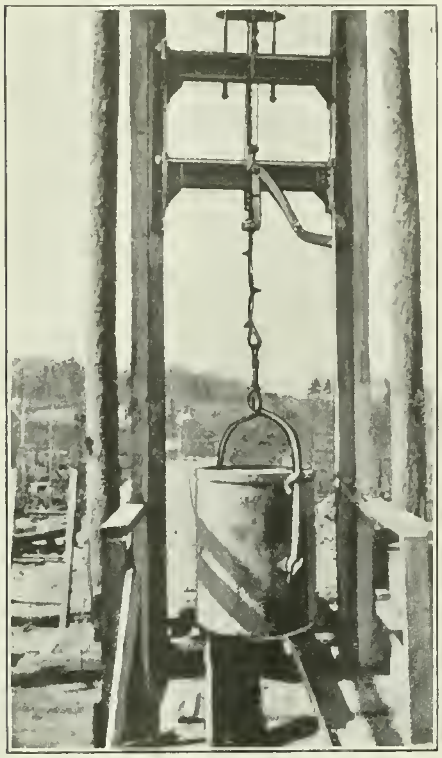


Fig. 1. Morin Crosshead

out the candle. When the candle burns down to about one-half inch from the bottom, the wax then gets soft, and the spring operating against the candle closes the jaws of the holder, putting the candle out, and holding the snoff until some one opens the clutch again, thus preventing the accumulation of grease on the level bottom. The jaw grip holds the candle erect and the stick being 9 inches long or 7 inches from the timbers to the candle flame, even a 8-inch candle cannot tilt against the timbers. Several of these candlesticks were tried out in the Mohawk mine, Aurora, Minn., for over a year, and in every case the candle was put out, and the snoff held in the stick until released. These sticks can be made by any mine blacksmith in a few minutes, the cost being small.

* Negaunee, Mich.

Manganese Discoveries in Philippines

According to the Bureau of Science at Manila, manganese ore has been discovered in the Philippines in considerable quantities, and it seemed possible to develop the industry, but when the matter was looked into it appeared that an export wharfage charge exists on all kinds of ore. If the ore was taken in ballast to Japan, this charge would not be serious, but if it was shipped to the west coast of America, the freight rate would reduce profits to the vanishing point. The same is true in regard to iron ore. A geologist from Japan in the employ of the Mitsui Bussan Kaisha, examined the iron deposits on a small island in Mambulao Bay in Ambos Camarines where iron ore occurs, but the royalty to be paid to the persons owning the land, and the export dues, would leave little for the expenses of mining and the profit. It is recommended that a law remitting these export dues be passed as soon as possible.

Safety Crossheads

In the report of Mr. E. K. Corkill, Chief Inspector of Mines, Ontario, Can., on the number of shaft accidents, he says "that quite a number of accidents have occurred through the falling of crossheads in shafts." To overcome this difficulty, a crosshead has been devised by Messrs. Morin and Sargeson, master mechanics at the Nipissing mines, Cobalt. In the Sargeson crosshead, shown in Fig. 2 (*a*), (*b*), and (*c*), the attachment is fastened to the crosshead at *C*. If the crosshead sticks, this arm automatically engages the clip *B* attached to the rope, and so stops the bucket. In sinking operations, the arm *A* is automatically tripped by a stop-block *E*, allowing the bucket to descend to the bottom of the shaft.

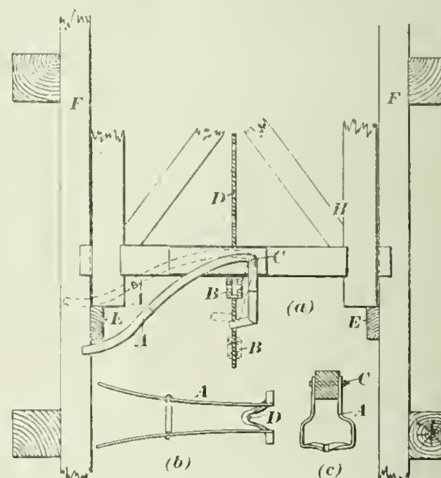

Fig. 2. Sargeson Crosshead

The same equipment is adopted in the Morin crosshead shown in Fig. 1. It is further equipped with an automatic safety device which, by the aid of springs, enables the dogs to grip the guides, thus making it impossible for the crosshead to fall.

The Woodbury Slime Classifier

A Proposed Method of Milling by Using Plunger Jigs on Mixed Feed Not Coarser than 3/8-Inch Round

*By Edward T. Wright**

UNDER the sizing system of concentration, classification is the bugbear of the mill designer and operator. No part of the mill presents so much of detail, all preliminary to the actual work of separating mineral from gangue. The "preliminary separation" has been elaborated until many mills are very complicated. The proper graded sizes of ore must be determined, and a selection made of the kind of screens to be used; the merits of trommels, impact, vibratory screens, etc., must be considered to suit the service and ore in hand. Sizes such as $1\frac{1}{2}$ inch, $\frac{7}{8}$ inch, $\frac{3}{8}$ inch, $\frac{3}{16}$ inch, $\frac{3}{32}$ inch, and $2\frac{1}{2}$ millimeters may be made with screens, then for the finer sizes hydraulic classifiers are selected, with their four to eight classifications and large consumption of water.

All this detail is to prepare the ore for the concentrating machines—jigs and tables—that to do perfect work must treat nicely sized ore. The hydraulic classifier in making a separation of slime from sand causes a dilution of slime of from 50 per cent. to 100 per cent., making it necessary to provide elaborate settling systems with resulting overflow losses in fine mineral in order to obtain material of proper density for treatment on tables or vanners.

The purpose of this article is to point out a means of simplifying and modernizing the mill, with largely increased recovery.

Jigs of the Hartz type do indifferent work on mixed or unsized feeds, and the sizing system has been built to conform with them. Consider, therefore, a means whereby the complications of the sizing or "preliminary treatment," can be almost entirely eliminated, while at the same time the slime is separated with little or no dilution.

An ideal concentrator would be one that would effect a perfect separation of all free mineral and middling from an unsized feed. As a matter of fact, an unsized feed when passing over a suitable jigging apparatus separates naturally into two fundamental classes; viz., slime, i. e., suspended material which will not settle and which floats along over the jig; and sand, i. e., material which will settle. Therefore, to bring the ideal concentrator down to a practical basis, a device must be provided for separating the slime as an unfinished product for subsequent treatment; at the same time, the apparatus must be capable of stratifying and separating from a mixed feed the free mineral and middling from the gangue.

The Woodbury slime classifying jig, shown in Fig. 1, in use at the Calumet and Hecla mill, Lake Linden, Mich., is a form of plunger jig so arranged that the feed flowing on to the jigs parallels the currents of water, caused by the plunger impulse, enabling the jig to rapidly stratify the sand in an absolute mixed feed. An unsized ore (not coarser than $\frac{3}{8}$-inch round) is delivered at the head of the first compartment of the slime classifying jig.

This compartment is a jig of the plunger type 24 inches wide. The feed flowing over the sieve quickly separates into its two fundamental classes; viz., slime, and sand which settles and is stratified. The latter is thoroughly scrubbed free of slime which is held in suspension by the hutch water, introduced under the plunger.

A device for skimming off the slime in suspension delivers a dense original slime from this compartment as a product for further treatment on suitable tables. This separation is positive and complete, the sand on the sieve acting as a filter and being itself discharged thoroughly freed of slime. At the same time this classifying jig performs all the regular functions of a jig, and separates a large tonnage of clean cup and hutch mineral, usually from 50 per cent. to 60 per cent. of all free mineral being separated on this slime classifying jig.

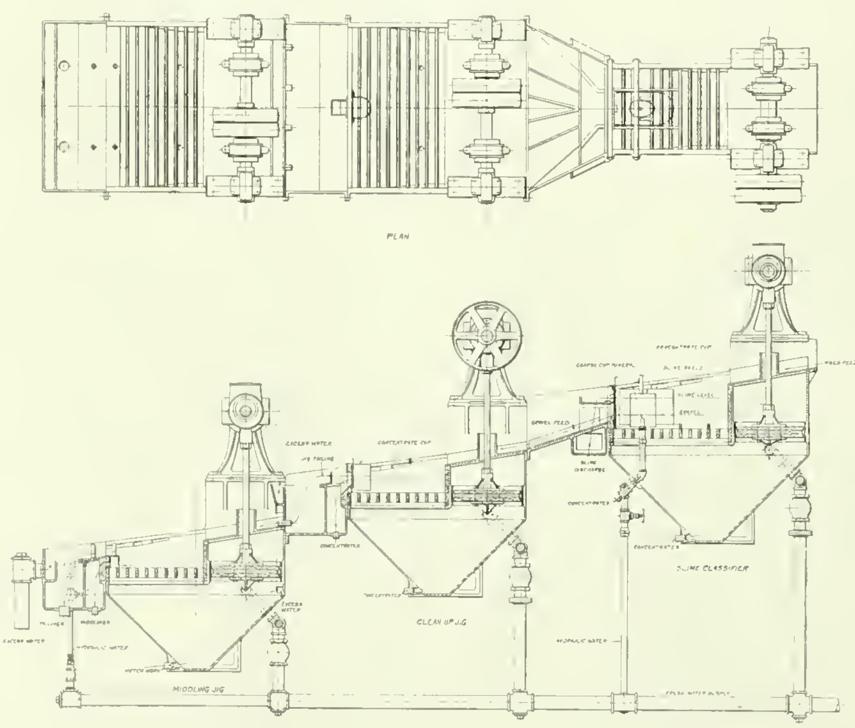

Fig. 1. Concentrating Plant

The second compartment, which follows the jig described above, is a "clean-up" jig for completing the separation of free mineral. This jig is 48 inches wide and usually discharges two finished products, viz., "cup" and "hutch" concentrates. The tailing from jig No. 2 passes to jig No. 3 termed "middling" jig, and provided with suitable middling discharge.

These middling jigs are equipped with a very efficient device for discharging middling from an unsized feed; viz., the "hydraulic middling discharge." An angle-iron shield is fastened across the tail of the jig, extending down into the middling stratum which seals it against the entrance of tailing. From under

---

*Ore Milling Engineer, Chicago, Ill.

this shield a number of openings placed at intervals of 6 inches lead into a hydraulic chamber. A fresh water supply therein, under valve control, regulates the quantity and quality of middling discharged from under the shield through these openings into the hydraulic compartment and out through plugs in the bottom. The advantages of this device are a uniform discharge over entire width of jig; and the separating and discharging of a true middling as stratified on the jig, the hydraulic water controlling and holding back any light tailing material.

An important feature of these jigs is the "water-saving device for diverting the excess water in the feed into the hutch of the next succeeding jig. The tailing from one jig passes over the angle-iron shield and the hydraulic compartment to the "water lessener" box of next succeeding jig, from which it is discharged through plugs over the plunger compartment and becomes the feed for the next compartment. The surplus water which cannot discharge through the plugs flows over the top of the lessener into a trough communicating with the hutch under the plunger, thus effecting a material saving in hutch water as well as reducing the quantity of top water which otherwise accumulates and tends to carry off the light values.

The material discharged from the hutches of the jig compartments No. 1 and No. 2 is usually clean mineral, and is included in the general concentrate. From the hutches of the middling jigs is obtained an enriched sand containing any light fine mineral which may have been carried over from the second compartment, this sand usually being redressed on a table of the Wilfley type. From the end of the last compartment is discharged tailing to waste.

To summarize, this is a means of handling large quantities of a mixed feed without preliminary sizing, and to classify it into the desired products; viz., slime (approximately 60 mesh and finer) for subsequent treatment on tables; concentrate; middling for regrinding; hutch sand for further table treatment; tailing to waste.

This mixed-feed system has been applied to various kinds of jigging ores, including native and sulphide copper, lead, zinc, tin, iron, and sapphires, and has thoroughly demonstrated its practicability and superiority in coarse, medium, and fine jigging. Any ore amenable to wet concentration can be handled to advantage with this system. In ores other than native copper, the mineral is usually softer and more friable than the gangue; and in the process of crushing is more easily slimed. It is therefore advisable to begin concentration as early in the process as possible, in order to recover the mineral as soon as liberated and before it is slimed by further crushing. The proper limiting size at which concentration should begin varies materially on different ores; in some the mineral is liberated during coarse crushing, while in others the mineral is so finely disseminated that the rock requires pulverizing.

Inasmuch as the Woodbury machines will treat unsized ores, preliminary sizing is unnecessary, except where material coarser than $\frac{3}{8}$ inch is to be concentrated, when a screen separation is necessary at $\frac{3}{8}$ inch, the oversize is treated on coarse jigs and the undersize on the classifier jigs. The material coarser than $\frac{3}{8}$ inch is treated without further sizing on special jigs, having adjustments and discharges suited to coarse material. When the maximum size of the ore is not over $\frac{3}{4}$ inch, the 48-inch oversize jig is used; on a larger maximum size the 60-inch "bull jig." The undersize of $\frac{3}{8}$-inch screens is treated without further sizing on the Woodbury classifier and jigs.

Where it is desired to rough out the free mineral before grinding, nothing approaches the simplicity of this arrangement, as the ore from the crushers has simply to be screened at $\frac{3}{8}$ inch, the coarse mineral in the oversize material being separated on an oversize or bull jig, and the free mineral and slime in the undersize material being separated on the two-compartment classifier jigs. The rich original slime is gotten out of the system without undue dilution and is passed on to the slime department. The tailing from the roughing jigs is recrushed, the coarse jig tailing being crushed to $\frac{3}{8}$ inch while the classifier jig tailing is finely pulverized and retreated. In case the mineral is not freed by coarse crushing in sufficient quantity for jigging, the coarse jigs are omitted and the classifier jigs only used as roughing machines.

Brown and red hematite, coal, pyrite, chalcocite, and chalcopyrite, can be roughed in immense tonnages and with great economy in floor space, water, attendance, etc. The unfinished products, slime and middling, are in far better condition than under the sizing system, the slime being dense, not coarser than 60 mesh, and separated high up in the mill. The middling is a thoroughly classified "included" product, being cleaned of free mineral which otherwise would be slimed in the regrinding.

In the Woodbury slime classifier and clean-up jig, two compartments only are required to clean the free material and slime from an unsized feed. When it is desired, however, to finish the operation by separating the middling material for regrinding, two middling jigs are usually added to the unit, making the standard finishing unit four compartments in all.

A finishing unit of jigs will handle approximately 250 tons per 24 hours, and separate the following products: Slime, concentrate, middling, table sand, and tailing. The feed is unsized and may be the undersize of any size screen not to exceed $\frac{3}{8}$-inch round.

The advantages of the system on finishing work are marked, a dense slime, clean concentrate and classified middling being separated with lowered tailing losses. Considerable economy is effected in water, floor space and attendance, and the mill greatly simplified. It should be noted that hydraulic classification and fine screening are entirely eliminated in this system.

Where it is necessary to separate two minerals of different specific gravity, a jig of five or even six compartments is required. The slime is separated as above on the first compartment, the heavier mineral on compartment Nos. 1 and 2, the lighter mineral on Nos. 3 and 4, and middlings on Nos. 5 and 6, tailing being discharged from the end of the jigs.

Asbestos Mines in China

Consul Baker, of Antung, China, states that valuable deposits of asbestos have been found in the vicinity of Kuantien, a small town lying about 45 miles northeast of Antung. The product appears to be of good quality. The price at Antung is about 60 cents United States currency per pound, but as the mining is done in a desultory and primitive manner, the cost could be greatly reduced by using modern machinery and up-to-date methods. There are three mines now in operation, each employing about 30 workers. These workers, however, are mostly farmers who devote only their spare time to mining and use simply hammers and chisels and gather only the asbestos which lies near the surface. For this reason the output is limited, but further working should disclose the extent and value of the deposits.

Equalizing Load Moment on Hoisting Engines

*By Mark Ehle**

In hoisting ore from considerable depths by the ordinary method of two drums operating balanced cages, the problem of equalizing the load moment on the engine, due to the great variation in rope loads, must be met, if anything like maximum efficiency is to obtain.

In the larger installations the problem is usually met at the outset by the use of conical drums, flat rope and reel, or some form of tail-rope. It often happens, however, that a hoisting engine, originally installed to care for considerable output from relatively shallow depth, is called upon to do the hoisting from depths far exceeding the original estimate. In such case the long lengths of

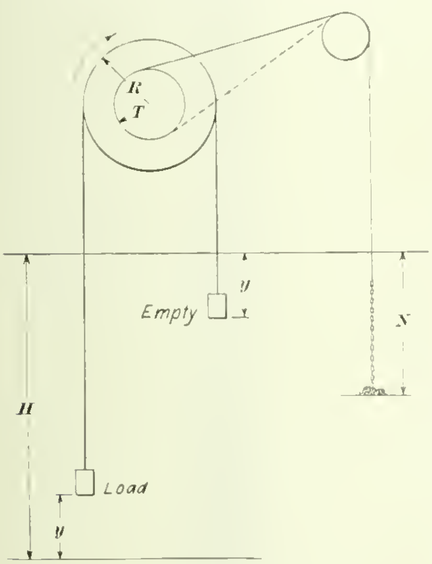

FIG. 1

unbalanced rope may easily become a determining factor in the possibilities of the engine, and some simple method of annulling this variable rope load must be provided. It is the object of this paper to set forth a few of the many successful devices employed to this end.

The drawings, in each case, are simply diagrammatic sketches of the load moments acting on the winding drums and are not intended to show any true relation of parts.

The system outlined in Fig. 1, simple of construction and very effectual in operation, is known as the "Despriz."

The two winding drums, of radii R, are shown with the loaded and empty cages at some general position during a hoisting period. A third drum of radius T has been keyed to the main drum shaft and carries a small rope to which is attached a chain, as shown. The small rope is so wound on to its drum that at the commencement of the hoist the chain, of length N, is suspended at full length in a small compartment specially provided. Immediately as the hoisting commences the small rope starts to unreel, piling up the chain at the bottom of its compartment until the cages reach their point of passing midway of the shaft, at which instant the hoisting-rope loads balance, the piling up of the entire chain length is complete, and its load moment on the main shaft is zero. At this instant, also, the small rope, carrying the chain, has all unreeled from its drum and its point of fastening is about to pass around underneath and take the rope into the position shown by the dotted line.

Hence, as soon as the cages have passed each other the chain rope begins to reel up again, extending the chain upward until, at the termination of the hoist, it again hangs at full length, giving a load moment of opposite sign to that which it had at starting of the hoist. That is, during the first half of the hoisting period the load moment of the chain on the drum shaft is plus, while during the second half of the period it is minus.

The problem then is to deduce the proper weight of chain in order that the system, in so far as the rope loads go, represents at all times a balanced one.

Let W = weight of the hoisting ropes per unit length;
w = weight of the chain rope per unit length.
H = total depth of hoisting;
N = total length of chain;
y = distance the loaded cage has ascended, which will also equal the distance the empty cage has descended.

In the position shown the equation of moments would be:

$$(H-2y)WR = \left(N - \frac{Ty}{R}\right)wT;$$

$$\text{but } N = \frac{HT}{2R}$$

Substituting,

$$(H-2y)WR = \left(\frac{HT}{2R} - \frac{Ty}{R}\right)wT,$$

which reduces to

$$w = \frac{2R^2W}{T^2}$$

which gives the relative weight of the hoisting rope and chain in terms of the radii of the drums, for

$$R = T;\ w = 2W \text{ and } N = \frac{H}{2}$$

It may be noted that the weight of the small chain rope has not been taken into acount. While this weight might have some influence, its effects may very properly be neglected.

The system outlined in Fig. 2 is known as the Monopol. An auxiliary drum of diameter equal to the winding drums, is keyed to the main shaft and is of sufficient width to carry two relatively small ropes, one of which is underwound and the other overwound.

These ropes support a length of heavier balancing rope in the position shown; this balancing rope is usually a length of old hoisting rope of the size used in the hoisting operations and which has been discarded on account of wear. A glance at the

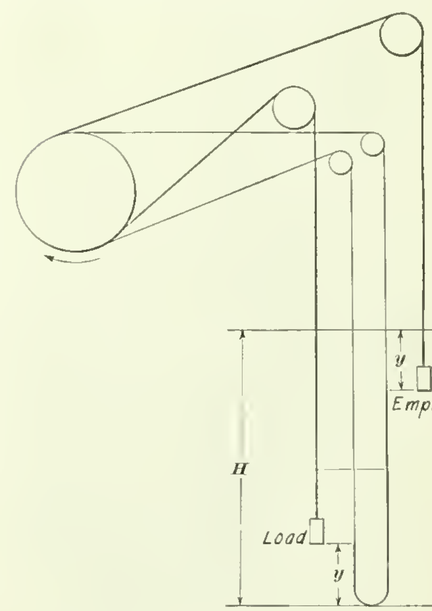

FIG. 2

diagram makes it evident that if this balancing rope is adjusted at the outset, so that each of its ends is in position opposite one of the cages, as shown, they will so remain whatever the position the cages take during a hoisting period, and the load moment on the drum shaft, so far as the hoisting ropes are concerned, will be equalized throughout. As in the former case, the weight of the small rope can be neglected.

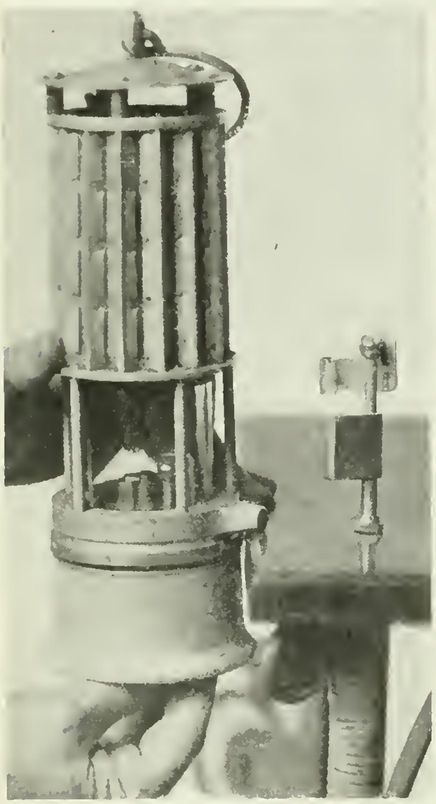
In practice either of the above systems requires that a small compartment be provided for the accommodation of the balancing device. This is usually partitioned off from one end of the pump compartment of the main shaft at a nominal expense. As for the rest of the arrangements almost any mechanic at the mines would find little trouble in providing whatever would be required for the installation.

*In the *Pahasapa Quarterly*, December, 1912.

NEW MINING MACHINERY

Safety Lamp Igniter

An igniter for safety lamps has been invented by Mr. L. D. Vaughn, Mine Inspector in the Third District of West Virginia, for use with the common Wolfe lamp to take the place of the explosive igniters generally used. No change need be made in the lamp as the igniter fits easily into the space occupied by the ordinary igniter. In the illustration the



Safety Lamp Igniter

device is shown standing by itself on the table as well as in position in the lamp.

The principle of this igniter is the common one of scratching a steel disk with a pencil of carborundum and so getting a spark hot enough to ignite naptha fumes arising from the wick. The steel disk is mounted on a spindle which passes through the bottom of the lamp and which can be turned between thumb and finger. It is on a level with the wick of the lamp when the igniter is in position. A pencil of carborundum is so placed that the steel disk when rotated, rubs against it, the carborundum being pressed forward by a small spring. The pencil is mounted on a piece which hooks around the wick of the lamp so that the spark always is emitted in the correct direction. A blank is placed on the middle of the spindle to fill up the space occupied by the match box in the ordinary igniter; 5,000 lights can be obtained from one pencil of carborundum.

Tests have been made on lamps using this igniter by the Bureau of Mines at Pittsburg, and it has proved safe in a gaseous atmosphere and in atmospheres of high velocity. With it, no particles will be cast against the gauze to lodge there and flame afterwards when the lamp fills with gas, so lighting gas outside the lamp. The igniter is for sale by the Vaughn-Miller Co.

A New Acetylene Mine Lamp

Acetylene is now recognized as a most economical illuminant for use underground, and the Arnold carbide candle, developed by Ralph R. Arnold, a mining engineer of Cripple Creek, Colo., is an improved device for the generation and burning of acetylene gas.

Fig. 1 shows the form of the lamp, which consists of a tubular body of 22-gauge brass $1\frac{1}{4}$ inches in diameter by 12 inches in length and weighs but one-half pound. A diaphragm in the center divides it into a water (upper) chamber closed by a revolving shutter at the top, and a carbide (lower) chamber closed by a gasket-lined cap at the bottom; there is a water-control valve in the diaphragm and a gas tube extends from the chamber through the diaphragm to the top where there is an improved burner.

A cartridge containing the charge of calcium carbide is placed in the carbide chamber, the water chamber filled, and upon opening the water valve the water is fed by gravity on to the carbide cartridge, which being made of absorbent material, the generation of gas is immediately begun, it being ignited at the burner. The flow of water, the consequent generation of gas and thereby the size of the flame, is controlled by the water valve, permitting a variation in the candlepower of the light of from $\frac{1}{2}$ to 10 candlepower, the charge of carbide being sufficient to furnish a 4-candlepower light for 4 hours or more.

The lamp is non-explosive, and as soon as the pressure of the gas exceeds the maximum water pressure (5 inches) the pressure will stop the flow of water, and any gas in excess of that burned will pass through the water chamber and flash at the burner instead of escaping into the atmosphere. When the carbide is consumed, the cartridge may be instantly removed, and a new one, carried in a pocket tube, substituted, the water chamber refilled, and the lamp relighted, within a few seconds.

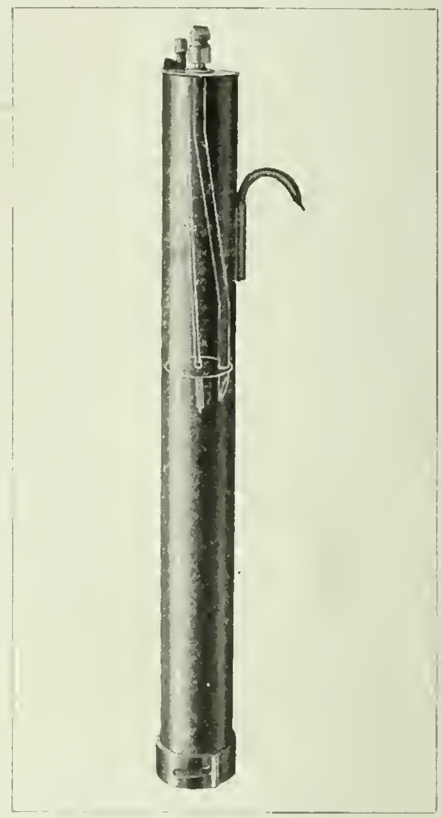


Fig. 1. Carbide Candle

The cartridge case is made of an especially woven absorbent fabric that acts as a conductor for the water to insure the constant generation of gas, admits of the expansion of the carbide, filters the gas generated therein, and retains the residue, thereby preventing the obstruction of the water valve, gas tube, or burner, and eliminating the necessity of cleaning the filtering chamber after using and the use of filtering devices; a maximum water pressure of 5 inches insures the maintenance of a steady flame from start to finish, and the total consumption of the carbide without any attention whatever.

A removable sliding reflector answers the purpose of a wind shield and water deflector as well, and when slid down below the flame, when general illumination is required, serves as a guard for the burner tips. The burner produces a fan-shaped flame, giving maximum illumination with a minimum of gas.

This lamp has demonstrated its value by continuous use at Cripple Creek for the past 2 years, and the fact that it is made by Wm. Ainsworth & Sons, the well-known instrument makers of Denver, Colo., insures that the workmanship and material are of the best.

Locking Device for Electric Switch

Fig. 1 shows a locking device that prevents the blade of a disconnecting switch from opening except under the direction of the operator. Instances are on record where the blade of a disconnecting switch not protected by this device has been thrown open, or partly open, by magnetic repulsion and destroyed when a short circuit has occurred on the line, resulting in the loss of the switch and putting the circuit out of commission till a new switch could be installed.

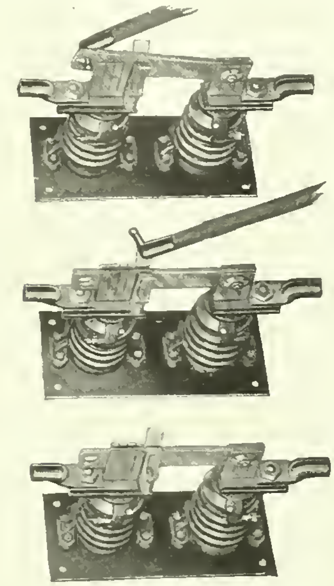
The safety catch, or locking device, is a unit in itself and can be applied merely by clamping it to a support placed between the clip block and the insulator cap. It is of rugged design and is operated with a switch hook.

The locking device consists essentially of two brass bell-cranks hinged together at the ends of the two shorter arms and held closed by compression springs. The projections or jaws in the outer ends of the two longer arms close in front of the blade thus preventing the latter from coming out of the clips. Each bell-crank is provided with a dog which moves in a slot in the bell-crank's elbow, the dog being hinged at this point. Two compression springs, one pressing outwardly from the switch base against the elbow of each crank and also against the dog, keep the bell-crank closed and the dogs pressed against the back of the switch blade.

To open the switch, the outer ends of the bell-cranks are pressed back away from the blade allowing the dogs to come forward so as to rest upon the sides of the blade, in which position they hold the jaws in front of the blade apart, allowing the switch to be opened. Withdrawing the blade of the switch from between the dogs causes the jaws to automatically close against the sides of the blade and to snap shut as soon as the blade is completely withdrawn.

As the outer edges of the jaws are beveled the switch blade can be readily pressed back in the clips into the closed position, when the jaws close automatically in front of the blade, locking the latter in the closed position. The operator can't forget to lock the switch closed as it automatically locks itself.

This device is made in sizes to fit 300, 600, 800, and 1,200 ampere switches as standard and can be furnished for a switch of any capacity. It has been on the market for a comparatively short time, yet it is being used by practically all the important electrical operating companies in the United States. The device is made by the General Electric Co., Schenectady, N. Y.



LOCKING DEVICE FOR SWITCHES

Trade Notices

New Supply Concern.—Fred M. Blethen, for many years with the Hazleton Machinery and Supply Co., announces that he has engaged in business for himself with office at 704 Markle Bldg., Hazleton, Pa., and will handle everything in the line of machinery, tools, power transmission, and equipment, either new or second-hand.

Stromberg-Carlson Telephone Mfg. Co. announce that they have transferred their Kansas City sales office to 708-710 West Jackson Boulevard, Chicago, Ill., where they have a more complete line of telephones and apparatus and also more complete and efficient sales organization. They will still continue to carry at Kansas City a selected stock of standard telephones, boxed and ready for immediate shipment to Kansas City territory, but all orders should be sent to the Chicago office.

Test of Wire Rope.—At the mines of the Pennsylvania Steel Co. at Mayari, Cuba, cars with a capacity of 100,000 pounds of ore are lowered by means of cable down an incline plane 5,800 feet long. Recently it was decided to ascertain the strength of the cable after a year and a half of service, as compared with the strength of portions not worn; and three pieces from the main cable, each about 20 feet in length, were shipped to the works of the manufacturers, the John A. Roebling's Sons Co., at Trenton, N. J. There special yokes were placed on the ends to make possible the tests, which were conducted by the Civil Engineering Department of Lehigh University at the Fritz Engineering Laboratory. Three tests were made, all highly satisfactory. A portion of the cable that had been in use for a year and a half withstood a pull of nearly 300 tons.

The construction of this cable was without a precedent in rope making. It consists of six strands, each of 19 wires, twisted around an independent wire rope center, this center having six strands of 19 wires each, twisted around a hemp core. The finished cable was 7,810 feet long and weighed 125,360 pounds.

The D'Olier Centrifugal Pump and Machine Co. is a new organization having taken over the plant and business of the Lathbury-D'Olier Engineering Co. General offices will be maintained in the Morris Bldg., Philadelphia, Pa.

Sullivan Machinery Co. Changes. Roy D. Hunter has resigned as general sales manager of the Sullivan Machinery Co. Howard T. Walsh, who has been the European agent of the company, with headquarters in London, is appointed general sales manager, with headquarters in Chicago. Austin Y. Hoy, representative of the company in Spokane, Wash., succeeds Mr. Walsh in London. Louis R. Chadwick of the St. Louis office, succeeds Mr. Hoy as local manager in Spokane.

Reduction in Price—The Joseph Dixon Crucible Co., of Jersey City, N. J., announce that the selling price of their Silica-Graphite "One Quality Only" paint is reduced. They say they make this reduction because the decrease in the price of linseed oil enables them to do it, and it is their aim at all times to give their customers any benefit possible in reduction of price of materials. This paint, which has been the standard for nearly 50 years with leading railroads and manufacturing plants as a maintenance paint, is a long service protector of exposed steel and metal surfaces.

Sirocco Fans.—The Pond Creek Coal Co., and the United States Coal and Oil Co., who are under practically the same management and have a common purchasing agent, are opening new mines at Williamson and Holden, W. Va., for the ventilation of which nine Sirocco fans, with a combined capacity of 1,800,000 cubic feet of air per minute, against 2-inch water gauge have been purchased. Each of these fans will make a carload shipment.

Western Agents.—The Goulds Mfg. Co., of Seneca Falls, N. Y., announce that the Mine and Smelter Supply Co., Denver, Colo., have been appointed as agents for the Goulds line of triplex power pumps. Their territory will include the entire state of Colorado and adjacent counties in the states of Wyoming, New Mexico, South Dakota, and Montana.

New Pump Co.—A new company, known as the Lea-Courtenay Co., Inc., with office at 90 West Street, New York City, has taken over the engineering and manufacturing business of Albert G. Lea. The company will manufacture high-duty turbine pumping machinery for all classes of service, and also cold metal sawing machinery. The officers are Albert G. Lea, president; Courtenay R. Rothwell, vice-president and general manager, and Edgar W. Heller, treasurer.

Coal Stations.—The Roberts & Schaefer Co., contractors and engineers, of Chicago, have been awarded a contract by the Queen & Crescent Route for two 500-ton capacity reinforced concrete Holmen coaling stations, electrically driven, for installation at Danville, Ky., and Oakdale, Tenn. Price $37,000. These plants are to be exact duplicates of two former plants that this firm erected for the Queen & Crescent at Montlake, Tenn., and Ludlow, Ky. They have also received an order from the Pratt Consolidated Coal Co., of Birmingham, Ala., for a 1,000-ton Stewart coal washing plant, steel tipple, and storage bins, to replace the structure recently burned at the mines at Banner, Ala.

New Asbestos Plant.—The completion of the new plant of the H. W. Johns-Manville Co., at Manville, N. J., marks another important chapter in the history of this concern. The company has manufacturing plants in different parts of the country. The new plant at Manville, consists of nine buildings, as follows: Textile and packing, rubber plant, electrical specialties and printing department, pipe coverings, paper mill, magnesia, roofing, mastic and waterproofing, roofing coatings, power plant and pump house.

These buildings represent the most advanced ideas in fire-proof construction, being of brick, steel and concrete, with roofs of J-M asbestos roofing. They are planned not only for safety but to afford the best operating conditions for the employes. Each building has an average length of 1,000 feet, and is a separate factory in itself. The combined floor area of all the buildings is about 1,000,000 square feet.

Chou Nickel Bronze is a product of the Exeter Machine Works of Pittston, Pa., developed after extensive experiments in an endeavor to secure a material for screen plates that will resist the action of acidulated water and provide uniformity in the sizes. Screen plates of this material are made with perforations of any size or shape required.

Wooden Pipe.—The early waterworks systems in this country made use of logs with holes bored through them for pipe, and nothing more durable has ever been found, as is shown by the existence of such pipe in good condition that were laid nearly a century ago. They were not, however, capable of withstanding high pressures. After much experimenting, the Michigan Pipe Co., of Bay City, Mich., has developed a method of reinforcing wood pipe by which it is able to stand pressures as high as 700-foot head. Such pipe has the advantage of being unaffected by acids and chemicals and the company states that it costs less than iron pipe, is cheaper to lay, and has other advantages, all of which are fully described in a new catalog which they will send on application.

Catalogs Received

Babcock & Wilcox Co., New York. The Stirling Water-Tube Boiler, 64 pages.

Roberts & Schaefer Co., Chicago, Ill. Combination Screens and Picking Tables, "Marcus" Patents, 12 pages.

When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

With this issue, Mines and Minerals appears under its former name — The Colliery Engineer. It will be devoted entirely to the publication of the best literature on modern methods of coal mining and the preparation of coal for market. With several new departments it will be the most useful and interesting journal for all classes from miners to mine managers and owners.

Rufus J. Foster
Managing Editor

WHEN a mine official really thinks he knows it all and that there is nothing more for him to learn about coal mining, it's time for him to resign, and thus avoid being discharged later for incompetency.

THE mine official who learns from every available source is the man who gets to the top and eventually fires the subordinate who knows it all and has nothing more to learn.

MANY years ago THE COLLIERY ENGINEER called attention to the well-founded supposition that the barometric pressure was a good index to the variation of outflow of methane in coal mines. From time to time this subject was called to the attention of its readers, and in connection with numerous gas explosions the barometric pressure of the atmosphere was noted. In all of these cases it was remarked that large outbursts of gas, other than those due to squeezes or heavy falls, were coincident with a falling barometer.

In our issue of last September we published an interesting article showing the result of the investigations of Messrs. J. W. Hutchinson and Edgar C. Evans, which strongly corroborated the fact that barometric pressure influenced the outflow of gas.

The attention of officers of the United States Weather Bureau was drawn to this article, and at the suggestion of Dr. J. A. Holmes, Director of the Bureau of Mines, the Weather Bureau has arranged to send to the American coal mines warnings of impending barometric changes.

Breaking an Agreement

THE constantly recurring strikes in the anthracite coal regions because non-union men are employed at the mines, or because certain mine employes refuse to join the union, are gross violations of that portion of the agreement made last spring which reads "No person shall be refused employment, or be in any way discriminated against on account of membership or non-membership in any labor organization, and there shall be no discrimination against or interference with any employe who is not a member of any labor organization, by members of such organization."

This agreement was entered into in good faith by the operators' committee and the United Mine Workers of America through its National President, John White, and a committee consisting of district presidents. Mr. White and his associates labored long and strenuously in the interest of the men they represented. They secured certain advantageous terms for the miners, and, relying on the loyalty of their followers, pledged them to a strict adherence to the agreement by affixing to it their official signatures. The breaking of the agreement by such strikes as mentioned above is contrary to Mr. White's ideas of fairness, and he has time and again emphatically expressed his disapproval of them. He has told his followers in plain language that if they expect others to keep an agreement, they must themselves strictly adhere to their part of it. In this policy Mr. White has the support of the most intelligent members of the organization. But there are members who permit themselves to be misled in some instances by men who do not realize the true principle of an agreement, or by men who are mischief makers and enemies of the United Mine Workers as an organization. In John P. White, the United Mine Workers have as a leader a man of strong character. His honesty and loyalty to his organization cannot be questioned. He is a man who commands the respect of his opponents by his honesty and fairness. He is worthy the loyal support of his organization and has time and again proved it. The members of the organization who listen to and follow emissaries of other organizations, and particularly those of the organization known as the Industrial Workers of the World, and by their advice break the agreement, should be disciplined by the United Mine Workers, and if they persist in such actions, they should be regarded by the loyal members as worse enemies of the organization than any other class of men, and the fellows who lead them into acts disloyal to the organization and its pledged policy should be so ostracized as to cause them to leave the region.

John Fritz

JOHN FRITZ, the grand old man of the iron and steel industry died at his home in South Bethlehem, Pa., on February 13 in his ninety-first year. The engineering profession knew *John Fritz*, or "*Uncle*" *John Fritz*. *Mr.* Fritz was only heard when comparative strangers or very young engineers spoke of or to him. By birth he was of German and Scotch-Irish blood, a mixture which has given to America many men who have been an honor to the nation.

His educational advantages in youth were limited, but no man could class John Fritz as an uneducated man. He gained the greater part of his education, and all of his professional skill, in the school of experience, in which he was a faithful student and a keen observer.

His character and his engineering skill and achievements won for him not only respect and honor in America, but leading scientific societies of Europe honored themselves by honoring John Fritz.

Space is too limited to even attempt to outline his engineering experience and accomplishments, or to portray his energy and kindly character. The latter, however, are well stated in the two following quotations, the first from Mr. D. A. Tomkins, a former subordinate, and the second poetical one, from Dr. Rossiter W. Raymond, one of Mr. Fritz's oldest friends:

"The best work done by him was the training of the young men who worked under him."

"Whose heart is warmer than his blast?
Whose faith more steadfast to the last
Than any steel he ever cast?
That figure hits
John Fritz.

"Whose fame commands our homage, such
As bears of envy not a touch,
Because we love the man so much?
Why, there he sits—
John Fritz."

Coal Mine Laws

MINE workers, mine officials, and mine owners have a common interest in the enactment of laws regulating the working of coal mines in a manner that will provide a maximum degree of safety to the mine workers and mine property. The framing of such laws requires extreme care and a broad knowledge of both practical mining and the technical principles involved. In framing such laws, politics or the differences existing, or likely to arise between capital and labor should have no consideration whatever.

If laws to regulate the relations between employer and employe are necessary, they should be separate enactments. They have no place in a law, the sole purpose of which is the safeguarding of life and property.

The man who tries to inject into a mine law, either directly or indirectly, a measure that is for any purpose other than the securing of safety, no matter whether he be mine official, mine worker, or politician cannot be too severely condemned by all interested in the industry.

If he attempts to inject provisions in the law that are foreign to the purpose of such a law, and which also weaken it in its true function, his action is that of an enemy to both mine worker and mine owner, and he is also a traitor to the class he professes to represent.

A mine law to be effective must be enforced. Mine Inspectors must inspect and enforce the law. They must be men of broad experience and of superior mining education. They must be absolutely independent and honest in their official acts. They must not be under obligations to any one. They must be paid fair salaries and in return must devote *all* their time to their official duties. No opportunities should be afforded politicians and "trimmers" to secure positions as State Mine Inspectors.

Taxing Coal Lands

THE question of the proper method of levying taxes on coal lands is one that is attracting attention in several states. In Pennsylvania, and particularly in some counties in the anthracite region, assessments have been based on the "foot-acre." Or in other words on the thickness in feet of workable coal under each acre of surface. This method of assessment is inaccurate, unfair, and a source of trouble.

It is inaccurate, because no man can tell what local conditions affecting the value of the coal will be met with in mining it. Two tracts of coal land lying side by side, may be, and often are, of widely differing values. Surface indications may show practically the same features. Actual mining may show radically different conditions. One tract may offer natural conditions under which practically all the coal may be mined. The conditions existing in the other tract may be such that only one-half or two-thirds of the coal can be mined. These conditions are often unknown until actual mining is being done. Under such circumstances, the first tract has from 50 to 100 per cent. greater value than the second. To assess two such tracts alike is manifestly inaccurate and unfair.

To make an accurate assessment on the coal in the ground requires an accurate knowledge of the geological conditions affecting each acre. Such knowledge can only be acquired with a fair degree of accuracy by careful and complete surveys and frequent geological cross-sections made by capable mining engineers. The cost of such work by men capable of doing it best, would be prohibitory. When done, no honest, capable mining engineer, would attempt to give more than a fairly approximate estimate of the coal in each tract, and further, he would not assume that such an estimate was a fair measure of the amount of coal that could be profitably mined.

Besides, there is as great a variation in the value of the coal in different tracts as there is in the value of city lots or farm property.

In many bituminous coal regions there are vast tracts of coal land which cannot be worked under present conditions, the conditions in general being lack of market or lack of facilities to get the coal to market. The same is true in the anthracite regions, but for a slightly different reason. In some cases, particularly in the heavy pitching measures of parts of the anthracite field, the conditions are such that even with present market prices the coal cannot be mined and prepared for market at such cost as will yield a profit. To tax such coal lands by the foot-acre, is not only inaccurate and unfair, but it also results in time to a partial if not a complete forfeiture of the owners' property.

As an anticonservation measure the taxing of coal lands by the foot-acre will be a success. It will compel many coal land owners to mine the coal held in reserve for future use. This will flood the market, prices will necessarily drop to a ruinous figure, lower wages will follow and partial time only will be worked. It will result in the speedy mining of the cheapest mined coal and the wasting of millions of tons unminable under such conditions. It will by this means hasten the exhaustion of, and cause enormous waste in, the greatest source of prosperity the nation possesses.

No rational man believes that the coal-mining industry should not bear its share of taxation. But it should bear only its share. The only just way to levy a tax is on the tonnage produced each year. The surface improvements and such surface area as is used for income-producing purposes should be fairly assessed as is the case with other industrial plants, but allowance should be made for the rapid deterioration due to excessively hard wear on machinery and buildings and to the fact that the exhaustion of the coal detracts from the plant's value every year.

Advocates of the foot-per-acre tax on coal lands contend that such a policy results in a tax that the general public, or coal consumers, will not feel. Such a contention is a mistake. Most coal-mining companies own the coal they are mining, in fee simple, and they naturally include taxes paid, or levied, in operating expenses, and as the cost of production, under normal conditions, regulates selling price, it makes no difference whether the tax is levied one way or the other.

The comparatively few operators mining from leased lands would of course, not pay the tax, if levied by foot-acre, and they would be given an unfair advantage, which would last until their leases expired. When they made new leases or renewed their old ones, they would naturally be compelled to pay a proportionate increase in royalty, and that of course will add to cost of production.

To tax coal properties on the tonnage produced is the only fair method, and it is one that is simple in operation, and it will avoid constant and expensive controversies.

PERSONALS

Geo. Watkin Evans, coal mining engineer, of Seattle, has recently moved into larger quarters, and will be found at 423-24-25 New York Block, Seattle, Wash. He will continue to specialize in coal mine examination and coal mining engineering.

Sir Richard McBride, Minister of Mines, for British Columbia, sent out in January a "Preliminary Review and Estimate of the Mineral Production of 1912 for British Columbia." The people of British Columbia are justly proud of their hustling Minister of Mines.

Wemyss Jackson has been appointed General Sales Agent of the Consolidated Indiana Coal Co., with headquarters at 139 West Van Buren Street, Chicago, Ill.

Frank Ragan has been appointed District Sales Agent of the Consolidated Indiana Coal Co., with headquarters at 403 Terminal Traction Building, Indianapolis, Ind.

Alfred Knight Chittenden, Forester in the United States Indian Service, Department of the Interior, has been appointed assistant to the Director of the Engineering Experiment Station and Lecturer on Timber and Timber Resources in the College of Engineering of the University of Illinois.

In our Letter Box of January the writer of the interesting letter on shaft sinking was Samuel Haines, of Negaunee, Mich., not Samuel Harris as signed.

W. R. Ingalls, Editor of the *Engineering and Mining Journal*, delivered a lecture to the members of the Lackawanna Chemical Society on the occasion of their annual dinner, February 27 last

F. A. Hill, of Pottsville, Pa., is general manager of coal mines for Madeira, Hill & Co., of Philadelphia. This company operates in the anthracite and bituminous coal fields of Pennsylvania.

Dr. James Gayley the inventor of the dry-blast process who began as a steel chemist and afterwards became first vice-president of United States Steel Corporation, has received the Sir William Perkin medal for achievements of high value in applied chemistry.

James S. Thompson, Division Superintendent of the C. F. & I. Co., in Las Animas County, resigned to accept a position with the Albuquerque-Cerillos Coal Mining Co., with headquarters at Albuquerque, and mines in New Mexico.

W. B. Lloyd, of Trinidad, well known to the readers of *Mines and Minerals*, is Secretary of the Prospect Coal Co., with headquarters at Trinidad, Colo. Mr. Lloyd will probably continue to represent The Colliery Engineer in southern Colorado.

Thomas Harvey, formerly of Forest City, Pa., is now superintendent of the Sugarite coal mine of the St. Louis, Rocky Mountain and Pacific Co. He made his advent in the West with the Bureau of Mines instruction car, and as he is a good student and practical miner he will be heard of again.

C. P. Collins, of Johnstown, an expert sanitary engineer who had much to do with the installation of the very efficient plant in Providence, R. I., is now engaged for the Berwind-White Coal Mining Co. in designing a sewage disposal plant for the town at their new No. 42 operation. He is also designing a plant for the treatment for bacteria of the domestic water supply of various mining towns of the Berwind-White Coal Mining Co. in that locality.

Telford Lewis, formerly a mining engineer of Johnstown, Pa., who has for many years been general manager of the Knickerbocker Smokeless Coal Co., at Hooversville, is interested in the formation of a selling agency known as the Knickerbocker Fuel Co. with its principal office at No. 1, Broadway, New York, who will sell the output of the Hooversville and other mines of the district.

James Crosby Brown and Davis L. Lewis, of the firm of Brown Brothers & Co., bankers, of Philadelphia, and Vance G. McCormick, of Harrisburg, who are interested in coal properties in the vicinity of Portage, Pa., recently spent some time in the district in a hasty examination of their various interests. They were accompanied by Andrew B. Crichton, mining engineer of Johnstown, and John E. Evans, attorney at law, Ebensburg, Pa.

J. C. McSpadden, the Rockwood contractor, who has had much to do with the development of southern Somerset County, Pa., especially with the building of its various highways and railroads, has entered into the coal business and is developing a mine on property he owns just west of Rockwood, the product from which will be shipped over the new Connellsville Division of the Western Maryland Railroad. The operation is on the C′ seam on a tract of 500 acres of land.

John E. Ashley, who for the past 6 years has been mine foreman of the Cambria Steel Co.'s Rolling Mill mine, has resigned to accept a position with the Ebensburg Coal Co., at their new Cambria County operation at Colver, Pa.

T. D. Morgan, formerly foreman of the mines of the Bolivar Face Brick Co., Bolivar, Pa., has accepted the position of superintendent of the Sunnyside Coal Co., at Johnstown.

OBITUARY

PROF. GEORGE A. KOENIG

Prof. George A. Koenig, of the Michigan School of Mines died in Philadelphia in January. Professor Koenig received the degree of M. E. at Karlsruhe; degree of A. M. and Ph.D. at Heidelberg; attended the Mining Academy, Freiberg, Saxony, in 1867-68. He was connected with the University of Pennsylvania, teaching in chemistry, mineralogy, and geology from 1872 to 1892, after which he taught in the Michigan School of Mines. He discovered a number of new minerals, and did considerable research work along chemical and mineralogical lines. He joined the American Institute of Mining Engineers in 1894 and has contributed papers to various scientific societies and journals.

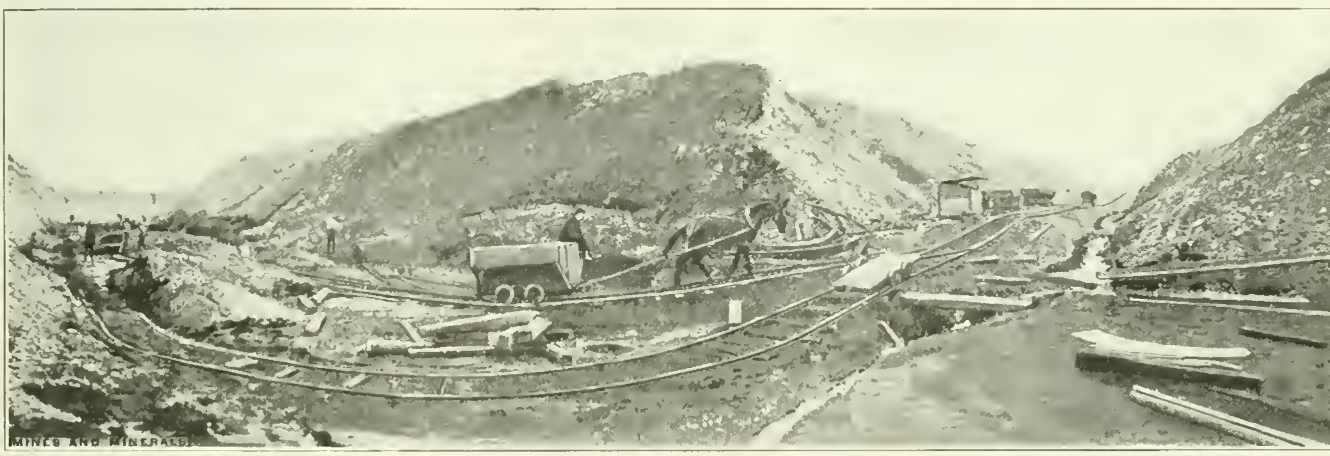
COAL MINING & PREPARATION

Coal Stripping in Kansas

The Use of Steam Shovels to Remove the Prairie Soil Overlying Coal Seams Near the Surface

*By Barry Scobee**

STRIPPING and open-cut mining in Cherokee and Crawford counties of southeastern Kansas, the Pittsburg coal district, has become a large industry. Already 15 steam shovels, with which the shallow lying veins of soft coal are uncovered, have been put to work and others are being installed. The coal, from 14 to 28 inches thick, is from 9 to 35 feet below the surface of a considerable portion of the two counties, which adjoin the Joplin mineral fields. The fuel beds are too thin to mine in the ordinary way, besides have no rock roof, and as the operators have exhausted partly the thicker veins far below, they are making use of steam shovels where the coal does not lie at a depth to exceed 30 feet.



A Strip Pit Coal Mine in Southeastern Kansas

Two of the shovels at work are remarkable for their size, being, it is claimed, the largest in the world, not excepting any even that are used on the Panama canal. They have 90-foot booms with 50-foot thrust arms to the dipper shovels and will strip to a depth of 30 feet. The dirt they pile up looks like small mountain ranges from a distance; and the machines are actually making a prairie country into broken land, for they leave ridge after ridge where they pass.

About 500 men are employed in the pits, and they have a division of the United Mine Workers' union all their own. Many men who will not work in underground mines are glad to get employment here, for the dangers from bad air, explosions, and rock falls of course do not exist in mining with the "lid off."

Where the "crop" lacks 20 feet or so of reaching the surface, the average steam shovel used in this district will strip, if employed pretty constantly, 10 or 12 acres a year, and some of the holdings offer work for the one or two shovels in use on them for 10, 15, and 20 years.

The coal is "shot" from the top by holes placed a few feet back from the face, this method being quicker than undercutting and more effective, for in many places the coal is hard. The shooting progresses with the work of the shovelers, who are on hand with mine cars the minute the coal is broken by the blast. All of the strip-pit hands here are being employed by the day.

The coal is hauled up the inclines from the pits by steam winches and cables and conveyed in the pit cars to the tipples at the railways, usually but a short distance away. Mules are used in the pits.

The country being decidedly prairie, there is but little slope for natural drainage and as a consequence the pit fills up with water in the rainy season and days are required to pump it out. In the spring of 1912, which was very rainy, shovels in some pits were under water for 2 or 3 weeks.

The cream of the shallow coal is being worked now, though not all of it is being touched by any means, the operators claim. They were inclined to reticence regarding costs, saying they have not been at work long enough yet to be familiar with

* Pittsburg, Kans.

33—8—3

them, but those given herewith are considered authentic, in fact, are the figures for one of the largest companies. Of the 15 shovels in the field very few, if any, are working in coal less than 36 inches thick, though the bed, taken all over the two counties where it crops close enough to the surface to be worked, averages not more than 20 inches in thickness.

The average thickness of covering being stripped now is between 17 and 18 feet, a little running as shallow as 6 feet and some as thick as 24 feet. The Elsworth-Klaner people have what is claimed to be the largest steam shovels in the world and they say they will strip to a depth of 30 feet before all their coal is removed.

The amount of coal yield to the acre, on the average holding, is 4,500 tons, according to figures given out by various mine superintendents; and this is secured by the removal of less than 20 feet of soil.

The average cost per cubic yard for stripping and removing the covering material of the coal is between 5 and 6 cents. The dirt is removed no farther than the shovels will place it.

The average amount received per ton for the coal at the tipple is approximately $2.07, running higher if anything. This is for lump or mine-run coal, the strip pits products not being screened. Figuring the average thickness of the coal bed as 36 inches, an acre will produce 4,500 tons and the selling price will be, approximately, $9,337.

The surface 6 feet of the covering material is dirt, soil partly; the next 6 feet below is soft shale or soapstone; and the portion below to the coal bed is blue shale. There is very little slate and the shovels work easily.

The average wage scale of the union for 8 hours' work is very close to $2.50, varying from $1.95 for a waterboy to $3.05 for a blacksmith. Most of the men receive from $2.42 to $2.62.

It is believed that this industry will develop to large proportions, because there are thousands of acres of coal yet untouched by the shovels, and it has developed from small landholders stripping very shallow crops with teams and scrapers for the last 15 or 20 years.

Stripping Coal With Steam Shovel in Kansas

Use and Care of Safety Lamps*

Two disasters have occurred within recent months due to certain defects in miners' safety lamps. The lamps were of the modern naphtha or gasoline burning type with double gauze, shield, and glass globe. Each lamp caused an ignition of gas within a mine; in one case a dozen men were killed, and in the other case several men were burned.

The first explosion resulted from the parts of the lamp being improperly assembled, the top asbestos gasket being doubled upon itself, so that a part of the glass was not in contact with the gasket, and an open space was left between the top of the glass and the gauze. When this lighted lamp was inserted into an explosive mixture of gas and air, the gas flamed within the lamp and ignited the gaseous mixture outside.

The second explosion also resulted from a lamp being improperly assembled. In this case the pull bar which operates the scratcher for igniting the match that lights the wick was left out of the lamp. The lamp when lighted and placed in an explosive mixture of air and gas in every case ignited the gaseous mixture outside of the lamp.

A number of miners' safety lamps have been found in use in gaseous mines with the pull bar removed. To remove the pull bar is a most dangerous practice, and should not be allowed, since it renders the lamp as dangerous as an open-flame lamp.

At one mine where safety lamps with magnetic locks are used, fine holes were detected in the bases of several lamps. These holes had been drilled so that the lamps could be opened in the mine by the use of a pin or needle, thus nullifying the safety value of the magnetic locks.

Lamps should be carefully examined when they are turned in at the end of a shift, as well as when they are given out, in order that the miner or other employe may be held accountable for any alteration or damage to his lamp.

*Abstract from Miners' Circular, Bureau of Mines

Common Sense Mine Ventilation

What Constitutes Good Mine Ventilation From the Economic Standpoint and How to Obtain It

*By J. C. Gaskill**

THE following paper, read at the West Virginia Mining Institute, gives some facts on the conditions met in mine ventilation and the distribution of air. Many are familiar with mine ventilation, but it is probable that all of them have not gone so deep into the subject as to determine what constitutes good mine ventilation from the economic end of the subject.

It is not necessary for a mine to have an overabundance of air, but it is necessary that it should have enough air to properly ventilate it and comply with the law. This will require that the air-current be split so as to avoid using doors on main haulage roads; and this air should be furnished with a reasonably low water gauge.

The question of what constitutes a low water gauge will depend on the quantity of fresh air wanted in the mine, the length of the airways, and the quantity of coal the mines are expected to produce per day. For example, take a mine producing from 400 to 500 tons of coal per day. This mine can be ventilated with a 3'×12' common fan, delivering from 50,000 to 55,000 cubic feet of air per minute. It is possible to do this with one main airway, provided the distance to the first room heading where the air is first split is not too great. It must be remembered that when the room headings are worked out the first air split will be abandoned, the second likewise, and so on, until after a while this 50,000 cubic feet of air, which started with a 1-inch water gauge, registers a 3-inch water gauge. Then the main airway is found to be too small and it is believed that a high-pressure fan will solve the problem of more air. After the high-pressure fan has been installed at a great expense, and is found to be running smoothly, it will be noticed that the water gauge remains at 3 inches for the same quantity, viz., from 50,000 to 55,000 cubic feet of air.

The next thing in order is to lay the blame on the fan and say it is not a good fan. If the mine is investigated carefully it will be found that the fan is not at fault; but that instead of one airway, through which to deliver 50,000 to 55,000 cubic feet of air at a 3-inch water gauge, there should be two airways, which would pass this same volume of air with one-fourth the water gauge, and at one-fourth the horsepower, for it takes four times the water gauge, and it requires four times the horsepower to deliver 55,000 cubic feet of air through one airway as it does to deliver the same amount of air through two airways of the same size and length.

The Consolidation Coal Co. is operating two fans of the same make, duplicates of each other. One was installed in October, 1910, at No. 43 mine, which had been in operation for about 18 years at that time. It had four main return airways 7 ft. ×10 ft., area about 4,000 feet in length. It was ventilated with a fan 8 feet wide and 11 feet in diameter, running at 224 revolutions per minute. The fan which replaced it is 6 ft.×20 ft., and with a 3.5-inch water gauge, at 90 revolutions per minute, delivers 202,320 cubic feet of air per minute. This fan delivered 100,000 cubic feet of air with a .855-inch water gauge, and gave 119 per cent. volumetric capacity. The water gauge and quantity of air were the same on the old fan as on the new one; but the peripheral speed on the old fan was 7,740 feet, while on the new one it is 5,654 feet, a difference of 2,086 feet in favor of the 6'×20' fan.

The second fan referred to was installed in 1912 at No. 119 mine, which has been opened for 6 years and has three return airways, 3 feet 8 inches high by about 16 feet wide. It is 4,200 feet to the first air split, and 3,800 feet from the first split back to the mouth of the mine. The fan gives 1.9-inch water gauge at 71 revolutions per minute and delivers 71,000 cubic feet of air. With this fan, to deliver 100,000 cubic feet would require a 3.77-inch water gauge, and to deliver 200,000 cubic feet of air would require a 15-inch water gauge, besides the fan gives but 53 per cent. volumetric capacity.

Here are two practical tests at two mines of two fans, equal in dimensions, and of guaranteed capacity, built by the same company. Both fans have 10'×12' shaft openings, about 60 feet deep. One fan has proven to be all that was expected, giving 119 per cent. volumetric capacity, while the other is disappointing, in that it gave but 53 per cent. volumetric capacity. These practical tests of fans in service at the mines prove conclusively that mine conditions make good and bad mine fans to a large extent. Notwithstanding these facts, the company which made these fans issued a guarantee that both fans would deliver 250,000 cubic feet of air with a 6-inch water gauge.

The fan at No. 43 mine would deliver 250,000 cubic feet of air with a 5.34-inch water gauge, while the one at No. 119 mine would require a 23.56-inch water gauge. At No. 119 mine two airways are being added which will reduce the water gauge. Calculations show that the water gauge will be .99 inch for 71,000 cubic feet of air; subtracting 10 per cent. loss in air and 19 per cent. on water gauge, .8-inch water gauge remains for the 71,000 cubic feet of air through five airways 4,200 feet long, and four airways 3,800 feet in length. With similar conditions, 100,000 cubic feet of air will require a 1.6-inch water gauge, nearly. If 200,000 cubic feet of air is desired it will require 6.4-inch water gauge. This mine will require about 150,000 cubic feet of air per minute. The coal being low, it will not need so much air to obtain the same velocity

* Consulting Assistant Engineer, The Consolidation Coal Co., Fairmont, W. Va.

and for 150,000 cubic feet of air will require 3.4-inch water gauge.

It was known before this fan was put in commission that a high water gauge would be reached, so other airways had been provided for. Before the 6'×20' fan was installed this mine was ventilated with a 5'×14' fan, situated at the mouth of the mine. The new fan, 6 ft.×20 ft., is located over an air-shaft 8,000 feet from the old fan.

It is common to prepare specifications for a fan for some particular mine, and invite bids for its erection. One of the conditions required of the fan will be "250,000 cubic feet of air with a 6-inch water gauge."

Almost any manufacturer will advise you that he can do "lots" better than this with a much smaller fan. Possibly he will not ask about the airways, but take chances on securing the contract for furnishing and installing the fan. Nine times out of ten this fan is to go to a new mine where the airways are short. It will do good work for a few years; but after a while the mine foreman complains that there is not enough air in the mine. The manager looks up the specifications and also the guarantee by the makers of the fan, and the foreman is directed to run the fan faster, as it is guaranteed to deliver the air. The air is not increased to an amount worth noticing, but a much higher water gauge is noticed. The manager and the mine foreman begin to think, look, figure, and finally discover the cause of the air shortage. It is more than likely that only one airway has been provided for in this mine where from 65,000 to 75,000 cubic feet of air are needed. One airway 7 ft.×10 ft., 6,000 feet long, will only pass 50,000 cubic feet of air; two airways of the same size will pass 100,000 cubic feet, with a reasonable water gauge of 2.85 inches, as 50,000 cubic feet of air in this size of airway gives a water gauge of .475 inch for every 1,000 cubic feet in length. If the airway becomes 3,000 feet in length one way, two ways would be 6,000 feet in length; 6,000 feet×.475-inch water gauge = 2.85-inch water gauge, and it is not long until the airways will reach this distance, and continue to be extended. Two airways will deliver 100,000 cubic feet of air per minute, three will deliver 150,000 cubic feet, and four 200,000 cubic feet, with a water gauge of 2.85 inches, where the airways are 6,000 feet long. Just as the length of the airway is increased, just so will the water gauge be increased.

Consider next the difference in horsepower and water gauge between 50,000 cubic feet of air and 100,000 cubic feet of air passing in the same airway 7 ft.×10 ft., 1,000 feet long. Using Fairley's value for the coefficient of friction or $k = .0000000 1$, then in equation $\frac{k s v^2}{a} = p$, $p \div 5.2 = 1.9$ inches water gauge for 100,000 cubic feet of air in one airway, while .476-inch water gauge will pass 50,000 cubic feet through this same airway. As this is one-fourth the water gauge, it will require one-eighth the horsepower, and if the airway is 3,000 feet long one way, it will be 6,000 feet long in and out. 6,000 ft.×1.9 in. = 11.4 inches water gauge for 100,000 cubic feet through one airway 6,000 feet long and would require 180 horsepower in air. All mining engineers and foremen understand from these figures that it would be impracticable to deliver 100,000 cubic feet of air through one airway of this size a distance of 6,000 feet against 11.4 inches of water gauge; but 100,000 cubic feet can be delivered through two airways 7 ft.×10 ft. area, 6,000 feet long, with a 2.85-inch water gauge and 45 horsepower in air. It will be necessary to add 40 per cent. to the horsepower in the air for friction of engines and fan wheels.

Assume that it is desired to know what total horsepower will be required to deliver 200,000 cubic feet of air through three airways 7 ft.×10 ft., 6,000 feet long.

It is found that 226 is the total horsepower that will be necessary, and the water gauge will read 5.08 inches. Thus it is possible for 200,000 cubic feet of air to be delivered through three airways of this size with 5.08 inches of water gauge and 226 horsepower, but 200,000 feet of air can be delivered through four airways 7 ft.×10 ft. area, 6,000 feet long with 126 horsepower and 2.85 inches of a water gauge, thus saving 100 horsepower by adding one more airway. Five pounds of coal will be saved for each horsepower saved. 100×5 = 500 pounds of coal per hour, or a saving of 12,000 pounds of coal per day. If the coal is worth $1 per ton it means a saving of $6 per day, $180 per month, or $2,160 per year.

At all mines the water gauge should be kept down to at least 1 inch per 100,000 cubic feet of air, for everyday duty, and if it could be kept lower it would be better, as a 1-inch water gauge for 100,000 cubic feet of air means a 4-inch water gauge for 200,000 cubic feet of air.

It requires 40 pounds of water per horsepower per hour, and 1 pound of coal will evaporate 8 pounds of water per horsepower hour. Some engineers say that it will not take 40 pounds of water per horsepower hour, but in practice an instance is known where 52 pounds of water was used per horsepower hour, the case referred to being a steam engine, which was working below capacity with the boiler house not over 30 feet from the fan engine. My opinion is, that where from 80,000 to 100,000 cubic feet of air is required per minute, two intakes and two outlets should be provided; and where from 120,000 to 150,000 cubic feet of air will be needed per minute, three intakes and three outlets should be provided; and where 200,000 cubic feet is anticipated, four intakes and four outlets should be provided. If this practice is followed a great saving in the coal bill will result.

In providing these airways, it is important that all overcasts on main airways be large, that the slopes on each side of the top reach well back, and that they be filled in behind the sides to a slope of about 45 degrees, so as to offer the least resistance to air passing. All overcasts and brattices on main airways should be of concrete so as to prevent leakage.

For the last 10 years it has been the practice of the Consolidation

Coal Co. when opening a new mine to project on the map enough intakes, returns, and overcasts to ventilate that mine with a low water gauge. Where old mines were contending with a high water gauge, air-shafts were sunk to shorten the airways and lower the water gauge. At No. 26 mine an air-shaft was sunk 11,700 feet from the mouth of the mine and a 6'×20' fan and the necessary boiler plant installed. By moving the fan to this location it shortened the airway one-half; besides, the two return airways could be either the former outlets or intakes; four inlets were thus provided in place of two as under the former arrangement. Previous to the transfer of the fan this mine had but two inlets and two returns, but by moving this fan the water gauge was reduced from 3 inches for 100,000 cubic feet to 1.36 inches, thus notably demonstrating the practical value of shortening airways. It will be noticed that a 1.36-inch water gauge is too high for 100,000 cubic feet of air, as for where 200,000 cubic feet is required the water gauge would be 5.44 inches, which is too high to maintain in every-day practice. It may be, however, that this is the best that can be done with an old mine.

The saving of coal by moving this fan was calculated on the difference in actual total horsepower required on each engine, which was found to be 123 horsepower saved on 150,000 cubic feet of air. Five pounds of coal per horsepower per hour means 615 pounds of coal per horsepower hour, or 14,760 pounds, or 7.4 net tons per day of 24 hours. If coal is $1 per ton, the cost is $7.40 per day, or $222 per month, $2,664 per year. The water gauge on the new fan will be 3.06 inches for 150,000 cubic feet of air, and on the old fan it would require a 6.75-inch water gauge for the same amount of air. The new mines opened in the West Virginia coal field are Nos. 63, 32, and 84.

No. 63 mine was opened about 8 years ago and an 8'×20' fan installed. The mine inspector's report states that on October 17, 1912, this fan was delivering 151,510 feet of air at 70 revolutions per minute and a 1.8-inch water gauge. This would equal a .78-inch water gauge for 100,000 cubic feet of air, and would require a 3.13-inch water gauge for 200,000 cubic feet of air.

No. 32 mine has been opened for 3 years. It has a 6'×20' fan, which was recently started. The mine inspector's report of September 26, 1912, states that this fan delivered 108,000 cubic feet with 48 revolutions per minute and .6-inch water gauge. This equals a .514-inch gauge for 100,000 cubic feet of air, and would require a 2.056-inch gauge for 200,000 cubic feet. It must be remembered that this mine is new and the airways are short.

No. 84 mine has no large fan, but has four return and four inlet airways 7 ft.×10 ft.

No. 43 mine, which has been referred to before, shows a rising in the water gauge. The mine inspector's report of October 16, 1912, states that this 6'×20' fan is furnishing 171,424 cubic feet of air at 84 revolutions per minute and a 3.2-inch water gauge. This equals 1.09 inches for 100,000 cubic feet of air, and will require 4.37 inches water gauge for 200,000 cubic feet of air. An air-shaft is being sunk at 8,500 cubic feet from the mouth of the mine to relieve this high water gauge.

At No. 3 mine, Frostburg, Md., the Consolidation Coal Co. had a 6'×20' fan installed some 3 years ago. This is an old mine, with large airways. The mine inspector's report of October 13, 1912, states that the fan at this mine is delivering 120,000 cubic feet with 68 revolutions per minute and a 1.1-inch water gauge. This would equal .76-inch water gauge for 100,000 cubic feet of air, and would require 3.04-inch water gauge for 200,000 cubic feet. There are some things concerning this fan to which attention is directed. The blades were put on backward, an error of the builders. The mistake was not discovered until after the fan had been completed and running some time. When the maker of the fan came to test it he found that his workers had made this error and the fan was running the wrong way. It was for the writer to decide whether the maker should take down the fan and rebuild it correctly. He had not seen the fan since its erection and in making an examination found that a part of the wind box, surrounding the fan wheel, would have to come down. This wall consisted of brick and concrete, no steel being used. It was decided to let "well enough" alone, as the fan was doing its work. That was 3 years ago, and it is believed that this is one of the best fans the company owns.

From the foregoing arguments it will be seen that all fans will deliver air when given a low water gauge. Some fans have a larger volumetric capacity than others, which is a good thing, as such fans can be run at slower speed and make the same water gauge.

The Consolidation Coal Co. has adopted the same method for the ventilation of their new coal field in Elkhorn division, Kentucky. The mines are all projected on the map of the coal field, showing how the mines will be developed and the amount of coal each mine is expected to produce and the amount of air to be put into each mine. Then the proper number of airways are projected on the map, together with all overcasts, so as to handle this amount of air with a given water gauge. The large mines from which it is intended to produce not less that 2,000 tons of coal per day, are expected to require about 200,000 cubic feet of air per minute when fully developed.

In these large mines there will be four return airways and four intakes, each of which will average 6½ feet high by 10 feet wide, making an area of 65 square feet. From the fan to the first split is generally about 1,200 feet and at that point two pairs of cross-entries turn off—two to the right at about 1,200 feet and two to the left about 1,320 feet—so that they will not come in the way of each other's switches, as the cross-entries are turned with a 112-foot radius curve. Each of these two pairs of entries will have four room entries, making eight room entries for each

25,000 feet of air, and these four room entries will be ventilated with one split of air of about 12,500 cubic feet to each four room entries, which will be about 1,000 feet long. Cross-entries will be turned every 2,100 feet, and room entries turned both ways from the cross-entries. I will give you the water gauge that calculations show will be made in passing 200,000 cubic feet of air to the first, second, third, and fourth splits. The water gauge to the first split which, say is 1,260 feet, an average between the two pairs of cross-entries where is taken 50,000 cubic feet of air for these four entries is as follows: Using Fairley's coefficient of friction, which is .00000001, the water gauge for 200,000 cubic feet of air will be $\frac{k s v^2}{a} = p \div 5.2 = .72$ inch for the first 1,260 feet. The next 2,100 feet it will be 150,000 feet of air, and the water gauge will be $\frac{k s v^2}{a} = p \div 5.2 = .68$ inch. The next 2,100 feet will have 100,000 cubic feet and the water gauge will be $\frac{k s v^2}{a} = p \div 5.2 = .3$ inch water gauge. This leaves 50,000 cubic feet of air to ventilate the next four cross-entries, which will be the fourth and last split until the No. 1 split has been done away with. The distance is 2,100 feet and the water gauge will be .071 inch for one way. These water-gauge values are multiplied by 2 to get the water gauge for the mine. There are for the 1,260 feet and 200,000 feet of air, four airways $6\frac{1}{2}$ ft.×10 ft., and a water gauge of .72 inch; call this No. 1 split. No. 2 split is 2,100 feet long, has 150,000 cubic feet of air, has four airways $6\frac{1}{2}$ ft.×10 ft., with a drag equal to a .68-inch water gauge. No. 3 split is 2,100 feet long, has 100,000 cubic feet of air, for four airways $6\frac{1}{2}$ ft.×10 ft., and a drag equivalent to a water gauge of .3 inch. No. 4 split is 2,100 feet long, has four airways $6\frac{1}{2}$ ft.×10 ft., passing 50,000 cubic feet that gives a water gauge of .071 inch. These water gauges doubled, will make a water gauge of 3.54 inches. Figuring that there will be a loss of at least 10 per cent. in air, which means a loss in water gauge of 19 per cent., then 19 per cent. from 3.54 inches leaves 2.87 inches water gauge for 200,000 cubic feet of air on the whole mine to this point. The splits to the cross-entries show a water gauge of only .071 inch for 2,100 feet with 12,500 cubic feet of air, so that the water gauge on main airways is always higher than the cross-entry water gauges.

All regulators on cross-entries should be placed near the main airway and must not be placed beyond the first room entry under any consideration.

Relative to the 19-per-cent. reduction in the water gauge, the writer has found this loss to reach as high as 25 per cent. in practice. It is safe, therefore, to call it 19 per cent., as 10 per cent. loss in air means 19 per cent. reduction in water gauge, and 20 per cent. loss in air means 34 per cent. reduction in water gauge. This reduction is not all from loss of air, but from air passing breakthroughs and wide places which reduce its velocity.

At some of the Consolidation company's mines there are three inlets and four returns, and it is about 1,000 feet to the first split. To pass 200,000 feet of air through three airways $6\frac{1}{2}$ ft.×10 ft. for 1,000 feet will require 1.027 inches water gauge. There are four return airways and the water gauge on them will only be .57 inch for 1,000 feet of length, making a 1.59-inch gauge total in and out, the 1,000-foot long one being one way, while four airways each way for 1,260 feet make 1.44 inches total water gauge for the 200,000 cubic feet of air in and out. With 200,000 cubic feet of air passing with 2.87-inch water gauge it will require 90.4 horsepower in the air, or a total of 127.5 horsepower in air, motor, and fan wheel.

The mine fans in the Elkhorn field will be operated by 150-horsepower alternating-current motors, which should not produce so much frictional resistance as a steam engine working below capacity, for the reason that the motor will run at regular speed at all times, and by having different-sized pulleys for the motor shaft any speed needed for the mine fan can be obtained. Even should the motors have the same friction in fan wheel, the 150-horsepower motor will work until the water gauge becomes higher and then a larger motor can be installed. The fan, 5 ft.×14 ft., should furnish 200,000 cubic feet of air at from 145 to 160 revolutions per minute at this water gauge and the volumetric capacity should be at least 180 per cent.

A boiler plant will be erected at each of the mines near the fan house, for the purpose of adding steam to the air-current whenever there is need of putting water vapor in the mine air, a plan that makes it unnecessary to do any watering to dampen the coal dust.

At one mine there was a fan 7 feet wide and $13\frac{1}{2}$ inches in diameter, which was delivering 116,000 cubic feet of air at 112 revolutions per minute with a water gauge of 1.3 inches. The fan was being driven by a 125-horsepower motor, and was guaranteed to deliver 300,000 cubic feet of air per minute against a 6-inch water gauge, at 300 revolutions per minute. At that time this mine was new and the airways were not long. But suppose 300,000 cubic feet of air had been desired while the airways were short. The water gauge would increase as the square of velocity and the horsepower as the cube of the quantity of the air. The water gauge and horsepower for each 25,000 cubic feet of air would increase from 100,000 cubic feet up to 300,000 cubic feet, as follows: Take 100,000 cubic feet as a base of beginning the illustration. The fan delivers 116,000 cubic feet of air on a 1.3-inch water gauge, which is equal to .966-inch water gauge for 100,000 cubic feet of air. Use Fairley's formula for the coefficient of friction (.00000001), and the water gauge for 100,000 cubic feet as a base of calculation. The volume of 116,000 cubic feet with 1.3-inch gauge could be used, but it is better to take 100,000 cubic feet, for the reason that the water gauge and total horsepower is in pounds for each 25,000 cubic feet increase of air.

From the assumed data, 100,000 cubic feet of air with .966-inch water gauge, the following results are obtained:

Cubic Feet of Air	Total Horsepower	Water Gauge Inches
100,000	21.5	.966
125,000	42.0	1.500
150,000	72.0	2.170
175,000	114.0	2.950
200,000	171.0	3.860
225,000	224.0	4.890
250,000	336.0	6.040
275,000	446.0	7.300
300,000	575.0	8.690

Allowance has been made in this calculation for 71 per cent. mechanical efficiency on horsepower for friction of motor and mine fan.

The Control of Ventilation

By Special Correspondent

No colliery manager in these days requires to be informed that the regulation of ventilation is one of the most important factors in the safety of his employes; or that efficient ventilation has a most important bearing on the output of the colliery. It will therefore be understood that the days for the old rule-of-thumb methods with regard to the supply of air to collieries have passed, and that it is one of the objects of every up-to-date colliery engineer to note precisely what air is being delivered into the workings and in what way it is being distributed. From both these points of view it is highly necessary that some form of measurement should be instituted as to the volume of air which is being passed into the mine.

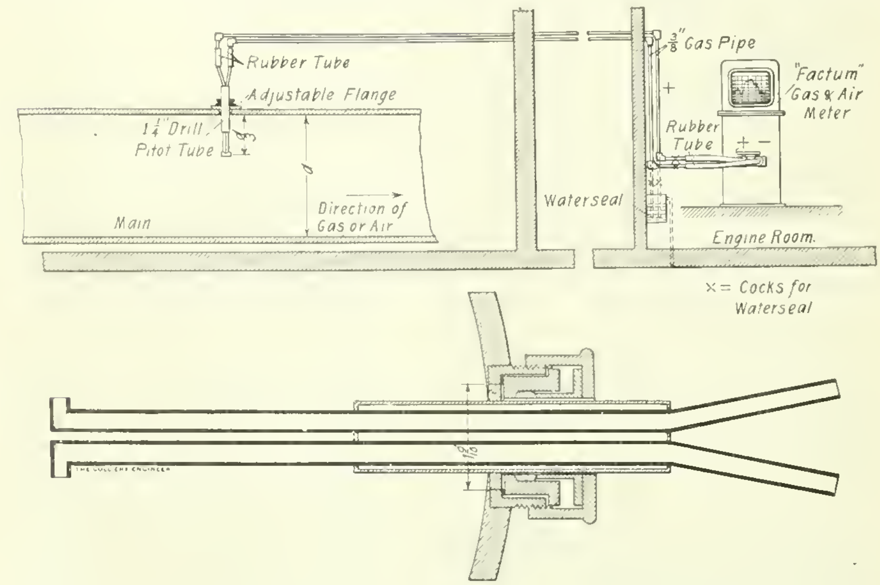


FIG. 2. METHOD OF INSTALLING AIR METER

An interesting instrument for this purpose is now being made in England, and is known as the "Factum" air meter or volume recorder. Its construction and method of operation will be observed by reference to Figs. 1 and 2, the former showing a partial vertical section while the latter shows diagrammatically the way in which this meter is installed. It will be seen that the instrument consists of a cylindrical body A in which are filling tubes B, a pressure pipe C, and a suction pipe D connected to a double cock E by means of which the difference in pressure created by the Pitot tubes installed in the airway is conveyed to the instrument by the tubes C and D. The float F is self-balanced and is supported in special non-evaporative oil, G being float guides and H lifting eyes for the float. It will be seen that the motion of the float is directly transmitted to L, a writing pen gear which operates on a chart placed on the drum U. This drum is revolved by means of the clock L and the gear is covered by a metal hood O to keep dust and dirt from interfering with the mechanism. The rubber disk P insures that the joint is perfectly sealed. Combined with the instrument is a depression recorder, the meter of which is shown at R, S being its float, and T being the pen gear of the depression meter. At U will be noticed the necessary small connection with the external air to obtain the atmospheric pressure. The method of installation requires no further description than is contained on the drawing Fig. 2.

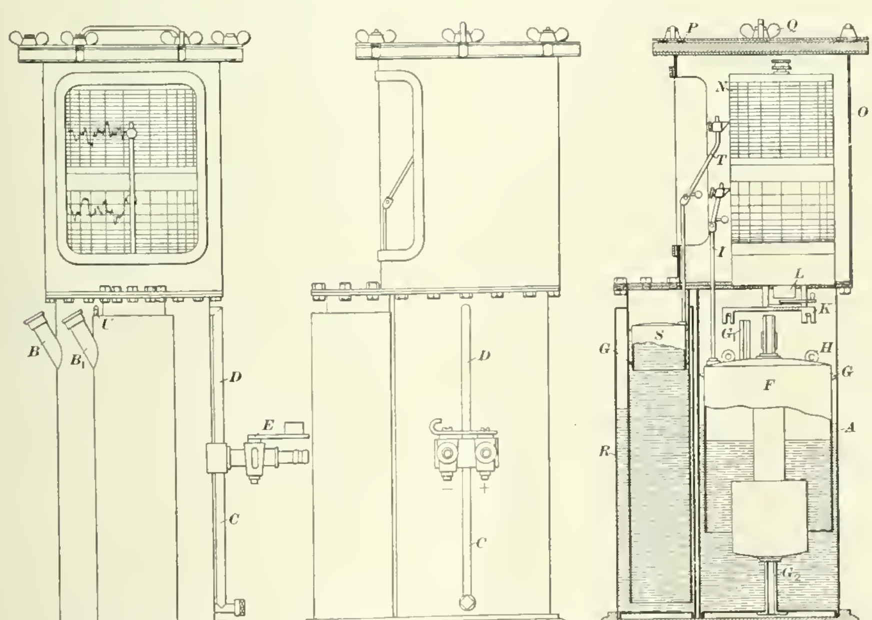

FIG. 1. FACTUM AIR METER AND VOLUME RECORDER

As the speed of the air in the airway increases in the proportion of the square of the difference in pressure, the speed itself can be recorded on the chart. By making use of the formula

Volume = Speed × Area of Airway

the actual volume of gas is recorded on the chart to a suitable scale, and these indications can be made in cubic feet per second or per minute as desired. It should be noted that the distance between the instrument and the place of measurement has no influence on the readings, so that this simple apparatus is of very considerable importance to the mine manager who desires to accurately determine the distribution of the air in his colliery workings. Another important feature in the accuracy of the method is that the Pitot tubes effect no such interference with the draft as would disturb the accuracy of the reading.

BOOK REVIEW

A review of the latest technical books on Mining Engineering and Metallurgy

Cyanide Practice in Mexico, by Ferdinand McCann. 194 pages and index, with 39 illustrations. Price $2. Mining and Scientific Press, San Francisco, publishers. Mr. McCann treats his subject entirely differently from the textbooks on cyaniding, evidently assuming the reader knows that end of the subject. This makes the book descriptive of the cyanide practice at the following mills: El Oro Mining and Railway Co.; El Oro, Ltd.; Dos Estrellas Co.; Esperanza Mining Co.; Guanajuato Consolidated Mining and Milling Co.; Real del Monte y Pachuca Có., Blaisdell Coscotillan Syndicate, Compania Beneficiadora de Metales Hacienda de San Francisco, San Rafael y Anexas Co., Lucky Tiger Combination Gold Mining Co.; Veta Colorado, of Parral, Chih. The method of treating the subjects, without going into the detail of machinery construction or chemical reactions is as follows: Grinding, Regrinding and Classification, Slime Treatment; Precipitation and Melting; Extraction; Chemical Consumption, and Cost of Treatment. Each statement is apparently official and concise; for instance, in Chemical Consumption at El Oro Limited, the author states: "Each ton of ore treated consumes 1.5 pounds KCN; from 1 to 1.2 pounds metallic zinc; from $\frac{1}{4}$ to $\frac{1}{2}$ pound lead acetate, and from 15 to 20 pounds of lime. The same concise statements are rendered in describing other plants, the subheadings necessarily varying to suit conditions involved. Probably no other book on cyaniding so far written is so well suited to the practitioner as this one.

Modern Mine Valuation, by M. Howard Burnham, 160 pages, 19 illustrations, cloth. Griffin & Co., London, and J. B. Lippincott Co., Philadelphia. This work has been prepared for the practicing mining engineer. It deals with the matter of estimating the values of mining properties from the sampling of the ore bodies. Nothing is said of the wholly undeveloped property—the prospect—and it is assumed that all ore reserves are of the vein type, or are, at least, in tabular forms. With this restriction, apparently unconscious on the author's part, the book is a very carefully prepared analysis of the methods to be practiced in taking samples of veins of varying "strike, thickness, color, texture, parting, and pay, such as might be observed when stoping, as practiced or practicable." The ordinary custom of cutting grooves is followed by this writer and he has presented numerous sketches to show how such grooves should be cut in various shapes of drifts and backs of stopes.

Mr. Burnham is a firm believer in the modern idea that a mining engineer should also be a good business man and should be held responsible for the successful financiering of every mine he examines. Accordingly, this book contains many tables on sinking funds, life of mines in terms of dividends, varying risk rates, delayed dividends, and similar economic features, and these are well worth study, although largely prepared from the British view point. The analytical portions of the book show that the author writes from experience; it is quite likely that the average reader will pass over the higher mathematical solutions and be content to accept the author's conclusions.

Modern Copper Smelting, by Donald M. Levy, Griffin & Co., London, and J. B. Lippincott Co., Philadelphia, 259 pages, 76 illustrations, cloth. The author may be pardoned for adopting a title that was used years ago by our American authority on this subject, on two counts, viz., he admits that Doctor Peters' work is a classic and also that there "exists a scope, particularly on this side of the Atlantic (the eastern side) for a compact volume dealing broadly with the principles underlying modern copper smelting." The first three chapters deal with generalities that have little bearing on smelting, as development of the copper industry, prices, costs of production, uses for copper, alloys, impurities, mechanical and chemical properties, compounds and ores, and sampling. In the succeeding chapters, preliminary treatments, briquetting, sintering, roasting, reverberatory smelting, blast-furnace practices, pyritic smelting, disposal of products, bessemerizing of mattes, converter linings, refining, and casting, form the special topics. A commendable feature of the book is the extensive list of references, at the end of each chapter, to recent published articles in the technical press. The book deals almost exclusively with American practice as exemplified at Anaconda and Ducktown, at which places the writer evidently spent cosiderable time in study.

Coal Discoveries in Holland

Good progress is reported in connection with the mining explorations which are being carried out in the province of Gelderland, near Winterswijk. The coal formation, consisting of five seams covered with an important bed of salt, has been reached. The borings of the state engineers have been completed to a depth of 485 meters. Coal has also been discovered in Overyssel.

Amortizing and Interest Charges

For Coal Mines (Leasehold and Fee)—Costs of Carrying Unmined Coal in the Ground—Economical Period for Exhausting Mines

By Louis Cleveland Jones*

IN Transactions of American Institute of Mining Engineers, Vol. 41, 1911, pages 912-913, in a discussion of a paper by J. B. Dilworth, is given Professor Merriman's formula for calculating sinking fund, thus:

When S = principal to be extinguished;

Q = periodical payment of charge for sinking fund;

B = Balance unpaid to date of nth payment, but before the payment is made;

r = rate of interest per period per cent.;

n = number of payments or periods.

$$\text{Then } Q = \frac{S\,(1+r)^n}{\dfrac{1+(1+r)^n-(1+r)}{r}}$$

By this formula the accompanying Table 1 has been calculated to give the equal annual payments required to extinguish the cost of coal in ground. Though column G gives figures at 6 per cent., 8 per cent. is considered a more liberal figure to cover interest, insurance, administration, and taxes, and most of the figures of the table are on this basis.

Certainly 8 per cent. is not too much to cover the always present risk of faults and other irregularities which may at any time greatly depreciate the estimated value of a coal property.

From the figures in the table have been plotted on accompanying charts, curves graphically representing the relations between the various cost factors due to interest, royalty, and other fixed charges against the coal as mined.

From this table and these charts (applicable to any kind of mine or quarry), it is possible to compare any leasehold mining proposition with the corresponding purchase of the mining land in fee. Further, there is indicated for any given cost of plant and coal in the ground, the most economical rate of exhaustion.

When Operator Owns Coal.—For example, when owner and operator are identical, with 1,000 acres of land containing 5,000,000 tons of coal, with plant cost equal to the annual output, and when coal cost in the ground is 2 cents or less, the most economical rate of exhaustion is about 150,000 tons per year. In fact the rate of mining (see curve C) that will exhaust any property, with plant costing $1 per ton annual output, and coal costing 2 cents or less per ton in ground, in about 25 or 30 years, will be the most economical. Coal costing 5 cents should be exhausted in 18 years and coal costing 10 cents in 12 years.

It therefore further follows that operators of fee lands should construct plants for mining low-cost coals (1 cent per ton or less) of such capacity that the land will not be exhausted within ± 30 years, while high-priced coal (costing 5 cents per ton or more) should be exhausted in 12 to 20 years. All land purchased or held above such requirements must

TABLE 1. SHOWING ANNUAL CHARGE REQUIRED TO CARRY AT 8 PER CENT. (TAXES, INSURANCE, AND INTEREST) AND AMORTIZE COAL AT ORIGINAL COST OF ONE CENT PER TON IN GROUND FOR DIFFERENT SPEEDS OF MINING

*V.-P. Solvay Colliers Co., Syracuse, N. Y.

be regarded as an investment entirely separate from the operating proposition.

Leaseholds.—In the case of leaseholds the lessor's interest is to induce the operator to exhaust as quickly as possible, the lessor's profit (curve *F*) being the difference between the flat royalty charged and carrying and amortizing cost given in column *D* (curve *A*), such profit decreasing rapidly with the increase of the period of exhaustion.

For coals costing more than 1 cent, the lessor's profit (curve *F*) falls still more rapidly with the increase in exhaustion period.

It is to the interest of the lessee to build a plant and operate at a rate that will exhaust the leasehold in not less than about 30 to 35 years (curves *B* and *E*). Below that point, the cost of carrying and amortizing the plant is excessive; while after the 30-year period, though the cost of carrying and amortizing the plant decreases slowly, an entirely new plant above ground must be constructed.

The cost of a second plant is not considered in the table and charts given.

In column *A* of the table it is rather surprising that 40 cents above the interest charge starts the forces which wipe out the debt of $50,000 in a 120-year exhaustion period.

Comparison of Leasehold With Purchase of Fee Land.—For example, if an operator desires to produce 166,600 tons a year from 1,000 acres, containing 5,000,000 tons (or 3×166,600 =499,800 from 3,000 acres) by purchase at 1 cent per ton, and exhausting in the most economical period, i. e., 30 years, the amortizing royalty required per ton of coal mined would be (column *D*—curve *A*) 2.67 cents. While to equal the payment of 10 cents royalty the cost of land could be increased to 3.75 cents (curve *D*) per ton in the ground, or $187 per acre.

In other words, under these conditions, leasing at 10 cents or buying at $187 per acre, would result the same to both the land owner and operator. 8.89 cents (column *J*—curve *B*) per ton additional, or 18.89 cents (curve *E*) total royalty, would have to be charged against coal as mined. The fact that the lessor might require a smaller minimum royalty would not be an inducement, since the cost per ton of coal for

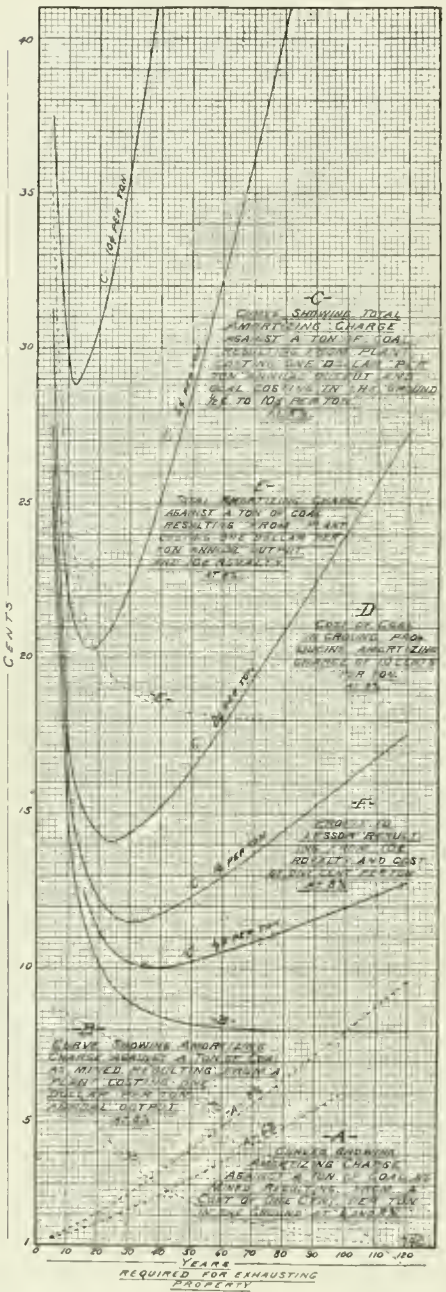

Chart A

amortizing plant would increase considerably, due to the fact that practically a renewal of the external plant would be necessary after 25 to 30 years. Taking this into consideration, the amortizing cost for plant (in column *J*) would increase considerably with the period of exhaustion and a still greater increase in cost for amortizing plant would likewise result in columns *J*, *K*, *L*, *M*, *N*, *O* (curves *C*).

Discussion of Curves on Chart A

Cheap Coal Even With Slow Exhaustion Rate Gives Lessor Good Profit.—Curves *A* show that coal costing 1 cent per ton in the ground can be exhausted slowly without producing excessive amortizing charge against the coal.

The period of exhaustion may be extended to 100 years, producing at 8 per cent. a charge against the coal of only 8 cents per ton as mined, or at 6 per cent. the resulting charge would be only 6 cents. A period of exhaustion extending to 125 years at 8 per cent. would be required to equal 10 cents royalty charge. In other words, for coal having a value of 1 cent per ton in the ground, a plant of a capacity of 400,000 tons per year at 10 cents royalty exhausting in 125 years, operating on 10,000 acres of 4-foot coal, 50,000,000 tons, would still pay the owner of the land 8 per cent. and amortize his investment.

In like manner, if the period of exhaustion is 60 years, the owner at 10 cents royalty gets his money back with 8 per cent. interest and ±5 cents per ton of coal besides as clear profit.

Value of Coal in Ground Corresponding to 10 Cents Royalty and Different Rates of Exhaustion.—Curve *D* indicates the value of coal in the ground equivalent to 10 cents royalty for varying rates of exhaustion. Thus, if the leasehold contract is such that the period of exhaustion is brief, the leasehold contract puts a higher value on the coal in the ground. That is, a 10-cent royalty and a period of exhaustion of about 28 years indicates an equivalent value of coal in the ground of 4 cents per ton, or $200 per acre of 4-foot coal. The period of exhaustion may be delayed to about 60 years for a value of coal equal to 2 cents per ton in the ground. Conversely, high-priced coal lands at 10 cents royalty require rapid exhaustion, coal costing 5 cents per ton in the ground at 10 cents royalty must be exhausted in 20 years, 3-cent coal in 40 years, in order to amortize the lessor's investment and pay him 8 per cent. interest.

For Given Coal Value, Plant of Definite Size Requires Corresponding Tonnage Coal in Ground.—Curve *D*, indicating the period of exhaustion required for coals of different values, consequently indicates the tonnage of coal that should be provided for a plant of any given output.

Three-cent coal exhausted in 40 years equals a 10-cent royalty, therefore a 400,000-ton yearly output requires 16,000,000 tons of coal in the ground, or at 5,000 tons per acre, 3,200 acres.

A small operation of 100,000 tons annual output in 3-cent coal requires but 4,000,000 tons, or 800 acres of 4-foot coal; 2-cent coal land permits a period of exhaustion of 60 years; that is, a 400,000-ton plant should have 24,000,000 tons coal, or 4,800 acres of 4-foot coal.

Profit to Lessor Falls With Slow Exhaustion.—Curve *F* (10—curve *A*) shows how profit to lessor falls off with increase of exhaustion period. For coal of higher value, say 2 cents per ton in ground, curve *F* would become (10—2*A*), in which case the lessor's profit would be reduced to zero for a period of exhaustion exceeding 62 years.

Total Amortizing Charges Resulting From Plant and Cost of Coal in the Ground.—Curve *B* showing charge against coal as mined resulting from cost of plant, and curve *E* showing total charge against leasehold coal at 10 cents royalty, suggest that operator of a leasehold gets little lowering of charge against coal by extending the exhaustion period beyond ± 40 years, especially when considering plant renewal. He would gain, however, by thus tying up a larger amount of coal or the same amount of coal for a longer period.

Total Charge for Leasehold and Purchase Compared.—Curve *E* also shows that coal could be purchased at 5 cents per ton and exhausted in 18 years for the same charge against coal (20.3 cents) as if operating under leasehold at 10 cents royalty exhausting in the same period. Leasehold at 10 cents royalty exhausting in 62 years gives the same charge against the coal as purchased coal at 2 cents exhausted in the same period.

Economical Period of Exhausting Coal Mines.—Curves *C*, as already pointed out, show the economical period of exhaustion for coal of different values in the ground, and also indicate the particular necessity of rapid exhaustion for high cost coals. These curves also indicate the amount by which the net selling price of the coal must exceed the cost to cover interest and depreciation.

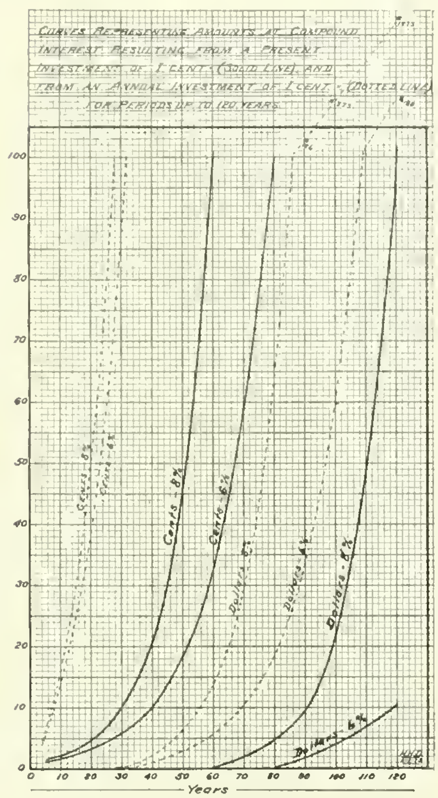

Chart B

Mining Cost.—Of first importance in considering a mining proposition are the factors influencing actual cost of putting the coal in mine cars.

In making comparisons of specific operations favored by thickness of seam, labor conditions, dip of seam, or freight differential, we have only to subtract the saving in costs thus brought about from the charges against coal indicated by the curves on the chart. For example, curve *C*, with coal in the ground costing 5 cents per ton; we may have physical mining conditions producing a lower mining cost by 10 as compared with a cheap coal costing 1 cent per ton represented by curve *C*; 10 cents should therefore be taken from all points of curve *C* 5 cents per ton, resulting in a minimum cost for a 20-year exhaustion period of 10.3 cents compared with 11.5 cents at 30-year period for cheaper coal.

Unusual Expense Due to Inaccessibility.—The influences upon amortizing charges against coal as mined, due to sinking shafts, constructing conveyers of unusual length, bridges, and railroad spurs, may be obtained by multiplying values in curves *A* by total cost of plant and accessories, in terms of cents per ton of coal to be mined. Thus, if a shaft cost 2 cents per ton of coal available with exhaustion period of 30 years, there is added, besides cost of operating shaft and pumping, a charge against coal of (2×2.67 or) 5.34 cents per ton of coal mined.

Cost of Carrying Unmined Coal as an Investment.—On chart *B* (solid lines) is given the amount at compound interest of 1 cent for periods up to 120 years. It is rather startling to learn that if coal land investments are to earn 8 per cent. less taxes and administration charges, coal now costing 1 cent per ton in the ground will at the end of 120 years have a value of $102 per ton. In other words, coal lands now worth $50 per acre for 4-foot coal should then be worth $510,000 per acre. Coal costing 4 cents per ton in the ground would then be worth $408 per ton. Even at 6 per cent., in about 170 years the same figures would be reached. In the case of anthracite the values would be proportionately greater. These figures are absurd, and of course coal could not be used at any such figures. The exhaustion of the world's coal supply is generally placed at a far more distant period than 170 years. These curves then show that coal, even at 1 cent per ton in the ground, can be held with profit only if mined in the not distant future.

In like manner, from these curves, values at 8 per cent. should increase 100 fold each 60 years, and at 6 per cent. each 80 years. Coal, now worth $50 per acre, 60 to 80 years ago should have been worth only 50 cents per acre. This is surprisingly near the actual values of coal land 60 or 80 years ago, and instead of making wonderfully profitable investments, the holders of coal lands have made only about 6 to 8 per cent. interest on their money.

Values Increase 10 Fold in 30 to 40 Years.—Values at 8 per cent. in 30 years increase tenfold, and to the same extent at 6 per cent. in 40 years.

Cheap coal (1 cent per ton) can be easily carried for this period, while coal costing 5 cents or 10 cents should be mined at once, since these greater values generally represent cheap mining conditions, accessibility, or some other advantage which does not appreciate in value commensurate with compound interest.

Amortizing Charge Against Coal for Various Plants.—With the data now at hand it is possible to find the overhead charge that must be made against coal mined under almost any actual conditions, also to say whether the addition of capital, and how much, with corresponding increased production would bring about a saving in costs per ton of coal.

CONCLUSIONS

1. The factors determining amortizing and interest charges against coal as mined, as shown by the table and charts herewith presented, are A, cost of coal in the ground; B, period of exhaustion; C, amount of coal available; D, annual output of plant; E, cost of normal plant.

2. For conditions of maximum economy a definite relation is fixed between all these factors.

3. Of these factors, A is fundamental; i. e., the cost of coal in the ground determines the economical period of exhaustion. A determines B.

4. Period of exhaustion equals the amount of coal available divided by the annual output or by the cost of normal plant.

$$B=\frac{C}{D}=\frac{C}{E}$$

5. Amount of coal that should be available equals the period of exhaustion multiplied by the annual output desired or by the cost of normal plant.

$$C=B\times D=B\times E$$

6. Annual output, likewise cost of plant, should equal the amount of coal available divided by the period of exhaustion.

$$D=E=\frac{C}{B}$$

7. For each period of exhaustion there should be a definite ratio between the cost of plant and the tons of coal available. For a 30-year period the cost of plant is about 3.3 cents per ton of available coal. For a 20-year period the plant cost should be about 5 cents per ton of available coal.

For 30-year period

$$\frac{E}{C}=\frac{D}{C}=3.3 \text{ cents}$$

For 20-year period

$$\frac{E}{C}=\frac{D}{C}=5 \text{ cents}$$

8. The value of coal in the ground equivalent to leasehold at 10 cents royalty (curve D—column E) falls rapidly with the increase of the period of exhaustion, and conversely, the shorter the exhausting period at any given fixed royalty, the greater the equivalent value of the coal in the ground.

For an exhaustion period of 30 years and 10-cent royalty a coal value is indicated of 3.75 cents per ton in the ground, $187 per acre of 4-foot coal.

9. The lessor's profits fall rapidly with the increase in the period of exhaustion allowed, while the operator's profits are not increased by slow exhaustion after ± 30 to 40 years.

10. Under conditions of maximum economy, with coals valued at 2 to 5 cents in the ground, the average bituminous coal operation requires that the net selling price of coal exceed the actual cost of administration and mining by 14 to 20 cents per ton (curves C).

11. It is remarkable that experience seems to have worked out in practice the economic relations between the cost factors due to investment which so nearly correspond to these reached from mathematical considerations.

Coal in Transvaal, S. A.

In addition to the gold and diamond mines, the Transvaal province, South Africa, has coal which is marketed as cheaply as anywhere else with the possible exception of some places in America and Japan. The only difficulty with the industry at present is that the coal supply far exceeds the local demand. There has been no great encouragement for export of the product. It is thought that if the Transvaal collieries could obtain an export trade for their coal the greater part of the gold mining and other industries could be run with "small coal" at a cheaper rate than that now paid for the kind used. The output of the coal mines of the Transvaal for 1911 amounted to 4,343,680 tons, valued at $5,102,000 against 3,970,069 tons, valued at $4,931,000, for 1910. The coal industry at present employs 500 white men and about 9,000 natives.—*U. S. Consular Report.*

Employes' Association of "River Coal"

The Employes' Association of the Monongahela River Consolidated Coal and Coke Co. of Pittsburg, Pa., was organized March 1, 1907, for the purpose of mutual benefit and accident association. Since its organization the total collected amounts to $323,752.41, of which employes contributed $262,394.19 and the company $67,432.35. To November 30, 1912, there have been paid out in benefits $274,867.46 for fatalities and $33,439.13 for nonfatal accidents. At the end of the fiscal year there was $15,445.82 in the treasury. The benefits paid to dependents in fatal accidents during the fiscal year amounted to $53,050.81.

Too Much Ventilation

Importance of the Amount of Moisture in the Ventilating Current, and the Methods That Have Been Employed for Its Control

*W. H. Booth, F. G. S.**

AIR at a given temperature will be saturated, if loaded with a certain fixed amount of moisture. The higher the temperature the greater is the weight of moisture requisite to saturate a unit volume. When air is taken from the surface and forced down a mine, work is done upon it by way of compression, and this work all appears as heat; other things being equal, the air will be hotter when it has descended a shaft, and its capacity for moisture will therefore be greater, and as that air flows through the mine it will tend to arrive at saturation point by absorbing moisture from the things with which it comes into contact. Over a great part of the year the interior of a mine is warmer than the external air, and air which leaves the surface fully saturated with moisture may become relatively dry when heated in the mine. In such a condition it will dry the mine, perhaps below the desirable extent of moisture, and may cause the very danger it is intended to avert.

Yet it is not desirable to reduce ventilation in gassy mines below what will preserve the percentage of gas well below the agreed minimum. As regards atmospheric purity, factories are considered to be well ventilated with 2,000 cubic feet of air per person per hour. The old English Cotton Cloth Factory Act provided for 600 cubic feet each per hour, but this has been raised to 2,000 cubic feet in a later amended act. The generally accepted datum of sufficient ventilation is such a supply of air as will prevent the accumulation of CO_2 beyond 9 parts per 10,000 of air, that is to say 5 parts per 10,000 in excess of the ordinary external atmosphere. When the CO_2 reaches or goes beyond this amount, the atmosphere commences to become more or less fetid. So far as concerns the CO_2 itself, this amount is very much less than what can be endured without discomfort if the CO_2 is pure, as it would be in case of its evolution from chalk by the action of sulphuric acid.

But where the gas is the product of the lungs of man or other animals, the presence of CO_2 is appropriately regarded as signifying a proportionate amount of organic impurity, and thus the CO_2, being easily tested for analytically, is simply an indication that organic impurity also stands at such a point as to be detrimental or otherwise, according as the gas is above or below 9 parts per 10,000 of air. Thus the air for ventilation, regarded from a sanitary standpoint, may ordinarily be neglected, for it is never more than a fraction of the 1,000 cubic feet per minute required by the dictum of a prominent engineer.

Factory ventilation may very well be quoted in terms of cubic feet per worker, but the care of the mine is different, for it must be regarded from the point of view of the amount of explosive gas given out. And probably there are few mines where ventilation as required by the workers is not exceeded by that required to sweep away the gas in a state of sufficient dilution.

Since over dryness of the air is to be avoided, it appears that mine air should be accorded the same treatment as factory air by way of moistening or conditioning. In factory ventilation, where the temperature and moisture are both desired to be within a narrow range, this is best secured by first warming the air to a certain degree, then saturating it with moisture at that temperature and finally warming it to the temperature at which it should enter the factory. The temperature at which the air is saturated is fixed so that when the air is finally discharged into the factory its percentage of saturation or relative humidity shall be correct. This system of warming is based on the fact that it is easy to saturate with moisture by means of steam or of water sprays, and it is not difficult to warm air to a given desired temperature. But it is more difficult to moisten air to a percentage of humidity 10, 20, or 30 per cent., as the case may be, below the saturation point. Hence the heating at two stages, each of which can be controlled by thermostat, and the saturation at the intermediate temperature.

Ordinary air has a relative humidity of 50 to 75 per cent. of saturation, and upon this depends its absorptive ability. Its absorptive capacity depends upon its temperature, for a cubic foot of air will absorb more at 70° than at 60°.

As an example of the working out of the double stage warming with intermediate saturation, let it be supposed that the air traverses the workings at about 70° and that it is desired to limit it to about 80 per cent. of humidity.

At 70° air is 80 per cent. saturated when it contains about 6.4 grains of moisture per cubic foot. Looking further into a table of relative humidity, it appears that air which is saturated at 63° contains nearly 6.4 grains of moisture; obviously, therefore, the air to be supplied must be heated to 63° and then saturated with moisture and then when it becomes warmed to 70° it will only be 80 per cent. saturated.

A very useful table of this kind is published by the Carrier Air Conditioning Co. of America. As an illustration of the moisture capacity of air, Table 1 shows the weight of moisture per cubic foot of air at different temperatures.

Now, air that is 80 per cent. saturated will carry, per cubic foot,

*Caxton House, Westminster, S. W., England.

moisture as follows: 70°, 6.38 grains; 75°, 7.49 grains; 80°, 8.74 grains; 85°, 10.19 grains; 90°,

Table 1. Moisture Capacity of Air

Degrees	Grains
63.0	6.35
68 0	7.48
73.0	8.78
78.5	10.11
82.5	11.80

11.83 grains; or approximately saturated air holds the same amount of moisture per cubic foot as is contained by air 7° hotter and saturated only 80 per cent.

And, similarly, 70 per cent. saturation represents 11¼° lower temperature air fully saturated. This means that the mere acquisition of 11¼° of temperature renders air capable of absorbing a considerable further weight of moisture, and if the air starts with only 50 or 60 per cent. of saturation its heating by 10° may render it absolutely parching in its effects.

To avoid this, it must be initially moistened to the necessary degree. This moistening will be determined by surrounding conditions. If the air must travel long distances along wet airways in which no dust can be produced, these may be allowed their effect; but ordinarily the moisture will be artificially added by water sprays in the manner described.

The degree of relative humidity in air is ascertained by the wet- and dry-bulb thermometer. With saturated air, a thermometer with a dry bulb reads the same as a thermometer the bulb of which is enveloped in wetted muslin; but as the degree of saturation decreases so does the difference between the two thermometers increase.

Table 2

Dry Bulb Degrees	Wet Bulb Degrees	Dew Point Degrees	Moisture Per Cubic Foot	Percentage of Saturation
87	65	50	4.08	30
82	65	55	4.65	40
78	65	57	5.13	50
75	65	59	5.61	60
72	65	61	5.96	70
69	65	63	6.18	80
67	65	64	6.52	90
65	65	65	6.78	100

Table 2, given by the Carrier company, will show this effect.

Here the final temperature is taken as 65° and the air is saturated. As the temperature rises the air is relatively dried. The dew point is the temperature below which any further fall of temperature causes deposition of moisture. Moisture is being absorbed by the air, and as the air cools and approaches saturation, both by absorption and cooling, the two thermometers read more and more closely until they coincide at 100° saturation.

The depression of the wet bulb thermometer is a matter of relative humidity at the then temperature. Thus the wet bulb will read lower than the dry bulb by so many degrees, according to the relative humidity at the then temperature and the difference is as follows: 80 per cent., 7°; 75 per cent., 9°; 70 per cent., 11¼°; 65 per cent., 13¼°; 60 per cent., 16¼°; 55 per cent., 19°.

These thermometers thus form a useful means of determining relative humidity at all ordinary temperatures, and it is this relative humidity that is needed to be known if a control is to be held over the drying quality of mine air.

It would hardly be correct from a physiological standpoint to humidify the air to the saturation limit, for it would be most disagreeable for miners to work in such air. Workers must always be supplied with air that will carry off the perspiration for the body. When men are working in a copious stream of air they can of course submit to a higher degree of humidity than when the air moves less slowly. In winter a mine is more apt to be dried out than it is in summer, simply because the air is taken by the fan at a lower temperature and it contains very little moisture; and if it also requires to be warmed it will become extremely dry, so that when artificial warming is needed in winter, the application of exhaust steam would serve the double purpose of warming and humidifying.

It is usual to speak of air absorbing moisture, but this is not scientifically correct. Water vapor to a certain fixed quantity, will occupy the space above any vessel of water of a certain temperature; it will do so whether air be present or whether it be absent from that space. The air has no effect except to retard the occupation of the space by the water vapor. But of course space by itself cannot have temperature. The amount of moisture in the space depends on the temperature of the parent water. And when no water in liquid form is present the space temperature is of course that of the air, so that the air so far does determine the amount of water in suspension in a given space, and in practice it is quite allowable to regard the air as a carrier of moisture, for without moisture purposely added air will deprive other substances of humidity.

Coal Mining Institutes

American Institute of Mining Engineers is a society devoted to the advancement of mining and metallurgy. With this society a number of college societies, composed of undergraduates, are affiliated as associates, but not as members of the Institute. Owing to the wide area covered, the parent society has a number of chapters whose members meet monthly in various cities. State Coal Mining Institutes meet twice a year, when the members read, listen to, and discuss, papers pertaining to coal mining. The members of such societies are engaged actively in coal mining or in some branch closely connected with coal-mining operations. The papers read at these institutes are excellent, practical, and usually provocative of wide discussion.

District Mining Institutes are local affairs confined to the coal fields and include the mine officials and their assistants locally. These meet monthly to listen to papers and discuss the various mining subjects on their minds. These meetings are practical and helpful. In connection with these institutes are mining schools for the instruction of miners, in many instances under the auspices of the Young Men's Christian Association.

Hogan on the Election of Mine Inspectors

Hogan, fwhat d'ye think of the eliction iv mine inspicthors?

Well, Reilly, I don't think much of the plan. It's not a raisonable way iv gettin' good min for the job. If the prisidint iv a coal minin' company wants a shuperintinder, does he ax the farmers, and bar tinders and praichers and sthore kapers and politicians and lawyers and docthers all over the county to help him pick a good wan? Not on yer loife, he don't. Iv he doesn't know the right man, he axes min that know coal minin' to ricommind a man. An' whin they tell him iv a good man, that doesn't settle id. He'll sind for the man an' question him. He'll find out phwat ixperience the lad has had, and does he know his business. He'll find out, too, is his charac'ther for soberness and dacincy good, and has he the good sinse that they call execu'tive ability.

Now Reilly, iv that's the right way for business min to get a man capable of doin' things, isn't it common sinse to pick State Mine Inspicthors in the same way, or be the most careful and intilligent way?

You know Reilly, a State Mine Inspicthor is in manny ways a shuperintinder, not only of wan or two mines, but iv all the mines in his dishthrict. The regular shuperintinder works for the mine owner. 'Tis his business to get out the coal as chapely as possible. The mine inspicthor is the shuperintinder that works for the State. 'Tis his business to see that the coal is mined in such a way as will consarve the health and safety of the min and the properthy of the mine owners. To be anny good at the job he musht know more about minin' and be more larned in manny subjects than most iv the mine bosses. Some min, an' I'm sorry to say min that have a lot iv influ'ence wid the mine workers, are thryin' to have a law med that will make anny man wid a mine foreman's certificate elligible for election as State Mine Inspicthor. This manes that manny min wid certificates that have had no ixperience as bosses, as well as min that have had and ben found wantin', can run for inspicthor. The besht min, the min that have the minin' education, the charac'ther an' the ixperience and common sinse nicessary for the job, are the min that sthay home nights, an' are not known be the bar tinders and politicians, and they'd have no show as candidates. The lads that would have the besht show in the eliction would be the fellows that cud get the mosht votes, and the vote iv a bar tinder or a hostler wud count as much as yours or mine. Av coorse the lad that spint the most money wid the saloon kapers and gev the farmers the most taffy, promisin' thim chaper coal, an' usin' the same kind of talk wid other classes of min, wud be the fellows to win, and they'd be the Divil's own inspicthors.

I see be the paapers that the proposed new mine law for the anthracite ragions, prepared by a subcommittay' of the Commission, provides for the seliction of min for mine inspicthors be a plan that is more likely to get good min than be anny other manes, and I can't undhersthand how anny man wid sinse, who raaly wants to see the mines med as safe as possible, and who has though the matther over can be agin id.

In the firsht place, no man but wan over thirty-five years ould of good charac'ther and good health and sthrength can be a candidate for examination. Besides this, he musht have had at laste tin years practical ixperience in the mines, five years of which just afore the examination musht have been in the mines of the ragion.

In the sicond place, the proposhed law says plainly phwat they musht be examined in, and begorra Reilly 'twill take a shmart lad to have brains enough to hould all he musht know.

Thin, in the third place Reilly, the law proposes an examinin' boord in which the miners will have a majority. This boord is to be appinted be the Governor, and musht be med up iv min of good charac'ther over thirty-five years ould. The boord is to consisht of nine min, five of thim to be reputable miners of at laste five years ixperience in gassy mines in the ragion, and four iv thim to be minin' engineers of not less than five years practical ixperience in anthracite mines.

Whin this boord houlds an examination it musht not only be open to the public, but ivery question, an' the answers med be the candidates, both in written examination, and whin questions an' answers are be word iv mouth, musht be put on file in the Minin' Department in Harrisburg, where anny wan wantin' to, can see thim an' detarmine was the examination fair.

Whin the examination is over, the boord iv examiners musht sind to the Governor the names iv all the candidates that have pasht wid a credit of ninety per cint. or betther, and the Governor musht appint the man or min havin' the besht record.

Isn't that the besht way to find is a man fit for the job? Av coorse it is. And, besides, the man that gets the job be this plan, is beholden to no wan but his own charac'ther and brains for the job, and he'll do his juty widout fear or favor. Wid such min as inspicthors, the mines will be inspicthed and the law enforced. It won't make anny difference who breaks the law, whither 'tis the mine owner, the boss, or the miner, the law will be put on him, bekase the inspicthor will not have to be kapin' frinds wid everybody so as to get their votes at eliction time.

Fwhat the Divil use is a mine law, if id isn't enforced, and how the Divil can a man who has to kape frinds wid everybody enforce it?

The hishtory I was radin' the other day tould iv George Washinton sayin "Etarnal vigilance is the price iv liberty." Be the same token etarnal vigilance is the price iv safety in the mines, and the mine inspicthor can't be etarnally vigilant if he has to spind wakes and months iv his time runnin' around to the grog shops electioneerin', insthead iv bein' in the mines seein' that conditions are healthy an' safe.

British Tests for Miners' Safety Lamps

The following information in regard to tests of safety lamps is given by Deputy Consul General Carl R. Loop, of London:

Pursuant to the provisions of the coal mines act of 1911, tests have recently been carried out by a departmental committee appointed by the British Home Office which, in the opinion of the committee, miners' safety lamps should pass in order to be admitted to the list of "approved" lamps. It is not proposed that each individual lamp used in coal mines should be tested, but it is considered that no lamp should be adopted if it does not conform, in all particulars, to an official specification which is the direct outcome of an official test.

The tests which the committee considers flame safety lamps should pass, fall under three heads: (1) Mechanical test, (2) photometric tests, and (3) tests in an explosive mixture.

Mechanical Tests.—In order to discover whether the lamp is capable of withstanding the conditions of rough usage to which it is likely to be submitted in a mine, it is proposed that it shall be submitted to three tests. First, it is to be dropped, complete with its glass, from a height of 6 feet upon a wooden floor five times in succession. A different glass is to be employed each time, and not more than one broken glass is to be permitted in the five tests. If two glasses break, the lamp is to undergo five more tests, and if the glass breaks in two of these it will be held to fail. The second test consists in dropping a weight of 5 pounds from a height of 6 feet vertically upon the lamp. If the glass is cracked, the test is to be repeated twice, when one failure will condemn it. The third test is intended to try the security of the attachment of the different parts, and consists of dropping a 10-pound weight, attached to a cord, from a height of 6 feet, the other end of the cord being secured to the bottom of the lamp, which is suspended at a height of 7 feet from the ground.

Two tests are also proposed for the lamp glasses separately. In the first a weight of 1 pound is to be dropped from a height of 4 feet upon them as they stand in a vertical position, and in the second they are to be heated in an air bath to a temperature of 212° F. and plunged into water at 60° to 65°. In both these tests 20 glasses of each kind are to be tried, and in each case 10 per cent. of failures will cause rejection.

Photometric Tests.—The committee considers that the minimum candlepower to be required of flame lamps should be .30 (pentane standard*), and that they should give this minimum for 10 hours. The lamps tested varied between .325 and .65 candlepower, the higher figure being given with naphtha as fuel and the lower with a mixture of half colza and half paraffin.

Tests in Explosive Mixtures.—In respect of explosion, two tests are proposed. The lamp, after passing the mechanical tests, is to have its behavior tried first in a still inflammable atmosphere and then in horizontal and inclined currents in an explosive mixture at a maximum velocity of about 1,200 feet in a minute. Each test is to last 2 minutes, and an ignition is to constitute a failure to pass. The mixture is to be, within limits, the most explosive obtainable with the particular combustible gas or vapor employed.

In addition the committee holds that all approved lamps should ultimately have double gauzes of steel or best charcoal annealed iron wire (or copper wire in the case of those used for surveying purposes) of 28 B. W. G. (.014 inch diameter) with 28 meshes to the linear inch (784 to the square inch); but they suggest that this requirement shall not be enforced until January 1, 1914. When lamp pillars are employed, the pillars ought to be so arranged that a straight line touching the exterior part of consecutive pillars will not touch the glass.

Electric Safety Lamps.—It is recommended that only the first of the mechanical tests be required for electric safety lamps, the test being carried out with the battery removed and a dummy of the same weight substituted. The lamp should be required to give not less than 1½ candlepower after 10 hours' use; and as regards the danger of causing explosion, it should be tested by having the light switched on and off while it is in an explosive mixture. Another requirement is, that no liquid escape from the battery when the lamp is turned upside down; and the committee think it desirable that the light should be well distributed outside the lamp and that a movable reflector should be provided to concentrate or shield the light at will.

[The United States Bureau of Mines is also studying the problem of improved lamps for miners, having already issued one pamphlet on the subject, and is preparing another. The above bureau (address, Washington, D. C.) may be communicated with in regard to any feature in connection with lamps or other devices for safety in mining.]

*The British standard candlepower is obtained from a sperm candle weighing 6 to the pound and burning at the rate of 2 grains per minute. The petane bunsen standard has the equivalent of 1 British candlepower, hence the above is .3 of a candlepower.

Coal Mine Ventilation

In the Connellsville Coke Region—The Conditions Existing and Manner of Dealing With Them by the Large Companies

*By Austin King**

IN treating this subject we regret that, with one exception, to which we will refer later, we cannot point to some newly invented system of ventilating mines, but the fact is that invention has done little to assist in simplifying ventilation methods underground during the last half century. The roads and airways now made are perhaps larger, straighter, and rougher than in the days of yore, otherwise there is practically no difference between them. The trouble from obstructions in them, caused by falls and water pools, is still the same.

The many disasters in the bituminous coal mines, which occurred during the past few years and which involved such enormous loss of life, have stimulated research into the chemical composition of mine gases and the physical properties of coal, to such extent and with such success that bituminous coal-mine ventilation as a factor in the prevention, or cause, of mine explosions is now better understood than ever before, and we sincerely hope that with such knowledge and its timely application the days of such disasters are past.

The purpose of this paper is to show what is to be reckoned with in coal-mine ventilation in the coke region and how the difficulties are met and overcome. It will show the practice of supplying large volumes of air per person in the mine for circulation around the working faces and through the roadways, as a means of preventing mine accidents and providing safe, comfortable, and healthy conditions for men to work in.

The territory intended to be covered by this paper includes, roughly, that portion of Westmoreland County, Pa., lying south of Latrobe, and between Chestnut Ridge on the east and the Indiana, or Blairsville, anticlinal on the west, and that portion of Fayette County, Pa., lying between Chestnut Ridge and the Monongahela River, being practically the western half of that county.

The way in which explosive gas appears in these mines is somewhat different in different portions of the region. In the mines located in the basin between Chestnut Ridge and the Indiana anticlinal, explosive gas is rarely encountered in the advance entries or rooms. In 1889 the writer had charge of what was then the deepest mine in western Pennsylvania, yet no explosive gas was met with in it until pillar drawing had so far progressed as to cause large falls of roof. Another large shaft operation near by was worked with open lights for about 8 years. Other operations might be cited to show the freedom of these mines from explosive gas from the coal seam prior to the fracture of the rocks above by the extraction of pillars.

The analyses in Table 1 give the composition of the air at the working faces of four entries in mines in this portion of the field, and at a very unusual distance from the passing air-current.

The purpose of taking samples from those places was to obtain positive information as to the composition of the atmosphere at the face of the most advanced and, therefore, the poorest ventilated entries in a large number of mines. It will be observed that a good percentage of oxygen and a very small percentage of deleterious gases were found to be present.

When the cover exceeds 200 feet, or thereabout, in thickness and the coal is mined out of a sufficiently large area to permit the overlying rocks to break or fall, explosive gas is usually liberated and, if the cover exceeds 300 feet, large quantities often escape into the workings of the mine from the fissures so produced.

During the extraction of the coal pillars the excess pressure of the strata on their ends disturbs the rocks beneath the seam for a depth of several feet and sets free explosive gas sometimes pent up in them. The escape of gas from the bottom happens occasionally, but the general opinion of mining men in the region is, that the floor of the mine gives off very little gas.

In that part of the region in Fayette County lying west of the Indiana anticlinal, explosive gas issues very freely from the chinks and crevices of the coal seam at and near to the freshly worked faces of the advanced entries. The composition of this gas is shown by the analyses in Table 2.

In the last place 16,560 cubic feet of air was passing. The place was idle.

When mining has so far progressed that pillars are extracted or mined out, additional quantities of explosive gas are liberated from the rocks above and the problem of ventilating such sections becomes very similar to that of the other mines located east of the anticlinal.

Table 1

Mine	CO_2	O_2	CH_4	N_2	Distance From Passing Air-Current Feet	Time Taken	No. Men at Work
A	.30	19.30	.40	80.00	345	11:30 A. M.	1

*Chief Inspector of Mines for the H. C. Frick Coke Co.

33—8—4

What are known as "hot gobs" are not infrequent in the mines of the region, and temperatures as high as 118° F. have been noted without any discovery of fire. The analyses of a sample of the air from the place having this temperature gave the following percentages: CO_2, 2.20; O_2, 15.20; CH_4, 1.20; N_2, 81.40.

In the central part of the region several mines were troubled with fires which originated spontaneously in the gob. A peculiarity of one of these fires was that it was not discovered until some years after the abandonment of the section in which it was found. These fires were due, no doubt, to some special chemical constituent in, and the finely pulverized condition of, the coal, which, together with the passage of air over the combination, favored rapid oxidation in them.

In addition to the intrusion of explosive gas and some danger from spontaneous combustion, there is the vitiation of the air, caused by the smoke from lamps and explosives, the breath and exudations from men and animals, the decomposition of timber, and the absorption of the oxygen by the gases evolved from coal and rocks in solid or pillar workings in contact with it.

Having briefly described the difficulties which relate to mine ventilation in the region, it will now be stated how they are dealt with and controlled.

The proper ventilation of a mine must accomplish two things: first, supply sufficient pure air to the men and animals employed; and second, remove, dilute, and render harmless the noxious and dangerous gases generated therein.

In several of the small non-gaseous mines of the region "furnaces" (or coal fires) are still used to produce ventilation. The workings are mostly of small extent and, not having much cover, "falls to daylight" frequently occur. The volume of air required by law for this class of mines is much less than is required in gaseous ones.

The appearance of inflammable gas in a mine calls for a large increase in the volume of air over that formerly required for its thorough ventilation. The increased volume of air meets with much increased resistance in passing through the mine, therefore, when the quantity of air required is large, ventilating appliances of ample capacity and driving strength must be installed. Experience has proved that mechanical ventilators are the best and that the fan is the most efficient, as well as the least troublesome, form of mechanical ventilator.

Many of the fans used are of steel and fireproof construction and are, generally, driven by powerful direct-connected engines. Table 3 shows the results of tests of three fans installed within the past 5 years.

Table 3

Mine	Size of Fan	Size of Engine	Revolutions Per Minute	Indicated Horsepower	Cubic Feet of Air Delivered	Actual Water Gauge	Remarks
A	25'×6'	30"×30"	84.0	216.33	251,929	4.00	Ventilating an old mine
			111.5	422.76	302,249	6.35	
			133.0	673.90	370,817	8.75	
B	26'×7'	Two 20"×30"	80.0	195.94	207,656	3.45	Ventilating a new mine
			102.0	417.46	281,818	6.05	
			117.5	631.90	334,745	7.85	
C	26'×7'	Two 22"×24"	75.0	157.74	218,796	2.85	Ventilating an old mine
			107.5	454.97	326,356	5.70	
			125.0	693.82	379,988	7.65	

The first of these fans was substituted for a 25'×9' fan and the last for a 25'×8' fan of an old type. Both delivered nearly double the volume of air, per revolution, that was delivered by the old fan.

As far as the writer has been able to discover, auxiliary fans are not used underground in the region.

In the matter of volume of air, the Bituminous Mine Law of Pennsylvania requires, in a gaseous mine, a minimum of 200 cubic feet per minute per person employed, to be directed to and around the working places, etc. The rules of the larger companies call for a much larger minimum. One of them requires that not less than 500 cubic feet per minute per person employed must enter the mine, and that not less than 300 cubic feet per minute must be conducted to the working places for each person employed in each split, or subdivision of the volume of air entering the mine. An average of 50 mines of that company, consisting of 20 slope and 30 shaft operations showed 824 cubic feet per person entering the mine; and 495 cubic feet per person passing in the last cross-cut. The total number of persons employed underground in these mines was 7,800.

These large volumes of air having been introduced, the greater difficulty remains, i. e., that of conducting it into the various districts, working places, gob sections, and other ramifications of the mine.

The air, on reaching the coal seam, or shaft bottom, is usually divided. The number of the divisions, or splits, may be two or ten, according to the layout and size of the mine, the number of persons employed, and the quantity of explosive or noxious gases to be dealt with; besides, a sufficient number of entries must be driven in which to pass the air without excessive resistance.

To effect the division above mentioned, it is often necessary to cross entries in which air must travel in a different direction. For this purpose overcasts (or air bridges) are built. These are made of brick or concrete walls, with steel-reinforced concrete floors and, to be efficient, they must be of large sectional area.

After the air is brought across to the entry or entries desired, it is frequently necessary to conduct it in one or more entries for long distances to the working faces, and to return it by like, or parallel, entries for the same distance, to the outlet of the mine. To do this, walls, called stoppings, are built in the cross-cuts between them. These walls must be of ample strength, air-tight, and made of incombustible material (usually brick or concrete). Every large mine contains many hundreds of such walls and, as the development progresses, additional ones must be constructed. If, however, the life of a pair of entries is short, stoppings made of wood are frequently made.

The larger mines contain from 20 to 50 or more miles of airways, which must be kept dry and clear of obstructions. The nature of the roof for a few feet over the seam makes it very difficult to maintain airways of such length free from obstructions.

When an air-current is conducted through a haulage or a traveling road, it is sometimes desirable to deflect it into a different road, or to prevent short circuiting. For this purpose doors are erected. If it is desired to have the air sweep the face of the working places or gob edges, canvas curtains, suspended in the path of the air-current at necessary points, are used.

In order to maintain proper ventilation in mines where the workings are greatly extended, auxiliary air shafts, usually of large section, are provided. These are located close to the working places. The economy of these shafts is effected by reduction of the resistance to the passage of the same quantity of air, or by an increase of quantity, with the former resistance.

When explosive gas is liberated in large quantities in gob falls, it is necessary to remove and dilute it as fast as possible, and for this purpose large volumes of fresh air are conducted to and, wherever possible, over the gob. When conditions, such as the proximity of a boundary line or barrier pillar, prevent the passage of air over or around a newly formed section of gob, if explosive gas appears and threatens the safety of the mine, holes from the surface are drilled into the cavities above the gob area to allow the gas to escape. Sometimes the gob penetrated by the drill is so tightly closed by the pressure of the superincumbent strata that no cavities remain and the results anticipated are not realized. Fortunately, in most gobs, blackdamp is generated in such quantities as to render the firedamp inexplosive, and when it descends to the workings it is immediately diluted and removed.

The composition of the gases that pass through some of these bore holes is shown in Table 4:

As these bore holes do not exceed 10 inches in diameter, and the velocity in them does not exceed 600 feet per minute, it can easily be seen that their effect is purely local and the great bulk of the air in most mines must be returned to the main outlet, which is usually but a few hundred feet from the main inlet.

For the purpose of providing against a sudden influx of explosive gas, the temporary failure of ventilation, or of those in charge of it to do their duty, the use of open lights is absolutely prohibited and safety lamps are substituted. These are owned, trimmed, and kept clean and in good condition by the operators, and, after close examination, are delivered, locked, to the workmen when entering the mine.

All these shafts, fans, airways, etc., are of no avail if careful supervision is not exercised over them and the same kept in good working order.

Table 4

Mine	CO_2	C_2H_4	O_2	CO	H_2	C_2H_6	CH_4	N_2	Remarks
F	2.50		10.40		1.35		11.90	73.85	525 feet deep
G	5.20		3.20				12.64	78.96	406 feet deep
H	1.80		14.90				2.20	71.68	One year later
I	4.60		4.20	.20	14.16		8.80	67.52	475 feet deep
I	6.90	.10	9.20	.40		1.60	38.30	48.50	

For underground supervision a specially qualified set of men, called "fire bosses," are employed. These men hold certificates of competency from the State Department of Mines. Their duty is to enter the mine, see if the air is traveling in its proper course, and carefully examine for danger, all the roads, working places, and places adjacent, and to record the condition of them within 3 hours before the next shift begins work. They must also make a second examination while the men are, or should be, at work, and enter a record of their findings. In addition to this policing of the mine twice each shift by the fire bosses, the mine foreman or an assistant must visit every working place at least once each shift during working hours and make a record of the condition of the mine. He must also examine, at least once each week, all the airways of the mine and enter their condition in a record.

As a further provision for safety, one company has a committee of workmen appointed in each mine, whose duty, among other things, it is to examine and report, once every 4 months, any dangers or defects in the ventilation that may come under its notice. As a further provision for safety, that company also employs mine inspectors who thoroughly inquire into and inspect each mine at least once every 60 days.

A danger not heretofore mentioned, and which deserves more than a passing notice, is that of coal dust. During the winter season a large volume of comparatively dry air passes through the mine, which absorbs the moisture, and, while providing good ventilation in the mine, creates a new and dangerous condition—that of a dry and dusty mine. For the purpose of avoiding this danger a system of water lines is laid through the mine and a sufficient number of spray nozzles and hose connections are placed at necessary points, so as to thoroughly moisten the air and airways and wash the dust from the top, floor, and sides, when necessary. In deep mines where forcing fans are used, exhaust steam is used to mix with the intake air-current, to assist in raising its temperature and moisture-carrying capacity. In very cold weather live steam is added for this purpose.

This will, no doubt, suggest to your minds the idea which has been discussed a great deal lately—that of the over or excessive ventilation of mines. Excessive ventilation, however, is to be viewed with concern only where the means to provide moisture are not installed and a careful and systematic use of such means is not rigidly enforced.

That the idea of excessive ventilation is held to be of serious import is evidenced by a recently expressed view, which some may call extreme, and which is diametrically opposed to over-supplying air to mines. This was made by a British scientist who, a few months ago, startled mining engineers with a proposition as to what constitutes good and safe mine ventilation. His scheme to prevent coal-dust explosions is to put into the mine, air of the following composition: CO_2, $1\frac{1}{2}$ per cent.; O_2, 19 per cent.; N_2, $79\frac{1}{2}$ per cent.

To prevent ignition of firedamp and fires of all sorts in mines, the composition would be: CO_2, $1\frac{1}{2}$ per cent.; O_2, $17\frac{1}{2}$ per cent.; N_2, 81 per cent.

This he claims (and he has his idea patented) would prevent future fires and explosions in mines. In such an atmosphere lamps using oil or naphtha as an illuminant could not be used. Acetylene or electric lamps only would be of service. We believe his theory is based on correct chemical principles, but its practicability and pathological effects remain to be tested. Should it prove practical, it will be beyond doubt the greatest step made since the discovery of the safety lamp, in the prevention of mine accidents.

In conclusion, we believe that the best means of keeping a mine in a safe and healthy condition is to supply large volumes of air and so conduct the same as to sweep every road, working place, and corner of it free of dangerous and deleterious gases.

Preparation of a Domestic Coal

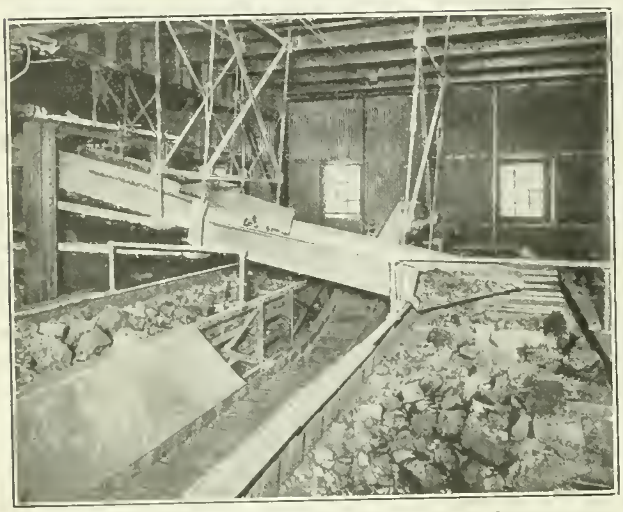
Methods of Avoiding Breakage and Securing Accurate Sizing by Which a Better Market May Be Obtained

By *J. D. Rogers**

THE following extract is from a paper read at the December, 1912, meeting of the Kentucky Mining Institute.

In eastern Kentucky, over an area covering several counties, there are a number of persistent coal seams of commercial value. Present information tends to show that the field is broken into fat and lean portions, with a preponderance of the lean ones, and local areas only promise a successful development.

At Van Lear, Ky., on the Levisa Fork of the Big Sandy River, 68 miles below Ashland, and 3 miles below Paintsville, the Consolidation Coal Co. commenced development 3 years ago, on what had been previously known as Millers Creek field. The most valuable bed of coal in this field, designated as the No. 1 or Millers Creek seam, is the lowest known coal bed of workable thickness in this vicinity. It is only with difficulty that it can be followed and recognized many miles distant. It is, however, not a generally accepted fact that the coals of the Millers Creek field are identical in formation with those found on Elkhorn Creek and on the headwaters of the North Fork of Kentucky River, there known as the Elkhorn coals. The structure and analyses of the two coals, however, are very different.



Shaking Screens Discharging onto Picking Band

Picking Band and Waste Conveyer

David White says it is probable that the Elkhorn coal beds belong to the lower portion of the Kanawha formation and the upper Elkhorn seam is probably at or near the Peerless or Cedar Grove coal on the Kanawha River, W. Va. Geographically, at Elkhorn, this is considered to be about 1,000 feet above the Lee conglomerate.

"Millers Creek Block," as it is known to the trade, is a splint coal of remarkable hardness and blocky and brittle, but it is an extremely good coal to ship. It can be stocked for almost an indefinite time without any appreciable weathering. Besides this, it is a high-volatile, quick burning coal, and is a most desirable product for domestic use. The thickness of the seam varies from 36 to 54 inches with no partings. It has pronounced butt and face cleavage, which must be

*Superintendent of Mines, Millers Creek Division Consolidation Coal Co.

followed in mining. All rooms are worked on the face of the coal, the course being approximately N 45° E, or the reverse.

A vertical section of the seam shows two different and distinct kinds of coal, the upper bench, varying from 18 inches to 36 inches, being a hard blocky splint almost a semicannel coal, while the lower 18 inches is softer, and resembling a strictly high-class bituminous coal. In mining, this lower coal breaks into comparatively small pieces, that make a good smithing coal and to a certain extent will coke. It might be noted here that as the thickness of the seam varies, this lower bench remains practically at 18 inches, the increase or decrease being almost entirely on the upper bench of splint coal.

All coal is cut by electric chain machines, the Sullivan six-foot low-bed machines predominating. The coal is gathered from rooms by motors and conveyed from the partings by haulage motors to the tipples.

The preparation of a domestic coal begins at the working face, and, with this end in view, the attempt is made to train the inside organization to load as clean coal as possible into the mine car. The man who shovels bug dust, slate, and coal, without any other object than to load as many mine cars as possible, seldom gets through the first day smoothly. By the time two or three cars of his coal have passed over the scales, the mine foreman is notified that check loader No. —— is loading dirty coal. Sometimes a personal warning does not have the desired effect, and upon his coming out that night, he finds that two or three cars of his coal are standing awaiting his inspection or have been run over the slate dump. A few lessons of this kind usually have the desired effect and the company is seldom compelled to resort to extreme measures.

In grading domestic coal at the tipple, probably the three most important points to be watched are as follows: (1) Absence of slack in the prepared grades; (2) absence of impurities in all grades; (3) uniformity in size of smaller grades.

Probably all operators are familiar with letters from the sales managers stating that a customer has forked over a certain car of coal and found 5 or 10 tons of slack in what was shipped as a car of lump coal.

Loading Boom

Of course he asks for a deduction of that amount, counting the slack as a total loss. It is surprising how many customers have absolutely no way of disposing of lump coal screenings.

From limited inspection in different coal fields it is evident to me that in many instances preparation of the output receives secondary consideration, if it is considered at all. Many mines are using the same equipment with which they started 5, 10, or 15 years ago. The coal is handled in the same way, and without doubt the screened sizes contain practically the same amount of slack and impurities as in the beginning.

The bituminous domestic coal trade has changed radically during the past 5 years. Previous to that time picking tables, loading booms, washers, etc., were associated with only anthracite breakers, bituminous coal being considered too cheap to warrant any such expenditures. The margin of profit per ton was too small, but in this day of competition a step in advance ought to be expected. Producers say there has been an overproduction of soft coal during the past few years, and for that reason, if for no other, the rivalry to secure contracts has brought out the best efforts of all concerned. If one operator had quality but not preparation, he was at a disadvantage with the fellow who had the reverse—preparation without quality.

When a sales department approaches an operator with a proposition that if he will eliminate all slack from his lump coal it will sell for 25 cents advance in price, the operator begins at once to figure how to secure that increase. If he does not he is no operator, or at least will not be one long. A proposition similar to this was placed before our company a little more than a year ago. Our tipples and equipment were then practically 2 years old, but the fact was obvious that first-class preparation could never be secured unless radical changes were made. Four grades, lump, egg, nut, and slack, together with combinations of any or all grades were being made at this time. The lump coal contained too much slack, as did also the egg and nut grades. A small amount of slate found its way into the egg and nut cars which could be removed by picking, but the slack could not be removed in that way.

Originally the tipples were equipped with 16-foot screen bars spaced according to the size of coal desired: 1¼-inch, 2-inch, 3-inch, 4-inch, or 6-inch lump. Upon dumping a mine car of coal the lumps passed over these bars, into a basket at the lower end of the chute from which they were dumped into the car. No other preparation was given and the car was billed and sold as lump coal. Owing to the fact that all kinds of equipments are furnished by the railroads, it was extremely difficult to regulate the height of the basket so that the lumps would not fall from 6 to 10 feet into the bottom of the railroad car. The resulting breakage caused a considerable percentage of loss to the customer, which in the end the operator usually had to stand. In addition to this there was also a certain amount of fine coal carried over the screen bars with the lump, which also found its way into the railroad car. You well know that if a customer orders a car of 4-inch lump, he expects every piece to be at least 4 inches in diameter. With a brittle coal it is little wonder that there were many complaints about the large lumps being broken and the excess of slack.

The egg, nut, and slack sizes were prepared from the coal that passed through the 4-inch screen bars. This was received on a double-decked shaker screen 16 feet in length, the upper deck being covered with plates having 2-inch circular perforations and the lower deck with $\frac{3}{4}'' \times 2''$ slots. The preparation in its simplest form was as follows: Over 4-inch bars, lump coal; through 4-inch bars and over 2-inch screen plate, egg coal; through 2-inch screen and over $\frac{3}{4}$-inch screen, nut coal; through $\frac{3}{4}$-inch screen, slack coal.

This method of preparing our small coal also got us into trouble. Providing the coal as it came from the mines was perfectly dry, everything worked fairly well and a good grade of egg and nut was secured; but as fully 50 per cent. of our output was wet, the resulting grades were unsatisfactory. Too much slack stuck to the egg and nut and found its way into the railroal car. On the whole, our preparations were far from satisfactory to the customer and salesman. Of a necessity the operator is not long ignorant of this fact. To obviate this and to take advantage of that promised increase in price, practically the entire screening and loading arrangements were remodeled. The lump coal is now received on the screen bars as before, goes thence to a shaker screen with 3-inch perforations in the bottom, which in turn delivers to a loading boom and picking table combined. This process practically frees the lump from all slack. The loading boom is controlled by mechanical devices so that the man operating it can raise or lower the end at will, depending upon the height of the railroad car. The lumps now never fall vertically into the car. As the loading proceeds and the car is dropped down, the end of the boom is raised or lowered to suit and the lumps roll off, never falling more than 2 or 3 feet, and usually less. The capacity of this arrangement has never been reached though the 4-inch lumps from 200 tons run-of-mine coal have been loaded per hour, and without delay. It is believed that this is as good preparation as it is possible to secure for this kind of bituminous coal. The fact that we have no more complaints from consumers is conclusive evidence that the new arrangement has greatly aided in satisfying our trade.

We have not done so much to increase the quality of the egg and nut sizes, partly because the tonnage is small, but principally because the original design of the tipples will not allow much change. However, we did make two shakers out of the original one and also added another to deliver the egg coal to the car. Every opportunity is taken to run this coal over extra screens, and all chutes have perforated bottoms, so that by the time the coal is delivered to the car it is practically free from slack.

In general this is an outline of some of the difficulties encountered in the preparation of a bituminous domestic coal and the manner in which they have been met. It is quite probable that every individual operation may have distinct troubles, but for continued success they must be met and overcome. You censure the miner because he shoots his coal so hard that he breaks up all the lumps; you censure the motorman for being too rough in the handling of his trip; you censure the dumper because he elevates his car too quickly and sends the coal over the screen so rapidly that the lumps are broken, by his carelessness you say, but might it not be that the force of gravity does more than all the others combined? I firmly believe that more coal is broken up in the loading and so-called preparation than is destroyed by the carelessness of the miner and tipple hand.

Car Couplings

Car couplings are the most aggravating if not expensive part of the car equipment. In Fig. 1 is shown a car coupling which is in use at the Fidelity mine, at Greenwood, Ark.

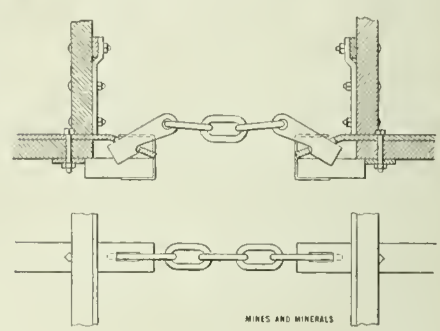


Fig. 1

The coupling was designed by a blacksmith at the United Iron Works, Springfield, Mo., and is giving satisfaction. It does not jar loose or come unfastened and is easily coupled. The drawbars and the couplings are made alike at both ends. The coupling has the advantage that the net section can be so designed that the cross-section is equal to the cross-section of the drawbar or center straps of the car.

The pin, which is rectangular, has a small notch on one side which catches on one end of a shaped slot in the drawbar end. Two of these flat-shaped pins are joined by three links. When there is a pull on the coupling the pins turn on the notch as a center and tighten in the slot, the side opposite the notch pressing against the back of the slot. When there is no pull, the weight of the links holds the pins in place. The center stay is bent down at the end so that all the bending strain does not come upon the pin.

Facts and Theories Relating to Fans

Methods of Testing Exhaust Fans and of Calculating Efficiencies from the Results Obtained

By David M. Mowat*

THE writer does not claim to propound new theories or to state new facts, but rather to express in form which he hopes will be readily understood, certain useful facts concerning fans.

In this paper he has confined himself to the consideration of exhaust fans.

If a weight attached to one end of a piece of twine is swung in a vertical plane round a fixed point until it acquires a certain velocity, and the twine is released when the weight is making an upward movement in a vertical direction, the weight will rise to a certain height, which can be easily calculated. It is the same as a height from which a body requires to fall, in order to obtain a velocity equal to the upward velocity of the revolving weight at the moment of its release. If v be the velocity of the body in feet per second, and g the force of gravity (which may be taken as 32 feet per second), then s is the distance in feet to which it will rise, the relationship between these factors being expressed by the formula:

$$s=\frac{v^2}{2g}, \text{ or } v=\sqrt{2gs}$$

The tips of the radial blades of a fan throw off at a tangent particles of air with a velocity equal to the velocity of the tips of the blades.

In an open running fan without a peripheral casing, the theoretical difference in pressure created between the inlet of the fan and the outlet at the periphery, expressed in feet of air column, will be:

$$s=\frac{v^2}{2g} \qquad (1)$$

In such a fan the air is discharged into the atmosphere at a high velocity after the fan has done its useful work. This is a waste of energy, which is partly recovered in a closed fan.

In a fan having an évasé casing, and chimney, the theoretical difference of pressure created is double that produced in the case of the open fan, owing to the restitution of energy stored up as velocity in the air leaving the tips of the blades, by means of the reduction in velocity of the air in the évasé casing; that is,

$$s=\frac{v^2}{g} \qquad (2)$$

s is expressed in feet of air column, and, in order to obtain practical results, it is necessary to find the value of this depression in inches of water gauge from the data usually available, namely, the diameter of the fan and its speed.

If v = the velocity of tips of blades of fan in feet per second;
d = the diameter of fan in feet;
r = the number of revolutions per minute,

then $$v=\frac{d\times 3.1416\times r}{60} \qquad (3)$$

$$s=\frac{v^2}{g}=\frac{v^2}{32}$$

Substituting the value of v in terms of d and r we get

$$s=\frac{\left(\frac{d\,r\times 3.1416}{60}\right)^2}{32}$$

$$s=.0000856\,d^2 r^2 \qquad (4)$$

The relative weight of air and water at ordinary temperature and pressure is about 820 to 1. Therefore, the height of air column which will be equal to 1 inch of water gauge is 820 inches, or 68.4 feet, or,

$$\text{Water gauge in inches}=\frac{s}{68.4},$$

$$s=68.4 \text{ W. G.} \qquad (5)$$

Substituting this value in formula 4,

Theoretical water gauge

$$=\frac{.0000856\,d^2 r^2}{68.4}$$

$$=.00000125\,d^2 r^2 \qquad (6)$$

This theoretical water gauge is never obtained, owing to defects in design and construction. The percentage actually obtained depends on the manometrical efficiency of the fan, which may vary from .4 to .75, the actual water gauge produced being, therefore, from 40 to 75 per cent. of the theoretical water gauge.

If the fan drift be closed to exclude the entry of air, the water gauge then produced at a given speed is the highest which the fan can produce at that speed. This water gauge thus measured, divided by the theoretical water gauge (equation 6), gives the manometric efficiency m.

Thus, $$m=\frac{\text{Actual water gauge}}{\text{Theoretical water gauge}}$$

or actual W. G. = theoretical W. G. $\times m$, the actual water gauge being measured with closed drift.

Actual W. G. = theoretical W. G. $\times m$

$$=.00000125\,d^2 r^2 m \qquad (7)$$

In actual practice how is this water gauge to be measured, and when will it be obtained? In a given fan running at a certain speed it will always be produced, but it will very seldom be possible to measure it under working conditions. It is only when the fan drift is completely closed, so as to prevent the entry of air to the fan, that this water gauge will be obtained. If air is allowed to enter the fan in increasing quantity, by opening up the fan drift, the water gauge will be found to be apparently decreasing, until it falls to a very low value, when the air is allowed to enter at the mouth of the drift freely.

To understand what has taken place, it is necessary to consider the relationship between the fan and the drift, or mine, as the case may be. By his conception of the equivalent orifice and the orifice of passage, Murgue has enabled a perfect analysis of these relations to be made. He has compared the resistances of the mine and the fan with the resistances offered to the passage of the air by two orifices in sheets of iron arranged in series, as shown in Fig. 1. O_e represents the orifice having a resistance equal to that of the mine, and O_p represents the orifice having a resistance equal to that of the fan. The area of O_e will

*From the Transactions of the Mining Institute of Scotland.

vary with every varying condition of the mine, while the area of O_p for a given fan will remain constant.

The "equivalent orifice" is the expression used to denote the measure of the resistance which the air encounters in a mine. In measuring electrical resistance in a conductor, the result may be expressed in two ways: (1) it may be said that, in

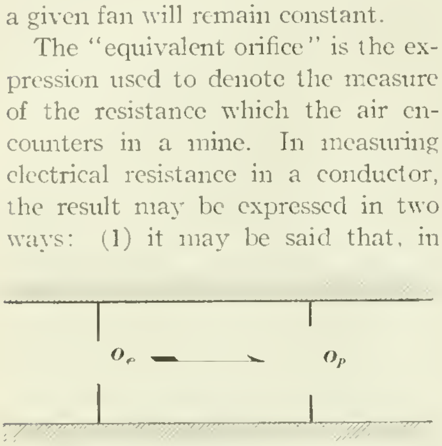

Fig. 1. Resistance of Fan and of Mine Compared

order to pass a quantity of 6 amperes along a conductor, a pressure of 216 volts is required; or (2) it may be said that the resistance of the conductor is 36 ohms.

In a mine it may be found, by means of the water gauge and the anemometer, that when the water gauge is 1 inch the quantity of air passing is 20,000 cubic feet per minute; but in this form the comparative impression conveyed to one's mind is very indefinite. Murgue found a definite value similar to the ohmic resistance for the resistance of a mine when he compared the mine with its "equivalent orifice."

The "equivalent orifice" of a mine is the area of an aperture in a sheet of iron which would, if subject to the same water gauge or difference of pressure between the two sides of the sheet, pass the same amount of air as would pass in the mine. To ascertain what this area is, it is necessary to go back to the relationship between the height and the velocity of falling bodies. The velocity of flow of water from an orifice in the bottom or in the side of a tank depends on the form of the orifice and on the height of the water above it. The theoretical velocity of flow in feet per second is $v = \sqrt{2gs}$, and the theoretical quantity of water flowing will therefore be $v\,a$, a being the area of the orifice. The actual quantity is considerably less on account of the "crowding" of the water through the orifice. If the tank be of sheet iron, the reduction of area, or *vena contracta*, may be taken as .65, so that the actual flow of water will be .65 va. The same laws apply to the flow of air, s being the height of air column equivalent to the ventilating pressure.

The problem is, therefore, to find the area of an orifice in a sheet-iron plate which will have the same resistance as a mine which passes a quantity q in cubic feet per minute with a water gauge in inches of W. G., the area thus formed being the equivalent orifice O_e of the mine. Let v and V be the velocity of the air passing through the orifice O_e in feet per second and in feet per minute, respectively,

then $v = \sqrt{2gs}$,

and $V = 60\,v = 60\sqrt{2gs}$.

Substituting for s its W. G. value by equation (5)

$$V = 60\sqrt{2g \times 68.4 \text{ W. G.}}$$

$$q = V \times \text{area} \times \textit{vena contracta} \qquad (8)$$

$$\therefore q = .65\,Va, \text{ or } .65\,V O_e$$

Substituting the value of v as in equation 8

$$q = .65 \times 60\sqrt{2g \times 68.4 \text{ W. G.}} \times O_e$$

$$\therefore O_e = \frac{q}{.65 \times 60\sqrt{2g \times 68.4 \text{ W. G.}}}$$

$$\therefore O_e = \frac{.00039\,q}{\sqrt{\text{W. G.}}} \qquad (9)$$

The area O_e thus obtained is therefore the area having a resistance equivalent to that of the mine. Similarly, the area of the orifice of passage of the fan,

$$O_p = \frac{.00039\,q}{\sqrt{\text{W. G. } p}} \qquad (10)$$

W. G. p being the water gauge required to pass the quantity q through the fan itself, W. G. p being that part of the total water gauge produced which is always invisible.

In practice, therefore, the actual water gauge produced is expended in two portions, one portion overcoming the resistance due to the passage of the air through the equivalent orifice O_e—that is, the mine—and the other portion overcoming the resistance due to the passage of air through the orifice of passage O_p—that is, the fan. The relationship between the values of O_e and O_p is a most important one. The work done in overcoming the resistance in O_e is useful work, while that done in overcoming the resistance in O_p is so much waste.

If we assume that O_e is equal to O_p, then of the pressure expended in producing ventilation one-half goes to overcome the resistance in the fan, and the other half to ventilate the mine. Ignoring altogether the losses due to friction, defective construction, or design, it is evident that the maximum efficiency cannot exceed 50 per cent., and will be, because of these defects, a great deal less, only half of the effort being usefully employed.

If $O_p = 2\,O_e$, the velocity in O_p will be to the velocity in O_e as 1 : 2. The pressure required to overcome the resistance in these areas will therefore be as 1 : 4. That is, a fifth of the water gauge will now be expended in overcoming the resistance in the fan, and four-fifths in overcoming the resistance of the mine. The maximum efficiency of such a fan on such a mine, ignoring losses due to friction and defects in construction and design, would therefore be 80 per cent.

If $O_p = 3\,O_e$, the velocity in O_p will be to the velocity in O_e as 1 : 3. The pressure required to overcome the resistance in these areas will therefore be as 1 : 9. That is, a tenth of the water gauge will now be expended in overcoming the resistance in the fan, and nine-tenths in overcoming the resistance of the mine. The maximum efficiency of such a fan on such a mine, ignoring losses due to friction and defects in construction and design, would therefore be 90 per cent. These efficiencies of 50, 80, and 90 per cent. are purely theoretical efficiencies, and are subject to reduction on account of (a) manometrical inefficiency, (b) defects in design and construction, and (c) frictional losses (mechanical).

The power lost under (a) is not directly in proportion to the manometrical efficiency. If the revolving wheel, on account of the form or angularity of the blades, is not producing water gauge, it is not using power to drive it as a fan, but is running only as a flywheel. The actual efficiency obtained will probably not exceed 80 per cent. of the theoretical efficiency, so that in the foregoing cases the actual efficiencies may be about 40, 64, and 72 per cent., respectively.

If O_p is more than 3 O_e, it will probably be found that the saving in power thus effected will be more than counterbalanced by the increased friction of the machine, owing to its greater size and weight.

The most economical relationship between O_e and O_p appears to be when O_p is from two to three times as great as O_e.

It appears to the writer to be very desirable that data should be obtained as to the most economical relationship between O_e and O_p in the various types of fans. It may be in a mine having a very large equivalent orifice, an open-running fan would give more economical results, on account of its comparatively low internal resistance. To ventilate a hall, which is just a mine of large equivalent orifice, no one would think of using an encased fan.

The principal difficulty in obtaining such data with the necessary degree of accuracy is that of measuring the power required to drive the fan. If the fan is engine driven, the horsepower obtained by means of indicator diagrams is a very uncertain measure of the actual power expended. In order to obtain such data accurately, the fans would require to be motor driven, and the motor carefully tested by means of a dynamometer or other suitable method, in order to ascertain its efficiency.

The writer had occasion several years ago to make careful tests of the performance of two fans on a mine. The tests were made at Bardykes colliery with one fan 7 feet in diameter by 7 feet in width and the other 10 feet in diameter by 7 feet in width. The smaller fan was first erected, but was found to be too small for the work to be done, and was therefore replaced by the larger fan.

Fig. 2 shows the fans and fan drifts connecting with the shaft. The fan drift has a minimum area of 100 square feet, varying in cross-section from 10 ft.×10 ft. to 17 ft.×7 ft., where it joins the shaft. When the tests were made, the pit mouth was not closed, the fans drawing air from the surface at the end of the drift. Resistances were inserted in the drift at A and B, consisting of spars and spaces, each 3 inches wide alternately, the spars in A being vertical and in B horizontal, so as to baffle eddy currents as far as possible. The area of the resistance A was altered during the tests by closing some of the spaces. The water gauge was measured at five gauges numbered 1 to 5. Nos. 1, 2, and 3 were fitted with Pitot tubes, while Nos. 4 and 5 were fitted on open-end tubes. No. 4 was fitted telescopically, so that the water gauge could be measured at any point of the drift from one side to the other.

The quantity of air passing was measured at C with an anemometer attached to a small traveling crane, by means of which the anemometer could be moved into any position in the drift, without the observer having to leave the manhole in which he was situated. The drift at that point was 10 feet square, and was divided by wires into 25 squares of equal area.

The fans were driven by a squirrel-cage motor of 150 horsepower by means of a leather belt 20 inches wide. The motor was connected with a 500-kilowatt turboalternator, the speed of which was varied, so as to obtain the required number of revolutions in the fan. The speed of the fan was measured by means of a speed counter. The velocity of the air was naturally much higher at the outside of the curve than at the inside, the current at the inside during the passage of the smaller quantities being reversed.

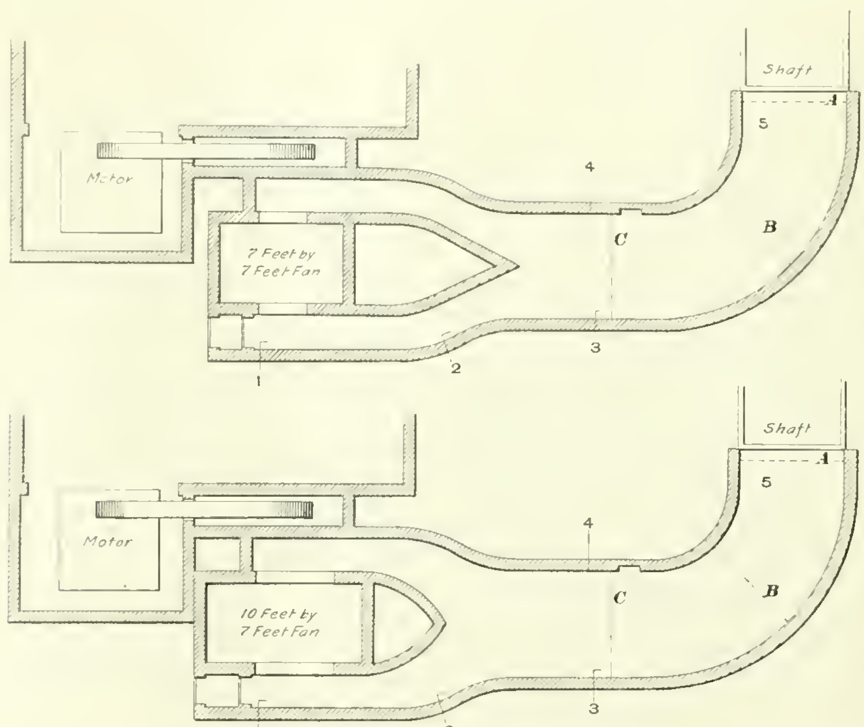

Fig. 2. Connections of Fans and Fan Drifts With the Shaft

It was found that the measurement of the water gauge by a plain tube at No. 4 was absolutely unreliable, the readings varying as the tube was moved from one side of the drift to the other. With a Pitot tube at No. 4 the readings were the same from side to side of the drift. It was also found that No. 1 gauge (which was out of the current) gave the same reading when hooded or when turned down. The form of Pitot tube used is shown in Fig. 3. Experiments were also made with various forms of hood on the ends of the tubes, but these were not found to be satisfactory.

The writer is satisfied that the

sults obtained with the Pitot tubes are quite reliable. The water gauges were carefully measured by means of a scale graduated to tenths of an inch. The anemometer used was a new one, which had just been adjusted; it was compared with another, and found to agree closely with it.

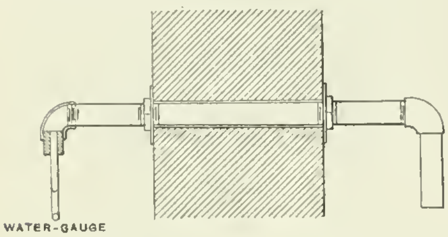

Fig. 3. Form of Pitot Tube

The result obtained by measuring and reading the velocity in each square separately was the same as was obtained by shifting the anemometer each half-minute or minute into another square and reading the total at the end of $12\frac{1}{2}$ or 25 minutes. The latter method, which was simpler, was therefore followed. One comparison was made simultaneously between the quantity of air passing in the drift and that leaving the chimney of the fan, and the results were practically identical.

The electrical horsepower at the motor was measured by means of a Kelvin wattmeter, which had just been adjusted. The efficiency curve of the motor obtained by actual tests is shown in Fig. 4. The results of the tests are stated in Tables 1 and 2.

Columns 1, 2, 3, 4, 5, 6, 7, and 8 are the result of observations; column 9 is estimated from the motor efficiency and the efficiency of the belt drive, which has been taken at 95 per cent.; whilst columns 10 and 11 are calculated from the quantity, water gauge, and horsepower, as follows:

$$\text{Efficiency} = \frac{q \times \text{W. G.} \times 5.2 \times 100}{\text{E. H. P. or H. P.} \times 33{,}000}$$

$$= \frac{.01576\, q \times \text{W. G.}}{\text{E. H. P. or H. P.}} \qquad (11)$$

Columns 12, 13, 14, 15, 16, and 17 are calculated from the foregoing data; column 18 shows the water-gauge readings with closed drift corrected for slight variations in the speed of the fan, the corrections being made on the principle that the water gauge varies as the square of the number of revolutions; whilst column 19 shows the total water gauge obtained in column 18 minus the actual water gauge registered at No. 1 gauge in column 2, the difference thus obtained being the invisible part of the water gauge created which is required to pass the air through the fan itself. The orifice of passage shown in column 20 is calculated by equation (10) from the data contained in columns 7 and 19. Column 21 shows the ratio between O_e and O_p.

An examination of columns 12, 13, 14, 15, 16, and 17 affords proof of the accuracy of the observations. With one or two exceptions, the relation-

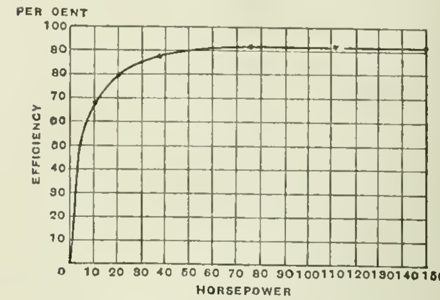

Fig. 4. Efficiency Curve of Electric Motor

ship between the speed of the fan, the quantity of air, the square root of the pressure (W. G.), and the cube root of the power is remarkably close.

Fig. 5 shows graphically the relationship between the speed of the fan, quantity of air, water gauge, power, equivalent orifice, and efficiency. It will be seen that the highest efficiency is obtained in the 7-foot fan with an equivalent orifice of about 15 square feet, and in the 10-foot fan with an equivalent orifice of about 28 square feet. The orifice of passage of the 7-foot fan may be taken as 30 square feet, thus giving the highest efficiency when $O_e : O_p :: 1 : 2$.

The orifice of passage of the 10-foot fan may be taken as 62 square feet, thus giving the highest efficiency when $O_e : O_p :: 1 : 2.21$.

Both these are Barclay fans of the double-inlet drum type, and the orifice of passage in this type appears to be:

$$O_p = .62\, d^2, \text{ or } d = \sqrt{\frac{O_p}{.62}} \qquad (12)$$

If similar reliable data were available for other types of fans, there would be no difficulty in determining the most economical size of fan for any required duty. For example, if a Barclay double-inlet fan was wanted to give 200,000 cubic feet per minute with a water gauge of 3 inches, by equation (9)

$$O = \frac{.00039\, q}{\sqrt{\text{W. G.}}}$$

$$\therefore O_e = \frac{.00039 \times 200{,}000}{\sqrt{3}}$$

$$= 45 \text{ square feet}$$

Taking the most economical ratio between O_e and O_p as $1 : 2.3$, then $O_p = 45 \times 2.3 = 103.5$ square feet.

By equation (12),

$$d = \sqrt{\frac{O_p}{.62}}$$

$$\therefore d = \sqrt{\frac{103.5}{.62}} = 13 \text{ feet diameter}$$

At the risk of repetition, and the restatement of many well-known formulas, the writer has endeavored to place before the members of the Institute a simple statement of some facts relating to fan ventilation, in the hope that others who may have the opportunity may repeat the experiments he has just described on other fans, so that reliable data on the subject may be obtained. Results are often published by fan makers in the form of advertisements, which, in the writer's opinion, are absolutely unattainable, and are therefore misleading.

DISCUSSION OF MR. MOWAT'S PAPER BY OTHER MEMBERS OF THE INSTITUTE

At a subsequent meeting of the Institute, Mr. John B. Thomson stated that Mr. Mowat's paper was of great interest and value, and that he had properly described how a fan should be tested. He particularly commended Mr. Mowat's emphasizing the fact that the use of the Pitot tube in ascertaining the true water gauge due to depression was the proper way, and that results obtained by a straight tube were inaccurate. In support of this he described a small experiment which he made a number of years ago.

He had connected up to the ear of a small fan a short pipe 10 inches in diameter, and to the other end of the pipe he had connected an old grease barrel, into the further end of which he had put another short length of 10-inch pipe. He had then inserted water-gauge tubes at three points in this air-course, one in each 10-inch tube, and one in the barrel. When the fan was started up, the water gauge farthest from the fan indicated a larger gauge than the one in the barrel. By reversing the process and blowing air through this same air-course, the water gauges should all have shown a positive gauge, but the one farthest from the fan showed a negative gauge, demonstrating clearly that the water gauge taken with a straight tube indicated the gauge due to velocity as well as that due to depression or compression, as the case might be.

The formulas that Mr. Mowat had given in his paper were old friends with new faces; they were very concise and easily understood. He could not, however, follow Mr. Mowat's reasoning when he said that the theoretical water gauge of an open-running fan should be calculated from the formula $s = \frac{v^2}{2g}$, and for a closed fan $s = \frac{v^2}{g}$, the difference being due to the fact the the closed fan had an évasé chimney.

Many old open-running fans had so-called "manometric" efficiencies almost as high as closed fans, and some newer fans had manometric efficiencies of over 100 per cent. He had a fan running which showed a manometric efficiency of 180 per cent. When Mr. Mowat had ascertained the initial water gauge, the fan draft was closed up, and there was no air passing, so that the évasé chimney could have nothing whatever to do with the manometric efficiency. This term puzzled him when he was a student, and he thought that Mr. Mowat's explanation was the first that had been given; but he thought it entirely erroneous, and considered that the term "manometric efficiency" was a dead letter.

The initial water gauge of a fan depended not only on the velocity of the tips of the blades, but also on the shape of the blades. If a fan was required to give a low water gauge, the blades had to be bent backwards, and if a fan was required to give a high water gauge, the blades must have a forward bend. The efficiency of these fans might be equally good although there would be a big difference in their manometric efficiencies. Mr. Thompson expressed surprise at the nearness of the ratios in columns 13 and 17 of Tables 1 and 2, which went to prove the accuracy of the tests made by Mr. Mowat. He would have expected a greater variation, due to the fact that the efficiency of the belt drive (namely, 95 per cent.) had been taken as constant at the various speeds. He believed that the efficiency of belt drives and rope drives had been overestimated, even when running at the most efficient speeds. He thought that 90 per cent. would be nearer the mark for the average belt or rope drive.

Before referring to the formula which Mr. Mowat had deduced from his experiments, by which he proposed to calculate the size of fan required to produce a given quantity

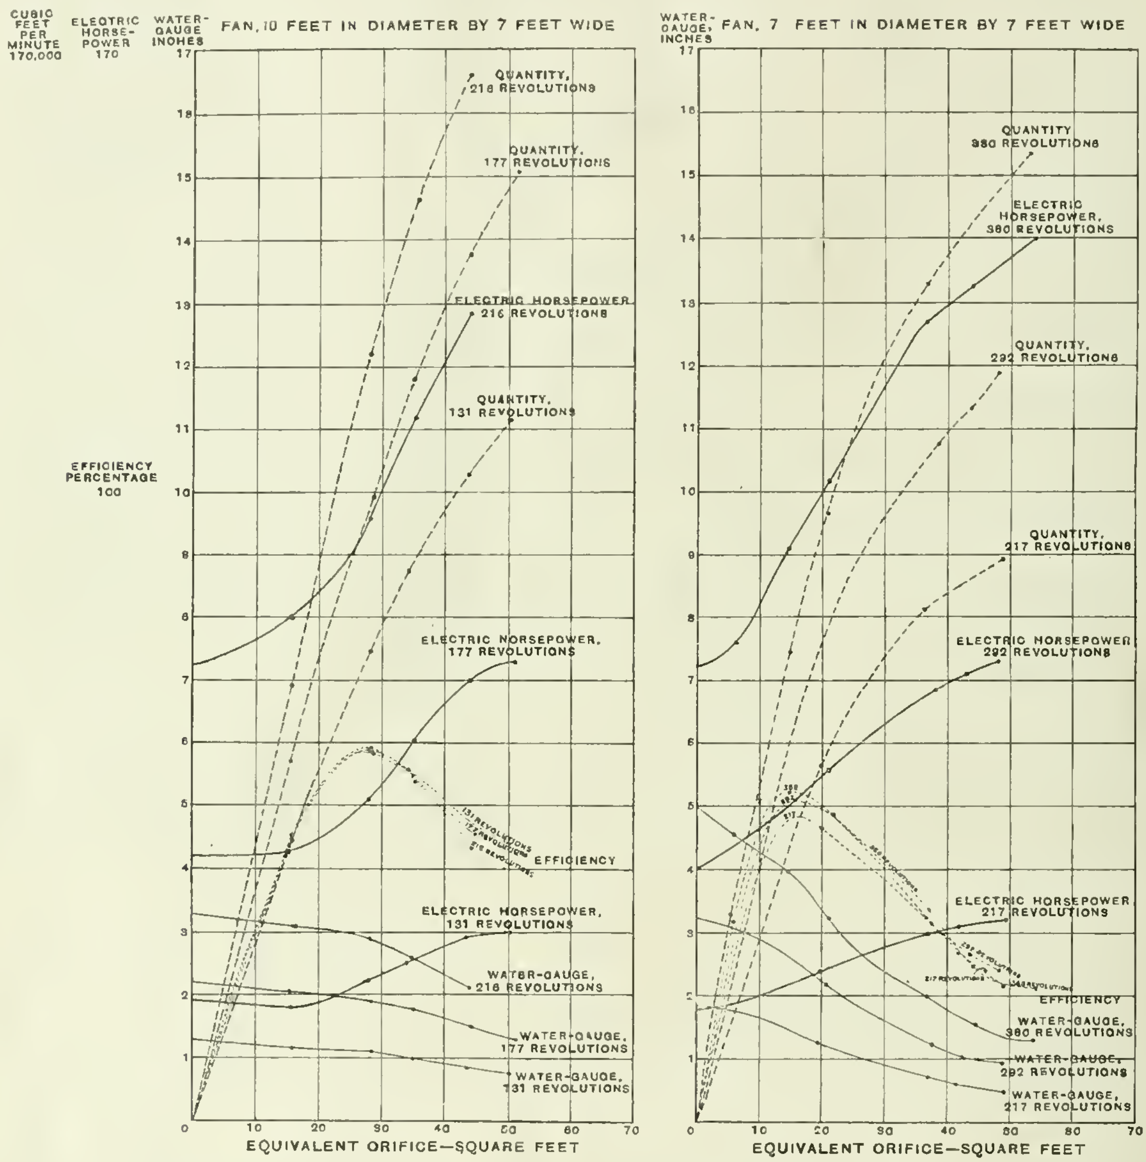

Fig. 5. Relationship Between Speed of the Fan, Cubic Feet of Air, Water Gauge, Equivalent Orifice and Efficiency

of air at a given water gauge, Mr. Thomson stated the results of tests that he made some time ago with a Sirocco fan, 8 feet 2 inches in diameter, driven by a cross-compound steam engine through a rope drive. He had calculated the invisible water gauge, orifice of passage, and the ratio between the equivalent orifice and the orifice of passage. He had also plotted the results, which are contained in the diagram Fig. 6. By referring to the diagram it will be seen that the quantity curve is almost an absolutely straight line; the water-gauge curve is also nearly straight after it leaves the initial water-gauge point, the slight bend being probably due to an inaccurate observation, as the difference at the various points is so very small. The overall-efficiency curve is fairly regular, but the fan-efficiency curve is not satisfactory, because the loss for engine and ropes is taken at a constant.

Referring now to Table 3, the invisible water gauge and orifice of passage gradually increased with the increased duty, and the ratio gradually diminished, if the second last experiment was left out, the water gauge of which was in doubt and affected the calculated portions of the table. These results did not fit in with the results obtained by Mr. Mowat, and he did not think that a similar formula to that given by Mr. Mowat for finding the size of a fan for a given quantity and water gauge could be deduced for a Sirocco fan. He was of opinion that it would not apply to any other than a Barclay, and even with a Barclay fan it did not apply very accurately. If one worked out the size required for 200,000 cubic feet of air with a 3-inch water gauge, from the results obtained from the 7-foot fan, the answer would be about 12 feet 4 inches instead of 13 feet. Very probably if a 13-foot fan were put to work on such a duty, and a test made, it would be found that it was either too big or too small, and this was about the state of perfection that fan makers and mining engineers had reached: that was, the correct size of a fan was obtained by the old-fashioned rule of trial and error.

He had yet to see a fan-maker's list of fans with truly reliable information of what the fans could do, so that the size for any given duty could be picked out, the fan erected and started to work, and a definite result given in the same way that could be done with a pump or a haulage gear.

Mr. William McCreath said that by giving in the first part of the paper the formulas for the calculations of efficiency, etc., in connection with centrifugal fans, and working them out from the velocity due to a falling body, Mr. Mowat had added greatly to the ease with which one could grasp the points brought out therein.

In comparing the equivalent orifice of the fan with that of the mine, Mr. Mowat had pointed out in a very clear way the mistake of using a small fan to produce a large quantity of air. In choosing a fan for the ventilation of a colliery, one was much tempted to put in a small one, on account of the small first cost and its adaptability to an electric drive. The use of small quick-running fans for the ventilation of a colliery of considerable size was, in his opinion, a mistake. A very high water gauge in many cases was not required, as with such much leakage was caused, owing to the air being drawn through doors and underground wastes, while a moderately high water gauge, with judicious splitting of the air and good airways, would be much more efficient. The

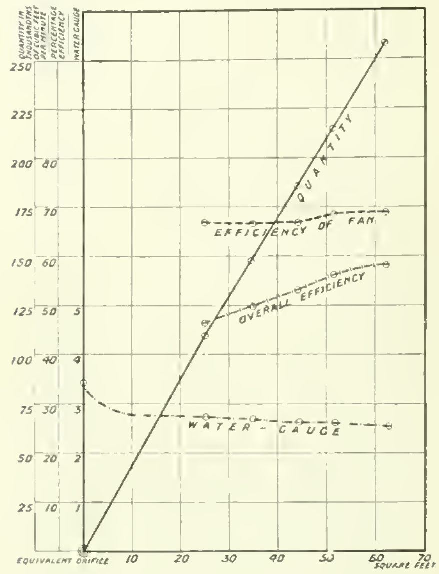

Fig. 6

size of the fan, however, depended to some extent on the design.

With regard to the pressure efficiency, as brought out by the formula given in the paper, it should be borne in mind that it was worked on the basis of a theoretically perfect fan receiving the air at the center and discharging it at the velocity of the tips of the blades, while the water gauge given by a fan depended to a considerable extent on the design of the blades. This was brought out very clearly by the experiments of Mr. Donkin, who showed that in most cases fans, the blades of which were curved forward or concave to the outlet, give a higher water gauge than those with concave blades, but give a lower mechanical efficiency. It was possible, therefore, to design a fan to give a high pressure or manometric efficiency with a low mechanical efficiency.

The readings of No. 4 water gauge were much higher than he would have expected, as compared with those of the other water gauges. Taking the author's Table No. 2,

Table 3. Results of Tests With a Sirocco Fan, 8 Feet 2 Inches in Diameter, Driven by a Cross-Compound Steam Engine With Rope Drive

Revolutions Per Minute	Water Gauge	Quantity of Air, in Cubic Feet Per Minute	Indicated Horsepower	Estimated Horsepower in Fan Shaft	Horsepower in Air	Efficiency: Overall Per Cent.	Efficiency: Fan Per Cent.	Equivalent Orifice	Water Gauge Corrected for Speed When $O_e = O$	Invisible Water Gauge A-B	Orifice of Passage	Ratio $O_e : O_p$
	B						Manometric Efficiency		A

and the highest velocity (1,659 feet per minute), the difference between the readings of Nos. 1 and 4 water gauges was .40 inch, representing a velocity of 2,520 feet per minute. The water gauge due to the mean velocity of the air (1,659 feet per minute) represented .17 inch, so that the reading was .23 inch greater than that due to the velocity in the air drift.

Mr. Mark Brand said that Mr. Mowat had provided a fund of information tabulated in a readily accessible and understandable manner, which would save much research, and stand as a model example in the testing and comparison of fan duties and efficiencies. In particular, Mr. Mowat had to be congratulated on the clear and convincing manner in which he had brought out the precise meaning and relationship between the theoretical water gauge and the maximum manometric efficiency; also the method of arriving at the information required to give the orifice of passage of the fan and equivalent orifice, and the relationship between the orifices under different conditions. Another point of great value, clearly brought out by the paper, was the area of equivalent orifice at which the fan gave its maximum efficiency.

Mr. Mowat had mentioned that the theoretical difference of pressure created in an enclosed type of fan was double that created in an open-running type, but it was doubtful whether this point had been sufficiently proved.

Generally, in papers on fans, little or nothing was said about the breadth of the fan, this apparently being a dimension which was left to look after itself; and, as the writer had occasion lately to make tests with a steam-driven Capell fan, which was a type of fan somewhat similar to that described by Mr. Mowat, the results of the tests might be of interest, as the question of breadth and volume came up rather prominently in connection with the tests.

The plant consisted of one rope-driven, double-inlet Capell fan, 10 feet in diameter by 7 feet in width, designed to run at about 285 revolutions per minute, the power being provided by a two-cylinder horizontally coupled engine, each cylinder being 21 inches in diameter with a 3-foot stroke, and designed to indicate about 300 horsepower when running at from 75 to 80 revolutions per minute, with steam supplied at a pressure of 50 pounds per square inch at the stop-valve. The fan was rope driven, the drive consisting of nine cotton ropes $1\frac{3}{4}$ inches in diameter. The inlet to the fan was 7 feet $2\frac{1}{2}$ inches in diameter. The fan drift at a point 30 feet from the ear of the fan, was 12 feet wide by 10 feet 10 inches high, which was equivalent to an area of 130 square feet. The water gauge was taken in the usual way at the same point in the vault as that at which the velocity was measured. The fan drift was divided by wires into 12 squares, and the velocity taken by means of an anemometer moved over each square for 1 minute. The total result of the 12 minutes' reading was divided by 12, so as to give the average velocity per minute of the air in the vault. The results of repeated tests showed less than $1\frac{1}{2}$ per cent. of error. Table 4 embodies the results of various tests made with the fan at full power, and one test at half power.

Table 4. Results of Testing a Capell Mine Ventilating Fan, 10 Feet in Diameter by 7 Feet in Width, at Dumbreck Colliery

Details of Test.	No. 1 Test	No. 2 Test	No. 3 Test	No. 4 Test	No. 5 Test

Volumetric capacity, per cent	116	111	117	131	143

Remarks.—*No. 1 Test:* No orifice in vault. Doors underground open to pass quantity. Doors at pit mouth all closed. *No. 2 Test:* Conditions same as in No. 1 test, except doors at pit mouth opened wider. *No. 3 Test:* Conditions same as in No. 1 test, except doors at pit mouth partly open. *No. 4 Test:* Conditions same as in No. 3 test, except doors at pit mouth opened further. *No. 5 Test:* Conditions same as in No. 3 test, except right-hand engine off. Four driving ropes off.

All the tests tabulated were made with the fan exhausting from the mine, with sufficient communication doors open underground, and with a slight adjustment of the doors on the pit head (where necessary) to give the various volumes and water gauges required for the tests. The first test tabulated showed that the fan was not yielding either the quantities or the efficiencies expected, and it was then suggested that the fan was rather large for the quantity of air passing, as this type of fan was stated to yield its maximum efficiency when passing about 160 per cent. of its volume per revolution.

Air was supposed to be reentering the fan from the évasé chimney, and to prevent this, four removable shutters, each 15 inches deep, extending the full breadth of the fan at the throat of the évasé chimney, were fitted. These shutters reduced the area of delivery at the throat as follows:

Number of shutters	0	1	2	3	4
Square feet	46.87	40.62	33.75	28.74	25.62

Results Nos. 2, 3, and 4 in Table 4 gave figures with four, three, and two shutters fitted. In No. 2 result, with four shutters fitted, the quantity of air was about the same as in No. 1 test, but the efficiency was improved by about 6 per cent. In No. 3 result, with three shutters fitted, the quantity of air was increased by about 2,000 cubic feet per minute and the efficiency by about 7 per cent. over No. 1 test. In No. 4 result, with two shutters fitted, the quantity had increased by about 26,000 cubic feet per minute over No. 1 test, and the efficiency by about 15 per cent. No. 5 test at half load, with two shutters fitted, gave the results expected. Designers of types of fans similar to that tested by Mr. Mowat in some cases made a claim for large volumetric results, the highest efficiency being said to ensue when the fans were passing from 150 to 160 per cent. of their volume per revolution. This did not appear to be the case with the fan tested by Mr. Mowat, as the first group of tests gave about 330 cubic feet of air per revolution of the fan, which had a capacity of 550 cubic feet. The next series of tests gave 565 cubic feet per revolution, and at that point the maximum efficiency of the fan was obtained. The next series of figures gave 670 cubic feet per revolution, the next 770 cubic feet per revolution, and the last 850 cubic feet per revolution, clearly showing that the fan could not pass more than about 100 per cent. of its volume per revolution at maximum efficiency under the test conditions.

In some cases designers had evidently difficulty in obtaining the guaranteed quantities and efficiencies in the fans, and this, in the speaker's opinion, might be due in part to the following causes:

1. There was a considerable leakage of air from the delivery to the ears of the fan along the clearance between the fan cheeks and the sides of the building, and this in many cases might be reduced by more attention being paid to the proper training of the fan on its shaft.

2. Fans with a smaller number of blades allowed a certain reentry of air at the back of the blades, which needlessly absorbed power.

3. Where fans were too large for the work for which they were designed, there was a certain volume of air carried round by the fan blades from the discharge at the throat of the évasé chimney, which also absorbed power besides increasing friction losses.

4. In some cases the design and finish of fans were such as to offer more resistance than was necessary to the passage of air through the fans.

Probably some of the difficulties experienced in this matter might be overcome if the ratio between the radial flow and the periphery speed of fans was considered.

Taking similar fans, each 1 foot wide, with different diameters, as in Table 5, all running at, say, one revolution per second, the ratios there given resulted and were constant, when passing 100 per cent. of the fan's volumetric capacity per revolution.

TABLE 5

Diameter of fan	2 feet	4 feet	8 feet	16 feet
Circumferential area, in square feet	6.28	12.56	25.13	50.36
Cubical capacity	3.1416	12.56	50.26	201.06
Radial flow of air, in feet per second	$\frac{3.1416}{6.2800}$	$\frac{12.56}{12.56}$	$\frac{50.26}{25.13}$	$\frac{201.06}{50.26}$
Equal to	.50	1.00	2.00	4.00
Tangential speed, in feet per second	6.28	12.56	25.13	50.26
Ratio $\frac{\text{Radial flow}}{\text{Tangential speed}}$	.08	.08	.08	.08
If the fans had been passing 150 per cent. of their capacity per revolution, the ratio would have increased to	.12	.12	.12	.12

This ratio would vary in different types of fans and in the same types of fans with different volumes passing, but if the ratio could be determined at which maximum efficiency was produced, that was to say, the quantity of air that the fan could put through efficiently per revolution, an exceedingly easy method of calculating fan dimensions and power duties would be available.

It would be interesting to know whether if shutters were fitted on the fan described by Mr. Mowat, this would in any way alter the results already obtained, as the volumetric capacity of this fan seemed very small.

The important points in fan construction might be summarized as follows: (1) The area of the fan inlet in relation to the resistance of the mine; and (2) the area of the fan outlet to the resistance of the mine. This to include the area of the passage through the fan itself. The efficiency of a well-designed ventilating plant depended on these two points.

With an electrically driven fan, tests could probably be more readily made than with one that was steam driven, but Mr. Mowat's contention that indicator diagrams were uncertain measures of the actual power expended would not (the speaker thought) be readily accepted by engineers, as this method of measuring the power exerted by engines of all kinds had been generally recognized and accepted in the past, and had yielded results sufficiently accurate for all practical purposes.

With properly calibrated instruments, the engine could be indicated correctly. The difficulty with indicator diagrams was that they were mostly taken by people who had not had the opportunity of understanding the best conditions suitable for the particular installation to be tested. A fairly correct method, and one which could be depended on, was to determine roughly what power was likely to be required in the engine, then to adjust the point of cut-off to suit that power, so as to give a low terminal pressure, and to put in a spring which would give the largest possible figures with the given initial steam pressure. The chances of error with a figure $2\frac{1}{2}$ inches deep must necessarily be much less than with a figure only 1 inch deep, both having the same initial steam pressure.

Mr. Henry Briggs said that it was not correct to make use of the expression $\frac{v^2}{g}$ in calculating the manometrical efficiency of fans of all characters, since it was true only for those the blades of which were radial at their tips. He believed that the use of the expression was due chiefly to Murgue's work; yet he thought that if Murgue's book on "Centrifugal Ventilating Machines," was referred to, it would be found that the author had expressly stated the formula in question to be true only for radial vanes. The result of making use of this formula for fans the blades of which were turned forward at a large angle, was that the manometrical efficiency worked out sometimes at more than 100 per cent. One such instance had been mentioned by a previous speaker. Now, the efficiency of no machine could be over 100 per cent.; it was an evident impossibility. For any other sort of machine, indeed, such a statement would never be accepted for a moment; but fans had always been considered rather mysterious contrivances. The fact was that such a result did nothing else than prove the theory false, and pointed to the need of revising that theory. The proper expression for fans with non-radial blades, although a little more complicated than the orthodox one, was quite workable, and gave reasonable results.

The manometrical efficiency could be put to good practical use, and a better criterion of the design of a fan did not exist, since it compared the work output and the work input without considering outside losses in the drive. In the fans which he had tested he had always found that, when rightly expressed, the manometrical exceeded the mechanical efficiency, and by means of the two efficiencies it was not difficult to find out the loss occurring in the fan drive—a useful achievement.

Mr. James Hamilton, the president, asked whether Mr. Mowat could explain why it was that in one test, namely, that of the 7'×7' fan, the orifice of passage was constant, while on the other fan it varied very much, and varied apparently very irregularly. The orifice of passage was calculated from the unregistered or unseen water gauge of which Mr. Mowat spoke, and this Mr. Mowat assumed was nothing while the ear of the fan was closed. There would be a certain amount of resistance in the fan running with the ear closed and no air entering, due to air friction on the casing and reentry of the air at the chimney. This resistance could be expressed by "orifice of passage," although it might appear a contradiction in terms to use that expression.

Mr. Mowat said that he was greatly indebted to the various gentlemen who had taken part in this discussion for dealing with the different points that he had raised in his paper. The subject was one regarding which they were a good deal in the dark, and he must confess that he was a good deal in the dark himself. In his paper he had given them the results of experiments which had been made as accurately as possible. He had recorded the deductions which he had drawn from these experiments, and he had to say that his opinions and deductions were to a large extent derived from his reading on the subject.

He did not propose to answer Mr. John B. Thomson fully, because he would require time to digest the figures which had been put before him. He would say, however—and this applied also to the criticism by Mr. Briggs—that in his paper he had been most careful to avoid any question relating to the design of fans, in so far as the angle of the blades was concerned. As a matter of fact, he believed that he had particularly indicated that in the paper. The formulas given were only applicable to fans having radial blades. With regard to the efficiency of the belt drive, he (Mr. Mowat) did not profess to have any experience thereof. He had heard of $2\frac{1}{2}$ per cent. and 5 per cent., and he thought that he was quite safe in taking it at 5 per cent. He quite appreciated what Mr. Thomson had said with respect to the efficiency with different loads, but he did not think that the difference would be very great when one considered that this belt was put in to develop 150 horsepower. The loads were all relatively small compared with the ability of the belt drive, and accordingly he did not think that the efficiency of the belt drive had much to do with the experiments. He did not understand one figure in Mr. Thomson's results, namely, the value of the equivalent orifice. From Mr. Thomson's figures the orifice of passage calculated from the first experiment would be 50 and from the last 112 square feet. It was rising all the time. Then Mr. Hamilton had mentioned the variation in equivalent orifice between the 10-foot and 7-foot fans in his (Mr. Mowat's) experiments. In the 7-foot case it was very constant, whereas in the other case, even ignoring the lower reading, it varied from 58.7 to 75. He believed that 75 was exceptional. He had gone over the observations and personally checked them to see whether there was any error in the calculations, and he was unable to give any explanation whatever of the variation. If they excluded the first two (43 and 49, and, of course, 75) they would find that the variation was not very great in the others—it was just about 58 to 62. There was one factor that might have a certain effect in the calculations, namely, that the method of making the closed test was not absolutely perfect. They had covered the wood resistance with brattice cloth, and it was quite possible that there would be a small amount of air passing through there. That might account for some little difference in the higher velocities, but he did not think that it would make any appreciable difference. So far as the point raised by Mr. McCreath was concerned, in regard to blades radial at the tips and blades turned backwards or forwards, he had no suggestion to make as to which form was correct, and he did not pretend to offer an opinion as to which was the better design for the mine. Much, he thought, would depend on circumstances as to whether it was a high or a low water gauge that was required in the mine. With reference to what Mr. McCreath had said regarding No. 4 gauge, he believed it possible that the reading might have been taken on the outside of the curve where the velocity was very much higher than in the inside. He did not pay much attention to that matter after he found the readings of No. 4 gauge erratic, and the explanation that he had given might account for the difference. He did not know at any particular moment where No. 4 gauge was. Mr. Hamilton had mentioned the point as to the power necessary when the drift was shut in churning the air. If they referred to the first three experiments, they would find what the power necessary was. The fan was throwing off the air which was entering behind the blades and preventing it from getting to the inside of the fan. He would put it in another way—that the power used was in overcoming the friction of the machinery and creating a vacuum. There was a vacuum being created, although there was no air passing, and there was a different pressure being maintained between the inside of the drift and the outside atmosphere. What he wished to emphasize was that, although they were not passing any air, they were maintaining a vacuum in the drift lower than the atmospheric pressure.

Mr. Hamilton said that a fan running in a perfect vacuum would not have the resistance of the air running along the blades. Would it not require more power to overcome that?

Mr. Mowat replied that the fan was throwing off the air particles. These air particles were entering behind the blades and being thrown off again, thus maintaining a difference in pressure between the outside and inside.

Mr. Mark Brand had been good enough to send him a copy of what he had just said at the meeting, and there were one or two observations that he would like to make in regard to his contribution. With reference to the shutters, Mr. Brand had stated (he took it) that these shutters were added as they used to be in Guibal fans.

Mr. Brand said that was so.

Mr. Mowat, continuing, said that Mr. Brand had touched on the question of breadth, and the position seemed to be something like this: Where the equivalent orifice of the mine was small, the breadth would be the minimum; and where the equivalent orifice of the mine was large, then the breadth would be as much as would be effective. The breadth would be a factor in determining the volume which would be passing through the fan and the resistance internally in the fan. The width of the fan would depend on the largeness or smallness of the equivalent orifice of the mine. He did not agree with what Mr. Brand had said in reference to indicator diagrams. He certainly did not think that many people would claim that an indicator diagram would give them an approximation nearer than 10 per cent. Most engineers would admit that the results obtained were very varied.

Testing for Firedamp with Wire Loop

A Device by Which a Safety Lamp Flame Is Rendered Non-Luminous Enabling the Gas Cap to Be Clearly Seen

By Henry Briggs, M. Sc., A. R. S. M.

THE purpose of this paper is to describe methods of detecting firedamp and blackdamp, and to give an account of some experiments made in putting the methods to the test. The British Mines Act of 1911 requires that workmen shall be withdrawn from a part of a mine in which naked lights are used should 1¼ per cent. or more of firedamp appear in the general body of the air in that part. Section 60 of the act makes it necessary to cut off the current from cables and electrical apparatus, if the same amount of inflammable gas should be found in the air in which that apparatus is at work. It is evident that no method of analysis would serve here; sudden danger, besides calling for prompt measures, must be met by still greater promptitude of detection. Thus, in endeavoring to find out a practical method of determining firedamp, sufficiently refined to allow not only of detecting these low percentages, but of discriminating between them, the experimenter is at once driven back on the "blue-cap" method as being, notwithstanding several drawbacks, the simplest, most rapid, and best known of all.

The report of Prof. John Cadman and Mr. E. B. Whalley on "The Methods of Examining for Firedamp" has established the fact that the usual safety lamp cannot be counted upon to show less than about 2 per cent. of gas on the average, under actual working conditions; and it seems impossible to distinguish with certainty proportions of gas so low as 1¼ per cent.

The aim of the Cunynghame-Cadman device is to improve the testing powers of the ordinary lamp by means of a simple attachment and, so far as firedamp testing is concerned, the attachment described is a modification of the Cunynghame-

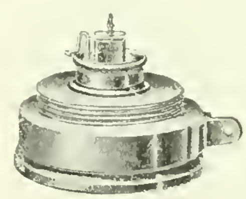

Fig. 1

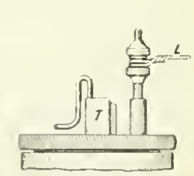

Fig. 2

Cadman device, although, as an indicator of blackdamp, its principle of action is new.

The device consists of a ½-inch loop of No. 22 gauge copper wire, pivoted on a spindle to swing horizontally in or out of the flame of a safety lamp. The position of the loop when in the flame and a side view of the loop *L* when in the "off" position are shown in Figs. 1 and 2. Immediately the loop is placed in the flame the luminosity disappears, although the dimensions of the flame are scarcely affected. The explanation is that the luminosity of the flame is due to the incandescence of minute carbon particles, which, cooled below a certain temperature, cease to be incandescent, and the flame ceases to give white light.

The writer's aim was to discover some medium which, when inserted

*Abstracted from the Transactions of the Mining Institute of Scotland, Volume 34, page 3.

in the flame, would abstract sufficient heat to render the flame non-luminous, without shortening or cooling it so far as to affect seriously its capabilities as a cap maker. Gauzes of different mesh were first tried, then a straight horizontal piece of strong copper wire, and after trying many different shapes and sizes, a loop ½ inch in diameter was finally selected as most suitable.

To convert the working flame of a safety lamp into a testing flame is practically an instantaneous operation with this loop. There is no need to draw down the wick when looking for gas; indeed it is usually better to lift it a little to minimize the risk of the flame being extinguished during the operation. If firedamp is present, a clear cap is seen on the flame on swinging the loop into place. To ascertain if gas is present takes almost exactly 2 seconds, that period being long enough to swing the loop across the flame, to notice if a cap forms, and to bring the loop out again. At no time, indeed, is a cap for one of the low percentages more clearly seen than during the very short interval between the moment the cold loop is brought into position and the flame's recovery of its original height. During that interval the cap is seen to form first; then the upper part of the flame drops down from above on to the loop. Of course, it takes longer than 2 seconds to make a conscientious estimate of the amount of firedamp present, for then the cap has to be studied for a long time and its length judged.

The question of standardization of the test flame (a very serious question for the ordinary method of testing) has not given any trouble during the experiments on the loop; for in estimating firedamp, the standard flame is merely that which is of the greatest bulk with a uniform, but very slight, luminosity. Of course, the amount of yellow light present is not allowed to be sufficient to mask the cap. The curves of Fig. 3 were constructed from data obtained by means of a flame so standardized. While the practical applicability of such a simple standardization must be admitted, it might be thought to be of only a rough nature. That this is not the case can only be proved by taking a considerable number of measurements of caps, preferably spread over more than one day, and necessitating a readjustment of the flame for each observation, when the concordance of the readings will be found somewhat striking to anyone familiar with the rather irregular indications given by a flame

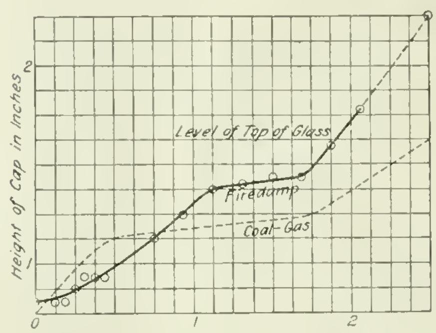

Fig. 3 Percentage of Inflamaple Gas

lowered in the ordinary way. The following set of readings will serve to show this; they were obtained on three different days, using the same lamp, and taking due precautions to prevent any one determination from biasing the next:

Percentage of coal gas, 1½.

Measured height of cap, in inches, $1\frac{3}{16}$, $1\frac{1}{4}$, $1\frac{1}{8}$, $1\frac{3}{16}$, $1\frac{7}{32}$, $1\frac{7}{32}$.

Mean height of cap, $1\frac{3}{16}$ inches.

Average error of a single observation, $\pm \frac{1}{32}$ inch.

This mode of standardizing the flame by making it always of the largest possible size, with a uniform tinge of yellow, has one great advantage when dealing with the effect of blackdamp and firedamp in combination.

The dotted line graph, Fig. 3, was constructed to show the relation between the height of cap and percentage of coal gas present with a loop of ½ inch. The lamp employed was one of Messrs. John Davis & Son's "A1" fireman's lamps, with brass oil vessel, copper wick tube, aluminum bonnet, and two copper gauzes. The lamp burned a half-inch wick, and the fuel used consisted of three parts by volume of colza oil to one part of paraffin.

The caps were measured from their tips to the base of the test flame. The reasons for abandoning the orthodox mode of measurement, namely, from the top of the flame to the top of the cap, were, firstly, because a cap is an envelope and not merely an extension of the flame; it actually covers the flame down to its foot; secondly, because with the flame standardization used, the flame was not always of the same height; and thirdly, a measurement between one definite and one indefinite point is more accurately made than between two indefinite points. The common method of measuring caps could perhaps claim the advantage that curves drawn from such measurements pass through the origin; yet the writer's experiments on large flames have led him to think that with no test flame, except probably that of hydrogen, ought it to be assumed that the origin must necessarily be a point on such a curve; for even when the fuel cap is not seen, its influence on the lower end of the curves like those of Fig. 3 is too marked to be neglected.

Fig. 3 shows a measurement that was obtained for ¼ per cent. of gas, the cap, largely due to the influence of a fuel cap, being quite clear. In this case the fuel cap was partly visible in pure air; the base was easily seen, but the upper part was too indistinct to permit of an accurate measurement; its length, however, so far as could be judged, was about ¾ inch from the bottom of the flame. The difference between the appearance of the flame in fresh air, and in air holding ¼ per cent. of gas was marked.

To be able to measure the cap for ¼ per cent. of gas, nevertheless, is not usual; in the majority of the trials made with different lamps and fuels, this proportion of gas was always discernible, but the length of cap could not be read. A person of ordinary eyesight, however, can always see the whole of the gas cap when the loop is employed and anything more than ⅜ per cent. of gas is present.

The points on the dotted curve of Fig. 3 represent the mean values of 68 measurements taken on several days. It will be seen that, for the most part, readings were taken at every eighth of one per cent. of gas. The measurements were, therefore, sufficiently numerous to fix the shape of the curves with considerable nicety, and there can be no question of the flattening evident in the middle of both curves being the result of experimental error. This curious flattening is not the less interesting because of the writer's complete inability to explain it at the present time.

To determine to what extent the results obtained by using coal gas were applicable to marsh gas, tests were conducted, with the same lamp and fuel and a half-inch loop, upon methane prepared from aluminum carbide and dilute hydrochloric acid. Before being led to gas cylinders, the gas was passed through a mixture of chromic and sulphuric acids—one of the strongest oxidizing agents known—in order to remove unsaturated hydrocarbons. As it was not easy to insure that the gas so made was free from air, which in a lengthy preparation sometimes finds a means of entry, and as such gas always contains a little hydrogen, it was necessary to ascertain its methane value. This was done by means of a Le Chatelier explosion tube, and the percentages of gas fed to the lamp were then modified accordingly. The heavy line in Fig. 3 contrasts the results obtained from coal gas and marsh gas. The points on the curve are observations. The remarkable flattening of the middle portion of the curve is again evident; it cannot then be due to a peculiarity of coal gas. The graphs indicate that although there is no wide difference, over the greater part of the range of the curves, between the two kinds of inflammable gas so far as their cap-forming abilities are concerned, yet firedamp is so much the stronger in that respect for the higher percentages as to lift the tip of the cap for 2½ per cent. about ⅝ inch above the level of the top of the glass of an ordinary lamp, while with the same proportion of coal gas the tip is just on that level. It is not difficult to remember that with 1¼ per cent. of firedamp present, another important proportion, the cap is about 1¼ inches high from the base of the flame, a statement which Fig. 3 shows to be a little on the safe side. At 2½ per cent. of firedamp the lowered flame gave a cap $\frac{9}{16}$ inch high; thus, at that percentage, the cap obtained by using a loop was four times the length of that given by the ordinary method of testing.

In testing for small percentages of firedamp underground, at a height of roughly 2½ feet from the floor, an indication of firedamp was seen on each of three lamps fitted with loops. The ordinary lowered flame gave no indication, and a Chesneau alcohol lamp gave a very indistinct reading of about ½ per cent. Two air samples were then taken, at intervals of about 20 minutes apart, and these were analyzed the same afternoon. The results of the analyses were, respectively, .36 and .28 per cent. of methane.

By dipping the loop or its twisted support in zinc-chloride solution (soldering flux), a chemical replacement of the zinc by copper takes place under the heat of the flame, and a green coloration is given to the flame, the fuel cap (if present), and, although to a lesser extent, the gas cap. This improves the indication considerably; but the chloride soon burns off. The wire, however, sometimes gives a fairly strong green flame reaction without treatment—especially if it has not been used for some days—and it generally gives a very faint one.

The Loop as an Indicator for Use With Electric Motors.—The usual safety lamp is not the most satisfactory contrivance to use with an electric motor working under conditions requiring the provision of such a lamp by the Rules for the Use of Electricity in Mines, since the lamp, if left to itself, could not continue to burn long with the wick drawn down to give a test flame. Hence it is not a continuous indicator. When fitted with the loop, however, the lamp will burn without requiring more than ordinary attention, with the loop standing in position from the beginning to the end of a shift. In this way a test flame is continually available, and a quick glance is sufficient to show whether gas is present.

Unless special means are provided for removing it, the crust which forms over a wick burning pure colza or a colza mixture gives a great deal of trouble when one is looking for gas by the ordinary method, and greatly increases the risk of losing the light. The loop, however, has been found almost equally efficacious with a crust present or with a clean wick.

Waste in Coal Mining

In reference to Doctor Holmes' statement that "in producing 500,000,000 tons of coal during 1911, 250,000,000 tons were wasted or left in the ground in such condition that it would not probably be recovered in the future," the following questions were asked of a number of prominent mining men: Does the waste occur in your field? Do you know from observation when such waste occurs, and if so, where? The following is one of the answers:

Editor The Colliery Engineer:

Sir:—I am in receipt of your favor of the 11th, with reference to a statement made by the Hon. J. A. Holmes, Director of the Federal Bureau of Mines, which, as you say, has been published broadcast, to the effect that 250,000,000 tons of coal are wasted or left underground annually which cannot be removed in the future.

The writer will say that in a general way Doctor Holmes is correct, and the systems of mining employed are very largely responsible for it, in this: that the blocks or pillars left for supporting the roof in working on the room-and-pillar plan, in all probability could not, for many reasons, be recovered in the future, and I think it is fair to say that, covering the entire coal fields now being operated on the room-and-pillar plan, 35 per cent. of the coal seam is left in the form of pillars when the mines are abandoned. In fact, I know of large fields where fully 50 per cent. of the coal was left in the pillars when the mines were abandoned, because any attempt to remove any portion of them would have caused a surface subsidence and such damage to the farm property (worth fully $250 per acre) that they could not afford, in those days of cheap coal, to pay for damaging the surface; and the question, of course, is: What is the remedy? And that brings us face to face with two all-important subjects in mining:

(1) Economy in operation, and particularly with reference to the timber supply, which is becoming so scarce and expensive.

(2) Conservation of the coal.

To accomplish the best results in economy and conservation in the operation of coal mines, an entire change of plans and methods is necessary:

First. No mine should be permitted to be located, in my opinion, directly on the line of a railroad, and the reasons are (*a*) because with their workings and shafts directly alongside of and underneath permanently-located railroads, there is constant danger from subsidences that must occur in the future; and (*b*) because they are unsightly. All mines should be located sufficiently far back from a railroad so that the boundary limit of its workings will not come within 200 feet or 300 feet of any railroad track.

Second. The coal company should be compelled to own its property in fee.

Third. It should be compelled to mine on the "retreating" system, which, like the longwall method, will permit of taking out all of the coal, and the subsidence which would naturally follow would not affect the railroad, and it would be practically uniform all over the territory mined, leaving the land in good condition for cultivation afterwards.

Fourth. In the driving of the entries to the boundaries before commencing to break off rooms, the work should be permanently done, in this: that where conditions would permit it, all roof stuff should be taken down to cap rock, making clean, safe, haulageways and air-courses, and where not possible to take down everything to cap rock, it should be secured with steel **I** beams and if necessary lagged with creosoted oak. Entries developed in that way would be permanently safe and secure. This method and system of operating would require the use of but little timber. At any rate, the use of it would be reduced to the minimum, and ventilation would be more perfectly maintained.

Fifth. All mining plants should have (especially where freezing winter weather prevails) an independent escapement shaft; in other words, there should be a hoisting shaft, airshaft, and an independent escapement way.

Sixth. No woodwork whatever should be permitted around pump rooms, stables, or anywhere in the underground workings, and particularly should there be no woodwork whatever around about any of the shafts, whether at the stables or other places of a similar character, or for roof protection, etc.

Seventh. All buildings on the surface should be fireproof.

If laws in the several states were enacted requiring mining to be done in this manner, then you would get the maximum of safety and the maximum of conservation, as well as the greatest economy of operations in general. It is the only way, in my opinion, that the severe competition which has had such a distressing effect upon the industry for years can be permanently done away with, because it would eliminate a class who construct and mine cheaply, taking out only such coal as can be secured at little expense and leaving large acreages untouched. Too often such workings are carried on in a manner that makes them a constant source of danger for all who must work in them. By the elimination of that class in the industry, it would become healthy in every respect and as reasonably profitable as it ought to be, and I believe this is the only way that permanent good for the business of coal mining can be accomplished, and that any other that may be attempted can only bring temporary relief, as is always the case with anything artificially supported.

It is not to be expected that such views as here expressed will meet with general approval by many of those now engaged in the operation of coal mines, but when we complain of wastage, and since our records show that coal mining in our country is far more hazardous and the loss of life and injuries far greater per ton of coal mined than is the case in the dangerous gassy mines of Europe, and further, since we complain that the business is unprofitable, we should be willing to face the situation squarely and tell the truth about it as we see it, and that is what I have tried to do in this case.

A. J. Moorshead,
President and General Manager Madison Coal Co.

The Unit of Quantity, the Coulomb

Since the quantity of electrical current passing a point in a circuit is rate of flow × time, i. e., current × time, the unit of quantity will be that which passes a point in 1 second when unit current is flowing.

Since the ampere is one-tenth of the absolute unit of current, it follows that the practical unit of quantity, or, as it is called, the *coulomb*, is one-tenth of the absolute unit of quantity.

The commercial unit of quantity is an ampere-hour, and is the quantity corresponding to 1 ampere flowing for 1 hour. Thus 1 ampere-hour equals 3,600 coulombs.

Practical Talks on Coal Mining

For men who desire information on Coal Mining and related subjects presented in a simple manner

Formulas and Their Use

A Simple Explanation of the Signs and Symbols Employed in Mining Calculations

To understand the principles upon which the ventilation of mines is based, and, in fact, to make many calculations which are necessary in laying out and working mines, it is needful to know what a formula is and how it may be used.

A formula is a short and simple way of stating a rule. It shows at a glance all the steps that have to be taken to get the result, uses much less space, and is much more easily remembered, than a rule. Often three or four letters when put together to make a formula explain a process more simply than 40 or 50 words written out in full. Men who have not had much schooling in their younger days and are not used to formulas, are apt to think of them as something far beyond their powers of learning. If such men are shown what formulas really are, what they are for, and how to use them, they quickly see their value. For this reason, the first article is, naturally, a short one on formulas.

To understand formulas the reader must learn the meaning and use of a few signs which are first met in the study of arithmetic.

The sign of addition, + (called plus), when placed between two numbers means that the two numbers are to be added together or that their sum is to be taken, as, $7+4=11$, which is read 7 plus 4 equals 11.

The sign of subtraction, − (called minus), when placed between two numbers means that the second or the smaller of the two numbers is to be subtracted from the first or larger of the two, or that their difference is to be taken, as, $9-3=6$, which is read 9 minus 3 equals 6.

The sign of multiplication, × (called multiplied by, or times), when placed between two numbers means that one is to be multiplied by the other, as $3\times 6=18$, which is read 3 multiplied by 6 equals 18. Multiplication is really a short way of doing addition because the calculation called for by the figures and signs, 3×6, means that six threes are to be added together.

The sign of division, ÷ (read divided by, or into), when placed between two numbers means that the first number is to be divided by the second, as $12\div 3=4$, which is read, 12 divided by 3 equals 4, or 3 into 12 makes 4, etc.

The sign of equality, = (read equals, is equal to, or makes), when it appears between two signs or numbers, or between a group of numbers on one side and a single number or group of numbers on the other, means that all the numbers or signs on one side are equal to all the numbers and signs on the other side, as $2\times 3=18\div 3$. This we see is right, because both 2×3 and $18\div 3$ are equal to 6. In a like way we can write $2\times 3=12-6$, or $2\times 3=5+1$, because in each case the figures on one side of the equality sign when multiplied, subtracted, or added, as called for by the signs placed between them (×, −, or +) are equal to six.

The sign of grouping, or the parentheses, may be written in either of two ways, as ( ), or [ ], etc. The latter of these signs are often called brackets. When a number of figures and signs are found between parentheses or brackets, it means that all the work called for by the signs (as +, −, ×, or ÷) must be done and the result taken by itself before the next step in the calculation is made. Thus, $(5\times 6)\div(2+3)$, is read 5 multiplied by 6 is to be divided by 2 added to 3. Now $5\times 6=30$, and $2+3=5$, and $30\div 5=6$. Thus $(5\times 6)\div(2+3)=30\div 5=6$. Now, if the parentheses were not there, instead of $(5\times 6)\div(2+3)$, we would have $5\times 6\div 2+3$. In this case we would first multiply 5 by 6 and have 30 for the result. This 30 would then be divided by 2 giving us 15, and to this 15 we would add 3, making 18 for the final result. When the parentheses are used the result is 6 and when they are not used the result is 18, so the need of paying attention to the parentheses is plain. These are sometimes indicated by a straight line above the figures. Thus $(4\times 3\div 6)$ may be written $\overline{4\times 3\div 6}$.

The sign of involution, or of squaring, cubing, etc., or of the power of a number, is a small figure placed above and to the right of the number and is called an exponent. This exponent shows how many times the number to which it belongs is to be multiplied by itself to get what is called a power of the number, which power is named or called from the exponent. Thus 2^5 means that five twos are to be multiplied together, and the result, which is 32, is known as the fifth power of two. So 2^5 is read two to the fifth power, or as the fifth power of two, and is exactly the same thing as $2\times2\times2\times2\times2$, and is equal to 32. In the same way 3^4 is read three to the fourth power, or the fourth power of three, and is equal to the product of four threes multiplied together, or $3^4=3\times3\times3\times3=81$. Again, 4^3 is read four cubed, or the third power of four, and is the same as three fours multiplied together, or $4^3=4\times4\times4=64$. In the same way 5^2 is read five squared, five to the second power, the square of five, etc., and is the same as two fives multiplied together, as $5^2=5\times5=25$.

A root of a number is another number which multiplied by itself a given number of times will make the first number. Thus the fourth root of 16 is 2, because four twos multiplied together make 16. In the same way the fifth root of 32 is 2 because five twos multiplied together make 32. The third root, or as is commonly said the cube root, of 27 is 3, because three threes multiplied together make 27. In the same way the second root, or as is more commonly said the square root, of 16 is 4, because two fours multiplied together make 16. The sign which shows that a root is to be taken, or extracted, is $\sqrt{\ }$. A little figure usually written above and to the left of the root sign, is known as the index of the root, or more simply the index, and shows which root is to be taken. Thus $\sqrt[5]{32}$ means that the fifth root of 32 is to be found, and as explained, is equal to 2 because two multiplied by itself 5 times (as called for by the index of the root, 5), or $2\times2\times2\times2\times2$, is 32. In the same way $\sqrt[4]{16}$, $\sqrt[3]{27}$, $\sqrt{25}$, are read the fourth root of 16, the cube root of 27, and the square root of 25. The square root is in very common use, so it has become customary in order to save space to omit the figure for the index. Really the square root of 25 should be written $\sqrt[2]{25}$, but it is always written $\sqrt{25}$, the 2 being omitted.

In formulas, letters are used instead of numbers because numbers represent or give the size, or value, (for example) of one thing only, while letters give the same thing in a general way. This may be made clearer by a simple example: A mine foreman's shanty is 8 feet wide and 10 feet long. Suppose the size of the floor of this shanty is wanted. The rule for finding the size of a room is to multiply the length in feet by the width in feet and the result is the area (size) in square feet. Now, if we say that in such rules the length of the shanty is to be called L and the width of the shanty, W, and the area (or size) of the shanty, A, we can write this rule as a formula, thus, $A=L\times W$, which means just the same thing as the rule and takes but three letters and two signs and takes less space and is much more easily remembered. This is what is called a general formula because it may be used to find the area of any shanty, room, building, and the like, no matter how long or wide it may be. In the example just given the shanty is 10 feet long and 8 feet wide; that is, the length of the shanty, or L, is 10, and the width of the shanty, or W, is 8. If for L and W in the formula we use these figures, we have $A=10\times8$, which is equal to 80, and the area (size) of this particular mine foreman's shanty is 80 square feet. But all shanties are not of the same size and the expression $A=10\times8$ for the size is good only for this particular one, but if we write a formula as $A=L\times W$, this can be used in any case simply by taking the values of L and W as we measure them.

When letters are used in formulas the $\times$, or sign of multiplication, is often left out in order to save space. The formula for the size of a room may be written either $A=L\times W$ or $A=L\,W$. In either case the meaning is that the area, A, is equal to the length of the room, L, multiplied by its width, W.

In some formulas a letter or group of letters is written above another letter or group of letters with a line between. Thus we may have $\frac{a}{b}$, or $\frac{a\times b}{c+d}$, or any other set of numbers above or below the line. In any case the meaning is that the single figure above the line, or the result gotten by combining the figures above the line, is to be divided by the single figure below the line or by the result obtained by combining the figures below the line. In the first case a is divided by b, and the formula may be written either $\frac{a}{b}$, or $a\div b$. In the second case a must first be multiplied by b; then c must be added to d, and the first result is then to be divided by the second. As with the first case, the second may also be written in two ways, either $\frac{a\times b}{c+d}$ or $(a\times b)\div(c+d)$.

To show the reader how formulas are used in connection with underground work two practical examples are given:

(1) What is the ventilating pressure per square foot in an airway with a rubbing surface of 36,000 square feet, when the velocity of the air-current is 500 feet per minute, and the sectional area of the airway is 20 square feet?

(2) What is the ventilating pressure per square foot in an airway with a rubbing surface of 48,000 square feet, when the velocity of the air-current is 300 feet a minute, and the sectional area of the airway is 25 square feet?

The rule to work out either of the above questions is: To find the pressure per square foot, multiply the coefficient of friction by the rubbing surface, then multiply this product by the square of the velocity, and divide this last product by the sectional area.

This rule may be changed to a simple and easily remembered formula by placing letters for the various things that are to be grouped together.

Thus, if we let

p = pressure in pounds per square foot;

k = Atkinson's coefficient of friction, or .0000000217;

s = the rubbing surface in square feet;
v = the velocity of the current in feet per minute;
a = the sectional area of the airway in square feet,

the rule, in the shape of a formula, becomes,

$$p = \frac{k\,s\,v^2}{a}$$

In place of these letters the numbers taken from example 1 may be written and the formula, in shape for making the calculation becomes,

$$p = \frac{.0000000217 \times 36{,}000 \times 500^2}{20},$$

or 9.765 pounds

The actual work is carried out as follows:

.0000000217
36000
1302000
651
.0007812000
250000

While in the second question the same formula is used, the letters, except k, stand for different numbers than they did in the first example. As in the first example

$$p = \frac{k\,s\,v^2}{a}$$

but when we use the new values for these letters the formula, in the right shape for calculation becomes,

$$p = \frac{.0000000217 \times 48{,}000 \times 300^2}{25},$$

or 3.74976 lb.

Gases Met With in Coal Mines

Air—Firedamp and Its Properties—Principle of the Safety Lamp—Detection of Gas With Safety Lamp—Blackdamp

TO MAKE this subject clear to the average miner, it is necessary to treat it in a different way than is commonly done in books. It is the custom in most books to first speak of the simple, single gases that when mixed with one another are found in mines, and after that to take up these mixtures or combinations. The miner, who knows these mixtures as "firedamp," "blackdamp," and "whitedamp," often finds it very hard to understand what is written about the properties of gases because words and names are used which he has not seen before and the meaning of which is not given. In this article we will begin with the mixtures of gases the miner knows, and he will be told what other things he should know about these gases in a plain and simple way.

Air, or as it is sometimes called the atmosphere, is a mixture of two gases which when alone are known as nitrogen and oxygen. If we could separate the two gases we would find that every five parts of air is made up of four parts by volume of nitrogen and one part by volume of oxygen. That is, 5 cubic feet of air consists of 4 cubic feet of nitrogen and 1 cubic foot of oxygen. These are not exactly the true figures but they are near enough for every-day use and are easy to remember. Both oxygen and nitrogen are without odor, color, or taste. Oxygen is about one-tenth heavier than nitrogen. Each of these gases has its use in the air, but in a different way. Oxygen supports both life and combustion; nitrogen does neither and serves to dilute or make the oxygen weaker, as by itself it is too strong. No one could live without oxygen, as it is drawn into the lungs with every breath and there combines with the blood and is taken by it through the arteries and veins to every part of the body. Likewise, without oxygen we could have no fires, as it combines and unites with the carbon of coal, wood, or oil, to make what we call burning, and this burning gives out heat.

FIREDAMP

Quite a number of people call firedamp by such names as marsh gas, methane, or light carburetted hydrogen. This is not correct because the gas which is known by the name of methane, marsh gas, or light carburetted hydrogen is one thing and firedamp is another. The best name and the one most often used for this gas is methane. Now firedamp is a mixture of methane with the ordinary mine air. Methane is the name of the pure, simple, unmixed gas; firedamp is the name given to the product when it is mixed with air.

Methane will not support life or combustion. In other words a person will die from suffocation if compelled to breathe pure methane, and likewise a lamp or a fire will go out if placed in it. Suffocation and death from breathing methane are just the same as suffocation and death from drowning. Neither methane nor water is poisonous, but in the one case the lungs become full of methane and in the other case full of water so that in neither case is there room for oxygen which alone keeps one alive. In just the same way pure methane will put out a lamp, or fire, or any form of burning, because it keeps oxygen away from the flame, and oxygen

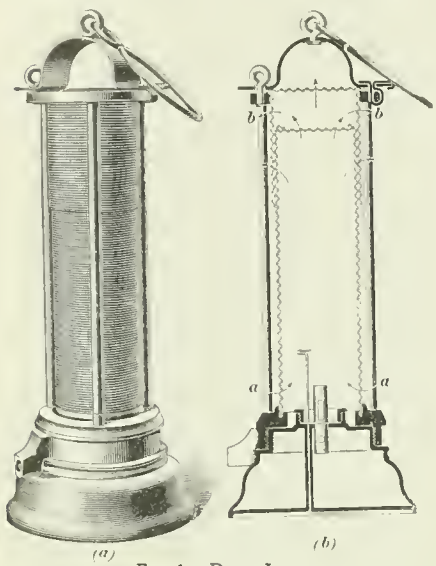

Fig. 1. Davy Lamp

is the only simple gas that will support combustion.

While methane will not support combustion, it will burn with a blue flame when the right amount of air is present, and in some cases will explode. When firedamp is composed of 1 part methane and 5 parts air it will explode when a light is placed in it, but the explosion will be a mild one. When firedamp is 1 part methane and 9⅔ parts air, a most violent explosion will take place. When the mixture is 1 part methane and 13 parts air, there may also be an explosion, but as in the case where the firedamp is 1 part methane and 5 parts air, the explosion will be light.

Very violent explosions take place when the mixture ranges from 1 part methane and 6 parts air to 1 part methane and 12 parts air. When the mixture is diluted or weakened by air so that it is composed of one-fifth gas and four-fifths air, the chances are that, if set fire to, the men in the neighborhood of the explosion will simply be burned more or less severely. Just the same will be the case if the mixture contains one-fourteenth gas and thirteen-fourteenths air. Between these two mixtures, however, say 1 part gas and 9½ parts air, there is a very explosive point. If such a mixture is set fire to, the men near the explosion will not only be burned but will be thrown around in a violent manner and will likely be struck violently by timber, coal, rock, or any other hard object in the path of the explosion.

As the gas, methane, is but little more than half as heavy as air it would always be found in a layer next to the roof if it were not for the properties of expansion and diffusion common to all gases. Owing to diffusion it is not always true that firedamp will collect against the roof or at the highest point in a pitching place, but as a general thing it will do so.

As methane is colorless, tasteless, and odorless, just the same as air, firedamp cannot be found by sight, taste, or smell. Therefore, the safety lamp gives the only practical means of finding it in mines.

To make clear the principle of the safety lamp, to understand how and why it is safe, the reader must be told how flame acts when it comes against fine wire gauze. In 1815, Sir Humphrey Davy made a safety lamp, now known the world over as the Davy lamp. This lamp is made on the principle that a piece of wire gauze with 784 square openings to a square inch will not allow a flame to pass through it; 784 openings to the square inch means that there are 28 openings in each inch of length and breadth of the gauze. Wire makers call this "28 mesh gauze," or "28 mesh wire cloth." If a piece of wire gauze of this "mesh" is placed above a flame, the top of the flame will flatten out against the gauze without passing through, just as it would against a solid plate of iron or tin.

The Davy lamp is still in use among fire bosses for testing for gas, but it is so unsafe for general use in the working places that it is prohibited by law as a working lamp in many states. Fig. 1 shows a Davy lamp. The Davy lamp when used by fire bosses is often provided with a movable metal shield encircling the gauze for two-thirds of the way around, and arranged to slide upwards when desired. This shield protects the flame of the lamp against strong air-currents, and is of great use when testing for gas in airways or other places where the air is moving with considerable velocity. Owing to the free admission of air through the gauze, this lamp shows a good flame cap in gas. The presence of 3 per cent. of methane in the air can always be

Fig. 2

detected with this lamp, and a careful and experienced fire boss will see a cap when as little as 2½ per cent. of gas is present. Some fire bosses claim to be able to detect as low as 2 per cent. of methane, but there seems to be some doubt as to this. In using the Davy lamp for testing for gas, the flame is lowered as much as possible without entirely putting it out. The lamp (it must be held straight up so that the flame does not play on the gauze) is slowly and carefully raised and stuck into any place it is desired to examine, a sharp watch being kept on the small oil flame. Fig. 2 shows the cap of gas on the flame which will appear in a Davy lamp when it is held in firedamp containing different amounts of methane. Very few can see with the naked eye the cap formed by less than 2½ per cent. of methane. A Davy lamp fitted with a Beard-Mackie sight indicator and in the hands of a competent man, will show as little as one-half of 1 per cent. of methane. This indicator, shown in Fig. 3, is a piece of No. 14 Birmingham wire gauge brass wire bent in the form of the letter U turned upside down, and is firmly fixed to a thin brass disk fitting into the neck of the lamp, and held firmly upright by the nipple which holds the wick tube in place. Sometimes this inverted U is attached to the nipple itself, as shown at *b*. On the standard formed by this inverted U, fine platinum cross-wires are arranged at such heights above the flame as to indicate by their glow the amount of methane in the air. The indicator shows the presence of gas varying in amount from one-half of 1 per cent. to 3 per cent., each successive strand of platinum wire showing by its glow an increase of one-half of 1 per cent. In the use of this indicator the flame of the lamp is first lowered in pure air so that the lowest wire, called the standard wire, is aglow. The other wires, called percentage wires, are looped in the center to make them show better through the gauze. This indicator is based on the principle that platinum wire is very sensitive to methane.

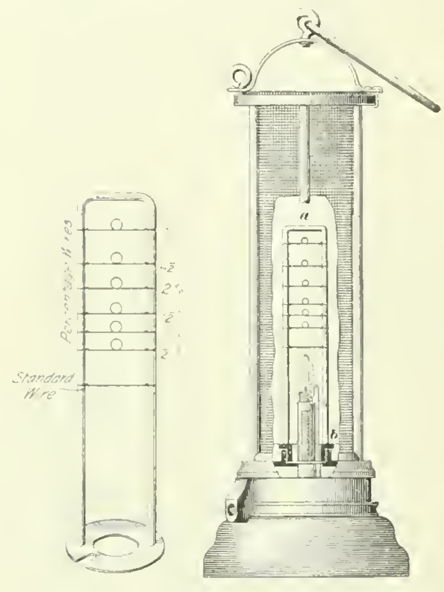
Methane is composed of the elements carbon and hydrogen in the proportions of 1 part carbon to 4 parts hydrogen. Its chemical symbol is CH_4. This symbol shows at a glance the constituents of methane. The letter, C, without any small figure attached, means that the proportion of carbon is one, and the small figure, 4, written at the lower right side of H means that the proportion of hydrogen is 4. In other words, 1 atom of carbon combined with 4 atoms of hydrogen forms methane. Carbon has an atomic weight of 12 and hydrogen has an atomic weight of 1. In other words, carbon is 12 times as heavy as hydrogen. Then the atomic weight of methane is:

1 part carbon with atomic weight of 12 =	12
4 parts hydrogen with atomic weight of 1 =	4
	16

This is known as the molecular weight. Chemists in practice use the atom as the smallest division of any gas. A combination of atoms to form the smallest division of the combination is called a molecule. A molecule of methane is composed of 1 atom of carbon and 4 atoms of hydrogen. In this case the molecule is composed of 5 atoms. The molecules in different combinations varying, it is evident that a molecule of any gas will differ in the number of atoms it contains with the molecule of another gas composed of varying numbers of atoms. For instance, a molecule of carbon dioxide, the gas which when mixed with air forms "blackdamp," is composed of 1 atom of carbon and 2 atoms of oxygen (CO_2) and is, therefore, a molecule composed of 3 atoms, while a molecule of methane is composed of 5 atoms. As mentioned previously, a cubic foot of methane weighs but little more than one-half as much as a cubic foot of air. In other words, if a certain specified volume of air weighs 1 pound, the same volume of methane will weigh .559, or about $^{14}/_{25}$ of a pound.

BLACKDAMP

There is another "damp," or mixture of air and a gas known to miners as blackdamp, although sometimes called chokedamp, which



(a) (b)

Fig. 3

is composed of air and carbon dioxide. Just as the term firedamp is often given to the methane which when mixed with air forms the real firedamp, so the term blackdamp is often wrongly given to carbon dioxide, which is only a part of the real blackdamp. Carbon dioxide gets its name from its composition, which is shown by the symbol, CO_2, which means that a molecule of the gas is composed of 1 atom of carbon and 2 atoms of oxygen; the symbol *di* meaning two. So carbon dioxide is carbon two-oxide, there being another oxide of carbon with the symbol, CO, and known as carbon monoxide (or one-oxide), which will be described under the head of whitedamp. Carbon dioxide was at one time known as carbonic acid, but this term is now rarely used.

Carbon dioxide is a very common gas as it is always present in the air to a slight amount. It is given off by the breathing of all men and animals, and by all burning, such as the flame of lamps, of coal or gas fires and the like. In the mines, it is also given off in other ways than these, and like methane is given off by the pores of the coal. It is formed by the decomposition or rotting of wood and the weathering of coal, so decaying props and slack piles in the gob give off this gas. It is also given off by gob or mine fires and very large amounts are formed when there has been an explosion of firedamp or of coal dust.

Carbon dioxide is the heaviest gas commonly found in coal mines, its specific gravity being 1.529. That is, if a cubic yard of air weighs 2.186 pounds, a cubic yard of carbon dioxide will weigh 3.343 pounds or a little more than one and one-half times as much. For this reason this gas is commonly found near the floor and particularly at the bottom of dip workings, in old shafts and wells and the like.

Carbon dioxide is colorless and has a prickling, faintly acid taste and smell. It does not support combustion because it is a product of complete combustion, and a light placed in it will go out. The gas is not poisonous but causes death by suffocation because it is a compound gas that will not give up its oxygen to the lungs.

Mechanics of Mining

An Explanation of the Principles Underlying Calculations Relating to Engines, Pumps, and Other Machinery

By R. T. Strohm, M. E.

To understand how to make calculations relating to engines, pumps, haulage systems, and various classes of machinery used in and about mines, it is very necessary to know something about forces, because the action of all kinds of machines depends on forces.

To begin with, it may be said that a force is something that causes motion. If a stone is lying on the ground, it rests there without moving, so long as nothing touches it; but when a man stoops and takes hold of it, it is lifted, or moved upwards. The difference between its lying still and its movement upwards is caused by a force, and the force is the effort put forth by the strength of the man in lifting it.

Again, suppose that an empty mine car is standing on a level track and that it is to be moved a short distance. A man simply pushes against it in the direction in which he wishes it to go, and it moves along the track. The motion of the car is due to the force of the push exerted by the man. When the car has moved to the proper spot, the man stops it by pulling in the opposite direction to that in which he had been pushing. The stopping of the car is due to the force of the pull; therefore, it may be said that a force is something that stops or destroys motion, as well as causes motion.

Forces may act in any direction. In lifting a stone, for example, the force acts upwards. In pushing a car along a level track, the force that moves the car acts parallel to the track, that is, in the same general direction in which the track runs. In the case of a hoisting rope that runs down on a slant from the head-sheave to the drum, the force of the pull in that part of the rope acts at an angle to the ground level.

The values of forces are usually stated in pounds, and it is then an easy matter to compare them with one another. For example, suppose that the stone mentioned in a preceding paragraph weighs 20 pounds. Then, to lift it from the ground the man must exert a force of 20 pounds. If the stone had weighed 40 pounds, he would have had to lift with a force of 40 pounds, or twice as much as in the first case. In lifting weights by pulling straight upwards, therefore, the force required is equal to the weight lifted.

In moving a car along a level track, the force required may be measured in pounds by using a spring balance, as shown in Fig. 1. The balance *a* is hooked fast to the coupling link of the car *b* and a steady pull is exerted on the ring *c* at the end of the balance, until the car moves along the track *d*. The amount of this pull, as shown by the hand on the dial of the spring balance, is then the force in pounds, required to move the car. Under ordinary conditions, a well-lubricated mine car weighing about 6,000 pounds can be moved along a level track by a force of 60 pounds.

In the last case, the force required to cause the car to move is a great deal smaller than the weight of the car; whereas, in the case of the lifted stone, the force was equal to the weight of the stone. The difference is due to the direction in which the force acts. It always takes a greater force to move a body straight upwards than to move it along the level; and if the body is moved up a slope, the force required becomes greater as the slope grows steeper. These facts are proved by every-day experience.

Forces may act without producing motion, however. Take the case of a mine prop that is carrying a load of 4 tons. The overlying rock and earth are pressing down on the prop with a force of 4 tons, or 8,000 pounds; but at the same time the prop is pushing upwards with an equal force of 8,000 pounds. The result is that the two forces just balance each other and there is no motion of either the prop or the rock. In general, then, if a body is at rest, or has no motion, the forces that act on it are balanced; or, stating the same fact in the reverse way, if the forces that act on a body are balanced, the body will not move.

Whenever a body is in motion, there are two kinds of forces acting on it. One force is acting to keep it moving, and the other force is acting to prevent it from moving, and these forces act in opposite directions, or against each other. The force that acts to keep it in motion may be called the driving force, or the motive force; and the

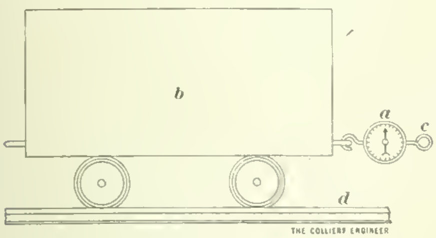

Fig. 1

force that tends to prevent it from moving may be called the resistance. As long as the motive force is greater than the resistance, the body will keep on moving; but when the resistance becomes greater than the motive force, then the motion will stop.

To illustrate these points, take the case of a mine car on a level track. While the car is moving along the rails, the force that keeps it in motion is greater than the force that tends to stop it. The resisting force, or resistance, is caused by dirt on the rails, flat spots on the wheels, friction of the bearings in which the wheels or axles turn, and so on. If the motive force is removed, or made less than the resistance, the car will slow down and come to a stop.

Another term that is very often used is *work,* which means simply the overcoming of resistance of any kind. In order that work may be done, there must be a motive force, a resistance, and motion of the body acted on. For example, if an engine hoists a car of coal in a shaft, it does work. The engine gives the motive force through the hoisting rope; the weight of the coal, car, and cage, and the rubbing of the cage against the guides, give the resistance; and as the pull of the engine on the rope is greater than the downward pull of the resistance, the load moves.

In the same way, a mine locomotive does work when it hauls a trip of cars. The locomotive furnishes the driving force, or motive force: the weight and friction of the cars produce the resistance; and the motion is due to the fact that the pull of the locomotive is greater than the resistance. The only difference between this case and the one just mentioned is that the locomotive does work by moving the load along a fairly level track and the hoisting engine does work by lifting the load straight up the shaft. But in either case work is done, because the resistance of a moving body is overcome.

It was stated in a preceding paragraph that forces can be measured; and so, likewise, it is possible to measure work. But work is not measured in pounds, as forces are. Instead, work is measured by the *foot-pound,* which is the amount of work done when a resistance of 1 pound is overcome through a distance of 1 foot.

The idea of the foot-pound of work may be made clear by a few simple examples. If a piece of iron weighing exactly 1 pound is lifted straight upwards a distance of 1 foot, the amount of work done is 1 foot-pound, because the resisting force, or 1 pound, has been overcome through a distance of 1 foot. If the piece of iron weighs 10 pounds and is lifted vertically 1 foot, the amount of work done is 10 times as great, or 10 foot-pounds. If the weight of the iron is 1 pound and it is lifted 10 feet, the amount of work done is 10 foot-pounds, as before.

The general rule to be followed in finding the amount of work done is to multiply the resistance, in pounds, by the distance it is moved, in feet. This rule may be used to find the work of hoisting a load up a shaft, hauling it up a slope, or drawing it along a level track. If a load of 6,000 pounds is hoisted up a vertical shaft 200 feet deep, the work done is $6{,}000 \times 200 = 1{,}200{,}000$ foot-pounds.

Fig. 2

If it takes a pull of 300 pounds to haul this same load up a slope 200 feet long, the work done is $300 \times 200 = 60{,}000$ foot-pounds. And if this load requires a steady pull of 60 pounds to draw it along a level track 200 feet long, the work done is $60 \times 200 = 12{,}000$ foot-pounds.

If a weight is moved from a lower level to a higher level, the work done is the product of the weight and the distance it is raised, and it makes no difference whether the load is moved straight upwards or on a slope. In Fig. 2, the two loaded mine cars *a* and *b* are supposed to weigh 6,000 pounds each and to be at the same level. If the car *a* is hoisted vertically to the position shown at *c*, or 100 feet above, the work done is $6{,}000 \times 100 = 600{,}000$ foot-pounds. If the car *b* is pushed up the slope to the position *c*, it is raised 100 feet, and the work done is $6{,}000 \times 100 = 600{,}000$ foot-pounds, as before.

(To be continued)

Electricity in the Mines

What Electricity Is—Its Manifestations—Positive and Negative Electricity Explanation of Potential

By H. S. Webb, M. S.

While many persons have endeavored to determine what electricity is, no one has been able to give a more satisfactory definition than that electricity is the cause of all electrical phenomena. While this definition does not give us much information and although the exact nature of electricity is not fully understood, nevertheless, much is known about electricity and it is made to serve many useful purposes.

We do not know what gravitation is, and yet we know its laws and how to make use of them. Similarly, we have many laws relating to electricity that always hold true, and many of the effects of electricity are known and methods for controlling and utilizing it are well understood. For instance, a copper or iron wire can be suspended in a mine shaft, connected at one end to what we call a battery and at the other end to an electric bell, then by connecting both the other terminals, or binding posts, of the battery and the bell to the ground, or to another iron or copper wire, the bell can be made to ring. We cannot see and, except under certain conditions, we cannot feel the electricity, yet the bell by ringing demonstrates its presence and it rings only when the electrical circuit is completed. Electrical instruments have been devised with which the strength of electricity present in the wire when the bell rings can be measured.

The presence of electricity may be detected in many ways. Under certain conditions it will (1) attract and repel light particles of matter, such as small pieces of paper. (2) It will decompose certain forms of matter; thus if it flows through water it will break the water up into oxygen and hydrogen. (3) It causes a freely suspended magnetic needle to be deflected to one side or another, and magnetizes a piece of iron if it passes through one or more turns of cotton-covered wire wound around the iron. (4) It violently agitates the nervous systems of animals and men, causing shock and even death. (5) It heats substances through which it passes.

Electricity may reside on the surface of a body, in which case it is called a charge of electricity, or it may flow through the body, in which case it is called a current of electricity. The branch of the science that treats of surface charges is commonly called electrostatics, because it considers electrical charges in the state of rest and such charges are commonly called static charges of electricity. As static charges are of small importance in mine work, but little consideration will be paid to this subject in these articles. Electrodynamics is the branch that treats of the action of electrical currents or of electricity in motion. Electricity in motion is frequently called dynamic electricity. As a matter of fact there is really no difference between static and dynamic electricity. If a charge of electricity is moved along a copper or iron wire with sufficient rapidity, it becomes a current of electricity, because it then follows the laws which apply to dynamic electricity.

Static electricity is dangerous in some cases and quite troublesome in many others, and it is sometimes important to know how to eliminate or avoid it; furthermore, some electrical measuring instruments depend upon it for their operation. For these reasons practical workers should understand the production and behavior of static charges.

When a glass rod or a piece of sealing wax is rubbed with silk or fur, the parts rubbed will have the property of attracting light pieces of paper, feathers, wool, gold leaf, etc., which, after momentary contact, are usually repelled. These attractions and repulsions are caused by static charges residing on the surface of the body, which in this condition is said to be electrified.

If two light, dry pieces of pith are hung from the ends of two dry pieces of silk thread several inches long and each piece of pith is charged by bringing it in contact with a stick of sealing wax that has just previously been rubbed with a silk handkerchief, it will be found that the two pieces of pith, when brought near together, will repel each other. If one is charged from the sealing wax and the other from the silk handkerchief, or better from a glass rod after it has been rubbed with fur or flannel, they will attract each other when brought near together.

From carefully performed experiments of this character, it has been proved that charges of an opposite character are developed on the sealing wax and on the silk. If that developed on the sealing wax is called positive (+) electricity that on the silk may be called negative (–) electricity. The charge developed on a glass rod by rubbing it with silk is opposite in character to that developed on sealing wax when rubbed with silk. Hence, if the charge on the sealing wax is called positive (+) electricity, that on the glass may be called negative (–) electricity. These experiments further prove that two bodies charged with the same kind of electricity tend to repel each other and that two bodies charged with the opposite kinds of electricity tend to attract each other.

When an electrified body, such as a glass rod after being rubbed with fur, is brought into contact with the ground, as may be done by wiping it with the hand, the electricity on the rod disappears. It has been proved that the electricity has passed through the body touching it to the earth, which acts as a large reservoir of electricity. In the case of glass rubbed with fur, it has been commonly agreed that the glass has a positive charge, and further, that the electricity on the glass has a higher pressure than the electricity on the fur or in the earth, and hence the electricty on the glass always tends to pass to a body, such as the earth, which has a lower pressure. This may be likened to two tanks of water, one above the other. When connected with a pipe the water in the higher tank tends to flow into the lower tank because the pressure toward the earth of the higher body of water is the greater. In electrical work the term potential is used in place of pressure. Thus the electric charge on the glass is said to be at a higher, or greater, potential than the charge on the fur.

(To be continued)

PRIZE CONTEST

For the best answer to each of the following questions we will give any books on mining or the sciences related thereto, now in print, to the value of $3.

For the second best answer, similar books to the value of $2 will be given.

Both prizes for answers to the same questions will not be awarded to any one person.

1. The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.
2. Answers must be written in ink on one side of the paper only.
3. "Competition Contest" must be written on the envelope in which the answers are sent to us.
4. One person may compete in all the questions.
5. Our decision as to the merits of the answers shall be final.
6. Answers must be mailed to us not later than one month after publication of the question.
7. The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what books they want, and to mention the numbers of the questions when so doing.
8. In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.
9. Employes of the publishers are not eligible to enter this contest.

Questions for Prizes

13. *Horsepower of Engine.*—Calculate the horsepower of an engine that is capable of hauling a trip of 15 cars, each weighing 1,200 pounds, and having a capacity of 3,000 pounds. The haulage road has a uniform grade of 1 per cent. against the load, and is 4,000 feet long. It is desired to get out 600 cars a day. Assume the coefficient of friction as $\frac{1}{40}$.

14. *Tracks in Rooms.*—What is the maximum pitch on which tracks can be laid in rooms and cars handled with safety? What methods are adopted for handling the coal in the rooms on steep pitches? Answer briefly.

15. *Size of Airway.*—Are two airways 8 feet square equal to one airway 8 by 16 feet; and which will pass the most air and why, the pressure per unit of area being the same in both cases?

16. *Standing Props.*—How would you stand a prop in a seam of coal 6 feet thick, which has from one foot to two feet of slate above it, (1) when the seam is flat; (2) when the seam pitches 30 degrees; (3) when the seam pitches 70 degrees? Give details and reasons for your answer.

Answers for Which Prizes Have Been Awarded

Ques. 5. *Booster Fan.*—An exhaust fan at a mine is capable of supplying 150,000 cubic feet of air per minute, and 40,000 cubic feet per minute more are required. The amount of unmined coal is insufficient to warrant sinking additional airshafts, and leakage along the airways has been reduced to a minimum. Will a "booster fan" located in the mine meet the requirement? Give reasons for the answer, and state at what point such booster fan should be located, if in your opinion it will do the work.

Ans.—The question is whether or not it would be practical to use a "booster" or an auxiliary fan where the ventilation is to be increased above 150,000 cubic feet per minute? Two fans each being capable of providing 150,000 cubic feet of air per minute working on the same airways in a mine would fall short of providing the increased quantity of air.

It is well known that the power producing ventilation varies directly as the cube of the quantity. The increased power therefore would require to be $\left(\frac{190,000}{150,000}\right)^3$ or $\left(\frac{19}{15}\right)^3 = \frac{6,859}{3,375}$, or 2.033, nearly, that the power would have to be increased; for which reason it would not be practical to install a booster or an auxiliary fan. It is well known that the quantity of air in circulation varies directly as the cube root of the horsepower; therefore, if a small fan (booster) of about 10 horsepower were placed in the workings to increase the ventilation in a certain part of the mine, and the horsepower of the principal ventilating fan at the surface was 100, the influence of the so-called "booster" on the total quantity of air would be practically nothing, because the ventilation varies directly as the cube root of the horsepower and $\sqrt[3]{100} : \sqrt[3]{110^3}$ or $\left(\frac{110}{100}\right)^3 = 1.032$. So if 200,000 cubic feet of air per minute was produced with 100 horsepower, there would be produced with the increased power $\sqrt[3]{\frac{110}{100}} = 1.032 \times 200,000 = 206,400$ cubic feet.

The effect then of an auxiliary or "booster" fan for the purpose of ventilation in some part of a mine is merely local, having comparatively no effect on the entire bulk of the ventilation. But where the auxiliary or small fan is applied, its results no doubt will be beneficial locally.

Ques. 6.—*To Stop a Squeeze.*—A flat coal seam 8 feet thick lies from 350 to 450 feet below the surface, and has a strong bed of micaceous sandstone 40 feet thick next above the top slate which is 13 inches thick; a squeeze has started in an area of 20 acres which was originally worked on the pillar-and-stall system, and the pillars left are well distributed and constitute about one-third of the original coal. How would you proceed to stop the squeeze so as to eventually recover a maximum amount of coal in the pillars?

Ans.—Assuming that 1 inch of this coal to the acre weighs 100 tons, there will be 192,000 net tons, two-thirds of the coal being extracted. Therefore, for the area of 20 acres, not enough pillars are left to withstand the weight thrown on them. The best method of stopping a squeeze is to prevent the causes that lead up to it. Those in charge of this work could hardly have overlooked the conditions given in this question and it is self-evident that the pillar-and-stall method is not practical and should have been changed to the room-and-pillar system, extracting one-third of the coal and leaving two-thirds in the pillars. Assuming that there is a bed of soft fireclay on the bottom, the 13 inches of top slate may be also soft and cause the pillars to slab off, thereby weakening them more. Then to stop the squeeze or retard its progress as much as possible, work not too many men, restrict the gob line, and concentrate the work as much as possible. It is difficult to give a definite answer to this question, as the conditions vary in every case. There are times when the timbers will be crushed and broken as quickly as they are put in, and at times the floor of the roadway will heave so rapidly as to afford little opportunity to save the tracks, and yet the conditions of the roof and coal are such that there is no immediate danger to the lives of the workmen employed in the necessary work of securing the roadway or saving material. It is always wise to abandon work on the coal at the face of breasts where a severe squeeze exists. This is made imperative under many conditions in order to avoid the possibility of accidents from falls of roof or coal; it is not, however, necessary at all times to withdraw the men working in other parts of the mine during the progress of the squeeze. The writer has knowledge of squeezes where approximately all of the coal was recovered. Every reasonable effort should be made to withdraw standing timber in the gob and work out such pillar coal as can be done safely in order to cause a fall and thereby relieve the entry pillars of weight. If this is done and no fall is made, it will be necessary to blast down the roof in the worked-out area to get the first fall or break.

Timbers should be set and cribs should be built in all places along the roadway where it is possible to reinforce the pillars. This work should not be abandoned as long as there is reasonable hope of controlling the squeeze. In the removal of these pillars it would be a matter of wisdom to use nothing but the best types of safety lamps and employ shot firers to blast under this thickness of cover.

Ques. 7.—*Raising Water.*—In a certain region it is desired to concentrate into one sump the drainage of several mines, amounting as a maximum to 800,000 gallons per day of 24 hours, and raise it out through a shaft 550 feet deep. Which system will be most economical and efficient—piston pumps, centrifugal pumps, or hoisting in tanks, the water being slightly acidulated? Give reasons in detail.

Ans.—A triple expansion, duplex, outside-packed, plunger steam pump would be the most economical and efficient for the following reasons: The efficiency of a centrifugal pump is less than that of a reciprocating machine. The water flows through the rotary machine at a high velocity, and in case of acidulated water the rings, bushings, impellers, etc., wear considerably, making the cost of repairs high. The initial cost of a steam pump is probably a little higher than that of a centrifugal stage pump, but it is more easily cared for. The labor costs for looking after either pump are about equal, but a rotary pump needs more attention, because of its high motor speed and its liability to lose its water unobserved, unless a check-valve is placed at the end of the suction pipe.

Centrifugal pumps for 24 hours continual service in mines are not as reliable as plunger pumps. They are more compact and take less room, but the other disadvantages are more persistent. Without going into detailed calculations, would say that the amount of steam required to run an ordinary generator to furnish power to do this work would be far more than sufficient to run the steam pump in question.

To hoist the water, would mean to keep in repair a shaft having a depth of 550 feet, equipping it with guides, buntons, tower, sheave wheels, ropes, water tanks, hoisting engines, etc., all of which would require attention and repairs. The services of an engineer would also be necessary.

The maximum amount of water to be raised would be 550 gallons per minute, and taking all things into consideration, I would prefer the old reliable steam pump.

Ques. 8.—*System of Mining.*—In the case of two seams of coal separated by 36 feet of comparatively soft strata and lying at a dip of 10 degrees, the upper seam is 6 feet thick and the lower seam is 8 feet thick, and it is desired to mine them simultaneously through one shaft 560 feet deep to the lower seam, and to have the daily production approximate 1,000 tons. The top over the upper seam is strong, that over the lower seam comparatively weak, and both seams give off considerable gas. What system of mining would be best as regards safety and economy?

[Note.—This question has been answered from the standpoint of both the anthracite and the bituminous practice. As the answers are different and especially good, a first prize has been awarded to each of the following.—Editor.]

Ans.—*Anthracite.*—The question does not give the location of the shaft on the property. In case it is to be put down on the higher elevation, a slope would be driven on the dip of the seam at a convenient place on the shaft level. Lifts would be turned at right angles to the slope. If the shaft is put down on the lower or dip end of the property, an engine plane would be driven up the pitch and lifts turned at right angles, so arranged that trips could be dropped in on to the turnouts.

In either case the engine room should be on the surface, which would eliminate the steam and heat inconveniences and lessen the danger of fire in the mine. Gangways and airways should be driven nearly level, and the chambers driven up the pitch at right angles to the gangways. This is done to give the pillars greater strength and to avoid chipping of pillars, which would probably be the case if they were driven across the pitch at an angle of 45 degrees. It would also add to the strength of the pillars very materially when the work of taking them out was commenced.

A seam 560 feet deep, 8 feet in thickness with another seam 6 feet thick 36 feet above, with comparatively weak strata intervening is in need of all the strength that it is possible to provide. The intervening strata, on account of the upper seam being gaseous, and especially if the gas is pent up with much pressure, would tend to weigh heavily on the bottom-vein pillars, causing them to chip freely and increase the danger of a squeeze.

The work suggested so far has been in the bottom seam, because it is from this seam that the coal from both seams will be hoisted to the surface. The coal from the upper seam should be mined and taken to the lower seam by means of tunnels, at convenient intervals, driven on a level with the gangway in the bottom seam, back against the pitch. The seams pitching 10 degrees and the intervening rock being 36 feet thick, the tunnels would be about 200 feet long. They could be driven from each lift and the coal brought out through them to the turnouts at the foot of each lift. The same transportation facilities would then do for both seams without installing any

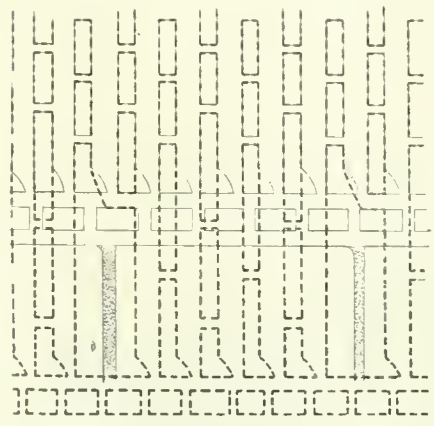

Fig. 1

machinery in the upper seam. The reduced help with such a system would pay for driving a great many tunnels during the life of the property

Good safe second openings should be driven from the bottom to the top seam for each tunnel. These openings could be additional tunnels, or shafts equipped with steps, and would be used for ventilation as well as a second way of exit.

The chief feature or successful mining in this case would be the size of the pillars to be left for support. Pillars 8 yards wide between headings and airways and 7 yards wide between chambers in each vein would make a strong mine. Places in the top seam should be driven on line immediately over the places in the bottom seam. The cross-cuts should be driven at intervals equal to the maximum distance allowed by law and alternated or staggered, so as to give all the strength possible, and that the faces of the places will not be more than one-half the distance of a pillar length away from a cross-cut when the pillars are left the maximum length.

Each seam should be ventilated separately.

The accompanying Fig. 1 shows arrangement of workings in both seams, the dotted lines representing the upper seam and the full lines the lower.

When the pillars are to be removed, it would probably be better to keep the pillar in the bottom seam about one-half a pillar length in advance of the one in the upper seam. In both seams the pillars should be drawn simultaneously. Experience in handling the breakage of the overlying strata would probably show best the proper manner of successfully removing the pillars.

S. J. Jennings,
No. 9 Prospect Place, Pittston, Pa.

Ans.—*Bituminous.*—The system of work which I would adopt under the given conditions would be bord-and-pillar panel system. My reasons for adopting such a system are because the question calls for safety and economy. As this is a gaseous mine the ventilation must be considered as the prime factor toward safety and perhaps economy. The conditions stated in this question give every inducement toward creep and thrust, so they must also be guarded against. To guard against creep and thrust and bring about a maximum of economy, strict discipline should always be enforced. Before explaining the bord-and-pillar panel system of work, it will be necessary to state that when the pillars are being formed it is known as "working in the whole," and when they are being extracted it is known as "working the broken." Bord-and-pillar working is divided into two distinct operations: First, driving narrow places 9 to 12 feet wide in the solid coal, and at every 60 to 90 feet driving places the same width at right angles, thus forming a pillar or rectangular block. The whole field is to be blocked out in this way. The panel system calls for a block of coal being left until the first panel of pillars is nearly all extracted. It is then cut into rectangular blocks and made ready for extraction when needed. This panel serves a double purpose. It is a means of confining creep to one locality, and it permits each territory to be separately ventilated, which is very important in a gaseous mine. Following up the "whole with the broken" should be commenced as soon as the first panel of pillars reaches the line. The great advantage of this method of working, as compared with the older system of forming pillars over large areas, is that the pillars stand only a short time after being formed, therefore better coal may be got and a larger number of men can be employed, hence a larger output or capacity. In simultaneous working of bord-and-pillar system, great precaution should be taken to see that both veins be kept in such a position as to allow the angle of break to be uniform; the angle of break may be approximated at 45 degrees; this is another great feature in favor of economy. In conclusion, the width of a panel should be at least the width of two pillars and the full length of the territory.

THE LETTER BOX

Readers are invited to ask or answer any question pertaining to mining, or to express their views on mining subjects in this department. All communications must be accompanied by the name and address of the writer—not necessarily for publication.
The editors are not responsible for views expressed by correspondents.

Are "Heat Waves" Visible

Editor The Colliery Engineer:

Sir:—Can any of your readers tell me why it is that we see "heat waves" when a current of warm air strikes a body of cold air or when a current of cold air strikes a body of warm air? The hot gases ascending from the top of a chimney are apparently visible, but are they really visible and what is the reason that they appear to be so?

Changing Hoisting Ropes

Editor The Colliery Engineer:

Sir:—Can any of your correspondents tell me how to change ends on our hoisting rope, the lay-out being shown in Fig. 1. It is about 3,600

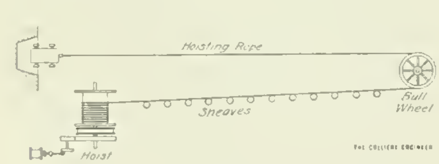

Fig. 1

feet from the engine to the bull wheel, and the sheaves, which are placed every 100 feet on the engine side of the bull wheel, are closed and not easy to open. What we want to do is to use the end now on the drum for attaching to the trip and vice versa, without going to the trouble and expense of opening the sheaves.

Superintendent

Law Regarding Mine Inspectors

Editor The Colliery Engineer:

Sir:—While all of us acknowledge the desirability and necessity for examination of mine foremen, superintendents, mine inspectors, etc., about the mines, still the most of us realize that in point of practical experience and technical knowledge a man may stand the very best examination in every respect and still be entirely unfit for one of these places.

Two years ago I submitted the following clause to be added to the mining law then before the legislature:

"Provided—That in the event of an accident costing the lives of twenty-five or more men, or if the death record for a year exceed that of one life lost for two hundred thousand tons of coal mined, then the tenure of office of the Chief Mine Inspector shall terminate automatically, but he shall be eligible to reappointment by the Governor."

The operators firmly opposed this. The miners were willing for it to go in, but indifferent.

The Governor favored it, so they compromised and left to the Governor the power to discharge any mine Inspector at any time with or without cause.

This is the law in Alabama today. I would like to have the views of those interested on this subject.

My idea is that mining laws are passed for the protection of those working in the mines.

That the law should be such that the Governor will only keep in charge of that department a suitable man. That the Governor should be relieved from having to discharge an official, but the law should be so that he can keep the same man in office if he thinks best.

J. de B. Hooper
Dixie Springs, Ala.

Booster Fans

Editor The Colliery Engineer:

Sir:—Herewith find an answer to Mine Manager's query in your January issue regarding booster fans. While not a superintendent or other mine official at present, I have been employed in and around mines from trapper up, therefore, I speak whereof I know.

Being employed in this instance as electrician, it fell in my line of duty to instal a "booster fan." The main fan was a steam-driven affair, running at about the limit of its speed with the load it had; viz., 60,000 cubic feet per minute. It was desired to raise this amount to 85,000 or 90,000 cubic feet, hence, the booster.

It was installed at the point marked $3x$. shown in Fig. 2, three-fourths of the total air being wanted down this airway. The booster was of the same capacity as the main fan. When started up, all air entering main airway went to booster, none went down the airway on the north side of first dip. This not being satisfactory, the fan was moved to point $2x$ in the main airway to boost the entire input; the amount going to the north side of the first dip being proportioned by a regulator. The booster did boost about 10,000 cubic feet per minute, running at full capacity, using a 25-horsepower motor which cost about $9 per day of 24 hours to operate. An expensive 10,000 cubic feet that!

An experiment follows: New gearing was made, that slightly increased the speed of the booster, and it was put on one Sunday morning. Conditions were ideal for an experiment. Air measures with both fans going before the gearing was changed on the booster, showed 70,000 cubic feet.

The outside fan was stopped, new gears were put on the booster and when started the air measured 85,000 cubic feet. With the old gear, the fan motor had a current consumption of 19 kilowatts, with the new gear 26 kilowatts. The motor, rated at 25 horsepower with a current consumption of 19 kilowatts, developed slightly better than 35 horsepower during the test with the new gearing.

Evidently these tests were not satisfactory to the management, for very soon the various parts of a new fan began to arrive which upon installation furnished all the air needed (with approximately 35 horsepower), running a little above half speed.

From the foregoing, I concluded that boosters were all right, say to boost the air in an out-of-the-way entry with an airway full of obstructions, that it would cost too much to clean up, but to boost the entire intake, never!

I might add that this opinion was shared by a former Mine Inspector of the State of Colorado.

I would call the reader's attention to the statement of fan capacities, each one 60,000 cubic feet, both together 70,000 cubic feet.

If 25 horsepower would deliver 60,000 cubic feet, which it did, why did it take 25 horsepower to boost just one-sixth of that amount?

I believe that if the above booster had been put on the extreme return there would have been more benefit realized than there was. How much more, I am not prepared to say.

33—8—6

I learn from this and other instances of a like nature, that if you want a greater amount of air in a mine, the only thing to do is to get a larger fan, and thereby save trouble and expense.

The foregoing figures are approximately correct, as applied to motor current, etc., but have been slightly altered as to air—the relative values, however, are correct, or nearly so.

Miner.

Editor The Colliery Engineer:

Sir:—In answer to the question asked by Manager in the January issue of Mines and Minerals regarding booster fans, I would say that such fans will help under certain conditions. I have installed one under the following conditions: I put a "booster" fan in the return airway and used one of 25 per cent. greater efficiency than the fan which was outside. But there are so many various local conditions to be considered that there is no rule in general by which you may go. If Manager would give me the details of the trouble I should be glad to give him a plan that I have used successfully in a number of such cases. Local conditions however must be considered first.

H. Gedosh.

Poteau, Okla.

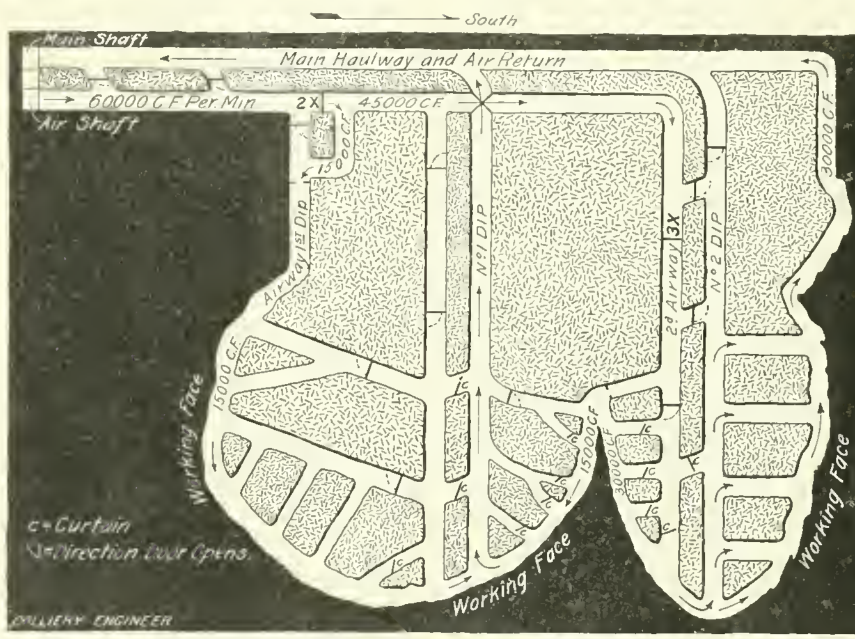

Fig. 2. Installation of a Booster Fan

Fast Hoisting at English Collieries

The following leading British collieries, which show fast hoisting under normal conditions, supply good examples of modern practice: Dowlais mine, Cardiff, 2,220 feet in 52 seconds, an average winding speed of 2,562 feet per minute; Ashton Moss colliery, 2,850 feet in 1 minute 25 seconds, or 2,010 feet per minute; Lady Windsor colliery, 1,500 feet in 35 seconds, or 2,571 feet per minute; Bolsover colliery, 1,116 feet in 28 seconds, or 2,388 feet per minute; Denaby and Cadeby collieries, 2,289 feet in 55 seconds, or 2,497 feet per minute; Rhodes Rotherham colliery, 1,650 feet in 45 minutes, or 2,358 feet per minute; while at the Rosebridge colliery, a maximum hoisting speed of 5,100 feet per minute has been recorded; but this is excessive, as, for considerations of safety, it should not exceed 4,000 feet per minute. From the foregoing data, and taking into consideration the needs of a regular output, an average hoisting speed of 3,000 feet per minute may be assumed to represent the best modern practice in England. A comparison of these figures with American and Continental practice would be of interest.

Answers to Examination Questions

Questions Asked at the Examination for the State Mine Inspector of Colorado, in 1911

(Concluded from February Issue)

QUES. 38.—What kind of safety lamps have you used in places where firedamp was known to exist? What lamp do you prefer and why?

ANS.—The answer to this question will vary according to the experience of the candidate. Some guide to the choice of the lamp is afforded by the answer to Ques. 18. A good lamp should possess the qualities named therein.

QUES. 39.—What is the highest percentage of explosive gas in which you deem it safe to carry on blasting operations in the mine?

ANS.—So much depends upon local conditions which are not named in the question that a precise answer is difficult to give. If the coal is properly undercut, the holes properly placed and properly charged with a permissible, short-flamed powder, and if dust is not allowed to accumulate, and the face, floor, ribs, roof, and timbers are *thoroughly* washed down and saturated with water for from 60 to 100 feet back from the face, electric shot firing is probably safe with as much as 4 per cent. of methane present, provided this amount of gas is confined to that portion of the working place which is inby the last cross-cut, and is not everywhere present in the mine air.

Under adverse conditions, where the coal is very dry and dusty and where watering is not employed, and particularly in those mines where black powder is used and the shooting done off the solid, blasting is absolutely unsafe, whether a mere trace of gas only is present or none at all, as a blown-out shot can easily ignite the inflammable dust.

QUES. 40.—Explain the law of the diffusion of gases, and its effect on their behavior in mines. Give rule and example showing how to find the comparative velocity of the diffusion of different gases.

ANS.—When a space is occupied by a certain gas and another gas is gently liberated into the same space, the velocity with which the gases will diffuse or mix uniformly with one another is proportional to the square root of the densities, or specific gravities, of the two gases. The operation of this law is to cause methane, carbon dioxide, or any other gas given off by a seam, to make a uniform, homogeneous mixture with the mine air, if sufficient time is allowed for the process of diffusion. Specific gravities are usually referred, in the case of gases, to air as unity. Thus, air being the unit, the specific gravity of methane is .559. The relative rate of diffusion of air and methane is, by the law given, as $\sqrt{1} : \sqrt{.558}$, or as 1 : .748; that is, 1,000 volumes of methane will diffuse into air in the same length of time that 748 volumes of air will diffuse into methane. Similarly, the specific gravity of carbon dioxide, CO_2, being 1.529, the velocity of diffusion is in the ratio $\sqrt{1} : \sqrt{1.529}$ or as 1 : 1,237; that is, 1,000 volumes of CO_2 will diffuse into air in the same length of time that 1,237 volumes of air will diffuse into CO_2.

QUES. 41.—Give a brief description of the Draeger helmet and what is it used for?

ANS.—This is one of the several types of helmet, or "rescue" apparatus, used in recovering mines after an explosion when the workings are full of poisonous gases. It consists essentially of a leather helmet, strengthened by ribs of wire, worn on the head, the part covering the face being provided with a plate of transparent mica so that the user can see. The helmet is air-tight and fits the head by means of an inflated rubber tube so closely that no outside air can enter through or around it. On the back of the wearer are two steel cylinders containing pure oxygen gas under a pressure of 125 to 150 atmospheres, a supply sufficient to last for 2 hours. On the back are also two tin flattened cylinders containing caustic soda or potash, the duty of which is to absorb the CO_2 given off by the breath. On the chest is worn a rubber-lined leather air bag divided by an interior partition into two parts.

When in use, the impure air from the lungs passes through a flexible tube to one compartment of the air bag and thence through other tubes to the potash cylinders, or cartridges, where the CO_2 is absorbed. This air is then charged with oxygen from the storage tanks, goes to the second compartment of the air bag, and thence by another flexible tube to the helmet for the use of the wearer. This cycle of operations is kept up as long as oxygen remains in the cylinders.

QUES. 42.—What is an explosive?

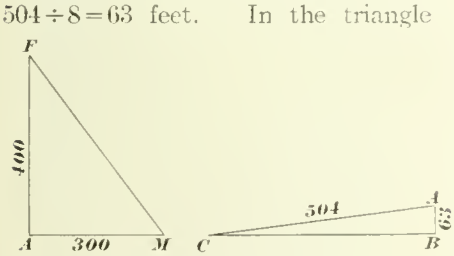
ANS.—An explosive is either a single chemical compound or a mixture of such compounds which, upon the application of heat, is instantly (for all practical purposes) converted into a large volume of gas through the decomposition or combination of the elements entering into its composition.

QUES. 43.—What are the threefold principles of all safety lamps?

ANS.—The question is not quite clear. The essential features of safety lamps have been given in the answer to Ques. 18. The single principle upon which a safety lamp differs from an ordinary lamp is the isolation of the flame from the outer air by a wire gauze; and the application of this principle is common to all safety lamps. The action of the gauze is: the burning gas in passing out through its meshes is divided into a series of very thin streams or jets, the temperature of which is reduced below the point of ignition by contact with the cool metal, and the flame thus is extinguished before it has had an opportunity to ignite the methane in the external air.

QUES. 44.—A slope dips 1 foot in 8 feet for a distance of 504 feet measured on the slope. What is the difference in elevation between the mouth and face and what is the horizontal distance between them?

ANS.—The total rise of the slope is $504 \div 8 = 63$ feet. In the triangle



(a) FIG. 1 (b)

ABC, Fig. 1 (b), the side $AB = 63$ represents the difference in elevation of the mouth and face, and the hypotenuse, AC, is the slope distance, 504 feet. The horizontal distance,

$$BC = \sqrt{AC^2 - BC^2} = \sqrt{504^2 - 63^2}$$
$$= \sqrt{250,047} = 500.46 \text{ feet.}$$

QUES. 45.—What do you understand by a water blast in a coal mine?

ANS.—A water blast is a sudden inrush of air from old workings which have been tapped at a point above the level of the water contained in them. The workings are, naturally, those which have been driven to the rise, and their upper portion contains air under pressure of water, the surface of the main portion of which is at a higher elevation than that in the room in question. The greater the head of water, the more will the air be compressed, and the more violent will be the "water blast" when the workings are tapped.

QUES. 46.— 100,000 cubic feet of air pass through an airway 6 ft.×5 ft. in sectional area, and 10,000 feet long, which is divided into three splits as follows: Split A is 6 ft. ×6 ft. in section, 2,000 feet long; split B is 6 ft.×5 ft. in section, 4,000 feet long; and split C is 6 ft.×4 ft. in section, 6,000 feet long. What quantity of air will pass in each split while the pressure remains the same?

ANS.—The main airway need not be considered in the calculation if we assume that the three splits start from the same point at its end and that the pressure is the same at the mouth of each.

The quantity passing each split will be proportional to the expression $a\sqrt{\frac{a}{s}}$, in which a = the area of the airway and s = the rubbing surface. For split A, $a = 6\times6 = 36$ square feet, and $s = (6+6+6+6)\times2,000 = 24,000$ square feet; for split B, $a = 6\times5 = 30$ square feet, and $s = (6+6+5+5)\times4,000 = 88,000$ square feet; for split C, $a = 6\times4 = 24$ square feet, and $s = (6+6+4+4)\times6,000 = 120,000$ square feet. By substituting these values in the above expression the relative quantity of air passing in each split is

$$\text{Split } A = a\sqrt{\frac{a}{s}} = 36\sqrt{\frac{36}{48,000}} = .9859$$

$$\text{Split } B = a\sqrt{\frac{a}{s}} = 30\sqrt{\frac{30}{88,000}} = .5539$$

$$\text{Split } C = a\sqrt{\frac{a}{s}} = 24\sqrt{\frac{24}{120,000}} = .3394$$

$$1.8792$$

The quantity of air passing in each split is equal to the total amount of air in circulation multiplied by the ratio of each of these individual ratios to the sum of the three individual ratios, and

$$\text{Split } A = \frac{.9859}{1.8792}\times100,000$$
$$= 52,464 \text{ cubic feet.}$$

$$\text{Split } B = \frac{.5539}{1.8792}\times100,000$$
$$= 29,475 \text{ cubic feet.}$$

$$\text{Split } C = \frac{.3394}{1.8792}\times100,000$$
$$= 18,061 \text{ cubic feet.}$$

QUES. 47.—Does a high water gauge always indicate a large quantity of air passing? What does a low water gauge with a large quantity of of air passing indicate?

ANS.—No; a high water gauge only indicates great resistance to the passage of the air through the mine. This resistance may indicate long airways or those of too small area and but a small amount of air in circulation, as well as meaning a large volume of air moving at high velocity.

A low water gauge with a large quantity of air passing indicates large and unobstructed, or short, airways of good area.

QUES. 48.—What is a dumb drift, and why is it used in gaseous mines?

ANS.—While the use of furnaces should be, and is in many states, prohibited by law, yet they are still to be found at small mines. When the return air-current is heavily charged with methane it cannot be carried through the fire of the furnace without serious danger of an explosion. Under such circumstances the furnace drift is isolated from the rest of the workings and the fire fed by a separate split of air from the main intake. At any convenient distance inby the furnace, a tunnel is driven through the rock on such a grade as to strike the furnace shaft at a point above the fire where the furnace gases are cooled below the temperature of ignition of methane. This rock tunnel, which conveys the return air-current of the mine over the furnace, is known as a dumb drift.

QUES. 49.—Find the rubbing surfaces of three airways each 6,000 feet long and all having the same sectional area, 75 square feet. The forms of the three sections are as follows: The first, A, is rectangular, 5 feet high and 15 feet wide; the second, B, is square; and the third, C, is circular.

Ans.—It is first necessary to find the perimeter of each airway. The perimeter of $A=5+5+15+15=40$ feet; the side of the square forming the airway, B, is $\sqrt{75}=8.66$ feet, and the perimeter is $4\times 8.66=34.64$ feet; and for C the diameter of the circular airway is $\sqrt{\frac{75}{.7854}}=9.77$ feet, and the perimeter is $9.77\times 3.1416=30.69$ feet.

The rubbing surfaces are, thence: $A=40\times 6{,}000=240{,}000$ square feet; $B=34.64\times 6{,}000=207{,}840$ square feet; $C=30.69\times 6{,}000=184{,}140$ square feet.

Ques. 50.—In an airway that has three sides, 6, 8, and 10 feet, respectively, and is 900 yards long, what is the area, perimeter, and rubbing surface? What quantity of air will be passing in this airway with a velocity of 425 feet per minute?

Ans.—This airway is in the shape of a right-angled triangle, the base of which is 8 feet and the altitude 6 feet. Its area is, thence, equal to $\frac{6\times 8}{2}=24$ square feet. Perimeter: This is found by adding together the lengths of the sides and is $6+8+10=24$ feet. Rubbing surface: This is equal to the perimeter multiplied by the length $=24\times(3\times 900)=64{,}800$ square feet. The quantity of air passing is $24\times 425=10{,}200$ cubic feet a minute.

Ques. 51.—How many horsepower will it take to pull 20 loaded cars up an incline 400 feet long in 1 minute, the weight of the coal in each car being 3,000 pounds, and the weight of the empty car 900 pounds; the resistance of the rope and pulleys is 13 per cent. and the grade is 7 per cent.?

Ans.—The weight of each loaded car equals $3{,}000+900=3{,}900$ pounds. As there are 20 such cars the total weight hoisted is $20\times 3{,}900=78{,}000$ pounds. But the resistance of the rope and cars, that is, the friction of the wheels on the axles and rails and that of the rope and rollers, is equivalent to that of a certain weight, which is estimated to be 13 per cent. of the real load lifted. This added "resistance" weight is equal to $78{,}000\times .13=10{,}140$ pounds. The weight the engine has to overcome is thus $78{,}000+10{,}140=88{,}140$ pounds. The distance through which this weight is raised in 1 minute, which is the unit of time in estimating work, is $400\times .07=28$ feet (the grade being 7 per cent., or 7 feet in each 100 feet, or .07 foot per foot).

$$\text{Hp.}=\frac{\text{Wt.}\times\text{Vert. Dist.}\times\text{Time}}{33{,}000}$$

$$=\frac{88{,}140\times 28\times 1}{33{,}000}=74.78+\text{ Hp.}$$

Ques. 52.—Presuming you had a 30-foot room in an 11-foot seam of coal pitching from 45 to 50 degrees with a 300-foot lift and a 50-foot pillar on each side, and that the room had been carried to a smooth 7 feet from the foot-wall and the coal taken out; how would you take the remaining 4 feet of top coal, starting the work from the bottom with a view of getting the highest possible amount of the 4 feet of top coal, and provide for the safety of the miners? Give answer briefly.

Ans.—If the top coal is still in place, as the question indicates, the method of mining would be the same as that employed in originally working out the lower 7-foot bench. The method used would be the room-and-pillar, with a battery at the room neck similar to that described in the answer to Ques. 37. It will be necessary to leave inside the battery sufficient loose coal for the miners to stand upon in order to reach the roof coal which they are working out. If the seam is gaseous, the original manway, which is also an airway, as shown in the cut under Ques. 37, will have to be replaced with one of the posts which are 11 feet long. The chutes, cross-cuts between rooms, and those connecting the room manway with the main return, used in the original working, may all be used in working out the top coal.

Ques. 53.—A pipe line in the slope of a mine has an area of 144 square inches, and is 3,000 feet long; the slope is on a grade of 1 in 10; what is the pressure per square inch at the bottom of the pipe when it is full of water?

Ans.—As the grade of the slope is 1 in 10, the vertical depth of the slope, which is the same as the head of water causing pressure on the bottom of the pipe, is $3{,}000\div 10=300$ feet. As a column of water 1 square inch in cross-section and 1 foot high weighs .434 pound, the pressure upon the bottom of the pipe will be $300\times .434=130.20$ pounds per square inch. The total area (144 square inches) of the pipe does not affect the pressure per individual square inch. The total pressure on the bottom of the pipe would be $144\times 130.20=187{,}488$ pounds.

Ques. 54.—Give the comparative advantages and disadvantages of the longwall and room-and-pillar methods of working coal mines.

Ans.—The main advantages of the longwall system of mining are: (*a*) the removal of all the coal in one operation with the minimum amount of roadways, working places, etc., to be maintained; (*b*) concentration of work in a continuous face making systematic working and proper supervision of men and operations much easier; (*c*) the gaining of a larger percentage of lump coal with a much less amount of powder, with consequent higher wages for the men, a better selling price for his product for the operator, and with lessened liability to all classes of accidents due to the use of explosives; (*d*) the maintenance of a minimum length of roadways until all the coal is removed, whereas in the room-and-pillar system (as ordinarily employed) many thousand feet of entries and rooms must be kept open until the pillars are drawn; (*e*) better and more efficient ventilation with decreased liability of gob fires, roof falls, etc.; (*f*) the risk of creep or squeeze is reduced to a minimum and the surface settles uniformly and evenly, whereas in room-and-pillar working, squeezes are common and the surface caves in a series of irregular breaks; (*g*) there is no expense for narrow work, and usually the expense for haulage and timbering is less than under the room-and-pillar system.

The chief disadvantages of the longwall system of working are: (*a*) in gaseous workings, the impossibility of isolating any particularly dangerous part of the mine, or the impossibility of dividing the mine into a series of disconnected panels or districts and thus confining the effects of an explosion to a small extent of the workings; (*b*) where the mine is not operated continuously, that is, where the car supply is poor and there are numerous idle days, the expense of keeping open the average longwall face is much greater than that required to keep in proper condition the rooms and entries in a mine operated under the room-and-pillar system; (*c*) the system is expensive where the coal is pitching steeply, where the roof is strong, and when the seam is clean and does not furnish sufficient rock for stowing.

Ques. 55.—If the anemometer records a velocity of 500 feet per minute in an intake airway having a sectional area of 60 square feet, and the thermometer shows a temperature of 32° F., what will be the volume of air passing in the same airway per minute, when the temperature has risen to 60° F.?

Ans.—The volume of air passing through the intake is $60 \times 500 = 30{,}000$ cubic feet per minute.

The change in the volume of any gas through an increase in its temperature is proportional to the absolute temperature, which is measured from the absolute zero, which is 459 degrees below the zero of the ordinary Fahrenheit scale. The absolute temperature of the intake air is $459° + 32° = 491°$, and that at the higher temperature is $459° + 60° = 519°$. The volume at the higher temperature is $\frac{519}{491} \times 30{,}000 = 31{,}711$ cubic feet.

Considerable coal is briquetted in South Wales. The briquets are of large size, and weigh from 14 to 28 pounds, the latter being generally in demand on account of the convenience in handling. These briquets are shipped abroad for steam raising, chiefly for railroad use, particularly in tropical countries where their gas retaining properties make them more valuable than coal.

The Use of Explosives in Coal Mines

*By F. H. Gunsolus**

When the problem is to get an explosive to be used in coal mines where gas and dust are present in dangerous quantities, the temperature factor of strength must be eliminated as far as possible in order to reduce the possibility of igniting the gas or dust by the blasts. In short, the strength of the best permissible explosives must necessarily be not equal to those of the higher grade dynamites. The strongest explosives on the United States Permissible List are the Monobels. By the use of ammonia nitrate as a base it is possible to manufacture a permissible explosive having a weight for weight strength equal to a 60-per-cent. dynamite, but on account of the low specific gravity of nitrate of ammonia, the bulk for bulk, or cartridge for cartridge, strength is only equal to that of a 35-per-cent. dynamite. Fortunately it is only on rare occasions that rock is encountered in coal mines, where extra strong explosives are required to give the most economical results. If this kind of rock is encountered where there is danger of gas or dust explosions, the only method of blasting to follow is to give the holes lighter burdens and use the permissible explosives.

The blasting of the coal itself is a problem of getting out the largest percentage possible in the shape desired, rather than to reduce the actual cost of extraction to the lowest possible figure. For instance, it is cheaper and the output per man is greater, to smash the coal up fine in the blasting, because it can be shovelled up in less time, than to break it in large lumps. But on the other hand the prices obtained for the large sizes of coal are enough higher to make it an object, except where the coal is to be coked, to maintain the output of lump coal at a maximum.

When blasting powder was the principal explosive used in coal mines, where the seams were undercut, the holes were placed in different positions than is done at the present time when permissible explosives have largely replaced blasting powder. With blasting powder, the holes were bored fairly flat about two-thirds of the distance from the floor to the roof. When permissible explosives were introduced, it was found that with undercut coal better results were obtained if the holes were started from 12 to 18 inches below the roof and given an upward slant that would bring the point against the roof about directly over the back of the cut. Also, where the tight shot is on one side of the room instead of the middle of the face, the blast would make more lump coal if the hole was about 18 inches from the rib.

In the coke regions the desire is to break the coal as fine as possible in the blasting. The rooms are narrower and in some fields often the blasting is done from the solid.

The first permissible explosives placed on the market caused some complaint by the producers of lump coal to the effect that they smashed the coal too much, thereby increasing the production of fine coal and diminishing their profits. This led to an extended study of their requirements by the principal manufacturers of explosives, and the consequent production of permissible explosives better adapted for the production of lump coal.

Among the best producers of lump coal are Monobel No. 3 and Monobel No. 5. These two powders, No. 5 being a low-freezing explosive, have the nearest approach to the action of blasting powder that it is possible to obtain with a high explosive, and when they are properly used will produce as much lump coal as the best grades of blasting powder. For coking coals and anthracite, Monobel No. 1, No. 2, No. 4, and No. 6 will give good results.

Where the work is wet the Carbonites will probably be more reliable. The Carbonites are really low-flame dynamites that have passed the United States Government tests

*Wilmington, Del., Manager Technical Div. E. I. duPont de Nemours Powder Co.

for permissible explosives and have the same water-resisting qualities as the ordinary dynamite. The Carbonites can be made with practically the same variations in quickness as the Monobels but where the latter can be used satisfactorily, they are to be preferred.

With the permissible explosives it is of the utmost importance to use strong detonators. The United States Government, with the exception of one or two that require stronger, states that the coal-mine explosives are only permissible when used with No. 6 or stronger blasting caps or electric fuses. In addition to this, photographs show that the flame of detonation of the permissible explosives is reduced when they are shot by means of No. 7 and No. 8 blasting caps or electric fuses. Also, the use of strong detonators increases the work done by the explosive and reduces the production of obnoxious fumes.

The best method for firing charges of permissible explosives is to blast by electricity. There are several cases on record where mine gas has been ignited by the spit from freshly lighted fuse.

It is also of the utmost importance to tamp charges well. This not only greatly increases the work done by the explosive (given as 30 per cent. increase in the United States Government tests) but it prevents flame from projecting out into the working places and reduces the amount of the bad fumes liberated.

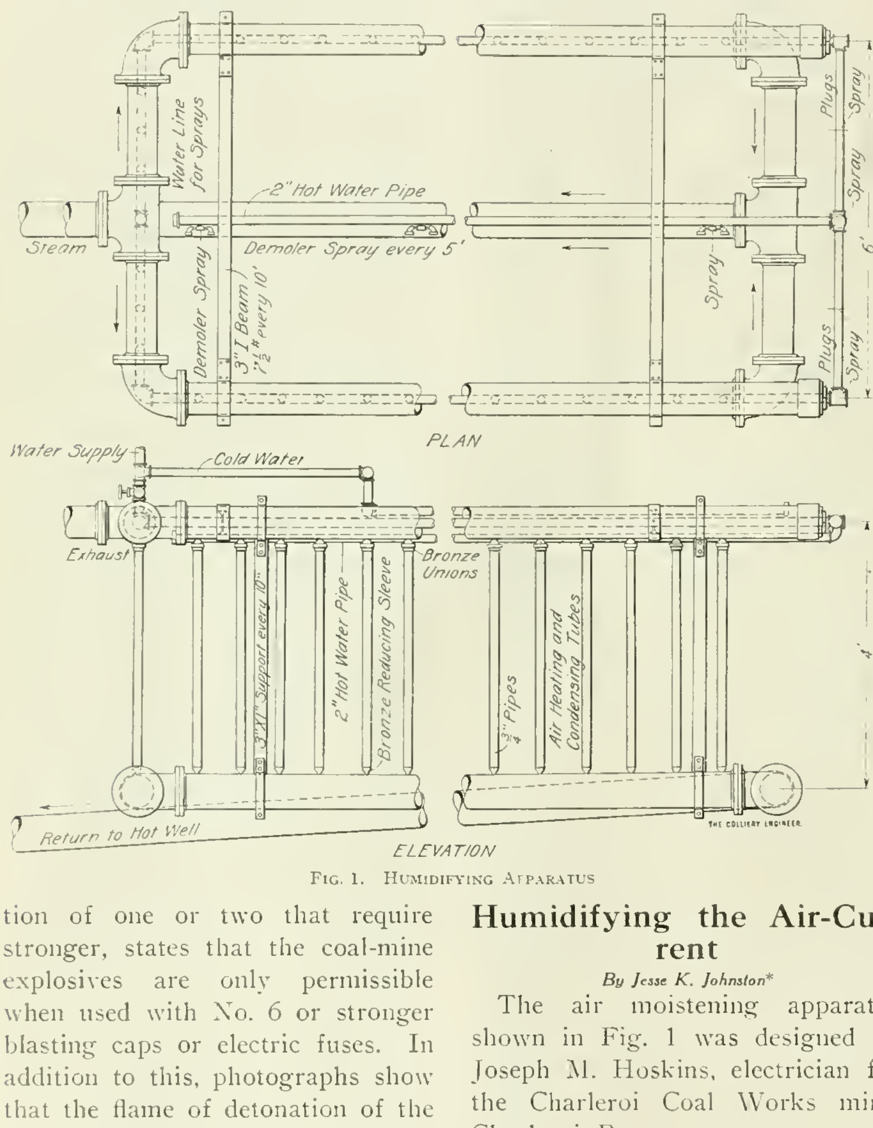


Fig. 1. Humidifying Apparatus

Humidifying the Air-Current

*By Jesse K. Johnston**

The air moistening apparatus shown in Fig. 1 was designed by Joseph M. Hoskins, electrician for the Charleroi Coal Works mine, Charleroi, Pa.

It was first put into operation in 1905, being one of the first systems used for humidifying air ventilating currents in southwestern Pennsylvania. The apparatus is used to heat the air going into the mine so that it will absorb a high percentage of moisture, and it is arranged so that warm water is used in winter time and cold water in summer. On account of the cold outside air in winter time having very little moisture, it rapidly dries out the mine dust inside of the mine and, therefore, warm water must be used in connection with the apparatus in order to equalize the inside temperature of the mine and have a large percentage of moisture in the mine air.

The apparatus is placed about 25 feet inside of the mine in the intake airway and receives the exhaust steam from the 20-foot Vulcan exhaust Guibal fan, on the return airway; the exhaust steam from the fan enters the center of the top cross-connecting pipe and is distributed along the top pipes. The ends of these pipes being plugged, the steam passes through the ⅜-inch openings into the ¾-inch pipes which condense the steam into water. The water then passes through the lower ⅜-inch holes into the bottom pipes, and then passes to the far end, where it enters the lower cross-connecting pipe and from the pipe it enters to the hot well.

The water line for the sprays enters the top cross-connecting pipe at the center, passes through the inside of the top pipes to the far end, then returns back in the center pipe to the front end. Demoler and Simplex spray nozzles are placed on each side of the water line every 5 feet or closer if desired, and, as stated, warm water can be used in the winter and cold water in the summer.

The air cocks on the inside of the exhaust steam pipes are to allow the desired amount of steam to be admitted to the air, and they can be placed at any distance apart that seems desirable.

The 20-foot Vulcan exhaust Guibal fan ventilates a coal field of about 1,200 acres. Hygrometer readings are taken at regular intervals at different points inside of the mine and have proven this apparatus to be very efficient in moistening the mine air.

*General Mine Superintendent, Charleroi Coal Works, Charleroi, Pa.

NEW MINING MACHINERY

New Safety Catch for Hoists

The new safety catch invented by Peter Hinkle is being installed by A. F. Plock, Park Building, Pittsburg.

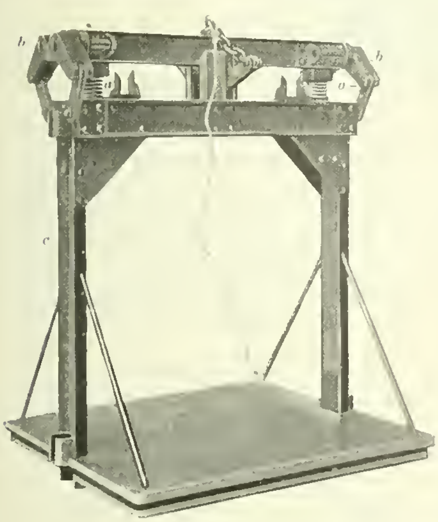

Fig. 1. Safety Catch on Cage

The catch may be applied to both cages and skips, and is arranged so as to form a double safety guard in case the hoisting rope breaks. As shown in Fig. 1 there are two powerful springs *a*, which bring the eccentric grippers *b*, in contact with the cage guides, not shown, but over which the cage shoes *c*, slide.

The mechanism employed to actuate the safety catch is entirely independent of the load carried by the cages, or the power used. But when once applied, the weight of the car and its load holds the cage locked to the guides and it is no longer dependent on the springs.

The device can be installed without any changes to the cage or the guides. In Fig. 2 is shown a skip with the safety cams *a* gripping iron or steel cage guides *b* and *c*. The guide *b* is worn until it is only one-quarter of the original thickness and the other guide *c* is only about three-fourths of the original thickness. It matters not how badly worn the guides may become on one or both sides, so long as there is a guide left the safety device will hold tight; besides, each side works independently of the other.

The presence of the guide shoes and guides make it impossible for the skip to jump the track, as is often the case with some kinds of skips, a feature which although not new prevents serious damages and delay.

Fig. 1 shows the cage of a vertical hoist. A number of tests have been made on a recent installation of this kind where varying loads up to 6 tons were "cut loose" and at no time did the device fail to stop the load instantly.

It is interesting to know that the smoother the faces of the cams the tighter they grip steel guides, and a cam designed for steel guides will not work satisfactorily on wooden guides. The powerful grip of the smooth cam

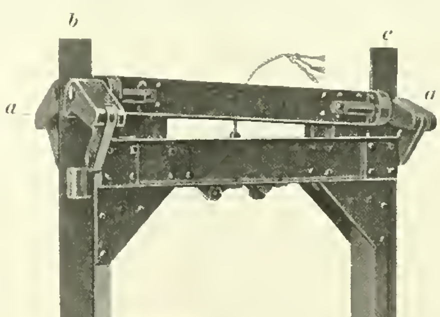

Fig 2 Safety Catch on Skip

causes the wood to spring outward, partly due to the oil which penetrates the guide and partly due to the elasticity of the wood. Thus it was found necessary to employ a cam or eccentric with a corrugated face, after the manner of ordinary corrugated iron, and arranged in such

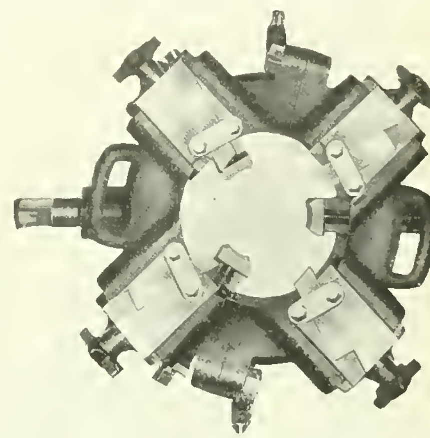

Fig. 3. Hand-Operated Pipe-Cutting Machine

manner that no sharp edges exist to injure the wooden guides. Even wooden guides are not injured by the action of the cams or eccentric in locking the cage; and the cams are immediately released and returned to their normal working position, so soon as sufficient tension exists in the hoisting rope, and the cage is again ready for service.

The safety catch will hold the cage in the shaft while necessary repairs are being made either to the hoisting rope or hoisting machinery. This dispenses with the necessity of holding the cage or car in place by means of chain blocks or other rigging as is often the case.

Pipe Cutter

The Toledo Pipe Threading Machine Co. is manufacturing a hand-operated pipe-cutting machine Fig. 3 for pipes ranging in size from $2\frac{1}{2}$ inches to 6 inches, inclusive. The cutting is done by four knives which are automatically fed by star feed. Two of these knives are beveled across the edge and cut out a V-shaped section of the pipe; the other two knives are square and follow in the V-shaped cut, cutting out the edges, thus eliminating any tendency the knives might have to bind in the cut. The tool is fastened to the pipe by a three-jawed chuck, each jaw being actuated independently and containing a set of size marks so the tool can be centered on the pipe. The knives are set down to the pipe by turning the stars by hand until each knife in succession comes in contact with the pipe.

The tool is driven by a pinion working on a bevel gear, the pinion being turned by means of a ratchet and handle. In order that the pipe which is already in place may be cut in two, the cutter is made in two parts and can be taken apart by removing four cap screws. When fastened together additional stiffness is given by dowel pins.

Temporary Electric Bond

The Ohio Brass Co. is manufacturing a rail bond for tracks in mines where electric locomotives operate, which can be used many times and is suitable for temporary tracks. It is well known that tracks are often laid down for temporary purposes only, but which need to be bonded while they are used.

Briefly, the Type N bond consists of two tapered steel terminals joined together by a flexible copper cable as shown in Fig. 4. The cable is headed and soldered into the terminals and the terminals are tinned all over. The taper has been carefully worked out so that when the bonds are first installed they need only be driven in a slight distance, and then the next time they are installed they are driven a little further, etc.

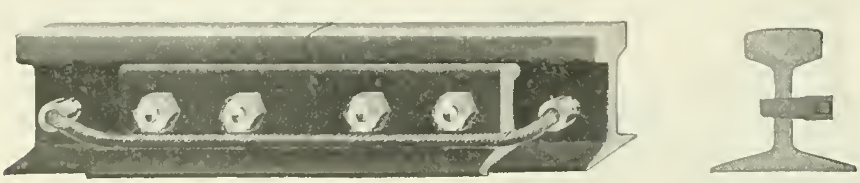

Fig. 4. Removable Bond, Installed and Sectional View

The compressed terminal bond is recommended for permanent work as the connection is better, but the use of this bond once, destroys the terminal, so that it cannot be used again. The steel terminal bond however can be used again and can be rapidly placed, requiring only that a $\frac{5}{8}$-inch hole be drilled in the rail and then the terminal driven in tight with a hammer. It is made up in 00 capacity only.

Brownell Engine

The application of several new ideas, and of other features not heretofore applied in steam engine design has resulted in the production of an engine, by The Brownell Company, of Dayton, Ohio, that has been highly commended by mechanical engineers. A general view of this new engine is shown in Fig. 5.

In this engine great flexibility in speeds and powers is secured by interchangeability of parts so that any size cylinder and stroke desired may be obtained. The frame is also constructed in such a way that fly wheels and cylinders of varying size may be used. In the construction of the frame extra metal is used, and where necessary, additional internal ribs are provided to stiffen and increase its strength. Between the guides and the cylinder a space is provided which forms a chamber into which the oil and water from the stuffingboxes drain. From here the oil and water flow to a pan, in the base of the frame, from which it can be drawn and filtered for reuse. The splash system of oiling, common in gas-engine practice, but new when applied to large steam engines has been so designed as to thoroughly confine the oil. The bottom of the cover plate which closes the opening to the crosshead, fits into a cast-iron groove draining to the guide chamber, from which the oil is carried by gravity to the main oil reservoir. There is also a covering or casing over the eccentric which carries the oil to the main reservoir.

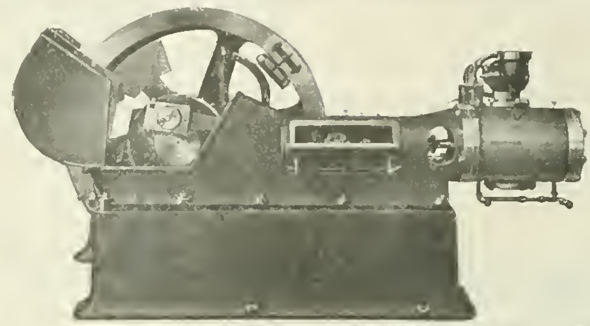

Fig. 5. The Brownell Engine

The four-part main bearing has an extra large bearing area to insure cool running. To prevent end motion the bottom piece fits into a bored seat with tongue and groove. Both side pieces are adjusted by wedges at each end, bearing the distance pieces, and the adjustment is made by means of bolts through the cap. The top piece is adjusted by liners and is held down by jamb screws through the cap. All pieces are babbitted and provided with oil grooves starting from the upper edge, but which do not carry quite to the lower edge, so that the grooves must fill before the oil will be wiped across the bridge into the reservoir formed by beveling back the quarter-box edges, from which the next grooves below take their supply.

Enclosing the crank disk, which is forced on the shaft by hydraulic pressure, there is a casing of planished steel and polished angles. This casing is vented by a hole, in the upper handle, having an L outlet, so that the oil is not forced out.

The solid end connecting-rod has split boxes with wedge adjustment in the same direction, and turns on a crosshead pin held into the head by a flange and four clamp bolts. Two distance screws through the flange and bearing on the crosshead, serve to remove the pin. The pin may be turned 90 degrees to insure even wear. The crosshead shoes have large bearing area with oil grooves cast in the surface; they are bronze castings of wedge shape, adjusted by nuts against an end lug, and having at the forward end stud bolts to clamp them to the head. The piston rod is held in the crosshead by a screw and jamb nut, and in the piston by a straight forced fit and nut on the outside end.

The flywheel, eccentric, and Rites governor are split and removable. The governor is specially designed to permit the use of a light spring, which, with long inertia arms, insures great sensitiveness to instantaneous change of load.

A forged steel valve rod guide bar, carried in brackets runs in a flood of oil supplied from a pocket which is kept full by the splash system.

The valve is of the Sweet double-ported type designed without center web, to obtain lightness and freedom from casting strains. It is covered by a flat plate held from endwise motion by adjusting screws so that the lead can be varied between the ends of the cylinder. The plate is held against the valve by flat springs, bearing on the steam chest cover, providing relief in case of excess pressure.

The steam and exhaust ports are designed for low steam velocity, the live steam not exceeding 4,500 feet per minute velocity, and the exhaust steam ranging as low as 2,000 feet.

For use where variable speeds are required, a form of Stephenson link is used, but with both eccentrics set ahead of the crank, one of them being 129 degrees ahead and the other 191 degrees ahead, so that the travel of the valve is changed by setting the link to bring the valve under the control of either eccentric. Engines so equipped are peculiarly adapted for fan engines as they permit of easily increasing or decreasing the speed of the fan. The illustration given shows the arrangement of the link and eccentric, and the form of cylinder head used in all Brownell engines.

The same type of engines are built either tandem or cross-compound, condensing or non-condensing.

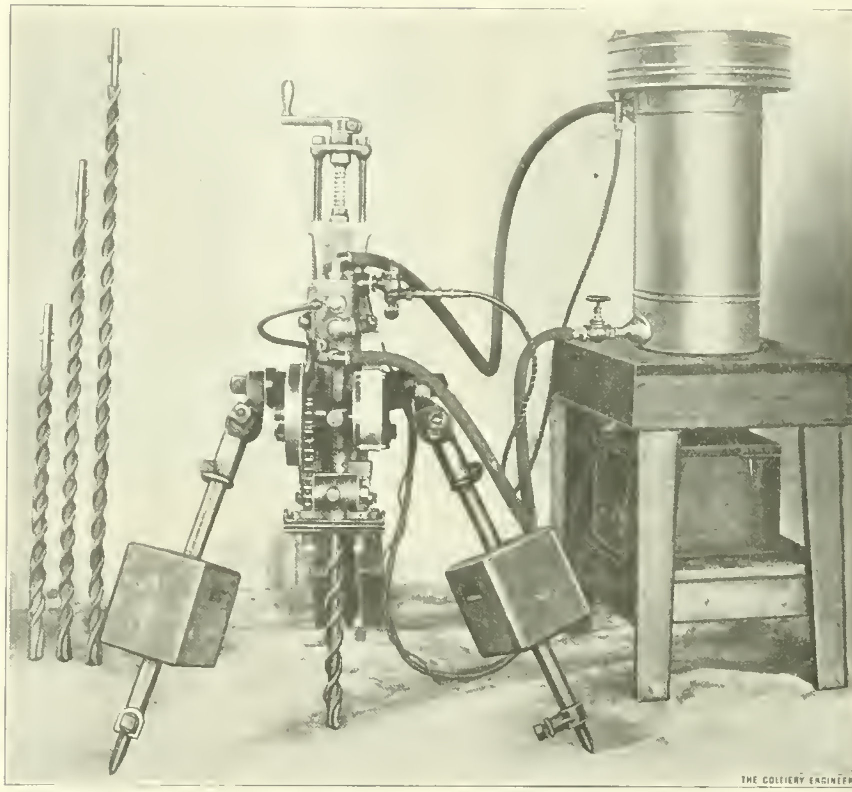

Fig. 6. Gasoline Rock Drill

Gasoline Rock Drill

A gasoline rock drill has been developed by L. L. Scott, of St. Louis. Mr. Scott has been engaged in the manufacture of mining machinery and has been working upon the development of a gasoline rock drill for 7 years, having finally perfected four sizes of machines weighing respectively 35, 85, 140, and 265 pounds. The smallest size is a hand machine while the others will drill holes to a depth of 5 feet, 10 feet, and 20 feet, according to the weight of the machine, and are mounted upon a tripod or column.

All of these drilling engines work on the two-cycle single acting principle; they are free from all gears, cams, push rods, etc., and have none of the common faults of two-cycle engines. Back firing is impossible; speeds up to 3,000 revolutions per minute can be had if desired; roller bearings are used throughout, and they are not exposed to crank-case pressure, so that leaks from the crank case are impossible; no deflecting plate is used on the piston, and the inlet and exhaust ports are not opposite, so there are no leaks between ports, as common to ordinary constructions. These machines drill rock on the "hammer" principle; the hammer piston is made of vanadium steel and is acted upon by a 300-pound explosive pressure, and when it strikes the blow on the shank of the drill steel, it is free from all connected parts of the machine, in fact it strikes the same blow as the air drill which has no crank shaft, i. e., direct, uncushioned, and free piston. The piston is moved rearwardly by energy stored in the fly-wheel, and is picked up for this return stroke on a cushion of air.

The drill steel used in this machine can be either the hollow steel, arranged so that a part of the explosive pressure will pass through the drill, or the solid steel with a thread, which is extensively used in Germany. The drills are set loose in the chuck, having lugs on each side which catch in slots in the chuck, while the chuck is rotated by means of a worm on the rotating parts which drives a sprocket and chain that in turn drives a worm connected to the chuck.

In narrow work where the ventilation is poor the exhaust from the drill must be piped out of the way, but in places where the ventilation is good, there is no necessity to pipe the fumes away any more than with the gasoline engines commonly used in the mines.

The drill was tried out at a quarry belonging to the Fruin-Bambrick Construction Co. The great advantage claimed for this drill is the elimination of the powerhouse requirements of the usual drill, for this drill is self-contained, in that the source of power goes with the drill, as shown in the Fig. 6 which is taken from a photograph.

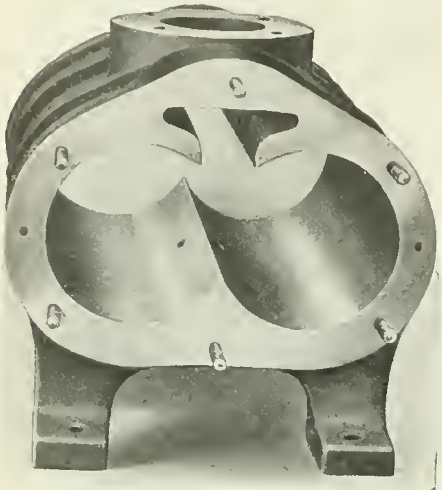

Fig. 7

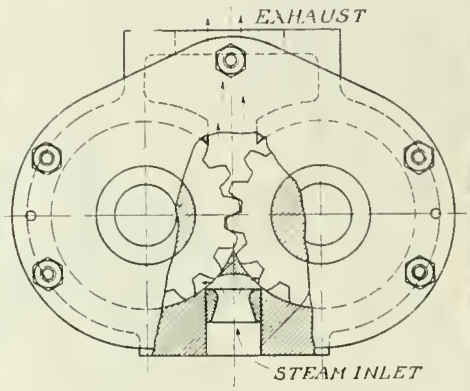

Fig. 8

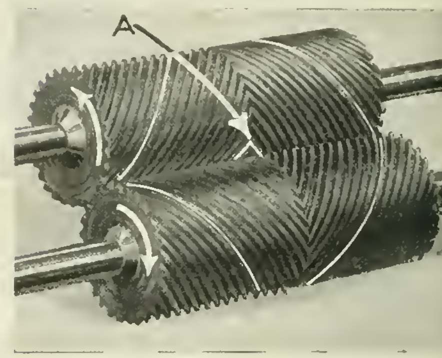

Fig. 9. The Rotors

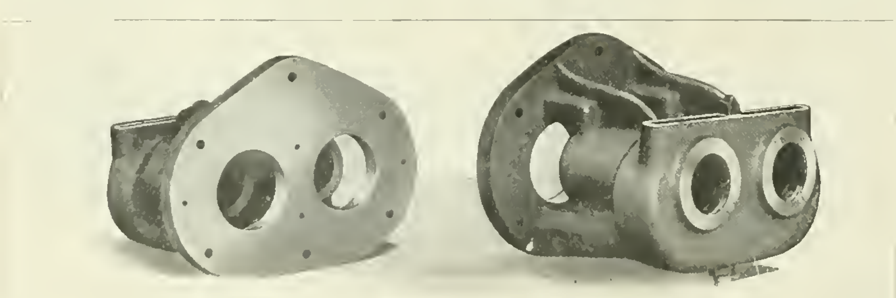

Fig. 10

The Spiro Steam Turbine

The Spiro steam turbine, a remarkably efficient and revolutionary prime mover has recently been put on the market by the Buffalo Forge Co., of Buffalo, N. Y. The rotors, shown in Fig. 9, run in mesh, enclosed in the casing shown in Fig. 7. The ends of the casing, which contain the bearings for the rotors are shown in Fig. 10, and a diagrammatic end view is shown in Fig. 8. The steam enters the turbine at mid-length through the port holes shown in Figs. 7 and 8, on each side of the central rib, which divides the casing into two partly-closed cylinders, in which the rotors revolve, . and the steam exhausts through the ports shown at the top in Figs. 7 and 8.

The steam when it enters occupies the space between two adjacent teeth, and this space is closed at the points by the closely fitting casing. As each rotor turns, the space occupied by the steam increases in length and the steam expands, finally escaping when the outer ends of the teeth pass the line of contact between the two rotors. The increase in the length of the tooth space from the time steam is admitted until exhaust occurs is shown by the length of the outer white lines on Fig. 9 as compared with the very short inner white lines.

The construction is very simple, consisting of only 60 or 70 parts, including screws, nuts, bolts, and every minor part. This is in striking contrast to the hundreds of parts usually found in engines and turbines.

There is an entire absence of the delicate parts, which usually require careful attention and repairs.

The ratio of expansion is dependent on the design and length of the rotors, and can also be made variable by the use of an adjustable port opening that is operated by a governor. The ratio of expansion ranges from 1 to $3\frac{1}{2}$ up to 1 to 6. As the steam velocity does not exceed 300 feet per second, there is no necessity for a diverging nozzle. As shown in Fig. 8, the steam jet is diverted into the general direction of rotation. The jets impinge against the angular pockets formed by the junction of the left- and right-hand helical teeth, and this results in a pressure drop and a corresponding turning moment, depending in amount on the rotative speed and initial pressure. The remaining available energy of the steam is used expansively in the tooth spaces. This expansion takes place at a high velocity. With, say 2,000 revolutions per minute and 20 teeth in each of the two rotors, there are 80,000 impacts and expansions per minute.

It is to this rapidity of the steam action that the Spiro owes its small size. There are also several minor reactions, which, while small, in the aggregate increase the general efficiency of the motor. The manufacturers claim that a Spiro with 8-inch rotors will develop the same power as a reciprocating engine with a $13\frac{3}{4}$-inch piston running at a speed of 600 feet per minute. The overall dimensions of such a turbine are 49 in.×$18\frac{1}{2}$ in.×19 in. It therefore provides a large amount of power with very small weight and space, and with no necessity for packing.

Tests made with Spiros, when condensing at atmospheric pressure showed a water rate as low as 31.8 pounds per brake horsepower per hour on a 150-horsepower turbine.

Two-Speed A. C. Motor for Mine Fan Drive

An excellent example of the efficient adaptation of electricity to mine service is illustrated in Fig. 11, which shows a two-speed, alternating current, three-phase, 60 cycle, 440-volt motor belted to a 12-foot Guibal fan installed in the Greensburg No. 1 mine of the Keystone Coal Co., near Greensburg, Westmoreland County, Pa.

The force of miners is considerably less at night than during the daytime, and consequently it is desired to run this fan at only about one-half the speed at night that is required during the day. For this service there was selected a Westinghouse squirrel-cage type induction motor with a rating of $7\frac{1}{2}$-horsepower at 600 revolutions per minute, and 15 horsepower at 1,200 revolutions per minute to perform the work.

The change in speed is accomplished by changing the number of poles. The stator of the motor is provided with two windings; one of which gives 6 poles, resulting in a speed of 1,200 revolutions per minute, and the other gives 12 poles, with a speed of 600 revolutions per minute. The connections are changed for one set of windings to the other by the controller. This is a most efficient form of control as the motor can be operated at low speeds at its highest efficiency; there being no losses in the control resistance.

Current for the operation of this motor is furnished by the West Penn Electric Co. In order to determine the results obtained from the installation, tests were made by Mr. C. V. Elliott, electrical engineer of the lighting company, which gave the following data:

The fan is 5 feet 6 inches wide, and the depth of blades 3 feet 6 inches. When running at 120 revolutions per minute, with 1.5 inches water gauge, or an equivalent pressure of .87 ounce per square inch,

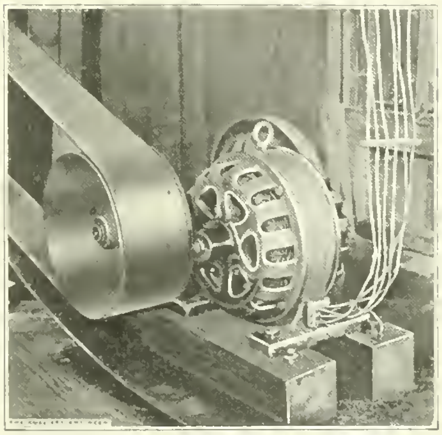

Fig. 11. Two-speed A. C. Motor for Mine Fan

46,200 cubic feet of air per minute were delivered. The motor in performing this work took 9.6 kilowatts, giving an efficiency of 63.03 per cent. for the outfit. When running at half speed, or 60 revolutions per minute, with .6 inch water gauge, or .29 ounce pressure per square inch, 14,850 cubic feet per minute were delivered, and an efficiency of 58.33 per cent. was obtained.

These results are particularly important as they show economy in the use of purchased power, which is becoming standard practice where alternating current is available.

Electric Hoist

The Vulcan Iron Works, of Wilkes-Barre, Pa., has recently built two electric mine hoists for the Woodward Iron Co., of Alabama. Both hoists are similar in design. One is to be operated on a slope inside the mines while the larger one is to hoist the ore to the surface and is located on the outside.

This large hoist is of 700 horsepower, geared for a rope speed of about 1,800 feet per minute on a 30-degree slope and having a load of 33,600 pounds of ore in a car weighing 30,000 pounds. The load is to be counterbalanced by a weight of 45,000 pounds arranged on a two-part rope, so that its travel will only be about 900 feet, the length of the slope being 1,800 feet; a $1\frac{1}{2}$-inch rope will be used. There are two 10-foot drums, grooved so that the rope will coil in two layers.

The motor for the hoist was built by the General Electric Co., and is a 700-horsepower, 10-pole, 3,300-volt, three-phase, 25-cycle, induction motor of the variable-speed type with polar-wound rotors. The speed is controlled by cutting resistance into and out of the rotor circuits, the rheostat being of the liquid type, with magnetically operated oil-immersed contactors. The resistance of the rheostat is varied by varying the level of the water, which is controlled by a hand-operated weir, though the level of the water can be made independent of the weir, so that automatic acceleration is obtained.

The motors are directly geared to the drums, there being only a single reduction. The gears are made of steel and are of the herringbone machine-cut type, each gear being protected by hinged covers. The brake is operated by a cylinder and is balanced by weights, the arrangement being so controlled that it cannot operate with a shock.

The hoist is equipped with overwind gear. A gear at the end of the driving shaft operates a worm and gear, a disk with adjustable cams being mounted on the shaft with the gear. The cams engage levers, which shut off the power and apply the brake.

The 500-horsepower hoist pulls the cars in trips of 20 up the slope to the point where the cars are dumped and the ore hoisted the rest of the way by the 700-horsepower hoist. The first hoist has a 500-horsepower, 8-pole, 375-revolutions-per-minute, 3,300-volt, three-phase, 25-cycle, form "M" General Electric motor. The arrangement is similar to the 700-horsepower hoist, except that all parts are sectionalized so as to facilitate transportation and erection inside the mines.

TRADE NOTICES

Pump Installations.—The Deane Steam Pump Co., of Holyoke, Mass., has installed seven electrically operated plunger pumps for one Pennsylvania mining concern. These pumps are especially adapted for use where the water is excessively acid. The Deane company is a large manufacturer of pumps and has issued a new catalog, No. D-218, which describes electrically operated pumps, and the vertical and horizontal in the duplex, triplex, and quintuplex types.

Orenstein-Arthur Koppel Co.—Mr. A. Reiche, general manager of the Orenstein-Arthur Koppel Co. is now in Berlin, Germany, where the head office of this company is located, for consultation with the executive officials regarding the extensive improvements to be made during the coming year at their American plant, at Koppel, Pa. There a new office building is being erected, two stories high, of brick and steel fitted with all modern conveniences, and the entire executive department of the American organization, which is now located in the Machesney Building, Pittsburg, Pa., is to be moved to the plant at Koppel, Pa.

Davis-Biram Anemometer. — Letters Patent for the Davis-Biram anemometer have recently been granted to John Davis & Son, (Derby) Ltd., All Saints Works, Derby, England, whose American representatives are J. F. McCoy Co., 157 Chambers St., New York. Messrs. Davis & Son state that, on account of the advantages contained in the new instruments many colliery companies are substituting them for the old form of Biram anemometer, even when the latter are in good condition. Full information and description of the instruments will be furnished on application to either the American or the home office.

The Roberts & Schaefer Co., engineers and contractors, of Chicago, have engaged Mr. Trevor B. Simon, formerly associated with the Jeffrey Mfg. Co., as one of their engineers. They have also secured the services of Mr. Arthur L. Ware as their representative in the Kentucky and Tennessee coal fields.

The Link-Belt Co., of Philadelphia and Chicago, designers and manufacturers of coal tipple equipments and other conveying machinery, announce that hereafter the contract work in the West Virginia and Virginia coal fields will be in charge of their engineer, Mr. F. F. Waechter, replacing Mr. A. Kauffmann, who has been transferred to the Chicago plant. Mr. Waechter has been in the Link-Belt Co.'s employ for the last 15 years, a great part of this time in the Engineering Department, as chief draftsman, and the last 2 years in the Sales Department.

Protection Against 40° Below Zero. A temperature of "40 below" is quite usual in the vicinity of South Porcupine, Canada, a gold mining settlement 500 miles north of Toronto. When the Northern Electric Heat and Power Co. built their new plant in that town they required a material that would prove an effectual insulation against this excessive cold and would not crack and go to pieces under low temperatures. It was necessary also to have a roofing that would withstand the melting snows of spring, without rusting or rotting, and that would not dry out and run during the short but often hot Canadian summer. They made a thorough test of J-M Asbestos roofing and a siding known as J-M Asbestoside, which proved so successful that they adopted these materials. The H. W. Johns-Manville Co., of New York, the manufacturers of this roofing, will send a booklet describing it upon request.

New Catalog.—A most complete catalog has been issued by the Joseph Dixon Crucible Co., Jersey City, N. J., describing the graphite, crucibles, paint, lubricants, pencils, and other productions of the Dixon company. Though this catalog contains over 100 pages, it does not attempt to carry a full description of the entire line, and only a few of the many hundreds of Dixon's American Graphite pencils are listed, the intention being to acquaint those who are already users of one form of graphite with its many other forms and uses. It will be sent on request.

Catalogs Received

A. S. Cameron Steam Pump Works, 11 Broadway, New York. Illustrated pamphlet of Steam Pumps; 48 pages.

The Bristol Co., Waterbury, Conn. Wm. H. Bristol Electric Pyrometer; 16 pages.

John A. Roebling's Sons, Trenton, N. J. Roebling Wire Rope and Where to Get It; 8 pages.

A. Leschen & Sons Rope Co., St. Louis, Mo. Leschen's Hercules, How to Splice Wire Rope; 11 pages.

Keystone Lubricating Co., Philadelphia, Pa. Lubrication of Mining Machinery; 19 pages.

The C. S. Card Iron Works Co., Denver, Colo. Coal Handling Machinery and Equipment; 71 pages.

The Deane Steam Pump Co., 115 Broadway, New York. Electrically Operated Mine Pumps; 100 pages. Triple-Plunger Artesian Well Pumps, 16 pages.

Sullivan Machinery Co., 129 South Michigan Ave., Chicago, Ill. Sullivan Portable Drilling Rigs, 16 pages.

Chicago Pneumatic Tool Co., Fisher Building, Chicago, Ill. Design and Construction Class G "Chicago Pneumatic" Compressors; 28 pages.

American Blower Co., Detroit, Mich. "A B C" Disc Ventilating Fans; 24 pages. Unit Heaters; 4 pages. Dry Kilns for Timber Products; 78 pages.

Mines and Minerals

Vol. XXXIII—No. 9 APRIL, 1913 Scranton, Pa.

PUBLISHED MONTHLY AT SCRANTON, PA.
ESTABLISHED 1881

INTERNATIONAL TEXTBOOK CO., PUBLISHERS

T. J. FOSTER, President S. P. ALLEN, Secretary E. H. LAWALL, Treasurer
RUFUS J. FOSTER, Vice-President and Managing Editor
EUGENE B. WILSON, Editor HUGH ARCHBALD, E. M., Asst. Editor

CHICAGO OFFICE: 1006 S. Michigan Ave.

Entered at the Post Office at Scranton, Pa., as second-class matter

Address all business communications to THE COLLIERY ENGINEER, Scranton, Pa.

Subscription Rates: $2.00 per year to United States and all possessions, and Mexico; $2.50 to Canada; $3.00 to all other countries. Single copies 25 cents each.

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

The resumption of our old name and the devotion of all our pages to coal mining literature has been fully justified. While we felt that the change would be welcomed, we were not prepared for the enthusiasm with which it was received in the various coal fields. It is impossible to answer each congratulatory and commendatory letter personally, therefore I take this means of thanking those who so heartily expressed their approval of THE COLLIERY ENGINEER.

Sincerely,

RUFUS J. FOSTER,
Managing Editor

IT'S simply outrageous! Anthracite mine owners made profits last year! The shameless heads of the companies declined to consider that anthracite mining was for recreation only. Is there any punishment severe enough for such miscreants?

THE newspaper report that 72 men were killed in an explosion at Yale, B. C., is some exaggeration. Our special correspondent interviewed Mr. Thomas Graham, Chief Inspector of Mines, who stated that "there was but a slight explosion and only one or two men slightly burned."

THE "prominent mining engineer" who finds valuable coal deposits in the Devonian rocks is usually the fellow who has a card in a country weekly describing himself as a "civil, mining, mechanical, and electrical engineer—farm lands surveyed and platted for $1.50 per day."

The Mine Gas Chart Supplement

THE Gloman Mine Gas Chart, issued as a supplement to this number of THE COLLIERY ENGINEER, contains in most convenient form all necessary information regarding gases met with in coal mines, and is well worth preservation by mine officials and mining students. It is not intended as a textbook for beginners, but as a reference chart. At the same time, its arrangement is such, and the information given so plain, that it is intelligible to almost any man familiar with coal mining practice who can read English. The chart was prepared and copyrighted by Mr. Chas. K. Gloman, Chief Clerk of the Susquehanna Coal Co., Wilkes-Barre, Pa., for use in mining institutes. For such use he has had the chart printed in smaller type, and of about half the size of our supplement, so that it can be folded and conveniently carried in the pocket. It was primarily prepared for local mining institutes in the anthracite regions, in which Mr. Gloman is greatly interested, but we have no doubt that he will be glad to furnish copies of the smaller chart to other mining institutes, or to mine officials, at a very low price.

The Report of the Anthracite Mine Cave Commission

THE Anthracite Mine Cave Commission has completed its work. Its report and the proposed solution of a difficult and trying problem is in the hands of Governor Tener. It is a voluminous document of nearly 600 type-written pages, and represents many days of careful thought, study, and investigation. A summary of the report is published on other pages.

The Commission was composed of able men, all but two of whom were experienced mining men. These two, were Mr. E. J. Lynett, Editor and Proprietor of the *Scranton Times*, and Hon. J. Benj. Dimmick, an attorney, President of the Lackawanna Trust Co., and a former Mayor of Scranton, and both owners of valuable real estate in Scranton—the city most interested in a satisfactory solution of a perplexing problem. They accepted positions on the Commission believing that a different solution was possible—a solution that would satisfy all real-estate owners in Scranton, even if it did mean the practical confiscation of the coal belonging to the coal owners.

They were honest in their belief and argued strenuously in its support, but they finally saw that the terms of the deeds held by most real-estate owners, and a restriction of the city's basic industry, made their plan impracticable.

They were not familiar with the technicalities and details of coal mining, and did not, at first, realize the great importance the industry is to the city, or the great loss the city would sustain through a curtailment of mining operations. When they realized these points they were broad enough to see the truth of the statements of able men who understood coal mining in all its details, and who are familiar with the annual production, and its value to the city, and who also are familiar with the extent to which exhaustion has advanced, and the actual amount of coal left. Then they joined with the practical and successful mining men in the solution proposed.

It is but natural that there should be much adverse criticism of the report. Such criticism, however, will not honestly come from men really capable of expressing an opinion on a subject so complex and technical as the one considered by the Commission. Some, who know better, may criticise it adversely with the object of getting in the lime light or for the purpose of aiding personal political advancement, but men who know, men who have given the matter careful consideration, will agree in pronouncing the report an exceedingly careful statement of facts as they are, and the most rational solution of the question.

Messrs. Dimmick and Lynett attended the sessions of the Commission. They took part in the examination of witnesses, they aided in all the efforts to get at bottom facts, they discussed every feature with their fellow commissioners, and made themselves familiar with every phase of the problem. They wanted another solution. They were convinced that no other solution was possible, and joined with their colleagues in making the report.

If men like Messrs. Dimmick and Lynett, after deep study and investigation, commend the report, it is very strong evidence of its sound value, no matter how much adverse criticism may be given it by men ignorant of facts or by demagogues.

The members of the Commission have done a great work. They have obtained from the coal owners liberal concessions—more liberal than we thought probable—they are entitled to the gratitude of the citizens of the region, and their report should be commended and concurred in by every real-estate owner.

The Mining Building at Pennsylvania State College

THE School of Mines building at Pennsylvania State College is a disgrace to the state.

The State College was provided to furnish free tuition to young men of the state, who have ambition enough to take advantage of an opportunity to acquire a higher education, but who have not the means to attend more expensive institutions of learning. In a state like Pennsylvania with its great industrial establishments, technical education is of prime importance. As coal mining is the most important single industry in the state, and Pennsylvania's metallurgical establishments are of great magnitude, special attention is given at the State College to the teaching of mining and metallurgical engineering.

The mineral production of Pennsylvania, including metals, is valued at over $500,000,000 per annum—a greater sum than the combined value of the mineral production of any three other states. Many states, with mineral productions less than one-fourth as large, have fine and well-equipped mining buildings connected with their state institutions of learning. New Mexico, whose mineral production is valued at less than one-sixth that of Pennsylvania, has a School of Mines building worth many times that of Pennsylvania.

The School of Mines building at Pennsylvania State College is a cheap wooden structure with a tar-paper roof, inadequate and unfit for the purposes of a first-class school of mines.

As the mineral industry of Pennsylvania is not only the greatest industry, but the one on which the prosperity of other industries, including agriculture directly depends, the Legislature of the state should at once make an appropriation for a building that will be suitable for use, and a credit to the state.

Every Pennsylvanian engaged in any branch of the mineral industry should urge his representative in the House and Senate, to not only vote for the modest appropriation of $120,000 asked by the trustees for a mining building, but for as much larger a sum, within reason, as will provide a building and equipment as good or better than that of any other state.

Welfare Work at Coal Mines

THE social uplift of the mine worker is a subject that merits the serious consideration of all mine managers, and it is receiving such consideration by some. Others, who have recognized the necessity for such work, have either endeavored to secure results too speedily, or have, by relegating the work to impractical faddists, spent considerable money to but little purpose. Others are watching the results of those who have initiated sociological work, so as to profit by the experiences of their more liberal colleagues. Some mine owners and mine managers in a very commendable desire to uplift their employes, and to inspire them to higher things and better citizenship have been too eager to bring about the desired end. As a result, their efforts and large expenditures are not appreciated by the employes.

A majority of the mine workers in many regions are men from southern and central Europe. They are not only unfamiliar with the English language, but their national modes of living and customs differ from their predecessors, who as a rule came from northern and western Europe. The latter in nearly every case understood and spoke the English language, and in their mode of living and customs were closely allied to American workingmen generally. Besides, the percentage of illiteracy among them was much smaller.

The mine workers from southern and central Europe are men whose ancestors for centuries lived in the most primitive manner Their diet was of the coarsest nature and often consisted of things that their predecessors in America would not eat. They brought, and are still bringing, to this country the ideas of life which they inherited and to which they are accustomed. If they thoroughly understood the English language, it would take considerable time to wean them over to our ideas of living. Not understanding English, they cannot be easily made to understand American ideas of cleanliness and sanitation. They prefer to live as they lived in Austria, Italy, and other countries from which they came. The average frame miner's house in America is palatial as compared with the thatched huts and dirt floors they are accustomed to. They must be educated gradually to better conditions. The experiment of putting them in houses equipped with bath tubs and toilets has invariably resulted in non-appreciation and a misuse of those conveniences.

We are not of the class, that says "anything is good enough for the Slav or Italian." We believe in every rational effort to help them to a higher plane of living and in the Americanizing of them.

If success in sociological work is to be secured, the work must be begun right and it must be accomplished gradually. It must originate with the mine management, and some responsible man must direct the work. It must not be tinged with any religious sectarianism. The more intelligent of the mine workers, particularly those who appreciate better things, must be enlisted as aids in the work. Their methods of life, their cleanliness, their regard for sanitation should be used as examples for the others.

As a first step in the work the houses in the mining village should be put in repair, tumble-down fences should be straightened, make-shift outhouses built of old discarded lumber and tin cans should be replaced with suitable buildings and sheds. Drainage should be supplied, the village cleaned up generally, and sanitary rules should be adopted. Then some one responsible man should be appointed inspector, who will see that the houses are kept clean, that the sanitary rules are complied with, and that each family is required to attain a standard of neatness and cleanliness as high as the best in the village. Objections to such rules should be met with kindly explanations showing the men and their families the advantages of such living. If any persist in living in squalor and amid unsanitary surroundings they should be discharged and required to move out of the village, as they are a menace to their neighbors.

When a community of mine workers has become accustomed to the foregoing, such conveniences as bath tubs, toilets, electric light, etc., can be gradually given them, beginning with the most progressive first.

Suitable play-grounds for the children and a recreation hall for the elders, not too elaborate, but plain, comfortable, and equipped with simple furniture and appliances, will aid in the preliminary work.

The sociological movement is one that will grow. It will grow because economic as well as social and sanitary conditions demand it. It will grow because American patriotism demands that the hundreds of thousands of non-English speaking workingmen coming to us must be Americanized and made good citizens as speedily, as possible.

To be successful, a sociological movement in a mining village must not only be started. It must be pushed by an energetic, competent man. It is not work that can be successfully carried out by some fellow that has failed in every thing else and then poses as a sociologist, or who uses a religious or philanthropic organization as a means to get an easy job with more salary than he could earn in any other position. If the local mine superintendent hasn't the time to attend to the work, and in most instances he hasn't, he should put it in charge of an able, energetic man who will be constantly on the job.

PERSONALS

George Watkin Evans, of Seattle, delivered an address, in February, before the British Columbia Section of the Canadian Mining Institute on the "Ground Hog Anthracite Field."

The Consolidation Coal Co. has made the following appointments in its operating department: F. R. Lyon is general manager of all the properties with headquarters at Fairmont, W. Va.; John G. Smyth is chief engineer; Everet Drenneen is manager of the Elkhorn division with headquarters at Jenkins, Ky.; Samuel Steinback is manager of the Pennsylvania division; R. L. Kingsland is superintendent of the power and mechanical department.

Thomas F. Grogan has been appointed deputy mine inspector for Belmont County, Ohio, with headquarters at Bluefield, W. Va.

Robert D. Hennen, civil engineer, and G. B. Hartley, civil and mining engineer, announce that they have combined their offices under the firm name of Monongahela Valley Engineering Co., with offices in the Brock, Reed & Wade Building, formerly occupied by Mr. Hartley. The firm will engage in the practice of general engineering.

Harry S. Matthews, former president of the Alabama Consolidated Coal and Iron Co., has been appointed vice-president and general manager of the International Steel Corporation, with headquarters in Seattle, Wash.

Patrick J. Freil has been appointed Mine Inspector of the Sixteenth Anthracite District, Northumberland, Pa., to fill an unexpired term. Mr. Freil lives in Mahanoy City, Schuylkill County, out of the district, but the judges of the county made the appointment because none of the citizens who were after the job were eligible on account of not having the necessary certificate issued by Mine Inspectors' Examining Board.

John P. Thomas, of Cañon City, has been advanced to division superintendent of the Colorado Fuel and Iron Co. to succeed J. S. Thompson.

George Osler, of the Monongahela River Coal and Coke Co., will be general manager in charge of the Charleroi and Panhandle mines of the Carnegie Coal Co.

William H. Grady, formerly with the Tennessee Coal, Iron and Railroad Co., at Birmingham, Ala., is now chief mine inspector of the Pocahontas Coal and Coke Co.

Charles Dorrance, Jr., former fuel engineer of the Lehigh Coal and Navigation Co., has been appointed chief engineer of the Mining Department of the company, with headquarters at Lansford, Pa.

Thomas Small, has resigned as superintendent of the United Fourth Vein Coal Co. The position is now held by Clayton Moss, of Jasonville, Ind. Mr. Small's resignation was due to ill health.

Frank Baldwin, until recently assistant to Superintendent Gibson of the mines of the United Coal Co. in the Boswell, Pa., field, has been placed in charge of the operations of the same company at Jerome.

Neil McHugh has been made general superintendent of the Hodleigh colliery of the Pittston Coal Co., at Sugar Notch, Pa. He is one of the youngest mine superintendents in the state. When given a Fireman's Certificate he was only 21 years of age.

Edgar I. McGee has been appointed assistant superintendent of the Mechanical Engineering Department of the H. C. Frick Coke Co.

James Beatty, superintendent of the Shawmut Mining Co., near Meadville, Pa., has resigned.

B. J. Lynch has assumed the general managership of the Superba Coal Co., at Evans Station, near Connellsville, Pa.

Whitney & Kemmerer are planning to make improvements at their Wise Coal and Coke and Sutherland Coal and Coke companies, in Wise County, Va.

Karl F. Schoew is a candidate for chief of the Department of Mines in West Virginia in case John Laing retires, which it is given out he wishes to do.

Dr. James H. Gardner, recently assistant geologist on the State Geological Survey of Pennsylvania, has formed a partnership with Mr. F. J. Fohs, of Lexington, Ky., the firm being known as Fohs & Gardner. They will engage in the practice of commercial geology and mining engineering with offices in the Security Trust Building, Lexington, Ky.

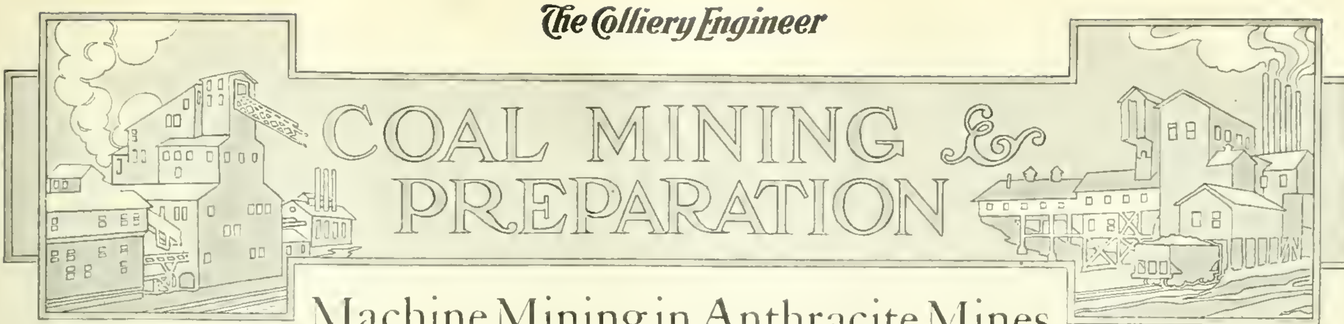
F. J. Fohs, geologist and mining engineer, of Lexington, Ky., is engaged in preparing a report on a large coal property in western Kentucky and upon its completion will take up work along similar lines in Oklahoma.

E. M. Chance, who for the past four years has been chemist for the Phila. & Reading Coal Co., with headquarters at Pottsville, Pa., has resigned, and will open an office and laboratory at Wilkes-Barre as consulting chemist for several coal companies.

OBITUARY

WILLIAM A. CATHER

William A. Cather, owner and manager of the Franklin Iron Works, at Point Carbon, Pa., died at his residence in Pottsville, on March 5, aged 50 years. In 1887, Mr. Cather, with a brother, succeeded his father in the ownership of the Shenandoah Iron Works, at Shenandoah, Pa., and in the same year moved the plant to Bluefield, W. Va. In 1901, Mr. Cather purchased the Franklin Iron Works from his uncle, Robert Allison, who many years ago established the business as a partnership under the firm name of Allison & Bannan, later becoming sole owner of the plant. It was at these works that the onetime celebrated Allison Cataract Mine Pumps were built.



Machine Mining in Anthracite Mines

Methods of Cutting and Handling the Coal that Render it Possible to Work Thin Seams Profitably

By Hugh Archbald

ALTHOUGH mining machines of the undercutting type have been extensively used for years in bituminous coal mines, they are just being introduced in anthracite mines.

Until recently the seams of coal worked in the Lackawanna Valley ranged in thickness from 4 to 6 and 8 feet, but only small areas of these seams remain for first mining.

The rapid exhaustion of the thicker seams, particularly in the northern coal field, has made necessary the mining of seams which until recently could not be profitably mined under conditions existing in the anthracite trade. Now much of the anthracite is being obtained from thin seams in which the coal is tight and tough, making mining difficult. The impression has prevailed that anthracite was too hard to mine with undercutting machines, however, it is a fact that their use is growing in those places where the mining by hand is most difficult, especially in those places where a miner can only break from three to four cars with a keg of black powder. It is probable that if it were not for the difficulty of mining, and the small output per miner, the undercutting machines would not have been introduced in anthracite mines.

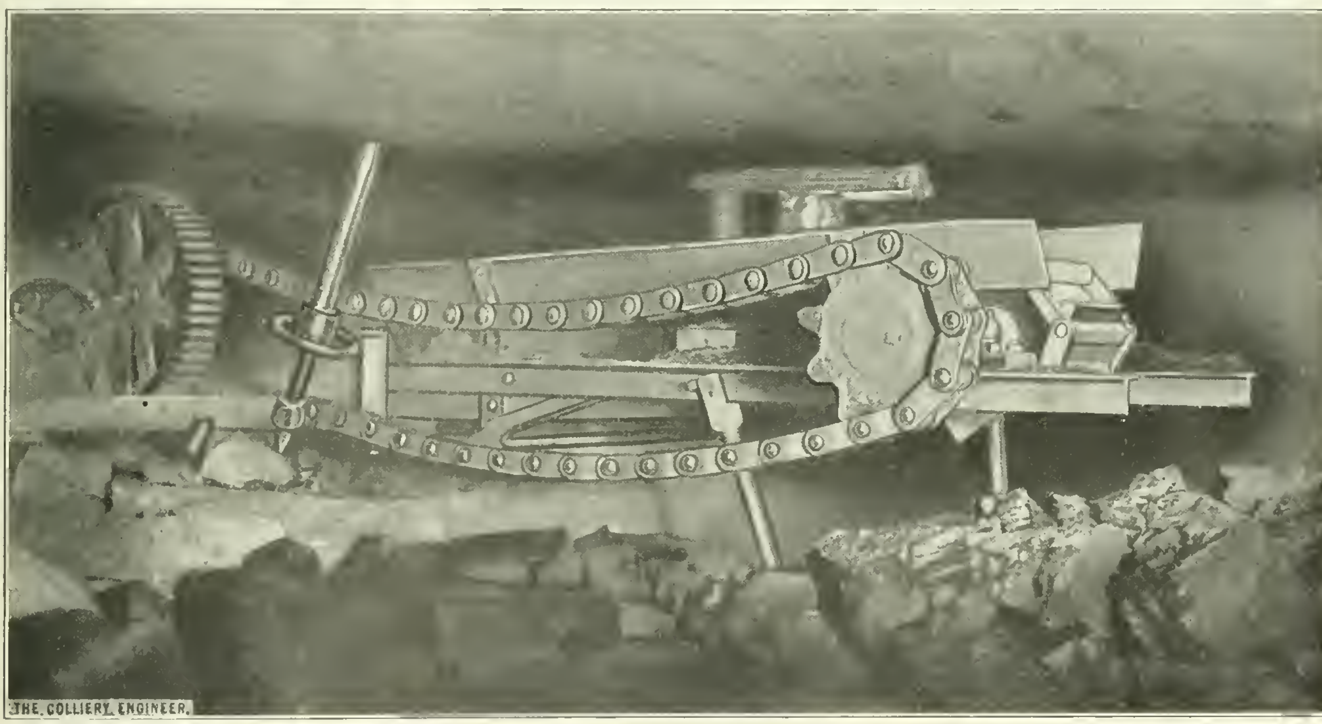


Fig. 1. Conveyer Delivering Into Car

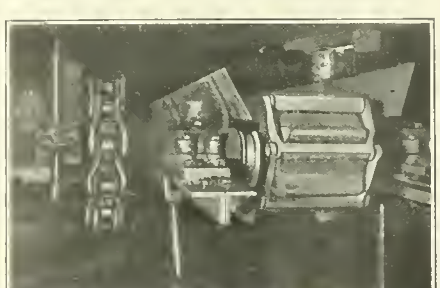

Fig. 2. Showing Shape of Conveyer

The cost of mining had become so high in the thin, tight coal beds, and the output so irregular, that a new way of doing things had to be devised; and while machine mining is not universal or even general it is obtaining a strong foothold.

At present there are 52 machines of various makes in use in the vicinity of Scranton, being divided between the manufacturers as follows: 3 Morgan-Gardner, 10 Jeffrey, 18 Sullivan, and 21 Goodman.

The Hillside Coal and Iron Co. were the first to experiment with undercutting machines, at their Butler colliery near Pittston. They used a Sullivan machine.

The coal in the Lackawanna Valley region is not so brittle as in the Lehigh and Schuylkill regions, and further it is not so tilted and folded; consequently, while conditions may be somewhat favorable in one locality for machines, it is possible that they may not be at all favorable in another. In this connection therefore a good way to test the matter is to experiment, because undercutters are susceptible to improvements, and might be made to meet and overcome unfavorable conditions as they are presented. In one place at present they are being used on a 15-degree pitch and they can be used on pitches of 20 and 25 degrees. The manner of doing this is to place an iron rail behind the machine, after making the sumping cut, parallel with the face of the chamber, holding the rail in place by means of a jack at each end and moving the rail when the machine has cut to the end. The undercutting machine has power enough to pull itself up to the coal and make the sumping cut at the same time.

The principal advantage of using undercutting machines, besides that of lessening the cost, is the obtaining of a greater percentage of the larger sizes of coal. At one colliery where an attempt was made to mine a thin coal seam without undercutting, it was found that 59 per cent. of the coal was broken by blasting into sizes smaller than those used for domestic purposes. Also the amount of coal blown into the gob when mining without undercutting has been estimated as varying from 9 per cent. to 22 per cent. No coal is blown into the gob where undercutting is done, and it is easier to clean the coal, as the bony coal is not broken into small pieces.

Fig. 3. Short-Wall Machine in a 4 ft. Anthracite Seam

As less powder is required where undercutting machines are used, there is less jarring of the roof and it is not so liable to fall; also props are not knocked out by flying coal, as only sufficient explosive is required to break down the coal. These two features tend to lessen the dangers from accidents and so increase the safety of mine workers.

By the use of machines, two features are particularly advantageous to economic coal production, namely, the concentration of work, and the increased regularity of coal output as compared with hand work.

Anthracite miners have become accustomed to shooting down the coal in their working places and then going home, leaving the remainder of the work to their laborers. When the thick seams of past times were being mined, this arrangement allowed the miner to reach home between noon and 2 P. M., however, under the present conditions he cannot do this, in the northern field at least, consequently, he feels somewhat disgruntled over the changes that have occurred, and which force him to work a full day shift in order to obtain his proper number of cars of coal.

The cost of production owing to the changed conditions in the thickness of coal beds has steadily increased, because the miners demand higher prices per car owing to their being unable to obtain as many cars of coal in a shift as when the coal was thicker and the facilities for working were more convenient.

Another reason why the cost of production has increased, is the lessened and irregular output, which naturally reflects on the fixed charges of a colliery. At one place where undercutting machines have been introduced and where one machine cuts two places daily, the cost per car of coal has been reduced from 35 to 40 per cent., and the cost in other places is about 50 per cent. less than hand mining. In addition, the quality of the coal reaching the breaker is better.

The manner of using the machines and the system of which they form a part, varies somewhat, according to the conditions at each colliery. In the majority of cases the room-and-pillar method of mining is followed, as there are overlying seams which have not been completely mined. The exceptions to this rule are found at the Dodge and Continental mines belonging to the D. L. & W. R. R. Co., where the surface seam is being worked on a panel longwall system.

At the No. 5 colliery of the Pennsylvania Coal Co. a Sullivan machine, shown in Fig. 3, is being used in the No. 1 Dunmore seam, which at this mine varies in thickness from 30 inches to 4 feet. The coal is tough, sticking to top and bottom, and when each chamber was driven by a miner and laborer only three or four cars could be obtained to each keg of powder. After undercutting with a machine, from 30 to 60 cars are obtained to a keg of powder. At this colliery only eight places are being mined by machine. The rooms are driven 30 feet wide and have been undercut in 15 minutes when especially favorable conditions prevailed, but as it is worked, the machine is not taxed to its full capacity.

After undercutting, the coal is drilled, shot down by a miner, and loaded by laborers, each miner taking care of two chambers and having four laborers, two loading the coal in each chamber. The cars are taken in to the face and the coal loaded directly. About 2 ft. × 10 ft. of the bottom rock on the left rib is taken up at night by a miner and laborer to give height for the car. The track is not carried close up to the face of the coal, a bench of rock being left on which to manipulate the machine and also blow down the coal. From this bench the coal can be loaded readily into the cars.

At the Taylor colliery (D. L. & W. R. R. Co.) the same system is being used under slightly different conditions, in the Clark seam. This coal bed is thicker, averaging about 5 feet. A section of the seam at one point gave coal, 6 inches; bone, 2 inches; coal, 12 inches; bone, 7 inches; coal 28 inches. When the chambers are driven by a miner and laborer, without undercutting, a miner will only send out from 28 to 30 cars in two weeks, because the coal is so tight and the bottom rock so hard. Also it takes the miner several days each week to break and take up the bottom in his chamber, as it is necessary to use a jumper in many of the places, a ratchet drill not being able to penetrate the rock.

The Goodman undercutting machine used here will cut about three places in a day, five places in a day being good work. The greatest cause of delay at this mine comes from the necessity for changing the cutters, 183 cutters being used in cutting one place where the bottom was particularly irregular and the coal mixed with pyrite, termed "sulphur" by miners. In trying a machine at the National colliery in the same seam, "the Clark," the undercutting was done in 5 inches of coal between the irregular bottom and a streak of bony sulphur, with the result that 245 cutters, or bits, were required. This is the high record for the number of cutters used in one place, nevertheless the machine made the cut across the place, 27 feet wide.

The rooms, at Taylor mine, are driven 24 feet wide, about 18 inches of rock being taken up on the left rib side to give head room for the cars. The machine cuts from right to left. The road, which is on the left of the chamber, is kept 5 feet from the face, in order to allow a bench for the machine to travel on. As the gob is kept on the right of the room, where the sumping cut is made it must be at least back 10 feet from the face in order not to interfere with handling the machine. If the gob is piled on the left, and the road is on the right of the room, with the machine cutting toward the left, the road would be kept 10 feet back from the face to give room to handle the machine while making the sumping cut.

To break down the coal after an undercut, three holes are drilled in the face. The center hole is charged with 30 inches of FFF black powder, the side holes with 28 inches, and these when fired bring down the coal in lumps, generally suitable for loading in the car, but sometimes in sizes which must be broken.

After the coal is broken it is loaded by laborers, five cars per man being considered a shift.

Fig. 4. Conveyer Carrying Coal, Near the Face

To advance the track, the rock is taken up at night, a miner and laborer being able to take up from 22 to 24 linear yards, 10 feet wide and 18 inches thick, in 2 weeks.

At the No. 1 colliery of the Pennsylvania Coal Co., undercutting machines are being used in a seam about 10 to 12 feet high. The undercut is made in a bench from 18 inches to 2 feet thick, which is blown down first. Above this bench there is about 3 feet of rock which is blown down and gobbed, so as not to mix the coal and the rock. After this the top benches are blown down. The chambers are driven 22 feet wide. The saving in the use of machines at this colliery is in the concentration of work and the saving of that coal which ordinarily is blown into the gob.

At the Bellevue colliery of the D. L. & W. R. R. Co., two machines are taking care of 34 rooms 24 feet wide in the No. 1 Dunmore coal seam. The undercut is made in a bottom bench of coal about 7 inches thick, above which there is about 10 inches of rock which is blown down separately. No bottom rock is taken up in the chambers, iron ties being used and the first mining taking about 5 feet of the seam. Above this there are 2 feet of rock and 20 inches of coal, which are taken down retreating, after the chamber has been driven to its length. Seven cars of coal only are obtained to a cut on account of the mixed material in the seam. The advantage to be derived from undercutting at this mine is the obtaining of clean coal in large sizes. As the seam is so mixed with impurities, mining in the customary way was not especially profitable.

At the Brisbin colliery of the D. L. & W. R. R. Co., two Jeffrey machines care for 20 rooms 24 feet wide in the 4-foot seam. The system of rotation in vogue at this mine is for each machine to cut three rooms a day, so that by the time the last rooms have been cut the first rooms have been cleaned of coal and rock, and are in readiness for the machines.

The undercut is made in bony and coal at the bottom of the seam, above which there is 3 feet of clean coal. Dynamite is used to break down the coal as it acts better in this case than powder.

Formerly top rock was taken down in each chamber to give height for the cars. With undercutting, no rock is moved, the buggy system being adopted; that is, the coal is loaded into a buggy or small car at the face and then reloaded into the mine car at the mouth of the chamber. Two loaders are employed at the face for this work and one at the mouth of the chamber. To obviate the necessity of the men pushing the buggies back and forth, a half-inch steel rope is used, by which a mule pulls the loaded buggy out of the place, one mule and driver taking care of seven places. The buggies hold about half a car of coal. Eleven cars are obtained from one undercut and about four cars are loaded per day from each chamber.

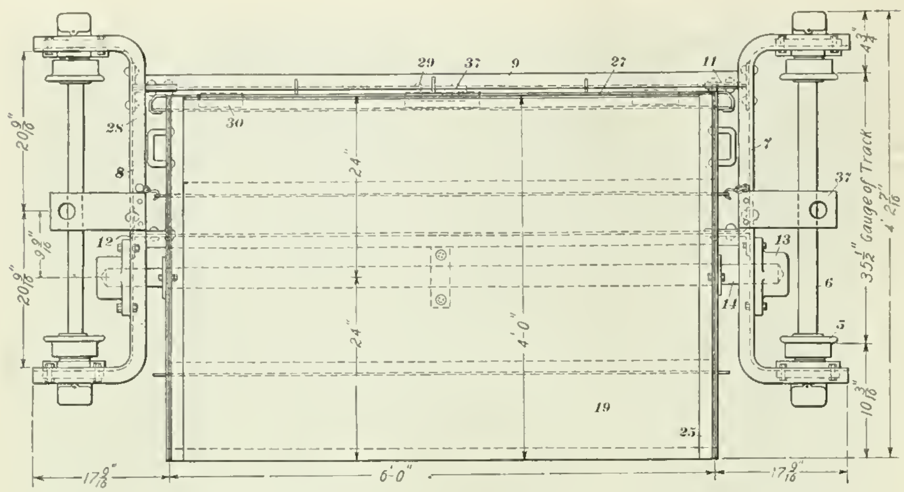

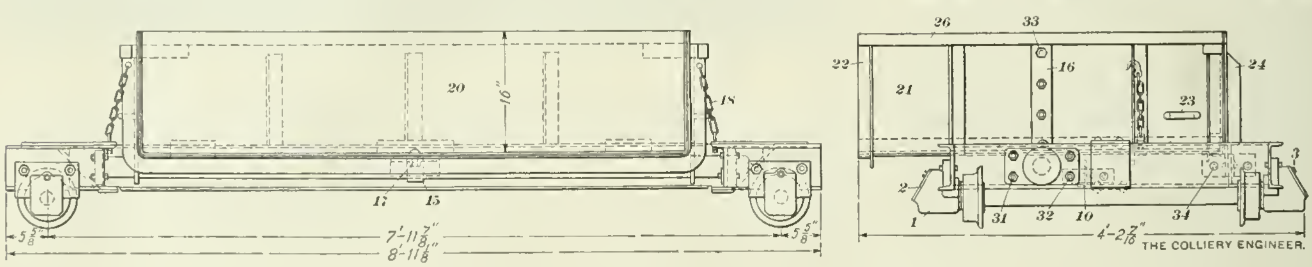

Fig. 5. Buggy for Low Places. For Explanation of Numbers See Table 1

A description was given in the February, 1913, issue of Mines and Minerals, of the buggy system as used at the Storrs and Diamond mines of the D. L. & W. R. R. Co. The buggy which has been designed by H. M. Warren, electrical engineer of the Coal Mining Department of that company, for use in these places, is shown in Fig. 5. Its frame is made of angle bars and channels, and its body of sheet iron.

The wheels are placed at each end of the frame outside the body so that the latter, which is pivoted to the frame, can be unloaded by tipping the coal directly into mine cars.

To bring the top of the mine car on a level with the floor of the coal seam on which the buggy stands, rock is taken up at the mouth of the room, and with this arrangement the coal in the buggy is tipped into the mine car without further handling. Because of the unusual construction of the buggy and because its use can be adopted to advantage in many other coal mines, the bill of material which has been kindly furnished us is given in Table I.

At the Dodge colliery belonging to the D. L. & W. R. R. Co., a seam of anthracite 30 inches high is being successfully mined by a panel longwall system, in which undercutting machines are used and the coal is loaded into the cars by means of a conveyer. The cost of mining this coal by the usual room-and-pillar method was prohibitive, and the coal obtained was excessively broken as the shooting was done from the solid. By undercutting the coal, the maximum percentage of large sizes is obtained and the cost is reduced to the normal cost for mining in a 6-foot seam.

The coal being mined is known as the 4-foot seam, and varies at this colliery from 24 to 40 inches in height, probably averaging about 30 inches. As it is clean coal, except for 2 inches of bony coal at the bottom, it can be loaded out as it falls, very little hand picking at the face being necessary. Over this seam there is about a hundred feet of cover, the roof being sandstone. There is this disadvantage, however, that the seams underneath this one, which is the surface seam, were mined some years ago and the rocks have settled so that both the top and the bottom are very much broken. Some of the cracks in the roof are sufficiently large for a man to put his arm into them. The breaks are not parallel to the face but run across it at an angle. This broken roof requires that extra precautions be taken in timbering and in taking down loose pieces of rock. Its condition also prevents the control of the roof, which probably would be simple as it is a sandstone which would bend behind the mining.

The manner of working the seam is to turn a gangway and airway off a main road, as shown in Fig. 6. The bottom rock of the gangway is taken up to give height for the cars, whose tops are 3 feet 9 inches above the rail. As soon as the two entries are far enough advanced so that a pillar can be left along the main road, two headings or rooms 220 feet long are driven in from the gangway. No rock is taken up in these places, a small car being used to remove the coal to the mine cars on the gangway.

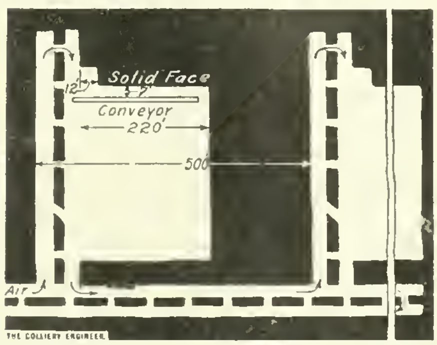

Fig. 6. Method of Working

As soon as the places are driven to the desired length, a conveyer and undercutting machine are installed. After the coal is undercut and broken down, it is loaded into the conveyer; carried to the gangway, and discharged into the mine cars placed beneath the end of the conveyer, as shown in Fig. 1.

The coal face is now driven parallel to the face of the gangway and all the coal is removed as the place advances. Starting at the inside of the room or heading which has been driven 220 feet, the undercut is made along the rib for the full length of the chamber. With a 6-foot undercut, and coal of 30 inches high, from 130 to 140 tons of coal is gotten out each day. The length of face is proportioned so that undercutting and loading can each be done in one shift, the loading being done during the day, while the undercutting is done at night.

Goodman and Sullivan shortwall machines have been used in this work, as well as a Jeffrey longwall machine. The longwall machine is used in the especially low places, as it stands only 17½ inches high, it being humorously stated that the place got so low that the name plate was scraped off the top of a 24-inch high machine when making an undercut. However, the fact remains that the Jeffrey machine is operating in coal which is only from 27 to 28 inches high. One great advantage which the longwall machine possesses, on account of its shape, is that props can be placed within 3 feet of the face without interfering with its operation. The cutter bar of this machine when in cutting position is at right angles to the body, whereas with a shortwall machine 7 feet must be left back from the face.

It takes usually from 8 to 9 hours to move the machine into position and make the undercut. During the day the machine is left at the end of the cut. In making the cut, from two to two and a half sets of bits may be used, though at times, when hard coal is encountered, three or four sets of bits may be needed for a cut. In comparison with some of the anthracite mines where undercutters are being adopted, this is not hard undercutting. The conveyer in use extends along the face of the room and is driven as shown in Figs. 1 and 2 by a motor and chain, placed near the gangway. About 5 feet of bottom rock is taken up in the gangway so as to give sufficient height to place the mine cars beneath the conveyer, and allow a topping to be put on the car. The top of the conveyer stands 12 inches from the floor. The coal moves in a flaring trough, 6 inches deep, along the bottom of which passes a chain with flat broad links, as wide as the bottom of the trough.

This chain passes over a sprocket wheel at the discharge end of conveyer and then travels back on angle iron guides underneath the trough. The driving motor and conveyer are built together, so that they can all be moved forward each day at one time. The height of the conveyer allows the coal to be shoveled in on top, and the conveyer is made in sections so that it can be lengthened or shortened as desired; however, it is not separated when being moved toward the face, but is drawn bodily forward by chain and pulley blocks.

The gangways and airways are driven both day and night shift, an advance of about 9 yards a week being maintained. No undercutting is done in driving them, the coal being shot from the solid as is the usual practice in anthracite mining. The face of the gangway is kept far enough in advance so that there is an open cross-cut ahead of the longwall face, in order to furnish ventilation and an avenue of escape in case the road behind should cave. The coal on the side of the gangway on which the face is driven, is mined as the haulway advances for a width of 10 or 12 feet, thus making the total width of the coal mined along the road from 20 to 24 feet, while the width of the bottom rock which is taken up for the track is about 10 feet. The purpose of this is to have a place for the undercutting machine to end the cut and to stand during the day, without interfering with the loading of the coal. The width of 10 feet in the bottom rock is taken so as to give room to pass on each side of the car.

Twenty-four or twenty-five men are employed each day in loading out a cut and doing all that is necessary to be ready to start on the next cut. They are employed on two shifts. The night shift is composed of a machine runner and his helper, a miner and laborer, who blast the coal down after the machine, and four (sometimes five) men cutting out props and moving the conveyer forward. The day shift is made up of eleven loaders along the conveyer, two timber men, a miner to put in pop holes, a man to run the conveyer, and a boss.

The conveyer itself can be moved forward readily, possibly two men could do this in a couple of hours, but local conditions interfere, the roof being so bad that it settles down on the props, which are set on each side of the conveyer, and to remove the props and stand them again after the conveyer is moved forward, requires time. Only props are placed on the inside, but along the gangways cogs are built, using old car lumber for the purpose. This allows the roof to come down and not hang so hard on the coal face.

Dynamite is used in blowing down the coal after undercutting, where the coal is cracked, otherwise black powder is used. Sometimes the coal is so broken that it falls as soon as it is undercut, no powder being needed. Over 200 cars of coal are obtained to a keg of powder.

The gangways for these panels are driven 500 feet apart. In this way half of the road is taken while advancing, and half while retreating. This method also provides that the shortest length of roadways shall be driven for the coal obtained. At the same time the working face is made the correct length so that a certain quantity of coal can be obtained from it each day. The length of undercut is such that it can be done in one shift, and even when the runners have been late in finishing the cut, the coal has been loaded out by hustling, so that the place was working regularly the next day. To obtain the same amount of coal by room-and-pillar mining as is obtained by this method, some 25 or more rooms would have to be maintained. Over 1,500 cars were mined by the panel system in February last. One great advantage that this method has, is that the work of taking up bottom rock and its great cost is reduced to a minimum. Moreover, a greater proportion of laborers are employed to the number of miners and skilled workmen, and the coal that is obtained makes a larger percentage of prepared sizes.

American Mine Safety Association

As the result of a conference held under the auspices of the United States Bureau of Mines last September, between men who are interested in the saving of the lives of miners, there has been formed a society known as the American Mine Safety Association, with headquarters at 40th and Butler Streets, Pittsburg, Pa. This association, which is now enrolling among its members the leading coal and metal mine operators, mining engineers, and mine safety engineers of the country, has for its purpose the conservation of the lives and health of the miner, and a reduction in property loss due to explosions or fires in mines. It will attempt to place before the miners standard methods to be used in rescue work and in first-aid to the injured. Membership in the American Mine Safety Association is open to any individual, firm, corporation, or society interested in reducing the loss of life and property in mines.

To Lay Out a Baseball Diamond

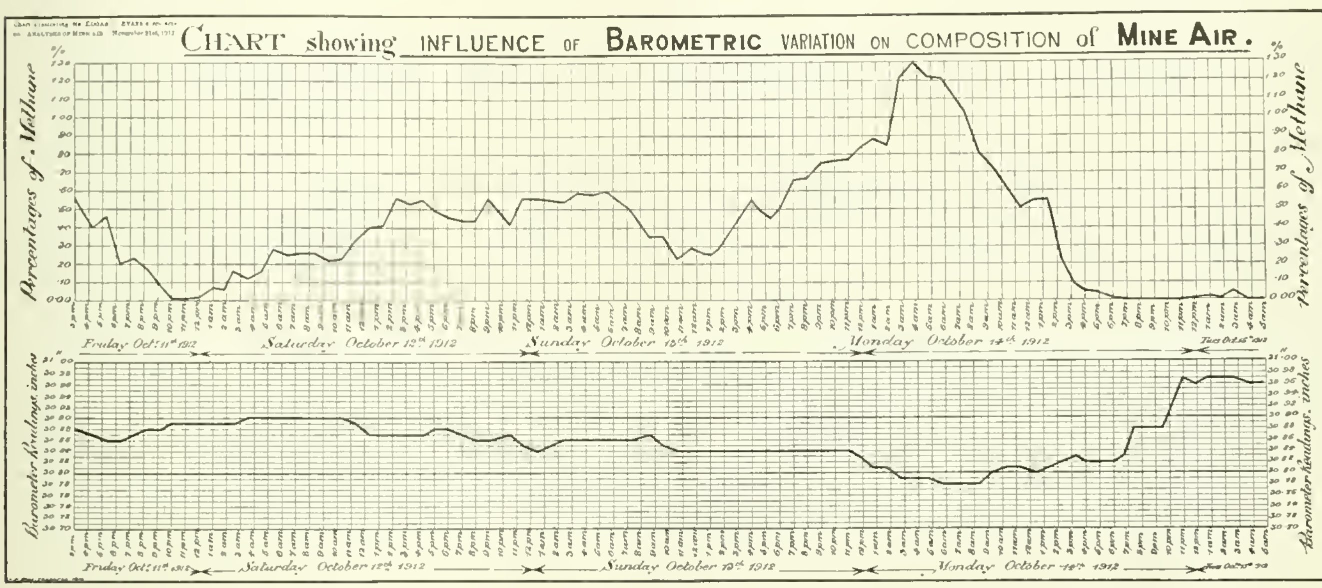
Boys or young men employed about a coal mine can easily lay out a baseball diamond of regulation size and shape with no other instrument than a tape line, by using the following directions: First, determine where the home plate is to be, and drive a stake there. Then decide in which direction, from the home plate, second base is to be. Measure in that direction a straight line 127 feet 3⅜ inches long and drive a stake there. That is the location of second base. Then with a twine exactly 90 feet long or 90 feet of the tape, hold one end on the second base stake, and with a stick held at the other end scratch arcs or parts of a circle on the ground at the approximate locations of first base and third base. Then with one end of the twine or tape held on the home plate stake, scratch arcs, as before, at the approximate locations of first and third bases. Where the arcs intersect drive stakes for the proper locations of first and third bases. Now all bases are located. To locate the pitcher's box, measure 60 feet, 6 inches, from home plate in line with second base, which gives the center of the pitcher's box.

Barometric Pressure and Mine Gases

A Discussion of the Paper by Hutchinson and Evans, an Abstract of Which Appeared in November, 1912, MINES AND MINERALS

IN THE November, 1912, issue of MINES AND MINERALS was printed an abstract from a paper by J. W. Hutchinson and Edgar C. Evans on "Analysis of Mine Air," in which were given the results of their experiments, together with curves that conclusively proved that changes in barometric pressure did have an influence on the flow of gas into a mine.

The following article is a discussion of that paper and is taken from Volume XXVIII, of the Proceedings of The South Wales Institute of Engineers:



Mr. Edgar C. Evans called attention to further work that had been undertaken by himself and Mr. Hutchinson since the publication of their last paper. In their second paper Mr. Hutchinson mentioned that under certain conditions a variation in the methane content of a mine preceded a barometric variation. It was thought that any further work on this point would be of interest; and for the purpose of their experiments they chose a time for taking samples that had been preceded by a period of 6 weeks of continued high barometric pressure. The same place was chosen for sampling as was described in their supplementary paper, and samples were taken hourly from 3 P. M. on October 11, to 2 P. M. on October 15. The results obtained are illustrated on the accompanying chart.

Two facts were clearly evident: First, considering the chart as a whole, barometric changes, however small, were in general accompanied by corresponding changes in the methane content. Second, variations in the methane percentage preceded barometric variations.

This second fact was noticeable in several places, but was especially marked in the period from 12 A. M. on Sunday, October 13, to 12 A. M. on Monday, October 14. From 12 noon on Sunday until midnight, the barometer remained steady at 30.84 inches, yet during that period the methane percentage rose steadily from .26 to .77 per cent., preceding a barometric depression of .06 inch during the next 7 hours. During that period the methane percentage further rose to 1.3 per cent., and then commenced to fall rapidly, the fall again preceding by several hours a rapid barometric rise. It was clearly evident that the methane in old workings was more sensitive to meteorological changes than the barometer.

One other important point was brought out by a comparison of these figures with those obtained in their previous experiments, and that was the great changes that were brought about in the methane percentage by only slight barometric depressions after an extended period of high pressures. Thus, in the example already given, a change of .06 inch of mercury in 7 hours caused an increase in the methane of 1.30 per cent. In absolute quantities (from a consideration of the volume of air passing) this meant that a rate of fall of only .01 inch of mercury per hour caused an ultimate evolution of 325 cubic feet of methane per minute from the old workings. The importance of these facts could scarcely be overestimated, and helped to account for the many mining disasters that had occurred after extended periods of high barometric pressure. The conclusions arrived at from a consideration of these results had been affirmed by some observers, but denied by others. The discrepancies were probably due to the different conditions under which the experiments were made. In the present case the conditions were peculiarly favorable; the authors were tapping a very large area of old workings, and the results were not affected by any other factors, such as those due to working the coal, etc.

Mr. T. E. Richards said the writers of the two papers on gas analysis were to be congratulated upon their contributions to the memoirs of the Institute.

By their efforts the rough-and-ready observations of the past had been proved and placed upon a more secure and scientific basis, showing, in the first place, that barometric movements were indicative of greater or less exudations of gas; and, in the second place, that by careful observation it was now clearly proved that variations of the gas pressure were more sensitive than barometric movements. It might be interesting to place on record how many of our old firemen were possessed of the knowledge of the above facts without being able to give scientific reasons therefor. The speaker remembered some 25 years ago seeing in a gob wall across a main level in a Rhondda colliery (which level had been stowed from the face back for some 150 yards) a hole about 15 inches square and about 3 feet deep, where the fireman was accustomed to keep his walking stick and deposit his lunch. It was his daily habit before the morning examination to make a preliminary test of the conditions of his district by pushing his Davy lamp into this hole each morning, and he invariably found that if the hole was perfectly clear of gas to the furthest extremity he would have no difficulties with gas feeders that morning. If he found a gas cap at the back of the hole he would expect to find the strongest feeders in his district manifesting themselves to a greater degree; whereas if he discovered that gas could be found within 12 to 15 inches of the mouth of the hole he could calculate upon having considerable trouble with the arrangements of his brattice sheets that day. The ingenious indicator very much impressed the speaker at the time; and for many years after, endeavors were made to correlate the movements of gas blowers with those of the barometer, and the observations made from time to time by a large number of officials were to the effect that with a fairly steady gas feeder the pressure variations of the atmosphere could be detected by it a considerable time before the barometer had commenced to move.

As to the effect of the ventilating fan upon the issue of gas, a number of experiments carried out by the speaker, under the superintendence of the late Mr. Wm. Thomas, Brynawel, Aberdare, conclusively proved that by watching closely the action of a number of constant feeders, that almost invariably the level of the igniting line was lowered as the fan speed was reduced; but there were one or two blowers which acted otherwise, a feature which could not be explained, but no doubt with further experiments it would have been shown, as indicated in the author's paper, that it was the result of opposing factors.

Further experiments were made at the same time as to the result of placing regulators of different dimensions between the downcast and return airways, and they bore, invariably, conclusive evidence as to the correctness of the remarks made by Mr. Wight during the last discussion.

One of the most important points emphasized by these papers was that the greatest percentage of methane was found in the return air at the end of the coal shift, and the effect of this on the question of shot firing has, he believed, not been brought forward yet. It has been a practice at some collieries to take advantage of the afternoon shift, when the fewest number of men are in, to perform any shot firing that might be needed. It was now clearly shown that it was very probable a new arrangement must be made, and that a considerable time must be allowed to elapse after the coal shift had terminated before any blasting could be permitted. The colliery manager was now between Scylla and Charybdis: he must, if necessity compelled, take the risk of carrying out the shot firing during the night shift, with its large body of men, or take advantage of the latest hour possible of the afternoon shift, with its risk of a dangerous cap; or if both are too far in the danger zone he will have to postpone all shot firing until Sunday, and thus keep his "rippins" in order (if possible) by taking advantage of this one day in the week for this work, with its consequent heavier cost, and disturbance of the Monday's output.

Mr. J. W. Hutchinson's remarks had reference to observations that were made at the previous meeting. He stated at the last meeting held in Cardiff that Mr. Evans and himself intended to submit a supplementary paper showing the effect which the variation in the speed of the fan had on the amount of methane on the return airways. The slowing and stopping of the fan certainly increased the barometric pressure through the mine. The effect this had on the amount of methane exuding from cavities and fissures was clearly shown in the charts and tables attached to the paper. The quantity of methane was, for a time at any rate, checked by the increased pressure, and when the fan was again started the methane at once exuded in large quantities.

He agreed with Mr. Hugh Bramwell that the natural changes in atmospheric pressure had no applicable effect upon the issue of gas from the coal itself, but he thought the experiments clearly proved that slight changes in the barometric pressure did affect the amount of methane issuing from cavities and old workings. With regard to the question of methane issuing from the strata before any changes could be observed on the barometer, mining engineers generally had for many years accepted this as an established fact. At a colliery in Durham a blower of gas was piped to the pit bottom and allowed to burn. The burner end of the pipe was fitted into a large glass case, and sometimes before any change could be observed on the barometer a change could be seen on the flame, a fall in the barometer being indicated by an increase in the length of the flame, and a rise by a decrease—sometimes 2 hours before any change took place on the barometer. He was inclined to agree with Doctor Atkinson that what was called the personal equation was not sufficiently appreciated. He had certainly proved by actual experiments that practical firemen of many years experience would differ as to the exact height of a gas cap, although their eyesight was shown by doctor's examination to be equally good.

Forecasting Barometric Changes

An Explanation of the Methods of Working. Use of the Information Given on the Daily Maps of the United States Weather Bureau

Written for Mines and Minerals

A WEATHER map of the United is issued daily by the Weather Bureau in the Department of Agriculture. It has been proposed by the Bureau of Mines that a warning be issued in the mining regions, similar to that which is now issued to shippers and which accompanies the weather forecast. For any one who is accustomed to reading the maps and understands the lines and figures which are printed on them, a special warning is not necessary, as that person can tell what atmospheric conditions are approaching his mine.

In the reproduction of one of the maps, Fig. 1, it will be seen that on the east coast of the state of Florida is marked the word "high." This indicates a center where a high barometric pressure exists. The curved line which passes through Florida is called an isobar, and indicates a line along which the barometric pressures are equal. At each end of this line are placed the figures 30.1, which indicate that the barometric pressure is 30.1 inches of mercury along this line. These lines of equal barometric pressure, or isobars, are drawn solid; whereas lines of equal temperature, or isotherms, are drawn dotted. There are only two lines of equal temperature on this map, both of them indicating zero temperature. Isotherms are only drawn for three temperatures, 0, 90, and 100 degrees.

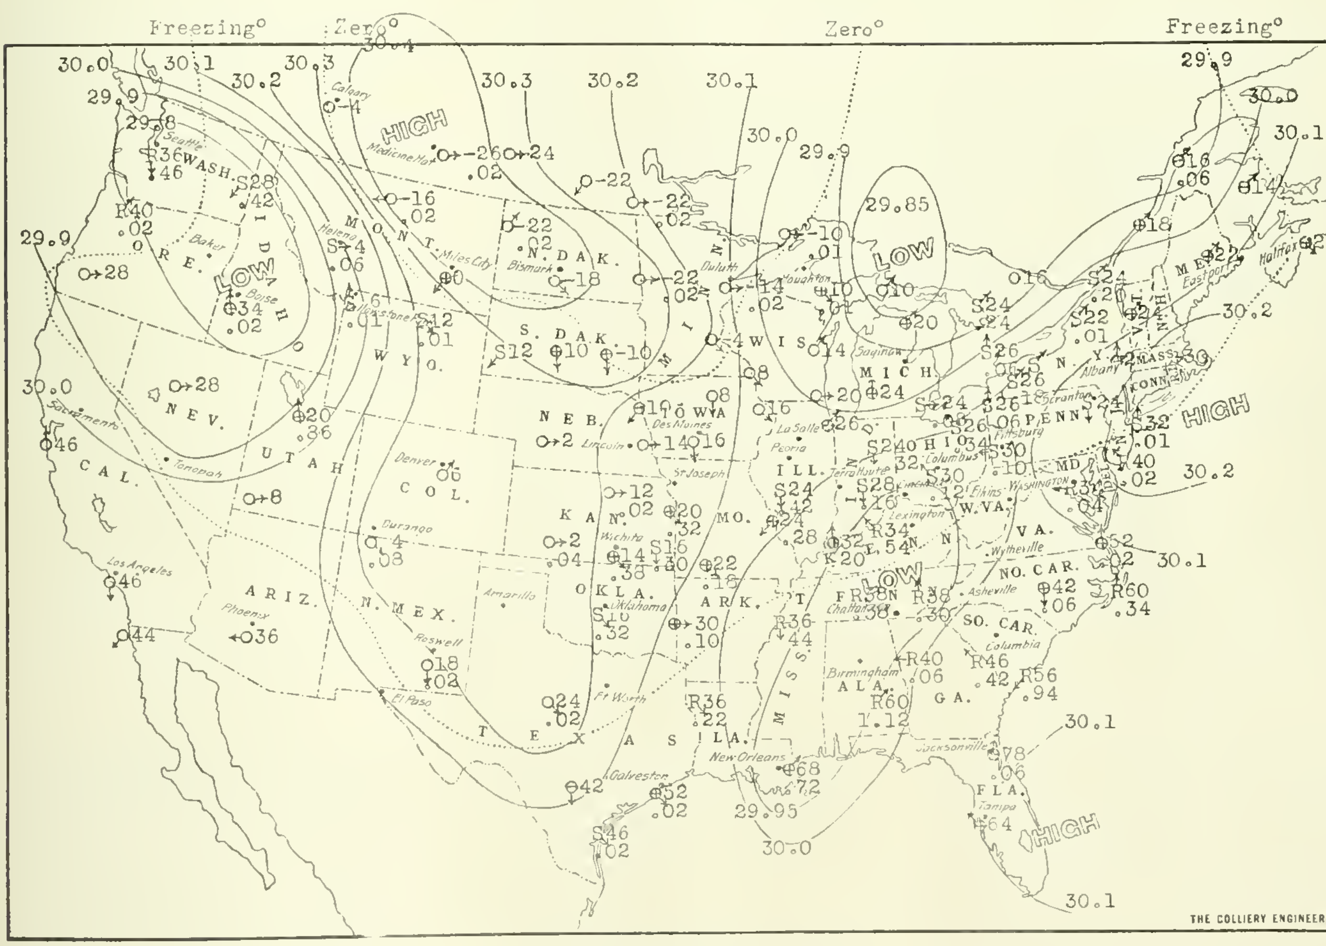


FIG. 1. UNITED STATES WEATHER MAP

Marked on the state of Tennessee is the word "Low," indicating a center of low barometric pressure, which is less than 29.95 inches of mercury. For the low is marked inside of an equal barometric line—an isobar—indicating a barometric pressure of 29.95 as marked on the map in the break on the line off the coast of Louisiana. Another low is marked on the map just above the Great Lakes, where the pressure is less than 29.85 as shown by the figures just above the word Low, placed in a break in an isobar.

All the barometric pressures are reduced to sea level. The barometric pressure of places such as Denver and Pittsburg have air pressures as recorded, which are less than at a point at sea level, as barometric pressure decreases with altitude above sea level. But when an addition is made to the recorded barometric pressure, which is equal to the decrease due to altitude, it may so happen that Pittsburg and Denver have equal air pressures.

The map has also certain symbols and numerals, which indicate various things; a circle indicates clear weather at that point; a circle with a horizontal bar through the center means partly cloudy weather; a circle with a cross in it shows cloudy weather; the letter R means rain; S snow; M report missing. Arrows attached to the circles or letters, show which way the wind blows, pointing with the wind, not in the direction from which it blows.

The figures which are printed associated with the circles indicate first the temperature; below that the rain precipitated during the past 24 hours; and then sometimes below that the maximum wind velocity.

For instance at Tampa, Fla., is found a circle with a cross in it, an arrow pointing northwest, and 64; it means that the weather was cloudy at Tampa with a southeast wind and a temperature of 64 degrees. At Jacksonville, Fla., the wind blew from the south and it was partly cloudy with .06 inches of rain during the day, at a temperature of 78 degrees. The maximum wind velocity is not given at either place on the map but in the printed record which accompanies the map can be found a record of the velocity of the wind at 8 A. M.

In one corner of the map is the following legend: "When the wind sets in from points between south and southeast and the barometer falls steadily, a storm is approaching from the west or northwest and its center will pass near or north of the observer within 12 to 24 hours, with wind shifting to northwest by way of southwest and west. When the wind sets in from points between east and northeast and the barometer falls steadily, a storm is approaching from the south or southwest and its center will pass near or to the south or east of the observer within 12 to 24 hours, with wind shifting to northwest by way of north. The rapidity of the storm's approach and its intensity will be indicated by the rate and amount of the fall in the barometer."

Centers of low barometric pressure are storm centers. It has been found that storms move across the United States in certain general directions, and therefore forecasts can be made.

The things which the miner must watch are not the storms with high winds, which are so much feared at sea, but the atmospheric conditions of cold dry air or of a low barometer. When there is in a mine a large area of old workings, which might contain a body of gas, then the variations in the barometer must be watched. For gas explosions often occur at times of low barometric pressure. Dust explosions, however, may occur when the barometric pressure is high, but when the air does not carry much moisture, or has not for some time. This will happen when the temperature is low and the weather clear.

As an advantage to the miner, the Weather Bureau might publish the hygrometric condition of the air, that is the amount of moisture which it contains, so that dangers from dry dust might be more thoroughly avoided. For when the daylight temperature falls below the temperature of the mine, it is probable that, unless the outside air is very moist, water will be absorbed from the mine. And this absorption will vary slightly according to the barometric pressure, being greater with a high barometer, especially with a blowing fan.

Trinidad Chapter, Rocky Mountain Coal Mining Institute

The first quarterly meeting of the Trinidad Chapter of the Rocky Mountain Coal Mining Institute, was held at the Columbian Hotel, in Trinidad, Colo., in February. About one hundred members of the chapter were present. Mr. M. O. Danford was the chairman of the evening and in opening the meeting explained the purposes for which the institute had been organized and the formation of local chapters.

The first paper of the evening was read by Robert McAllister, mine inspector for the Colorado Fuel and Iron Co., the subject being "The Duties of a Fire Boss." Mr. McAllister showed how much dependence is placed upon the faithfulness of the fire boss in the operation of a mine. Mr. Dave Griffiths added some remarks to those of Mr. McAllister.

Mr. E. H. Weitzel, general manager of the C. F. and I. Co., who is president of the Rocky Mountain Institute, spoke upon the relation between employe and employer, especially in the avoidance of accidents, and of the need of the steadiest men as those to be employed in the mines, reviewing at the same time the statistics of accidents in Colorado mines, showing that in Las Animas County 220,339 tons of coal had been mined for each fatal accident. Dr. T. J. Forhan delivered an address upon first-aid and welfare work around the mines.

Institution of Mining and Metallurgical Engineers

The Institution of Mining and Metallurgical Engineers has been established in London, England. Its object is to advance mining and metallurgical science, more particularly for promoting the acquisition of that species of knowledge which constitutes the profession of a Mining Engineer. At present the headquarters will be at offices of *The Mining Journal*, 99 Shoe Lane, Fleet Street, London, E. C., England.

WELFARE WORK AT COAL MINES

A Bath House Proposition

*By J. E. Butler**

The bath house for the use of coal miners is not an innovation. In the older mining communities it is as much a part of the equipment of the modern mine as the tipple, the machine shop, and the power plant, but in Kentucky, and especially in the mountain district, it is uncommon.

The Stearns Coal and Lumber Co., when it attempted to improve the condition of its miners, by erecting for them a wash house, did so with misgivings. It is rather a delicate subject to approach, to suggest that any man would feel better if he had a bath once a day, and some men are sensitive, especially when it is the "company" which does the suggesting.

The first experiment, for it was so considered, was at mine No. 4, which employs about 200 men. A simple wooden building, with 60 lockers, four showers, and about a dozen basins, over which were hot and cold water faucets, was constructed. It was heated by a stove and electric lighted. The water was piped from a reservoir and heated by an old portable boiler.

The problem of supporting the bath house was a serious one, for an attendant, night and day, was required. It was solved by charging all who used a locker 50 cents per month, and all other employes at the mine 25 cents per month "whether they needed a bath or not." There was considerable opposition to this at first, but the miners soon realized the advantages and were willing to pay for them. As it stands the company furnishes the building, equipment, water and light free, and the miners pay the other running expenses. This means of maintenance seems based on sound business principles. Luxuries that cost nothing are not usually appreciated.

In a short time the miners at No. 10, a larger mine of the company, sent a petition signed by no less than 90 per cent. of their number, asking for a bath house on similar terms.

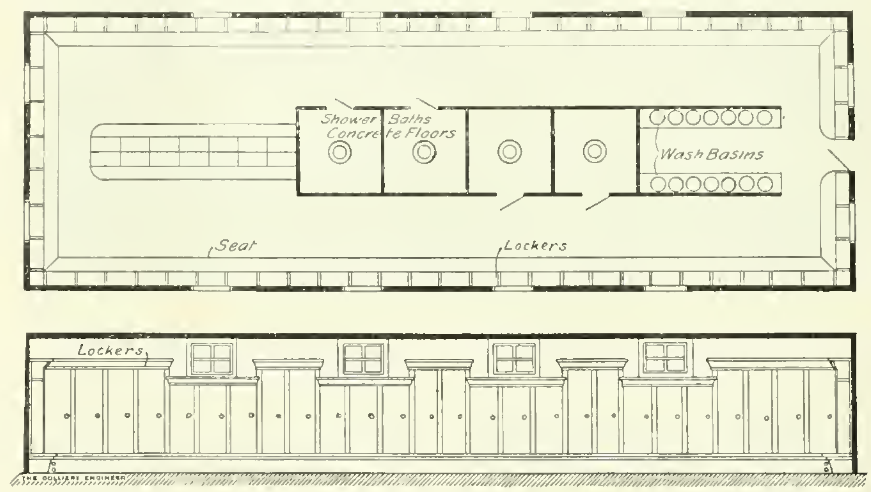

Fig. 1. Plan and Elevation of Bath House

The plan shown in Fig. 1 will give an idea of the one which was constructed in answer to their request. It is larger than that at mine No. 4, and contains 100 lockers, four showers with concrete floors, and a good supply of basins. No lockers are placed over others and they are of such height as will receive a full suit of clothing without folding. Holes are bored in the doors for ventilation. The building is electric lighted and steam heated. A motor-driven pump and a 10,000-gallon tank take care of the water during dry weather, at other times water will be piped from hillside springs.

Possibly the principal beneficiary of the miner's bath house is the housewife, but the miner derives much comfort from it, since it permits him to leave his working clothes at the mine, where they belong, and to appear on the trains, in the office, commissaries, and at home in apparel befitting the well-to-do workman.

*General Manager of Mines, Stearns Coal and Lumber Co., Stearns, Ky.

Saved by the Mine Telephone

The public at large has for some time past appreciated what great reason they have to be grateful for the invention of the telephone; but there are today two miners in Kansas who are more than grateful. They owe their lives to it.

These two miners are shot firers, employed by the Girard Coal Co., in a mine at Radley, Kans. The mines of this company have recently been equipped with mine telephones. According to the rules of the coal company, the shot firers must report to the night engineer, by means of the telephone, the progress of their work as they go through the mine lighting the shots. This enables the engineer to know where the men are, so that if he does not hear from them at certain intervals, a rescue party may be sent down.

One evening after the miners had left, the shot firers went down as usual to fire the shots. The two men had entered a refuge hole and one was in the act of ringing the engineer to tell him that they had lighted the shots in that particular entry, when an explosion occurred. The force of the explosion was so strong that it blew in the back end of the refuge hole and the shot firer did not have a chance to talk, but was stunned and overcome by the afterdamp. His partner was likewise overcome. The night engineer, knowing that this was the station from which they should next report, immediately tried to call them, and being unable to get any response, blew the distress whistle. Fifteen minutes after the explosion had occurred, a rescue party was in this refuge hole. The two shot firers were carried out and resuscitated. Had a little more time elapsed before they were reached it would undoubtedly have been impossible to revive them.

Fig. 2. Lunch Room, Prospect Colliery

Lunch House at a Colliery

The Lehigh Valley Coal Co. have remodeled the old machine shop at their Prospect colliery, near Wilkes-Barre, Pa., into a building where the outside employes can eat their lunch and change their clothes. The Prospect colliery buildings are built on a knoll that rises above the level of the Wyoming Valley, so that they are exposed to winter winds. It was realized that it was due to the employes, especially the boys and the old men, that a place should be provided where they could eat their lunch in warmth and comfort and have a smoke at noon.

The building which was taken for the purpose, is 54 feet square and planned as shown in Fig. 3. It stands several hundred feet from the breaker on the south side of the knoll, so that it is somewhat protected from the winds, has the warmth of the sun, and is away from the thick dust of the breaker.

The building inside is divided into three rooms and a hall. The lunch room, shown in Fig. 2, occupies one-half of the building, the other half being divided into the hall, a locker room, and a wash room. To form the partitions between the rooms, expanded metal has been fastened to all the joists and upon this has been placed concrete plaster. The ceiling has been plastered in the same way, so that all the rooms are completely plastered. The plaster has been painted black up to a height of the usual wainscoting and white above that, the white surface being relieved by stenciled borders. The woodwork around all the windows is also finished in white. The result is that the rooms are very cheerful. The floors are concrete, the ground being leveled and then 6 inches of concrete placed on top, and painted gray.

Of the 225 outside employes, not all care for the use of a locker, so 100 lockers of the common metal form, have been provided, that those who may desire to change their clothes before and after work, may do so. In the wash room there are six toilets, two shower baths, and 12 enameled wash basins. Hot and cold running water is provided and the building is heated throughout by steam. Drainage is by means of a 6-inch bore hole at a little distance from the building, which goes down about 100 feet to the old workings in one of the seams.

In the lunch room there are six tables 30 inches wide, made with a bench on each side, the bench being made as a part of the table. They are made out of 2-inch oak, being finished in the natural color, oiled and varnished, so that they can be easily taken care of. City water is supplied for drinking purposes.

It is not the intention of the company to supply food, but to provide a place where the men can eat what they bring in their buckets. About 50 of the men have formed a small club to provide warm coffee, each man paying his share of the expense. To facilitate this, the company has agreed to put coffee percolators in the lunch room which the men are to use.

It is the intention of the company to grade about the building, cover the ground with loam, and over this lay sod and possibly have flower beds. A fairly good idea of the way the Lehigh Valley Coal Co. is improving the grounds about its collieries can be obtained from the August, 1911, cover of Mines and Minerals.

When the Buck Mountain breaker was built by the same company a year ago, a room beneath the coal pockets was provided for the men. This breaker was built with a combination of concrete and steel, the pockets being made out of concrete and the rest out of steel with corrugated iron siding. The room for the men was

Fig. 3. Plan of Lunch House, Prospect Colliery

built under the breaker floor. An emergency hospital was provided here also. The arrangement at Buck Mountain is not so elaborate as at the Prospect colliery, as it is not a separate building; but owing to its situation on top of the mountain, and its distance from the men's homes, it is fully as much appreciated by the men as the Prospect colliery lunch room.

Emergency Car—C. F. & I. Co.

The Colorado Fuel and Iron Co., in addition to their helmet car, have a standard box car fitted with material that is likely to be wanted in the case of a coal-mine fire or coal-mine explosion. Fig. 4 is a plan of the car showing the positions in which the supplies are kept. The equipment on this car is as follows: One 5-foot diameter Stine disk fan complete, with a sectional case bolted together and all mounted on a truck. The fan shaft extends beyond one of the bearings and has on its end one-half a flexible coupling to which a motor supplied with a similar half is attached. As it is the intention to use the fan at mines which are supplied with either alternating or direct current, three kinds of motors are carried in the car, each of which will fit the conditions of current at some one of the mines.

No. 1 is a direct-current motor, semienclosed, 20 horsepower at 550 revolutions per minute under 250 to 500 volts. It has a controller. No. 2 is an alternating, 25-cycle, three-phase-wound rotor, induction motor of 20 horsepower at 480 revolutions per minute and 440 volts. No. 3 is an alternating, 60-cycle, three-phase-wound rotor, induction motor of 20 horsepower at 575 revolutions per minute and 440 volts. As the motors are of different heights, a special bed-plate with bolt holes to match those of the motors is provided. The motors which have the half couplings are brought to center with the fan shaft by building up the bed-plate with ready-made liners. In this manner no time will be lost in getting the fan in position and to work. Each machine is mounted on a truck constructed especially for it and having a movable wheel base, as shown in Fig. 6, so that it can be run on a 36-inch, 38-inch, or 40-inch track gauge.

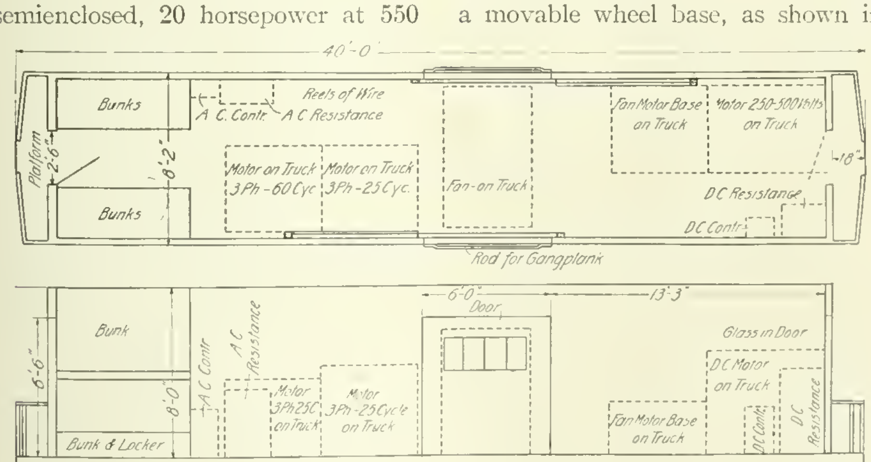

FIG. 4. PLAN AND ELEVATION OF C. F. & I. Co., EMERGENCY CAR

The additional electric equipment consists of one resistance for direct-current motors; one controller for direct-current motors; one resistance for the alternating-current motors; one controller for the alternating-current motors.

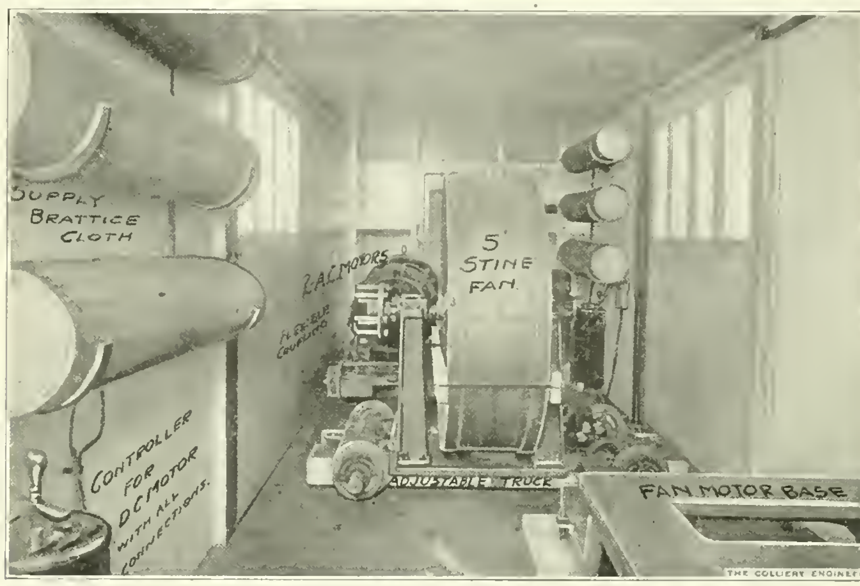

FIG. 5. PART OF INTERIOR OF EMERGENCY CAR

The trucks containing the machinery are pushed through the side doors of the car and over two gang planks connecting the car with the platform or unloading station. These gang planks are 3 inches thick, 18 inches wide, and 14 feet long, properly shod and ironed. In the car there are 2,000 feet of No. 4 wire duplex rubber-covered cable on a reel; two 4-ton jacks; three iron blocks for 1-inch rope; 250 feet of 1-inch rope; two 10-foot $\frac{3}{8}$-inch cable chains with loops and hoops; four iron dollies; six rolls of 72-inch brattice cloth which are shown in Fig. 5 supported on the sides of the car; and the two gang planks already mentioned which are used for handling the heavy material.

The supplies carried on this car are supplemented by those carried on the helmet car, it being the intention to move the two cars together; they consist of a full supply of shovels, picks, axes, saws, hammers, bars, sledges, disinfectants, rubber gloves, cooking utensils, 2,000 feet of $\frac{1}{2}$-inch fire hose, stretchers, tents, pipe wrenches, dies, pipe fittings, nails, besides the eight Draeger helmets, two Pulmotors, a good supply of potash cartridges, oxygen, safety lamps, gasoline, fire extinguishers, complete first-aid equipment, flash lights, lanterns, a full set of blueprints of all mines, and eight portable telephones equipped with 1 mile of twin conductor cable made up in accordance with the United States Army General Specifications No. 548, as follows: Each conductor made up of seven wires .010 inch, the center wire being copper, surrounded by six steel wires, each conductor insulated with $\frac{1}{64}$-inch 30 per cent. rubber compound and braided conductor, laid parallel, and covered with weather-proof braid.

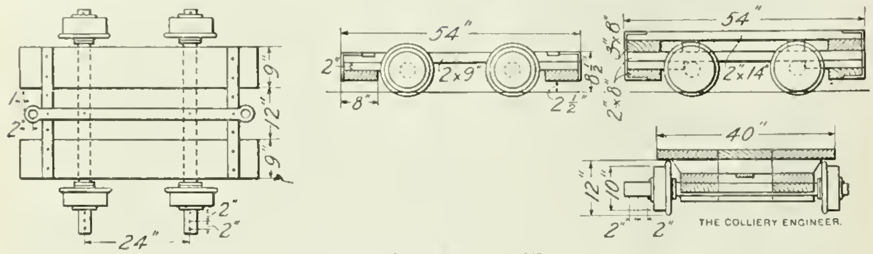

Fig. 6. Truck With Movable Wheel Base

The telephones are for use in rescue work, which, with the light wire to be carried by helmet crews will facilitate advancing, in case of necessity.

First Aid in Kentucky

The following letter has been sent by the Chief Inspector of Mines to all coal operators in the state of Kentucky:

Naturally, I am solicitous that our mining companies shall adopt every means possible for reducing the death rate from mine accidents, and for affording quick and proper relief for the injured generally.

I am thoroughly satisfied that many a man has died from loss of blood, from shock ("heart failure"), from delayed attention to fractures, from asphyxiation due to electric shock, etc., who might have been saved had his associates known what to do for him while waiting for a doctor. I think it unquestionable that many an injured man has died really from the way he was handled while being taken from the mine. I have good reason to believe that men who have died from blood poisoning following injuries not otherwise fatal, suffered blood poisoning simply because of improper treatment, or lack of proper treatment, at the time of the injury and before the physician could see them. A man had a leg broken; some weeks thereafter he died from blood poisoning. It appears quite probable that the infection occurred through improper treatment before the doctor could reach the patient. Other examples will occur to you.

Men are hurt in the mines almost daily. Simply through lack of proper care, or because of ill-advised treatment before the physician arrives, a comparatively simple injury may result in permanent disability.

I deem it of utmost importance, therefore, that the men employed at mines shall know what to do and what not to do in the case of accidents; they should know the methods of "first aid." With the miners themselves trained in such methods, a long step will be taken toward the reduction of fatalities; and through intelligent application of "first aid," suffering will be relieved, fewer cripples will be made, and recovery will be hastened in the case of non-fatal accidents generally.

If you have not already done so, I respectfully but earnestly urge that you take this matter up at your mines, and arrange for instruction in "first aid" to be given your men.

The cost of the necessary outfit is very little; your mine physician can readily take care of the training. Moreover, the United States Bureau of Mines now has mine safety cars in the state especially for instructional purposes, and I am advised by Mr. Wilson that the cars will remain in the state so long as there is work for them to do. I do not doubt that the Bureau will gladly send a car to your mine or vicinity if you will ask for it. You should address H. M. Wilson, Engineer in Charge, Bureau of Mines, Pittsburg, Pa.

The Red Cross, Washington, D. C., also offers to assist in giving "first aid" instruction at our mines.

As you doubtless know, the Kentucky Mining Institute is arranging for a state-wide "First-Aid Contest," to be held at Lexington next May. This affords an opportunity for you to arouse an interest in "first aid" on the part of your men, by organizing a team or teams at your mines to take part in said contest. I hope you will do so, for I believe if the mining companies generally will heartily cooperate in making the contest notably successful, it will exert an influence for great good throughout our mining fields. "Do it now."

I will be glad to hear from you in regard to this matter. Anything that I can do to serve you will be done with pleasure.

C. J. Norwood,
Chief Inspector of Mines.

American Museum of Safety

The Jury of Awards of the American Museum of Safety met in the United Engineering Societies building in January last and awarded four medals. The Scientific American Gold Medal is presented for some safety or life-saving device, invented within the past 3 years, and exhibited in the Museum's collections. The device selected for 1912 for this medal was the Pulmotor, belonging to the Draeger Oxygen Apparatus Co., of Pittsburg, Pa., a machine for setting up artificial respiration in a person asphyxiated, or whose nerve centers having been partly paralyzed by electric shock, causing respiration to stop, although there may still be some slight heart action.

The Pulmotor has been very successful in saving life and is worthy of all the praises, never mind the medals, it has been receiving; for example, in one place in one year 24 lives were saved; two people had taken overdoses of morphine; two others were revived after serious operations; one recovery was a case of electric shock and the remainder were cases of gas poisoning.

The phenomena of respiration are combinations of mechanical action and chemical reactions. The presence of poisons in the blood current stimulates the brain cells, which automatically start up the muscles of diaphragm and thorax whereby the chest cavity is expanded and air flows in to react upon the blood exposed to such oxygenating action. If the poison is excessive, if the lung cavity is filled with water, or if the chemical compound in the blood is stable and unbreakable, oxygenation does not take place, the nerve centers are paralyzed and death results. Artificial respiration has been accomplished by hand many times, but it is hard, tedious work that only the most determined will stand, and the Pulmotor comes therefore as a relief, and great help, for it operates automatically and will continue for 40 minutes, or until its oxygen tank is exhausted.

Relative Vocational Hazards

A Comparison of the Number of Accidents Occurring to Those Engaged in Various Trades in Different Countries

*By Hywel Davis**

THE most perfectly regulated industrial organization is liable to disaster unless a perfect knowledge exists of the dependence of each unit and the absolute necessity for a harmonious whole.

The present age of good intentions is paving the way to a greater number of injured mankind than existed in prehistoric times, because with our limited knowledge and ignorance some sacrifice is prerequisite to success. The six bloodiest battles of the Civil War sink into insignificance compared with the annual industrial toll of casualties extracted by the present so-called civilized age.

In 1908 Great Britian had 3,447 killed and 323,224 injured, the German Empire 9,687 killed and 662,321 injured, while the United States had 40,000 killed and over 500,000 injured, the railroads contributing 10,396 killed and 150,159 injured.

Our statistical records of accidents, outside the railroads and mining, are far from being as complete as the German and British, and it is interesting to note the analysis of the German records showing the actual proportion of all accidents divided between the different vocations and their respective hazards:

GERMAN PERCENTAGE OF ACCIDENT HAZARDS

Classification	Deaths	Injured	Partial Disablement	Complete Disablement
Agriculture and horticulture	30.5	43.50	45.00	32.50
Iron and steel industry	7.5	10.50	13.00	13.00
Mining	19.0	8.25	6.00	5.00
Building construction	8.5	7.50	6.00	5.50
State employ and railroads	8.5	4.00	4.00	18.00
Wood industry	2.0	3.50	3.25	1.00
Warehouses	2.5	2.00	2.25	2.25
Quarries	2.5	2.00	1.50	3.00
Textile	1.0	2.00	2.50	1.00
Excavations	2.0	1.75	1.50	4.25
Teaming	2.5	1.50		
All other industries	13.5	13.50	15.00	14.50
Total per cent	100.0	100.00	100.00	100.00

ANALYZED

	Industrial Per Cent.	Agricultural Per Cent.
The hazard of industry or occupation	43	33
Employer's fault	17⅓	18¾
Worker's fault	29¾	25
Employer's and worker's fault	10	23⅓

Note specially the surprising ratio of agricultural casualties.

German deaths caused by occupational accident have practically doubled since 1890, when they numbered only 45 per 10,000 deaths in the Empire, but in 1908 the latest record shows the number had grown to 80 per 10,000 deaths, or $\frac{8}{10}$ of 1 per cent. of the total annual deaths.

The British relative hazard of occupation other than agricultural is shown for the year 1908 as follows:

	Deaths Per 1,000 Employed
Home shipping trade	1⅘
Docks	1⅘
Mines	1¼
Quarries	1
Railways	1
Building trade	.9
Factories	⅔

British home and foreign shipping trade:

	Per 1,000 Employed
Deaths on sailing vessel trade	12.69
Deaths on steam vessel trade	4.45

The last attempt at a complete record by the United States Census Bureau is that of 1909, which gives the following surprising totals of deaths from accidents due to familiar causes:

Railroads	6,659
Autos	632
Gunshot and wounds	944
Horses and vehicles	2,152
Drowning	4,558
Street cars	1,723
Burns and scalds	3,992
Injuries at birth	3,508
Coal mining	1,779
Sunstroke and heat	816

Other causes not given in detail raise the total accidental deaths to nearly 43,500, which justified a recent writer to say that "the tragedy of death through industrial accidents is enacted 100 times daily in this country, or 35,000 times a year. The danger to the laborer increases with the progress of the age. With each new invention the number of the killed and injured rises." This being largely true, let the country at large know also that in what they consider a very dangerous avocation employing 750,000 in the coal mines, the toll of accidents places them *sixth* in the list of relative hazards, with a death toll of 1,779 in 1909 or only 60 more than the 1,719 total killed on 10 successive 4ths of July, ending with 1911, or only 56 more than killed by street cars in the same

* An abstract from a paper read by Hywel Davis, of Louisville, Ky., at the December meeting of the Kentucky Mining Institute.

year, and 1,000 less than the number killed by horses and vehicles and automobiles in the country at large.

The purpose of this paper is not to minimize the gravity of mining accidents, nor deplore their fatal recurrence the less, but rather a plea that the Government Bureau of Statistics shall give the subject of all industrial accidents the proper consideration, so that bulletins on accidents will furnish an intelligent review or analysis of causes, that will be fair and just to all industries, instead of the present policy of exploiting the accidents of one industry or vocation without regard to the greater contribution to the toll of deaths by industries, vocations or preventable diseases not supervised by commissions or tabulated by bureaus.

Analyses of the casualties or industrial accidents with such meager statistics as we have for the United States show the following relative hazards of vocations for the ten years ending in 1906:

First.—Navigation in 1910: 1,443 wrecks; 365 vessels totally lost with loss of vessels and cargo amounting to 13½ million dollars and 403 lives lost. The ratio of lives lost among the Gloucester fishermen was 11.7 per thousand employed.

Second.—Railroad trainmen, 7.46 per 1,000 employed. Railroad switch and flagmen, 4.50 per 1,000 employed.

Third.—Iron mines of Michigan, 4.25 per 1,000 employed.

Fourth.—Anthracite mines of Pennsylvania, 3.18 per 1,000 employed.

Fifth.—Lead and zinc mines of Missouri, 3.01 per 1,000 employed.

Sixth.—Gold and silver mines of Colorado, 2.85 per 1,000 employed.

Seventh.—Copper mining and quarries, 2.80 per 1,000 employed.

Eighth.—Bituminous coal mining, 2.77 per 1,000 employed.

A further analysis of the casualties in coal mining brings out some marked differences in the record of the different mining states, and no wonder the Western metal miners look upon coal mining as very dangerous compared with their own relative state experiences.

Although the average for the bituminous mines of the United States was only 3.08 per 1,000 employed for the last 42 years, the average for Utah for 15 years is 11.67 per 1,000 employed, while that of Washington for 17 years is 6.40; that of New Mexico for 14 years, 7.25; and of Colorado for 20 years, 5.51 per 1,000 employed.

Coming to the Southern States, the average for Tennessee for 18 years has been 4.38 per 1,000 employed; West Virginia for 25 years, 4.62; and Kentucky for 22 years, 1.71 per 1,000 employed.

But Kentucky has two distinct coal fields, which further show a very material difference in the element of safety. The Eastern field covers 10,000 square miles and forms part of the Appalachian coal field. This section of the state employs about 50 per cent. of the miners and produces 40 per cent. of the coal. It has never had a serious explosion that killed over five men at the same time, but two-thirds of the mining accidents in the state occur in this field—they are principally from falls of roof.

Western Kentucky has 6,000 square miles of the southeastern corner of the great Central States coal field, produces 60 per cent. of the coal or about 8,000,000 tons per annum, and employs nearly 12,000 men.

This district deserves the special consideration of the statistician of the Bureau of Mines, because here is a field almost as large as that of Great Britain, Germany, Belgium, and France put together, with untold possibilities of development, with its location adjacent to the Ohio and Mississippi rivers, yet with a mining record of freedom from accidents and industrial peace that shatters the much exploited records of low European mining fatalities.

The average for 13 years ending in 1905, according to Bulletin No. 90 of United States Labor Bureau, gives Western Kentucky the enviable record of only 1.05 killed in the mines per 1,000 employed, while the average for the following was:

	Per 1,000 Employed
Belgium, 20 years ending 1906	1.21
Great Britain, 16 years ending 1906	1.35
Prussia, 14 years ending 1904	2.30
France, 10 years ending 1910	1.25

The latter is one-third higher than the average on account of the Courrieries explosion, which killed more than 1,000 men and is the Titanic disaster of mining.

Western Kentucky not only holds the record for fewer fatal accidents per thousand employed than any coal field in the world, but in addition produces a much larger tonnage per death. Thus in 1906 the United States produced about 180,000 tons for each life lost; Great Britain 230,000 tons; Belgium, nearly 200,000 tons; and France nearly 240,000 tons. These were the best records for the European countries in several years.

Now take Kentucky with a record of an average of 300,000 tons for over 10 years, and then separate the Western Kentucky field, and you have a record of over 800,000 tons produced per life lost, with the largest company producing the average of 1,100,000 tons per annum for the last 10 years and only 10 men killed in the 10 years.

Here is a field that is rapidly expanding, and yet for safety of operation compares most favorably with the best part of the mining world.

Just one more comparison: Falls of roof cause approximately 50 per cent. of the fatalities in the United States. Bulletin No. 333 of the Bureau of Mines gives the following comparison of deaths from this cause:

	Per 1,000 Employed
1906, Belgium	.40
1906, France	.47
1906, Great Britain	.64
1906, Germany	.92
1906, United States	1.70
Western Kentucky for 1911 (3 for 12,000 men employed)	.25

These comparisons are given only to emphasize the danger and unconscious injury which indiscriminate collective statistics and the mania for general averages lead to.

Practical Talks on Coal Mining

For men who desire information on Coal Mining and related subjects presented in a simple manner

Mechanics of Mining

An Explanation of the Principles Underlying Calculations Relating to Engines, Pumps, and Other Machinery

By R. T. Strohm, M. E.

(Continued from March)

THE power of an engine or of a motor is the rate at which it does work. To find the power, it is necessary to take into account not only the amount of work done, but also the time required to do it. If one engine can hoist a loaded cage in 40 seconds, and another engine can hoist the same loaded cage in 20 seconds, then the second engine has twice the power of the first, because it can do the same work in just half the time; or, stating it in another way, it can do twice as much work as the first engine in the same time.

The power of engines and motors is usually measured by the horsepower, which is the doing of 33,000 foot-pounds of work in 1 minute, or 550 foot-pounds in 1 second. To find the power required to move a certain weight in a certain time, therefore, multiply the resistance, in pounds, by the distance moved, in feet, and divide the product by 33,000 times the time required, in minutes.

Suppose, for example, that it is desired to know how much power is required to lift the car a, Fig. 2, to the position c in 30 seconds, or $\frac{1}{2}$ minute. According to the rule just given the horsepower required is $\frac{6{,}000 \times 100}{33{,}000 \times \frac{1}{2}} = \frac{600{,}000}{16{,}500} = 36.4$ horsepower. If the car b is hauled up the slope in 2 minutes, the power is $\frac{6{,}000 \times 100}{33{,}000 \times 2} = 9.1$ horsepower. Thus, it will be seen that if the time taken to do a certain amount of work is made greater, the power required is made correspondingly less. By hoisting slowly, therefore, an engine of small power may be used for lift-

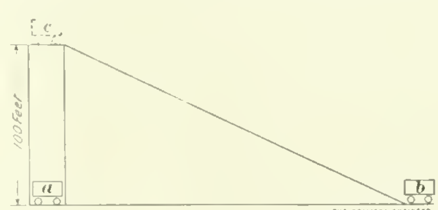

Fig. 2

ing heavy loads; but if these same loads are to be hoisted at high speed, the engine used must be of much greater power.

The power required to pull a load along a track may be found by the same rule. For example, suppose that a trip of cars requires a pull of 660 pounds to move it, and that it is hauled along at a speed of 300 feet a minute. The resistance is 660 pounds, the distance moved is 300 feet, and the time is 1 minute; therefore, by the rule given the power is $\frac{660 \times 300}{33{,}000 \times 1} = 6$ horsepower. If the speed is increased to 600 feet a minute, the power required is therefore $\frac{660 \times 600}{33{,}000 \times 1} = 12$ horsepower, or twice as much as in the former case. This shows that the power required for hauling a given load increases as the speed of hauling is increased.

The work done in and about mines depends very largely on machines of different kinds. Now, a machine is simply a device or contrivance by means of which a force acting at one place is made to produce another force acting at some other point. A hoisting engine is an example of a machine, because the force of the steam pressure in the cylinder is transmitted through the connecting-rod and the crank to cause a drum to turn, and a rope wound on the drum lifts the loaded cage in the shaft; thus the force of the steam acting in the cylinder produces a force that finally acts on the cage, and the engine and the drum form the machine by which this is made possible.

A hoisting engine is a machine that is composed of many parts; but a machine may have only one part, in which case it is called a simple machine. To this class belongs the lever, shown in Fig. 3. A lever is a stiff bar, usually of wood or metal, that rests on a supporting block, pin, or pivot, on which it may be turned or tilted. This support is called the fulcrum. In Fig. 3 the bar a is the lever and the block b is the fulcrum. The lever is shown as being used to move the weight c, a force being applied by hand at d, near the other end of the lever. It will be noticed that this arrangement is simply an ordinary crowbar such as is commonly used for moving or lifting heavy weights. But it is also a machine, because the force applied

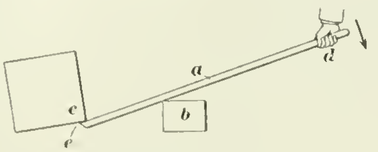

Fig. 3

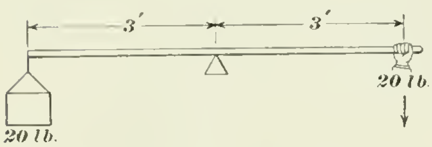

Fig. 4

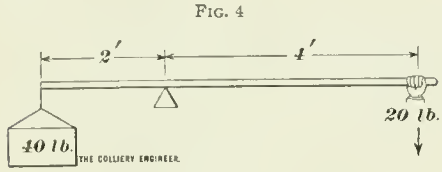

Fig. 5

at *d* causes another force to act at the point *e* and lift the weight *c*.

Now, every one knows that by moving the block *b*, or the fulcrum, closer to the lower end of the crowbar, or lever, the greater is the lifting power when the end *d* is pushed down; but if the fulcrum is moved toward the middle of the bar, it will take a much greater pressure at *d* to lift the weight *c*. It is possible to figure out just how great a weight can be lifted or how much force is required to lift a given weight with a lever of this kind. To do so, it is necessary to know the length of the lever on each side of the fulcrum.

In Fig. 4, for example, suppose that the straight lever *a* is 6 feet long and that it is placed on the fulcrum *b* so that half of the lever extends on each side. Then, if a weight of 20 pounds is placed on one end, a pull of 20 pounds on the other end will be required to hold up the weight. That is, if the fulcrum is at the middle, the force required is equal to the weight, and the two ends will balance. If the lever shown in Fig. 5 is placed on the fulcrum so that 4 feet extend on one side and 2 feet on the other, then a force of 20 pounds at the end of the long part will balance a weight of 40 pounds on the short part, because one part is twice as long as the other. And if the lever is placed as in Fig. 6, so that 5 feet extend on one side and 1 foot on the other, a force of 20 pounds at the end of the long part will balance a weight of 100 pounds at the other end, because the long part is 5 times as long as the short part.

The parts of the lever that extend on each side of the fulcrum are called the arms of the lever. The length from the fulcrum to the point where the force acts is called the force arm, and the length from the fulcrum to the point where the weight or load acts is called the weight arm or load arm. In Fig. 4, these arms are equal, each being 3 feet long; in Fig. 5 the arms are 4 feet and 2 feet; and in Fig. 6 they are 5 feet and 1 foot. Now, when the force acting on a lever balances the weight or load, it is always found that the force multiplied by the length of the force arm is equal to the weight multiplied by the length of the weight arm.

Take the case of Fig. 4, for example. The force is 20 pounds and the force arm is 3 feet, while the weight is 20 pounds and the weight arm is 3 feet; then, $20 \times 3 = 20 \times 3$, which agrees with the statement made at the end of the preceding paragraph.

In Fig. 5, the force is 20 pounds, the force arm 4 feet, the weight 40 pounds, and the weight arm 2 feet; then, $20 \times 4 = 40 \times 2$, which again proves the statement. Similarly, in Fig. 6, the force is 20 pounds, the force arm 5 feet, the weight 100 pounds, and the weight arm 1 foot; then, $20 \times 5 = 100 \times 1$.

If the lengths of the force arm and weight arm are known, and also the weight to be lifted, the force required may be found by multiplying the weight by the length of the weight arm and dividing the product by the length of the force arm. For instance, suppose that a weight of 240 pounds rests on the end of a weight arm $1\frac{1}{2}$ feet long, and suppose that it is desired to find what force must be used at the end of an 8-foot force arm to balance this weight. According to the rule just given, the force required is equal to

$$\frac{240 \times 1\frac{1}{2}}{8} = \frac{360}{8} = 45 \text{ pounds}$$

If the force and the lengths of the force arm and weight arm are known, the weight that can be balanced by the force is equal to the force multiplied by the length of the force arm and divided by the length of the weight arm. Thus, suppose that a lever has a weight arm of $1\frac{1}{2}$ feet and a force arm of 8 feet and that a force of 45 pounds is applied at the end of the force arm. Then, the greatest weight that can be lifted at the end of the weight arm, according to the rule just given, is

$$\frac{45 \times 8}{1\frac{1}{2}} = \frac{360}{\frac{3}{2}} = 360 \times \frac{2}{3} = 240 \text{ pounds}$$

In the levers thus far described, the fulcrum is at some point between the force and the weight, or load; but there are other kinds of levers. For example, in Fig. 7 is shown a lever *a* that has its pivot, or fulcrum, at the lower end *b*, and the force applied at the upper end *c*, the load being at *d*, between the force and the fulcrum. In this case, as before, the force arm is the distance *b c* from the fulcrum to the point where the force acts, and the weight arm is the distance *b d* from the fulcrum to the

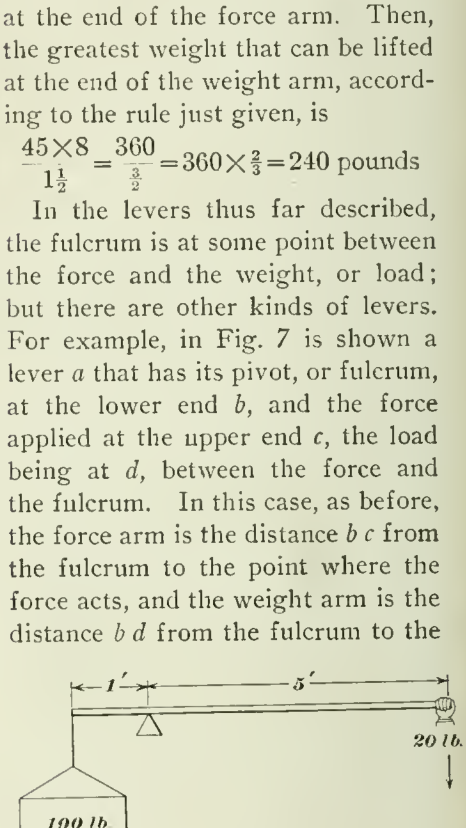

Fig. 6

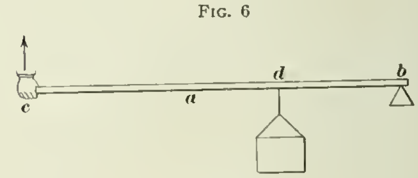

Fig. 7

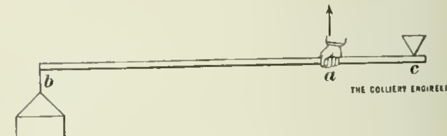

Fig. 8

point where the load rests on the lever. The upward pull that can be exerted at *d* may be found by the same rule that was used for the other levers. Thus, if $b\,c$ is 6 feet long and $b\,d$ is $1\frac{1}{2}$ feet, and a force of 20 pounds is applied at c, the upward pull at d is

$$\frac{6\times 20}{1\frac{1}{2}}=\frac{120}{\frac{3}{2}}=120\times\tfrac{2}{3}=80 \text{ pounds}$$

Another kind of lever is shown in Fig. 8, in which the force a is between the weight b and the fulcrum c. The force arm of this lever is $a\,c$ and the weight arm is $b\,c$, and the weight that can be lifted at b is found by the rule already given. If $a\,c$ is 2 feet and $b\,c$ is 6 feet, and the force at a is 60 pounds, the greatest weight that can be lifted at b is

$$\frac{60\times 2}{6}=\frac{120}{6}=20 \text{ pounds}$$

Several important things should be observed in the examples that have been given. If a lever like that in Fig. 3 is used, having the force arm longer than the weight arm, the force required will be smaller than the weight moved; but the force will have to move considerably farther than the weight. If the force arm and the weight arm are equal, as in Fig. 4, the force required is equal to the weight, and each moves the same distance in the same time. If the lever is like that shown in Fig. 8, the force is shorter than the weight arm and the force required is greater than the weight; but the force will move only a very short distance in order to make the weight move through a much greater distance.

From these statements the following facts may be obtained: If it is desired to use a small force to move a heavy load, without regard to the amount of time required, the force arm should be made much longer than the weight arm. But if the load is to be moved rapidly, so as to save time, then a large force should be used, and the force arm should be made much shorter than the weight arm.

If a very great weight is to be balanced by a very small force, without using a lever with an extremely long force arm, a compound lever may be used. This is a series of simple levers in which the force arm of one is connected with the weight arm of the next. An example of a compound lever is shown in Fig. 9, which is similar to that used in a platform scales. The weight or load a on the platform b rests on the short end c of a lever d having a fulcrum at e. The other end f is connected by a rod g to the short end h of a second lever fulcrumed at i, and the end j of the long arm of the second lever is joined by a rod k to the short arm l of a third lever fulcrumed at m. The scale bob n hung on the long arm of the third lever is the force acting to balance the weight a.

With this arrangement, the arm $e\,c$ is a weight arm and $e\,f$ is a force arm. But the upward force at f pushes against the end of the arm $h\,i$, which is thus a weight arm, while $i\,j$ is the second force arm. Similarly, the pull at j acts through the rod k on the end of the third weight arm $l\,m$, and $m\,n$ is the third force arm. Now, in a compound lever, the force times all the force arms is equal to the weight times all the weight arms. Suppose that the lever arms have the lengths as marked on them. Then a force of 4 pounds at n, or a bob weighing 4 pounds, will balance a load of 1,200 pounds at a, because $4\times 40\times 36\times 50 = 1{,}200\times 10\times 6\times 4$.

In any compound lever, the load that can be balanced by a given

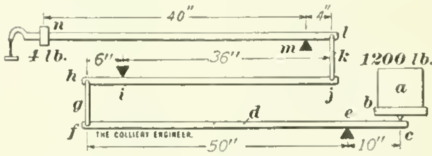

Fig. 9

force is as many times as great as that force, as the number obtained by dividing the product of all the force arms by the product of all the weight arms. In the case illustrated, the product of all the force arms is $40\times 36\times 50 = 72{,}000$ and the product of all the weight arms is $10\times 6\times 4 = 240$. As $72{,}000 \div 240 = 300$, it follows that a force at n will balance 300 times as much at a; that is, a 4-pound bob at n will balance $300\times 4 = 1{,}200$ pounds at a.

Electricity in the Mines

Conductors and Non-Conductors—Static Electricity—Electric Currents, Direct and Alternating

By H. S. Webb, M. S.

(Continued from March)

If a piece of sealing wax is rubbed with fur or silk, the charge on the sealing wax is negative and it is said to be at a lower, or smaller, potential than the charge on the fur; because if the two are left in contact the electricity on the fur is supposed to pass to the sealing wax and there neutralize the negative electricity that previously resided on its surface. All we really know is that both charges disappear and it is supposed that they neutralize one another. When an electrified body positively charged is connected to the earth by a conductor of electricity, electricity is said to flow from the body to the earth; and, conversely, when an electrified body negatively charged is connected to the earth, electricity is said to flow from the earth to that body. That which determines the direction of the current is the relative electrical potential, or pressure, of the two charges in regard to the earth.

It is impossible to state with certainty in which direction electricity actually flows, or whether there is any flow of electricity at all, nor can we declare which of two points has the higher and which the lower electrical potential. All that can be said with certainty is that, when there is a difference of electrical potential, there is a manifestation of electricity, which is called an electric current and that it tends to flow from one point, which is said to be at the higher, to another point, which is said to be at the lower potential.

For convenience, it has been agreed that the electrical condition called positive is at a higher potential than that called negative, and that electricity tends to flow from a positively to a negatively electrified body. The earth may be regarded as a reservoir of electricity of infinite quantity, and its potential is considered as zero.

The electrical condition called positive is assumed to be at a higher potential than that of the earth, while that called negative is assumed to be at a lower potential than that of the earth. Electricity will, therefore, flow from a positive body to the earth, but will flow from the earth to a negative body.

Electricity does not flow in a metal wire in the same manner that water flows in a pipe, because water is matter and its particles move, while we do not know that electricity is matter; anyway it cannot be scientifically treated as such. However, a great many things that are true about electric action are simplified by the assumption that electricity does flow in a manner like water, and the comparison of electricity to water, as far as it can be conveniently carried, is helpful in studying electric currents.

CONDUCTORS AND NON-CONDUCTORS

When a glass rod is rubbed with fur, only the rubbed part of the glass will be electrified; the other parts will produce neither repulsion nor attraction when brought near a small piece of paper. The same is true of sealing wax or resin. The charges seem to remain exactly where produced and such bodies do not readily conduct electricity; that is, they oppose or resist the passage of electricity through them. When a metal receives a charge at any point, the electricity immediately flows through its substance to all parts of the metal body. Metals, therefore, are said to be good conductors of electricity. Substances are accordingly divided into two classes: non-conductors, or insulators, which are those substances that offer a very high resistance to the passage of electricity, and conductors, which are those substances that offer a comparatively low resistance to its passage. All bodies conduct electricity to some extent, while there is no known substance that does not offer some resistance to its flow. Furthermore, there is no sharp dividing line between conductors and non-conductors. Some substances are poor conductors and also poor insulators.

In the following list are given conductors in the order in which they conduct electricity, and the insulators in the order in which they resist it.

Conductors.—Silver, copper, gold, aluminum, zinc, iron, platinum, steel, lead, charcoal, ordinary (not pure) water, the human body.

Non-conductors or Insulators.—Hard rubber, paraffin, shellac, dry wood, glass, mica, asbestos, dry paper.

Silver is not used, except in some electrical instruments, because it is not a better enough conductor than copper to make up for its much greater cost. Aluminum is used as a conductor somewhat, but the difficulty of soldering or otherwise making good electrical joints between aluminum wires, and also its somewhat greater cost per pound, has seriously interfered with its use. Zinc, platinum, and lead are not good enough conductors compared with their relative cost to warrant their use commercially for wire. Platinum, on account of its freedom from corrosion, has been extensively used for small contacts on bells, telephone and telegraph instruments, but its constantly increasing cost has led to the use of hardened silver in its place. Practically the only materials used for conductors of electricity, in the form of wires and cables, are copper, iron, steel, and aluminum. While iron and steel are poorer conductors than copper, nevertheless they are extensively used for bare overhead telephone and telegraph lines, because they are stronger and cheaper than copper, and sufficiently good conductors for the purpose. Iron and steel wires are not only poorer conductors than copper wire of the same size, but they corrode much more rapidly when subject to moisture, and then, of course, become weaker and weaker until they break or are replaced. To protect them from corrosion they are generally coated with a thin layer of zinc and are then called galvanized iron or steel. Galvanized iron and steel will last much longer than ungalvanized iron or steel, but not near so long even then as copper or aluminum. The least scratch or break through the thin zinc coating that leaves the iron bare, allows it to rust and rapidly deteriorate at that point. Hence care should be taken in handling galvanized wire not to nick, scratch, or otherwise produce a break through it so as to expose the iron.

For use in mines, where there is generally moisture, copper should be used for conductors for all purposes, except perhaps for a bell or signal circuit that is not to be used more than a few years, when galvanized iron or steel may be good enough. Compared with most metals, water and the human body are very poor conductors. The fact that horses and mules are so much oftener shocked and killed by electricity than human beings under similar circumstances is generally attributed to the steel nails which are driven into the animals hoofs to hold on the steel shoes, thereby affording a much better contact through the nails and the steel shoes with the ground than in the case of a person, whose feet are further protected by the leather soles of his shoes.

When working upon circuits through which a current of electricity is passing and from which disagreeable or dangerous shocks might be received, protection may be secured by fastening four good porcelain, or glass insulators to the under side of a stout board or box. By standing upon such an insulated platform, one is comparatively safe when working upon any electrical circuits ordinarily used in any mine. Another good point to remember, when working upon circuits from which disagreeable shocks may be received, is to use one hand only at a time, keeping the other away from the circuit and especially from all objects that may be in contact with the ground. While the hand in use may be shocked or even burned, the electricity has less opportunity to flow through the body and less opportunity to do harm to the heart or other vital parts of the body.

To insulate conductors, such as line wires, from the ground and from other conductors, use is made of porcelain, or glass, knobs, called insulators. Sometimes hard dry wood is used where the potential is not high. Hard rubber is used as an insulator for parts of electrical instruments, and paraffin or shellac is used to make wood, paper, and other such substances better lasting conductors by painting or soaking them in it so that moisture cannot enter. Mica and asbestos are used in electrical devices that are apt to get warm or hot, because heat has little effect upon their insulating qualities and they will not burn. Paper is used where is can be sealed up so that it is protected from moisture which it would otherwise quickly absorb and become a very poor insulator. It is used to insulate wires and conducting cables that are enclosed in a moisture-proof casing of sheet lead. Sometimes the paper is saturated with moisture-proof insulating compound.

Before leaving the subject of static electricity it may be useful for the reader to know that belts used between any two rotating pulleys sometimes become so charged with electricity that they will give a disagreeable shock if touched or even closely approached. The electricity seems to be developed partly by the internal friction between the fibers of the belt when the latter bends around the pulley, and partly by the friction between the air and the belt. Most of the electricity so developed is conducted harmlessly to ground through the pulleys and shafting. More electricity is apparent in a dry atmosphere than in a damp one, because moist air is a better conductor than dry air, and consequently in a moist atmosphere the electricity passes more readily over the damp surface of belts, pulleys, and shafts to the ground.

If a belt is charged to a high enough potential a spark or a pale bluish-colored discharge will pass from the belt to one's hand or to any piece of metal held near it. Also one's hair may stand out and a peculiar sensation as if brushing against cobwebs may be observed when standing near a charged belt. Sometimes a peculiar odor is produced due to the chemical action of the discharge upon the air, forming what is called ozone. Such ozonized air is healthful, but it also supports combustion better than ordinary air, hence more care than usual should be taken not to leave oily waste or cloths around where ozone may be produced, as spontaneous combustion may result.

If sufficiently troublesome, static electricity can be removed from belts by arranging a row of wires, nails, or tacks across but not quite touching the moving belt. Their ends should be within an inch of the belt and preferably at a point just after the belt leaves the pulley. The wires, nails, or tacks must all be connected together with an iron or copper wire and well grounded to water pipes, to the metal frames of machines not insulated from the ground, or to a metal plate buried in the earth. Such a device can be made by driving tacks through a piece of sheet metal, such as so-called tin, and grounding the piece of tin, which may be fastened to a board or plank to hold it in the desired position.

Lightning is considered to be due to the accumulation of static charges of opposite polarity on the surface of the earth and in the clouds. When the difference of potential becomes great enough, the air can no longer stand the electric strain and breaks down, the result being a lightning discharge.

When properly put up, lightning rods are undoubtedly a source of much protection. The conductor may be copper or galvanized iron; one is just as good as the other as far as protection from lightning is concerned. Flat strip is a little preferable to wires, the object being to secure as much surface as practicable from a given amount of material. The conductors should be carried to all high points of the building, up all the corners, along all ridges and eves and over all chimneys. All should be connected together and thoroughly grounded by burying several feet of the ends in damp earth. Broken coke or charcoal holds moisture and therefore a load of it in the hole where the ends are buried will assist in making a good ground. If the earth connection is broken, the network of wires over the building is a source of danger rather than a protection. All metal work on or in the building, such as water, steam, or gas pipes, metal cornices, etc., should be connected together and also grounded, but should not be connected to the lightning conductors.

In cities the network of telephone, telegraph, electric light, and other wires seems to be a great protection to buildings. Lightning does more damage in the country and towns not so protected.

For a fluid, as water, to do work it must have motion; the same is true of electricity. To give electricity motion, electrical pressure is required. The electrical pressure necessary to make electricity do work may be secured from chemical action, such as occurs in primary batteries, or from electromagnetic action, as in dynamos.

To produce what is called an electric current, it is necessary to cause a difference of potential between two bodies, or between two parts of the same body. For instance, if a rod of zinc and a rod of carbon are dipped into a solution of sal ammoniac, which is a white granular material composed of the elementary substances hydrogen, nitrogen, and chlorine, the two projecting ends will be at different potentials. The rods should not touch each other, either inside or outside of the solution, which is made by dissolving about 4 ounces of the sal ammoniac in about a quart of water. This constitutes the essential features of an ordinary Voltaic cell or primary battery, such as is used for ringing electric bells.

Furthermore, it has been determined that the exposed terminal of the carbon rod is charged with the same kind of electricity that is on a glass rod after it has been rubbed with a silk handkerchief, and the exposed end of the zinc rod is charged with the same kind of electricity as that on the silk handkerchief. Hence, if the glass rod is positively charged and at a higher potential than the silk handkerchief, then the exposed end of the carbon rod will be positively charged and at a higher potential than the exposed end of the zinc rod. Conversely, the exposed end of the zinc rod is negatively charged and at a lower potential than the exposed end of the carbon rod. The potential of the charge on the glass is, however, much greater than that on the carbon rod, which is a matter of little importance for the purpose of these articles.

If the exposed ends of the carbon and zinc rods are joined by a conductor, a piece of copper wire for instance, a current of electricity is said to flow from the carbon rod through the conductor to the zinc rod, into the solution and through the solution back to the carbon rod. The path just traced is called an electric circuit. If this experiment is actually performed by the reader he may be unable to observe any current of electricity because there may be no apparent manifestation of it. However, it can be readily proved that what is called a current of electricity does actually pass through the circuit that has been traced. For instance, if the piece of wire joining the carbon and zinc is fine enough and short enough it will get hot enough to be felt or perhaps even to make the wire glow. Thus an electric current is produced and is expended in heating the conductor. In fact all electric currents tend to heat the conductors through which they pass. If the connection between the copper wire and the carbon is suddenly broken, as by pulling the wire from contact with the carbon, a minute spark of electricity may be observed, which, also shows that electricity has been produced by the battery.

The difference of potential between the protruding ends of the rods depends upon the materials used for the rods and for the solution. The rods should be of different materials. Pieces of zinc and copper properly immersed in solutions of copper sulphate and zinc sulphate, give a smaller potential difference but a much more uniform current than is obtained from carbon and zinc immersed in a solution of sal ammoniac. The passage of the electricity through the conductor joining the exposed ends, which are called terminals, is primarily due to the terminals, but its maintenance is due to the chemical actions that take place in the solution. If the chemical action becomes weak, the current will diminish in strength. In many cells, the chemical action will cease as soon as the circuit is broken by separating the conducting wire from either terminal. The terminals of batteries are usually provided with binding posts or screws by means of which a good firm contact may be made between the terminals and the wire. While it has been stated that electricity will flow through a wire when it is connected between the terminals of a battery, the reader should not try this experiment unless he is willing to stand the consequences of damaging the battery or rendering it useless either temporarily or permanently. Very few batteries are made that will stand uninjured such use. This will be better understood a little later.

(To be continued)

Gases Met With in Coal Mines

A Description of the Nature of Whitedamp, Chokedamp, and Afterdamp—The Properties and Laws of Gases

(Continued from March)

WHITEDAMP.—Still another "damp" is "whitedamp," a mixture of air and carbon monoxide, the other oxide of carbon mentioned under the head of blackdamp. Carbon monoxide, which in the early days was known as carbonic oxide, derives its name through its chemical symbol, *CO*, which shows that one molecule of the gas is composed of 1 atom each of carbon and oxygen. As *mon* means one, carbon monoxide is the same thing as carbon one-oxide, or the first oxide of carbon, the second oxide being carbon dioxide with the symbol CO_2, as explained under blackdamp.

Carbon monoxide weighs just a little less than air, its specific gravity being .967, so that if a cubic yard of air weighs 2.186 pounds a cubic yard of this gas will weigh 2.114 pounds. Since it has so nearly the same weight as air it mixes with it very easily, and so is found in all parts of a working place (if present at all), on the roof as well as at the floor.

Carbon monoxide is colorless, tasteless, and without any smell. It does not support combustion keeping the oxygen away from the flame just as carbon dioxide. Unlike the other oxide of carbon, it will burn and forms carbon dioxide in the process. It is not known to be given off by the coal itself as are both the gases just described. It is a product of incomplete combustion and is formed in the mines by the explosion of powder, particularly the old-fashioned black powder, by smoldering gob fires, and above all and in large amounts as the result of what is called a dust explosion, as will be explained under the head of afterdamp.

Carbon monoxide is the most treacherous and deadly gas with which the miner has to deal and has probably caused the death of far more men than have all the others put together. While an explosion of firedamp will kill a few men near the room where it has exploded, the carbon monoxide resulting from a gas or dust explosion will often sweep through the workings killing all in its path. The 1,100 men at Courriéres, France, and those at Monongah, Darr, Harwick, etc., were nearly all killed by inhaling carbon monoxide. This gas is not only suffocating, but is also poisonous, as it coagulates the blood, something the other gases do not do.

Even as little as one-fifth of 1 per cent. results in death if breathed for any great length of time, so it is clear that there is no way of determining its presence in a mine by its action on the flame of a safety lamp, as the fire boss who gets into air containing enough of this gas to show in the flame, will be killed almost instantly. The only test thus far found for this gas is its action upon small animals such as mice and particularly canaries or other small birds, which are affected by much smaller amounts of this gas than are men. For this reason the United States Bureau of Mines Rescue Corps use canaries. Other small birds will serve as well, but canaries are easily purchasable, and compensate the men for their care by singing when kept in the cars. When the birds begin to show signs of weakening or fall off the perch it is evidence of the presence of carbon monoxide, and the men then seek safety in a better atmosphere.

Carbon monoxide will explode as does firedamp but a much larger amount must be present, a little over 15 per cent., to cause a violent explosion.

CHOKEDAMP

Chokedamp, while a name sometimes given to blackdamp, is more properly a name for that mixture of gas and air given off from a smoldering gob, or mine, fire. It consists of air with which is mixed more or less of both oxides of carbon, carbon dioxide and carbon monoxide, resulting from the burning coal. As it sometimes contains as much as 3 per cent. of carbon monoxide it is particularly deadly in its effects upon those breathing it. Chokedamp generally has a peculiar, burning smell.

AFTERDAMP

Afterdamp is the name given to that mixture of air and gas found in a mine after a mine explosion. What is in the afterdamp will depend upon the substances or gases which have caused the explosion. If, as is the case in the anthracite regions of Pennsylvania, it is a simple explosion of methane, the afterdamp will be a mixture of air and carbon dioxide and a very small quantity of carbon monoxide. But gas explosions in the anthracite regions are trivial in comparison with the gas and dust or dust explosions in bituminous coal fields and in which as many as 1,100 men have lost their lives at one time, as at Courriéres, in France. In these explosions the powdered coal dust found on the roof, floor, and ribs, is gathered up by the force of a small gas explosion, of a blown-out shot, or of any large amount of blasting material, and the heat is sufficient to distill or drive out the volatile gases from the dust, which also explode, and the incomplete combustion of dust causes the formation of carbon monoxide in such proportion that its deadly effect is more potent than the effect of the carbon dioxide due to the complete combustion of some of the dust and all of the gas. This afterdamp is carried by the force of the explosion and aided by the ventilating currents to all parts of the mine. It is the carbon monoxide given off by the imperfect burning of the dust that renders the mixture so deadly that all those reached by it, who have not been killed by the direct force of the explosion, are poisoned by the carbon monoxide.

PROPERTIES OF GASES

All gases have certain properties which must be understood by any one who wishes to study the subject of ventilation. A few definitions must be given at the outset.

Matter is the substance of which anything consists or is anything that has weight or occupies space or can be recognized by our senses. Thus, iron, gold, coal, water, and the like are forms of matter with different names and different properties, and are called matter because they have weight, occupy space, and may be recognized by the senses of touch, sight, or taste. There are three divisions of matter. A mass is a body of matter than can be recognized by the senses regardless of its size or weight; thus, a single drop of water is as much a mass as a barrelful. A molecule is the smallest subdivision of a mass of matter that can exist. A molecule is composed of the same material or materials as the mass from which it came, because many molecules combined or added together form a mass. Thus, the molecules that go to form the mass known as a barrelful of water are each one composed of water and nothing else. An atom is a subdivision of a molecule and is a distinct chemical substance which cannot be further subdivided. Atoms have distinct names, as an atom of carbon, an atom of hydrogen, an atom of oxygen, or the like, and combine to form molecules, which in turn combine to form masses. A familiar example is water. A mass of this substance may be of any size from a single drop to an ocean. This mass may be divided into a great many molecules, each of which is still water of the same identical kind as that in the drop or the ocean. But when we come to subdivide any one of these molecules of water into atoms a change takes place and we find that the simple molecule of water is composed of two atoms of a gas known as hydrogen combined with one atom of a gas called oxygen. But here we must stop. These atoms cannot be further subdivided; no matter how we attempt it, they always remain hydrogen and oxygen just as when they were first separated out of the molecule of water, which, itself, was separated out of a mass of similar molecules of water, called, perhaps, a glassful, or an ocean.

The properties or peculiarities of matter in general are called the physical properties of matter and among them are weight, volume, density, mass, the action of forces as heat, light, electricity, etc. The study of these properties constitutes the science of physics.

The properties of matter, considering it as composed of atoms of distinct kind, are chemical properties, and the science which treats of atoms and how they combine and act toward one another is known as chemistry. In a general way, physics has to do with molecules and masses, while chemistry deals with atoms.

PHYSICAL PROPERTIES

The force that binds atoms together to form molecules is a chemical one, because, as said before, it causes a combination of atoms. As an illustration, it is the force which causes two atoms of hydrogen to unite with one atom of oxygen to form one molecule of water. This combining force between atoms of the same or different kinds to form molecules is known as chemical affinity, or more simply as affinity. The force or attraction that holds two or more molecules together to form a mass is a physical force known as molecular force or cohesion. By the application of other forces to matter, such as heat, the force of cohesion between the molecules is gradually lessened and the molecules show less and less attraction for one another until they finally fly apart. This tendency on the part of the molecules of a mass to separate or fly apart under the action of some outside force is known as repulsion.

The mass of a body is the matter it contains, and this is proportional to its weight; thus, a body weighing 2 pounds contains twice the matter and twice the mass of another body weighing 1 pound. A pound of cork has the same mass or amount of matter as a pound of lead, although it occupies a very different space or volume.

Density has reference to the amount of matter in a given volume of any substance, or is the compactness of mass. There is more density and therefore more weight in a cubic foot of iron than in a cubic foot of water; hence we may say that iron is more dense than water.

Weight is the result of the attraction that exists between the mass of the earth upon which we live and the mass of any substance. The weight of a body is always proportional to its mass.

Specific gravity is the ratio between the weight of a given volume of any substance and the weight of an equal volume of another substance which is taken as the standard. There are two such standards in common use. Water, which weighs approximately 62.5 pounds per cubic foot, is the standard for liquids and solids, and air, which weighs .07638 pound per cubic foot is the standard for gases. When we say that iron has a specific gravity of 7.21, anthracite a specific gravity of 1.50, or slate a specific gravity of 2.80, we mean that any volume of these substances, whether it be a cubic inch, foot, or yard, weighs 7.21, 1.50, or 2.80, times more than a cubic inch, foot, or yard of water. In the same way when we say that the specific gravity of nitrogen is .971, of carbon monoxide 1.529, of methane .559 we mean that a cubic inch, foot, or yard of these gases weighs .971, 1,529, or .559 times a cubic inch, foot, or yard of air. Whether we are dealing with solids or liquids where water is the standard, or with gases where air is the standard, these measurements must all be made at the same temperature, as measured by the thermometer, and under the same pressure of the atmosphere as measured by the barometer. Knowing the specific gravity of a substance, it is easy to calculate the weight of any volume of it through the relation

Weight of a given volume of any substance = specific gravity of substance × weight of an equal volume of the standard

Example.—What is the weight of a cubic foot of iron the specific gravity of which is 7.21?

By substituting in the formula, water being the standard, we have

Weight of cubic foot of iron = 7.21 × 62.5 = 450.625 pounds.

Example.—What is the weight of a cubic yard of carbon dioxide gas the specific gravity of which is 1.5291?

We use the same method as before, remembering that in the case of gases the standard is air which weighs .07638 pound per cubic foot. Also since there are 27 cubic feet in a cubic yard, the weight obtained must be multiplied by 27.

Weight of cubic yard of carbon dioxide = 27 × 1.5291 × .07638 = 3.1534 pounds.

Example.—What is the weight of a cubic yard of anthracite in the solid, if the specific gravity of the coal is 1.50?

As the first example, the standard is water weighing 62.5 pounds per cubic foot, and as in the second example, the weight per cubic foot must be multiplied by 27 as there are that number of cubic feet in a cubic yard. From this we have

Weight of cubic yard of anthracite = 27 × 1.50 × 62.5 = 2531.25 pounds.

Example.—A certain room in a mine is 300 feet long, 20 feet wide, and the coal is 5 feet thick. What is the weight of nitrogen in this room if the specific gravity of this gas is .971, and four-fifths of the air consists of it?

The solution of this problem is made in three steps. We first find the volume, that is, the number of cubic feet of air in the room, which is done by multiplying the three dimensions together thus, $300 \times 20 \times 5 = 30{,}000$ cubic feet. The second step is to find the amount of nitrogen in this number of cubic feet of air. This is done by multiplying 30,000 by four-fifths, or $30{,}000 \times \frac{4}{5} = 24{,}000$. The final step is to find the weight of 24,000 cubic feet of nitrogen, the specific gravity of which is .971 and the weight per cubic foot of the standard, air, is .07638. We then have

$$\text{Weight of nitrogen} = 24{,}000 \times .971 \times .07638 = 1779.96 \text{ pounds.}$$

As stated before, all matter is believed to be made up of a very great number of molecules of the same kind as the mass, and further these molecules are supposed to be in constant motion, moving about in the mass of the substance, striking and clashing against one another. The motion of the molecules is called vibration and it is this motion which causes the sensation or feeling known as heat. The faster the vibration of the molecules, the greater the heat and the slower the vibrations the less the heat, or, as it is commonly said, the greater the cold. The more rapid the vibration the more the molecules fly apart and this causes the body to expand. A familiar illustration of this is the expansion of a rod of iron when heated in a blacksmith's fire.

(To be continued)

Electrical Unit of Current "Ampere"

The absolute unit of current is defined as that current which, when passing through a conductor 1 centimeter long, bent in the arc of a circle of 1 centimeter radius, produces a unit force of 1 dyne on a unit magnetic pole at the center, or in other words, produces at the center a magnetic field of unit strength. This absolute unit of current was found to be inconveniently large and the practical unit was fixed at one-tenth its value and called the ampere.

The ampere is that unvarying electric current which, when passing through a solution of silver nitrate of particular strength, deposits silver at the rate of .001118 gram per second. The ampere therefore denotes the rate of flow or the strength of the current.

BOOK REVIEW

A review of the latest books on Mining and related subjects

Book of Standards. This book, which is an excellent pocketbook for reference, contains material which makes it strictly a pipe handbook. Unless a man is in the pipe business he will be astonished at the numerous purposes for which pipe is required about mines, and it is probably news to mining men that the index of this pipe book has 4,000 subjects all bearing on practical matters which are apt to arise in the use of pipe. The National Tube Co., of Pittsburg, Pa., have assembled these data and placed them in a pocketbook 4 in. × 6½ in. with 559 pages.

The formulas and data for flow of air, gas, steam, and water through pipes make it extremely useful to the mining man. Several pages are devoted to descriptive articles on the manufacture of butt-welded, lap-welded, and seamless drain pipes. There is a glossary of terms used in the pipe trade, which will undoubtedly be found useful as will be the factors for calculating the weight, strength, areas, and properties of tubes. The price of this book, which is to replace the 1902 edition, is $2.

Building Stones and Clay Products, by Heinrich Ries, Ph. D. Published by John Wiley & Sons; 415 pages, illustrated. $3 net. This book is intended as a handbook for architects, and follows in its general arrangement the course of lectures delivered each year to the students in the College of Architecture of Cornell University, where Professor Ries is Professor of Economic Geology. It is interesting to the mining man as it supplies information concerning the stones used for building.

Johnson's First Aid Manual, by Fred B. Kilmer. Published by Johnson & Johnson, New Brunswick, N. J. 144 pages, illustrated. This book is invaluable to any one who is likely to be responsible for the treatment of an injured person after an accident. It is written in a simple manner telling how to do simply those things which ought to be done before a doctor arrives, whether it be a serious or a small accident. The directions are concise and not technical and in their application call for only the usual material which is handy. The manual is well illustrated throughout so that the descriptions are easily comprehended, the illustrations being taken from photographs which were especially posed.

Report of the Department of Public Works of the Province of Alberta, 1911, A. L. Sifton, Minister of Public Works. Published at Edmonton. This book contains the reports of the mine inspectors for the Province of Alberta, pages 58 to 153, inclusive, being devoted to the Coal Mines Branch of the Department of Public Works.

Determinative Mineralogy, by J. Volney Lewis. Published by John Wiley & Sons, 151 pages. $1.50 net. This book covers 380 minerals. In order to simplify the procedure and facilitate the use of the tables, the more difficult and elaborate chemical tests have been avoided, and blowpipe or "dry" tests have been preferred, in general, to those made in the "wet" way. The plan of the Brush-Penfield tables has been followed in the main, but with considerable modification. The book is intended for students, which is rather hard on the student, since no method of verifying his results with the blowpipe are at hand unless he purchases Brush and Penfield's book. Several minerals will furnish the same colored bead, and frequently the minerals are mixed with impurities which destroy the color so that blowpipe tests are about as decisive as looking at the mineral and testing its physical properties. The person testing minerals is sure to make mistakes if he depends alone on the blowpipe and physical tests, particularly when a mineral is new to him.

The Resources of Tennessee, which for 18 months has been issued as a monthly bulletin of the Tennessee Geological Survey, begins Vol. 3, January, 1913, as a quarterly. A. H. Purdue, State Geologist, is editor, and Wilbur A. Wilson, Assistant Geologist, assistant editor. With two short exceptions the issue is devoted to the Tennessee coal fields. Home office of the Survey, Nashville, Tenn.

Heaton's Annual, 1913. The commercial handbook of Canada and Boards of Trade Register, is published at 32 Church Street, Toronto, Canada. The price is $1, and 13 cents postage. British edition, 5 shillings. This ninth edition of Heaton's Annual is not only a commercial handbook but an encyclopedia of Canada, her government and industries, clubs, engineering societies, etc. Every Canadian needs this book for reference, and every American and Englishman interested in the development of Canada's natural resources.

Mineral Resources of Missouri. H. A. Beuhler, State Geologist, Rolla, Mo., has issued a neatly illustrated vest-pocket pamphlet which gives the mineral resources of Missouri. It shows that Missouri leads all other states in the production of zinc, lead, barytes, and tripoli. It has beds of coal, limestone, granite, fireclay, and glass sand, and it also has deposits of cobalt, nickel, copper, pyrite, and iron ore. The output of the mineral deposits of Missouri is valued at more than $45,000,000 annually.

American Mine Accounting, by W. H. Charlton, P. A.; McGraw-Hill Book Co., publishers, New York, 367 pages. $5 net. Many people find things that are needed. Few people take it upon themselves to satisfy that need. In a book on mine accounting Mr. W. H. Charlton has supplied a need. He has gathered together the details of different systems of accounting, as in use with various companies engaged in different kinds of mining, from coal and coke to gold and copper smelting, and, although the book is one of ordinary size, the things stated are put briefly and concisely, the meat of a subject in a few words. The text is accompanied by 250 figures illustrating that number of forms which are in use in these systems.

Essentials of Electricity, by W. H. Timble, of Wentworth Institute, Boston; edited by J. M. Jameson, Pratt Institute, Brooklyn, 262 pages, 223 illustrations. John Wiley & Sons, New York, publishers. This book is one of the Wiley Technical Series intended for vocational and industrial schools, and was developed from notes which Mr. Timble has been using in short trade courses for students who wish to advance in some one branch of the electrical trade. While designed as a book of self-instruction it lacks at least one material essential, viz., the answers to problems given. This omission is not so noticeable when the student is able to attend a vocational school. The price of the book is $1.25 net.

Metal Statistics, 1913, sixth annual edition, issued by American Metal Market and Daily Iron and Steel Report, 81 Fulton Street, New York. This, as its name indicates, is a statistical report of the production and price of metals for the year 1912. A very useful book for those who purchase, manufacture, and sell metals, for as P. Henry is quoted "I know no way of judging the future but by the past."

The Railroads Invisible

In the February issue of the *Railroad Man's Magazine*, Frank J. Arkins, under the above title describes mine haulage. He has unconsciously chosen an appropriate title, for such mine railroads as he describes were never seen. The following quotation from his article will be read with amusement by mining men.

"Every mine has such a railroad. Some have several tiers of them. One has forty-eight, each one hundred feet below the other. Some have systems that are six, eight, and even ten tracks wide in places, and have terminals far in the bowels of the earth, the roofs of which, sometimes weighing millions of tons, are held up by joists.

"A train starts up the incline from the bottom of one of these mines. It enters a passage barely wide enough to admit it. It roars by a number of great, abandoned openings that resemble a series of forgotten catacombs. It hugs the side of a cliff, below which the miners have excavated a world of raw material. It passes a heated zone, on whose other side a furnace, acres in extent, awaits only a breath of air to give it headway. Now it crosses a series of timbers that shake and tremble.

"Now the train rumbles through deserted workings, from the roof of which water drips. It strikes the face of the one human being on this weird ride, the single man the train carries. The next instant the cars plunge into a corridor that roars with the sound of other trains, and a moment later it dashes into the night air made damp by a steady drizzle.

"A short distance from the mouth of the mine a locomotive waits, burning an electric headlight. A lantern swings. The cars that have traveled miles underground are coupled onto the engine. They have now become a part of the country's mighty railroad freight."

Unwatering Two Notable Excavations

Methods Employed in Sinking a Shaft on the Catskill Aqueduct and in Driving Tunnels Under the East River, New York

PERHAPS the most remarkable feature, aside from the Hudson River siphon, of the Catskill Aqueduct is the Rondout siphon, for the same aqueduct. The distance across Rondout Creek Valley is about 4½ miles and the method of carrying the water across this valley is to sink two shafts, one on each side of the valley, and connect them by a horizontal rock tunnel, the combination making what is termed an "inverted siphon," the intake shaft mouth being higher than the outlet shaft mouth. In order to facilitate tunnel driving, six intermediate shafts were excavated, five of them being for temporary use. One temporary shaft, No. 4, having an area of 18 ft.×22 ft., required the excavation to be carried to a depth of 500 feet before the tunnel level was reached.

To reach the level of the tunnel 500 feet below the surface required 18 months. During this time the shaft was partly filled with water six times. Looking back over the experience, one may now say that some of those floodings could probably have been prevented. Indeed, it is possible that not all the precautions were taken to prevent flooding that prudence would have dictated from the start. A section of the strata passed through here is as follows:

	Feet
Glacial drift	6
Helderberg limestone	226
Binnewater sandstone	39
High Falls shale	92
Shawangunk grit	134
Total	497

When the shaft had reached about the 80-foot level and was in the midst of very dry limestone, a sudden inrush of water took place through a 4-inch bore hole which had been put down for exploratory purposes and which the shaft followed. The quantity of water entering was not greater probably than 600 gallons per minute, and could probably have been taken care of without difficulty by a very moderate pumping equipment. But the inrush caught the contractor unprepared, and continued until the shaft was half full. It is perhaps not to be wondered at that the contractor was taken off his guard, as the limestone had not yet been penetrated half way. A considerable pumping plant for emergencies had been ordered; but had not yet been installed. However, the shaft was pumped out to within a short distance of the bottom and measures taken to seal up the bore hole. A nipple was driven into the hole casing, and carried up to a point above. Down through the casing, a 1-inch pipe was let down to the Shawangunk grit below. The water was permitted to return, thus providing against currents of water. Through the 1-inch pipe, cement mortar was put down, the pipe being raised as the grout filled in. By persevering with this procedure, the bore hole was filled with cement, including its immediate ramifications. This cement filling was so successful that the contractor reached, eventually, the 260-foot level without a flooding. The shaft was now in the Binnewater sandstone, and was making perhaps 225 gallons of water per minute, which inflow was being taken care of by two Cameron sinking pumps. While drilling the sump, however, an additional inflow of about 600 gallons per minute came in through one of the drill holes, with the result that the shaft was again flooded. The water did not, however, reach the same level as before but fell 30 feet short. The shaft was unwatered after a time, only to be flooded three additional times in as many weeks, with little or perhaps no advance in the excavation. Altogether, the shaft had now been

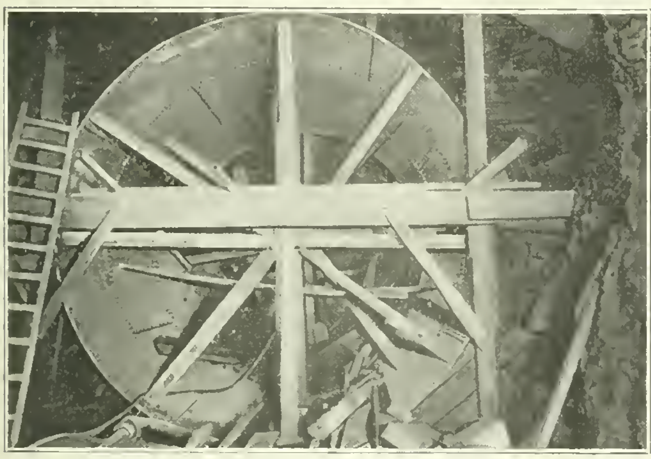

Fig. 1. Interlining Mud Seam, Rondout Tunnel

Fig. 2. Rondout Tunnel, Showing Concrete and Steel Lining

flooded five times and had only been excavated a little over half-way to the tunnel level. It was known that, just a little below the foot of the shaft, large crevices were to be expected in the rocks. In fact, one 8-inch opening was distant only 1½ feet. Four floodings had occurred because of the crevices being tapped by drill holes, and fears were entertained relative to what was yet to come when the large openings began to be laid bare. The excavation could scarcely have been continued had it not been for the grouting operations undertaken and carried through. Four grouting machines on the surface were connected with suitable piping run to the shaft bottom. The main piping had a diameter of 2½ inches, the terminal hose, 2 inches. Difficulty was at first experienced because of back leakage. This trouble was overcome by the use of finely ground horse manure intermingled with the grout. The holes were cemented up in three days with the consumption of 2,900 bags of Portland cement. A few additional holes were now drilled, and 60 additional bags of cement forced in. Conditions were, however, not yet to be trusted. Six holes were put down about 100 feet to the Shawangunk grit. Half of these had 1-inch cores and half 2-inch cores. Using a pressure of 275 pounds per square inch, the machines were able to force into the crevices only about 175 bags of cement. It was doubtful what this small amount of cement indicated. The excavation was resumed and carried to a depth of 320 feet, when the shaft was flooded for the sixth time.

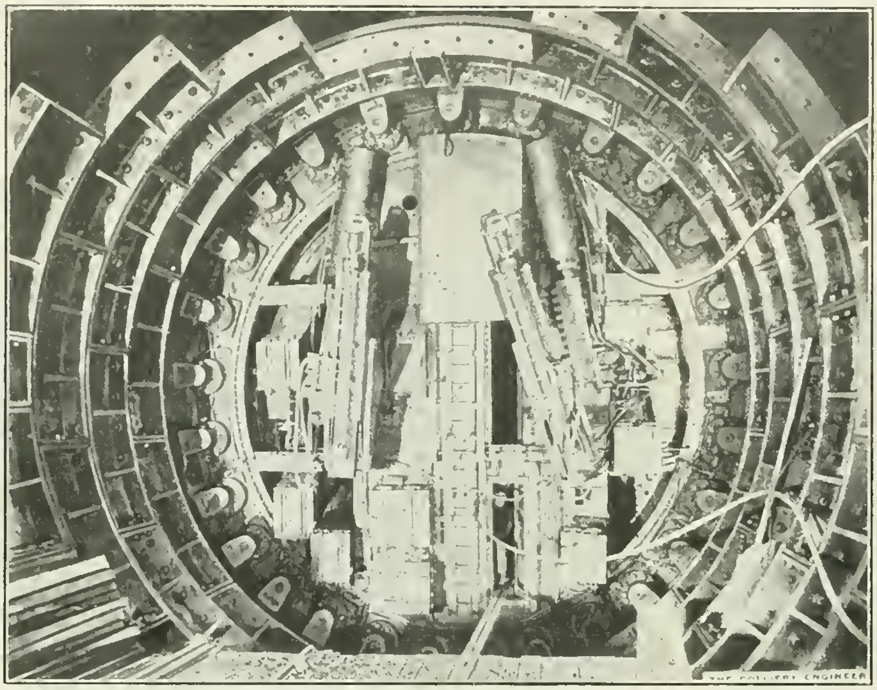

Fig. 3. Shield in Pennsylvania Tunnels Showing Circular Row of Jacks and Tunnel Lining

At the 309-foot level, an excavation was made on one side of the shaft with the view of providing accommodations for a stationary pumping plant. A pump chamber 10 feet high and having a floor area of 17 ft. × 24 ft., was made together with a sump 5½ feet deep beneath the floor level. This sump had a horizontal section of 16 ft. × 22 ft., and a capacity of 14,500 gallons. In the chamber were installed three horizontal condensing pumps, each of the 24 × 10 × 20-inch size, built by the A. S. Cameron Steam Pump Works, of New York City. The combined capacity of this plant was 1,050 gallons per minute. Steam was furnished by three 100-horsepower boilers on the surface near the mouth of the shaft. The steam connections were made with 4-inch piping wrapped first with asbestos, then with felt, and finally with tin.

No great trouble was experienced thereafter and the success of the final operations is to be attributed largely to the grouting of the strata as well as the fixed pumping plant of considerable capacity.

The foregoing gives an account of the methods employed recently in connection with an open shaft. It will be of interest to place alongside a short narrative dealing with the withdrawal of water from headings under air pressure.

It is only now and then that compressed air is employed in tunnel work to hold back the ground and water from the excavation. This is due in part to the fact that excavation under air pressure has a distinct limitation. The air pressure has to be increased continually with depth below the water line. As the increase amounts to .433 pound per square inch per vertical foot, the short distance of 100 feet below the water level requires a pressure of 43 or 44 pounds per square inch. This is about the greatest air pressure the excavation men can endure and so marks the point near which the compressed-air method must be abandoned.

The most important horizontal excavation through wet material that has ever been carried out was no doubt that of the four tunnels for the Pennsylvania Railroad beneath the East River at New York. The amount of water to contend with was unlimited; and so the method of excavating and boring had to conform with this condition. A modern form of the shield originally patterned by Brunel, in England, nearly one hundred years ago, was adopted as the principal aid in excavation. The heading in which a shield would be working would be put under compressed air. The actual excavation took place just ahead of the shield. Back of the head which partitioned off the air chamber, would be the permanent cast-iron lining. This lining is composed of metal rings 2 or 3 feet long, securely bolted to one another. Each ring consists of a number of segments bolted to each other, end to end. The extreme forward end of the iron lining would lie within the shell of the rear of the shield. When the face of the heading would be excavated the length of a ring, the shield would be forced ahead by means of hydraulic jacks operating between the end face of the final ring and an inward projection of the shield. There would thus be left a space within the shell which would then be filled by means of a new ring. Just back of the shield, grouting operations would be carried on to seal the spaces just outside the newly constructed rings.

The water was excluded by the resistance supplied by the air. Of necessity, the air pressure had to be equal, or nearly equal, to the hydrostatic head, a condition which entails a difficulty that pertains to horizontal compressed air work but not to vertical. In such large tunnels as those of the Pennsylvania Railroad the hydrostatic head corresponding to the top would be less than that at the bottom. Ordinarily, a pressure suited to an intermediate head is employed. Consequently, the water above the roof of the new excavation will be subjected to an upward pressure. This is offset at times, however, by the excess specific gravity of the soil over that of water.

In consequence of the interplay of nearly balanced upward and downward forces, danger of "blow-outs" would arise wherever the material overhead is loose and open or where its thickness is much diminished. At the bottom, on the contrary, the insufficient air pressure would often result in the inward leakage of water. In fact, the removal of the bottom water was an ever present problem where the ground permitted the passage of water.

The withdrawal of this water was accomplished in an interesting manner during the progress of a portion of the work beneath the East River. All four tunnels were driven simultaneously from both shores of the river. Shafts were put down on each shore to permit the inception of this work at the proper levels. Some of the shaft work was done under compressed air; some was done in the open. After the commencement of tunneling it was ordinarily unnecessary to have a shaft under air, even where air had been used in vertical excavation. Consequently, with the heading under air pressure and the shaft open, there would be a very considerable difference between the air pressures in the two. Advantage was taken of this condition to drive water from the heading into the sump of the shaft. That is to say, a pipe would be laid horizontally from the shaft through the bulkhead and along the tunnel to a point in the vicinity of the shield. A stuffingbox was bolted to this pipe, in which was a telescopic pipe fixed rigidly to the traveling stage. From this a 6-inch flexible pipe dropped to the invert with a strainer on the end of it. Water would be forced by air pressure through the strainer and the pipe to the sump. At the bulkheads branches would be arranged to care for water at these points. However, a difficulty manifested itself. When passing through sand, a great deal of this material would be forced in and driven along, with water, which resulted in cutting the pipe. The pipes were easily replaceable except at the bulkheads, and it was necessary that they should be replaceable there. In some of the bulkheads 8-inch pipes had been placed and by using 6-inch pipes for the passage of the water through a bulkhead, the 8-inch pipe could be used simply as a sleeve. In this way, the interior pipe when cut could be replaced without disturbance of the 8-inch pipe imbedded in the bulkhead. The extra heavy 6-inch pipes would be run through and flanged, and the annular space between the two pipes calked with lead. The sumps in the shafts were unwatered ordinarily by means of Cameron pumps.

The American Institute of Mining Engineers

The one hundred and fourth meeting of the American Institute of Mining Engineers was held in New York City at the headquarters of the society, February 17, 18, and 19. There were twenty-seven papers on mining geology and allied subjects, and seventeen papers on iron and steel subjects.

The American Institute of Mining Engineers is the second in age of the four great national engineering societies. The American Society of Civil Engineers preceded it by 19 years. The Institute was called into being by a circular issued from Wilkes-Barre by Eckley B. Coxe, Richard B. Rothwell, and Martin Coryell, all three at the time engaged in anthracite mining. This circular brought together in Wilkes-Barre, May 16, 1871, twenty-two persons, who founded the American Institute of Mining Engineers. Three of the twenty-two are still on the rolls. They are, President Henry S. Drinker, of Lehigh University; Dr. Rosco W. Reynolds, who was secretary of the Institute; Mr. Williard P. Ward, mining engineer, in the Mills Building, 15 Broad Street, New York.

Before the first meeting adjourned 46 others were elected, of whom 10 are members today, and among whom are Mr. Anton Eilers and Prof. George W. Maynard, representatives of the metallurgical profession in New York, and Mr. Stewart M. Buck, dean of the coal mining profession in West Virginia. Martin Coryell was the first secretary, Prof. Thomas M. Drown, of Lafayette College, was the second secretary. Doctor Raymond was elected secretary in 1883.

At the recent meeting Charles F. Rand, president of the Spanish-American Iron Co., was elected president, and Bradley Stoughton was chosen secretary by the Board of Directors.

Answers to Examination Questions

Questions Asked at the Examination for Fire Bosses and Mine Foremen, Held in West Virginia, 1912

Ques. 1.—What are the legal qualifications and duties of a fire boss in the state of West Virginia? Should he have any other qualifications than those demanded by law? If so, state them.

Ans.—The legal qualifications of a fire boss are: "He shall be a citizen of this state, and shall have such knowledge of firedamp and other dangerous gases as to be able to detect the same with the use of a safety lamp, and shall have a practical knowledge of the subject of the ventilation of mines and the machinery and appliances used for that purpose, and be a person with at least 3 years' experience in mines generating gases."

The duties of a fire boss, condensed from those set forth in the code of mining laws, are (*a*) he must prepare and place at the entrance of every gaseous mine a colored danger signal beyond which no one but the operator, mine owner, or his agent may pass (and then only in case of an emergency) until the mine or dangerous parts of it have been examined by the fire boss and reported safe; (*b*) he must visit all the working places in a mine where gas exists, or may exist, and examine them with a safety lamp and, if gas is present, shall remove it himself or have it removed by others; (*c*) he must make his rounds and the examination and removal of the gas (if there is any) within 3 hours of the time the shift goes to work; (*d*) he shall leave some evidence or mark of his visit at the face of each working place examined; (*e*) he shall remove or change the color of the danger signal if no gas is found in order that the men may know the mine is safe to enter; (*f*) he shall have no superior officer while performing his duty, all employes inside the mine being subordinate to him; (*g*) he shall, upon leaving the mine, make a written record of the condition of the workings in a book provided for the purpose.

Yes. A fire boss should possess the same qualities to succeed that are demanded of other men. Among these qualities may be named faithfulness and attention to duty, a willingness to work hard, a sense of fair dealing, the power of observation, with the ability to reason well and rapidly so that he may be able to act promptly and properly in an emergency, bravery in the face of danger, etc., etc.

Ques. 2.—What are the gases found in coal mines? How are they produced? Where are they found? What effects are they likely to have upon the workmen? How are they detected? What are their specific gravities and compositions? What would you do to render them harmless?

Ans.—Aside from the oxygen and nitrogen composing the air, the gases generally met in coal mines are methane, carbon dioxide, and carbon monoxide.

Methane is generally slowly given off from the pores of the coal, or rapidly from blowers or from crevices, should these latter be encountered in mining. Being lighter than air, it is found near the roof of level workings or at the face of pitching places. Methane is not poisonous, but if much is present in the air it fills the lungs in place of the necessary oxygen and the person exposed to it dies of suffocation. Methane has a specific gravity of .559 and its symbol, CH_4, shows that it is composed of four parts of hydrogen and one part of carbon. It is detected by its effect upon the flame of a safety lamp upon which it produces a slightly luminous cap which increases in height as the percentage of gas in the air increases. Mixed with air, methane forms what is commonly known as firedamp, which is often explosive and the cause of many serious mine accidents. Methane is also known as marsh gas, light carburetted hydrogen, or merely as gas.

Carbon dioxide is produced by the breathing of men and animals, by the burning of lamps or any other burning where there is an ample supply of air, by the slow decomposition of coal and wood (timbers), by the explosion of powder, and sometimes is given off from the rocks enclosing the seam itself. Carbon dioxide is frequently found in the gob or abandoned workings where the ventilation is poor. In any particular working place this gas is generally found near the floor or at the bottom of dip workings, as it is very much heavier than air. The gas is not poisonous, but when breathed for any length of time produces headache, nausea, and pains in the back, etc., followed by death from suffocation. The only means for its detection is afforded by the behavior of the lamp flame which in the presence of this gas burns with less and less brightness and finally goes out. The specific gravity of carbon dioxide is 1.529, and its symbol, CO_2, shows that it is composed of two parts of oxygen and one part of carbon. This is also known as carbonic acid gas and, when mixed with air, forms blackdamp.

Carbon monoxide is not given off by the coal or the rocks enclosing the seam, but is formed by the explosion of many kinds of powder, by mine fires where there is not enough air to burn the coal to carbon dioxide, and is one of the chief products of gob fires or of any other burning where the air supply is limited. The chief source of this gas is the afterdamp resulting from coal-dust explosions, and it is the cause of the vast majority of the deaths in these accidents. As this gas is very nearly as heavy as air it readily diffuses through it, so it is not generally found either at the roof or floor, as with methane or carbon dioxide, respectively, but in any part of the working place. This is by far the most dangerous gas met in mines, as it is highly poisonous even in very small amounts. It acts as a narcotic poison producing a speedy death. It coagulates the blood, which has 250 times the affinity for this gas that it has for oxygen. It is difficult of detection by mechanical means, as the percentage of it in the air which will show a cap on the safety lamp flame, will result in almost instant death. In rescue work after dust explosions it is customary to carry along one or more canaries or other small birds which are very much more sensitive to small amounts of this gas than is man. As soon as the bird begins to show signs of distress the party, unless provided with helmets, should leave the place. The specific gravity of the gas is .967 and its symbol, CO, shows that it is composed of one part of oxygen and one of carbon. It is sometimes known as carbonic oxide, and, mixed with air, forms what is known as whitedamp.

These gases are all removed in the same way, namely; by having an ample amount of air carried to all parts of the workings, particular attention being given to those places where these gases are being given off in unusual amounts.

Ques. 3.—Describe the structure of the safety lamp and show on what principle its safety depends. Under what conditions does it become unsafe? What effect, if any, do high velocities of air-currents have on it?

Ans.—The safety lamp consists essentially of a metal receptacle for oil, provided with the necessary wick, etc., for burning the same and producing a light. The wick is surrounded by a cylindrical shield of glass, the upper part of which is replaced by a fine wire gauze having 784 openings or meshes to the square inch. There is sometimes an interior conical metal chimney to increase the draft and the gauze may or may not be surrounded by an outer metal shield known as a bonnet. The safety of the lamp depends upon, or is brought about by, the fact that the flame of a mixture of methane and air burning within the lamp is so cooled by passing through the meshes of the gauze that its temperature is reduced below the point at which the same mixture outside the lamp will ignite.

The safety lamp is dangerous when there is a hole in the gauze that will pass the flame to the outside, or when the gauze is dirty so that any particular spot may be overheated, or when gas is allowed to burn within the lamp until the gauze is red hot, or when the velocity of the air is so great that the flame is blown through the gauze.

Safety lamps should not be used in air-currents of very high velocity, owing to the possibility of the flame being passed through the gauze, but much will depend upon the composition of the mine air. It is generally considered that the best modern safety lamps may be exposed to currents of velocity as great as 2,000 feet a minute, except where much dust or gas is present, in which case they are not safe in currents moving more than 1,200 to 1,500 feet a minute.

Ques. 4.—What are the instruments that are most useful in aiding the fire boss to determine the conditions existing in the mines? Describe the character of the information obtained by each of them and the manner of their use.

Ans.—Aside from the safety lamp described above, the instruments in common use are the water gauge and the anemometer, although at some mines a barometer, thermometer, and hygrometer are provided, but these latter are usually handled by the superintendent or mining engineer

The water gauge consists of a glass tube about one-half inch in diameter bent in the form of the letter U, and partly filled with water. It is placed in a brattice so that one end is open to the return and the other to the intake air-current. The difference in the pressure of the air in the two entries causes the water to sink in the tube open to the intake and to rise in the tube connected with the return. The difference in the level of the water in the two arms is read off, in inches and decimal fractions thereof, upon an adjustable scale. Each inch of water gauge reading corresponds to a ventilating pressure of 5.2 pounds per square foot. The water gauge thus measures the pressure necessary to overcome the frictional resistance of the passage of the air through the mine workings.

The anemometer consists of a small vane or number of blades fixed to an axle revolving in a circular frame. The number of revolutions made by the vane is recorded by means of a number of pointers on the face of the anemometer. This instrument is used to measure the velocity of the air-current by being held in a selected part of the airway for a definite length of time, say, 1, 2, or 3 minutes. The velocity of the air or distance traveled in 1 minute multiplied by the area of the cross-section of the airway will give the number of cubic feet of air passing in cubic feet per minute.

Ques. 5.—How would you proceed to look for and detect explosive gases in mines; also state the manner by which you would detect other dangers while making your examination and the precautions you would use to prevent accidents from these dangers.

Ans.—The flame should be lowered the better to show the "cap" formed by the burning gas (if any is present), and carefully watched for the first appearance of the flame cap as the lamp is slowly raised to the roof and into cavities where gas is apt to be found. The roof should be examined to see if it is sound and not apt to fall. If gas or unsafe roof is found, the place should be fenced off, or notice posted in some way, so that men will not enter until the dangers are removed. The fire boss should be on the watch for any evidences of squeeze, excessive amounts of water in the workings, broken or poorly working doors, bad track, accumulations of dust, blown-out shots or poorly mined coal, in fact he should look into, as far as his time permits, the same sources of danger and trouble as the mine foreman to whom he should report anything amiss in the mine.

Ques. 6.—Is coal dust explosive? If so, where are explosions from coal dust most apt to occur? What weight of dust in air makes an explosive mixture? What weight of dust and what percentage of marsh gas will make an explosive mixture? What means have been proposed to remove coal dust from air? What method has been found most successful for purging the air of coal dust? Is it best to prevent the suspension of coal dust in the air or to remove the dust after it has been suspended?

Ans.—Coal dust by itself is explosive and may be ignited by burning firedamp, by a mine fire if large amounts of finely powdered dust are thrown into the air passing over or through, by the flame produced by the short-circuiting of an electric current and when the trolley wires become crossed, by a blown-out or windy shot from a misplaced or over-charged hole and by the explosion of a large amount of dynamite or other high explosive even if not confined in a hole. The flame of an explosion, which in itself would do but little harm, is by coal dust carried throughout the workings.

Explosions of coal dust are apt to occur in bituminous mines where the percentage of volatile matter in the coal varies from 14 per cent. to 38 or 40 per cent., particularly if the coal possesses good coking qualities; where the coal is soft and makes large amounts of fine dust; where improper methods of mining, such as shooting off the solid, the use of too much powder in improperly placed holes, etc., are employed; where the climate is "dry," as in the Rocky Mountain regions, so that (usually) more water is being carried out by the air-current than is brought in by other means; where the outside air during the winter months is much colder than the mine, as in the eastern part of the United States, this having the same effect upon the power of the air-currents to absorb moisture as prevails in the dry climate of the West; and where, in general, anything may happen by means of which a flame is made and fine clouds of dust are, at the same time, thrown into it.

The United States Bureau of Mines has shown that when bituminous coal dust is fine enough to pass through a 200-mesh sieve (one with 200 openings in the length of an inch, or 40,000 openings in 1 square inch of area), and thus floated easily on a strong air-current, 1 pound of dust in 500 cubic feet of air readily spreads an explosion. Much, however, depends upon the kind of dust, and particularly upon the violence or intensity of the explosion of flame which first ignites the dust.

It is not possible to give an exact weight of dust and exact percentage of methane (marsh gas) that will form an explosive mixture, as this varies with the nature and fineness of the dust, etc. In general, however, a mixture of marsh gas and air containing less than 1 per cent. of gas is explosive if it also contains a highly inflammable coal dust.

The entrance of coal dust to the mine air can probably never be entirely prevented, but the amount in suspension in the air, and which is, of course, carried along and deposited on the floor, roof, and ribs, may be materially lessened if certain precautions are observed. In order to reduce the amount of dust made at the working face the seam should be undercut to a depth about equal to its thickness and if this is done by chain machine the outer edge of the cut should be snubbed so that the coal will fall easily. The shot holes should be so placed as to require the smallest possible amount of powder to bring the coal, and no hole should be charged with more than $1\frac{1}{2}$ pounds of explosive, which should be of the permissible type recommended by the United States Bureau of Mines. To prevent the distribution of coal, either as dust or lumps, along the haulage road, the cars should be made with tight joints and the topping should be low, so that the lumps will not roll off when the cars are bumped together. Fine coal, as was as larger lumps, is soon ground to powder by the feet of men and mules, and tight cars and little or no topping will prevent it falling on the track. Many recommend that the fan be stopped or slowed down at shot-firing time to lessen the velocity of the air-current so that the very fine dust made by the blast may settle where made and not be carried throughout the mine on the air. Also all bug dust should be loaded out and all working places should be well watered before shot firing, so that the fine dust may not be thrown upon the air by blasting. It is further recommended that the tops of all cars and their entire contents, if possible, be wetted before, or very shortly after, they are delivered to the gathering driver, in order, also, that the fine dust may not be blown, swept, or knocked from them as they are being hauled to the parting.

Two general methods of preventing dust explosions prevail, which may be called the wet method and the dry method, although neither of them purges the air of dust. In the wet method the mine roads, roof, and ribs are either washed down with hose and water, so that the dust is reduced to mud, or else moisture for this purpose is admitted by means of jets or sprays of water placed at intervals along the entries, or the intake air may be heated by exhaust steam and saturated with moisture at a high temperature, which moisture is deposited when the preheated and premoistened air comes in contact with the cooler mine. Sometimes one of these methods of wetting the mine is used by itself, in some mines two are used in combination, and in a few all three are used. In the dry method no attempt is made to settle the dust. Instead, the floor, roof, and ribs are heavily sprinkled with very finely powdered shale dust, which is also placed on racks and shelves throughout the mine. Shale dust is inert, that is, it will not explode and if enough is present it will prevent the explosion of an otherwise dangerous dust. The wet methods are preferred in the United States, being used in all but one mine and, although the wet method is in general use in Europe, there are many places where the dry method is used. It is absolutely certain that neither a perfectly wet mine nor a mine in which the coal dust has been replaced by powdered shale can explode, but just what amount of water or what amount of shale dust is necessary to prevent or stop a dust explosion is not yet determined. It depends in a very large measure upon the composition and fineness of the dust, the volume and velocity of the air-currents and the force or intensity of the initial explosion or burning which ignites the dust.

33—9—5

It is better, by all means, to prevent the dust getting into the air than to remove it afterward, but this is not possible. The best practice reduces as far as possible the amount of dust made at the face, and then washes down or deadens with inert dust that which is unavoidably carried away and deposited by the air-currents.

(To be Continued)

Steam Line Suspension

When a steam line crosses a railroad track or any similar obstruction, a simple suspension can be constructed by the use of old rails and old wire rope. In making it, a pair of rails (marked A in Fig. 1)

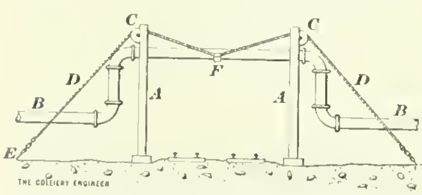

Fig. 1. Steam Line Hanger

is placed on each side of the track to support the steam line B. The rails are stood in the usual manner slanting toward one another. The bottom should be placed on a foundation so that the rails cannot work into the ground, and the top ends are held together by a strong rod to which the supports for the steam line are fastened. On the rod at each side of the steam line hanger is placed a pulley C over which the wire rope D is strung and which will allow the wire rope to move without a tendency to break. Two lengths of wire rope are used. They must be long enough to pass from an anchor E, located at a distance behind the rail supports, up over the pulleys on the uprights and under a stirrup F beneath the steam line at the center of the span and down to an anchor on the other side. The ropes should be coned and a turnbuckle used so that the rope can be pulled taut, for the support of the pipe depends upon the drawing taut of the rope. The pulleys over which the rope passes are higher than the stirrup, and consequently as the wire rope is tightened there is a lifting effect beneath the stirrup. The uprights are prevented from falling in toward one another when the ropes are tightened, by means of the hangers which are placed behind the flanges on the bends.

American Institute of Electrical Engineers

The meeting of the American Institute of Electrical Engineers will be held in Pittsburg, Friday and Saturday, April 18 and 19. Mr. George R. Wood, consulting engineer of the Berwind-White Coal Mine Co., is chairman. A number of papers on the use of electricity in mines have been promised and it is expected that interesting discussions will take place.

Owing to this meeting being in the largest bituminous coal mining district, it is expected that a number of coal mine papers will be presented, and mine managers and operators generally are invited to attend. E. C. Turpin is secretary of the Pittsburg section of the institute, and communications may be addressed to him, care of Westinghouse Co., East Pittsburg, Pa.

The annual meeting of The Iron and Steel Institute of Great Britain will be held at Storey's Gate, Westminster, London, May 1 and 2, in the rooms of the Institution of Mechanical Engineers.

The International Geological Congress will hold its twelfth session in Toronto, Canada, August 7 to 14, 1913, with headquarters at the University of Toronto. No professional qualification is necessary to become a member in this society, but a fee of $5 must accompany each application for membership. Address Secretary, Twelfth International Geological Congress, Victoria Memorial Museum, Ottawa, Canada.

Mine Cave Commission Report

The Recommendations of the Anthracite Mine Cave Commission—The Remedy Suggested to Meet Conditions

In the populous anthracite coal regions of Pennsylvania, the effect of the mine workings on the surface and the buildings thereon, particularly in the northern field, developed a serious state of affairs, and presented a difficult problem. In the majority of cases, when building lots were sold the coal rights were reserved to the original owners, their heirs and assigns. In the Lackawanna region, in most cases, the purchasers of lots, not only purchased them subject to the coal reservation, but also, in the deeds, agreed that the owners of the coal should have the right to mine it without liability for damages done the surface or buildings thereon.

Due to the extension of mine workings under the city of Scranton and adjacent boroughs, particularly in localities where all or nearly all the coal in the seams was extracted, there were numerous surface disturbances, and considerable damage was done to buildings. This damage, however, taken collectively, was comparatively small, when the entire valuation of the real estate in the city is considered. Naturally losses to individual owners of real estate were comparatively large, though in some instances the company mining the coal voluntarily repaired the damage.

The assessed valuation of real estate in the city of Scranton is nearly $80,000,000. The real valuation probably exceeds $125,000,000. The damage done by mine caves in the past 20 years has not totaled over $200,000 or $250,000—really less than the loss occasioned by a single large city fire, and very much less than the damage done by spring floods in many cities located on large rivers. However, the rapid exhaustion of the anthracite requires now, and will require in the future, the working of seams that were formerly regarded as practically unworkable, and the extraction of a maximum percentage of all the seams. This necessity, naturally, means that large sections of thickly populated territory will be seriously affected by the mining. For the purpose of thoroughly studying the situation and investigating methods of surface supports, and of offering a rational solution of the problem, Governor Tener, early in 1911, in accordance with an act of the legislature, appointed a remarkably well-selected and able Commission.

This commission consisted of W. J. Richards, of Pottsville, Vice-President and General Manager of the Philadelphia & Reading Coal and Iron Co., an able mining engineer and an executive with ability of the highest order; G. M. Davies, of Lansford, an experienced and intelligent coal miner; Wm. H. Lewis, of Pottsville, a retired mine superintendent of long and successful experience; W. A. Lathrop, of Wilkes-Barre, an able mining engineer and manager of many years' experience, and President of the Lehigh Coal and Navigation Co.; Charles Enzian, of Wilkes-Barre, a mining engineer of excellent repute, connected with the United States Bureau of Mines; Hon. W. L. Connell, former Mayor of Scranton, and a successful operator and mine manager; Hon. J. Benjamin Dimmick, of Scranton, former Mayor, and an attorney and banker; E. J. Lynett, editor of the Scranton *Times*, and one of the most progessive citizens of Scranton; and Col. R. A. Phillips, of Scranton, General Manager of the Delaware, Lackawanna and Western Coal Co., a man who knows coal mining through practical experience in every position from miner to general manager.

Owing to ill health, and his subsequent death, Mr. Lathrop did not serve, and the Governor appointed in his place, Samuel D. Warriner, an able engineer, at that time Vice-President and General Manager of the Lehigh Valley Coal Co., and later Mr. Lathrop's successor as President of the Lehigh Coal and Navigation Co.

From the time of organization until March 1, the Commission held upwards of 50 meetings, and in addition subcommittees devoted a great deal of time investigating details. Every obtainable source of information was drawn on and prominent mine officials and mining engineers were called before the Commission, their testimony taken and opinions asked.

Naturally, in a body of such men, there arose at times, differences of opinion, and these differences had to be fought out and reconciled. Finally, on the night of February 28 the work was completed, and the report of nearly 600 typewritten pages was delivered to Governor Tener on March 1.

During its deliberations, the Commission entered into negotiations with the presidents of the principal coal mining companies, and secured voluntary concessions from the companies as set forth in a general way in the following concise statement:

"On condition that and so long and so far as the exercise of their rights to mine coal are not restrained, restricted or penalized by the passage or enforcement of state laws or municipal ordinances, the mining companies agree to

"1. Protect all public highways and city streets; this protection, however, to be based generally upon the principle of the conservation of the coal thereunder for market purposes, and to involve a reasonable attitude upon the part of the communities having jurisdiction over said public highways and city streets, and also a reasonable use of the right of said companies to mine thereunder, so far as affecting the surface is concerned. On the one hand, the communities to refrain from unreasonably enjoining mining where no serious public injury will result, and, on the other hand the companies to refrain from so conducting their mining operations as to seriously interfere with the centers of traffic in municipalities where the conditions are such that serious public injury will result, and to provide for the security and convenience of the public by giving proper notice of proposed mining which may affect the surface, by providing temporary ways of passage, and finally, by repairing at their own expense any and all damage caused to the municipalities by said mining.

"2. Pay at least one-half of the cost of repairing all structures (except those of mining and railroad companies) damaged by mining having a value of $5,000 or less.

"3. Whenever danger of subsidence is imminent, sell, so far as they have the legal right so to do, for a fair consideration to owners (except mining and railroad companies) of structures exceeding $5,000 in value, such pillar coal as they may reasonably desire to purchase for the support of said structures, such consideration to be 25 per cent. above the prevailing value upon leases made at or near the time of purchase, the basis of computation being 1,800 tons to the foot acre. In the event of such purchase, however, the coal thus purchased to be forever appropriated to the support of the surface. If, however, support may be reasonably provided by filling or otherwise, then to flush, fill or build artificial supports in such portions of the mines as may be desired by the surface owner at a price not to exceed the cost thereof to the mining companies, but at the expense of such surface owner, provided that when such support is at the election of the mining company, the expense to the surface owner shall not exceed the cost of pillar coal as hereinbefore provided.

"4. In recognition of the peculiar conditions and the general fear of immediate surface damage in the city of Scranton and borough of Dunmore and with a purpose of relieving the public solicitude, but without admission or interpretation of the present value of the coal, the principal operators in this territory agree that during the period of 18 months after March 1, 1913, they will sell so far as they have the legal right so to do to owners (excepting mining and railroad companies) of structures exceeding $5,000 in value such pillar coal as they may reasonably desire to purchase for the support of said structures at the rate of 35 cents per ton on the basis of 1,800 tons to the foot-acre.

"5. Provision to be made for the adjustment of any disputes arising in connection with such sale or putting in artificial supports."

The coal mining companies agreeing to these points were: The Lehigh Valley Coal Co.; Philadelphia & Reading Coal and Iron Co.; Pennsylvania Coal Co.; Hillside Coal and Iron Co.; D., L. and W. Coal Co.; Scranton Coal Co.; Delaware & Hudson Co.; Green Ridge Coal Co.; Lehigh and Wilkes-Barre Coal Co.; Edgerton Coal Co.; Northwest Coal Co.; Sterrick Creek Coal Co.; Lackawanna Coal Co., Ltd.; Mount Lookout Coal Co.; Forty Fort Coal Co.; Elk Hill Coal and Iron Co.; Northern Coal and Iron Co.; Hudson Coal Co.; and the Susquehanna Coal Co. In expressing its unanimous opinion of the results that will follow the carrying out of the plan suggested the Commission says:

"The undertaking as set forth upon the part of the companies is revocable; on the other hand, the communities remain perfectly free as regards the exercise of police power, a power that they could not divest themselves of even should they consent thereto.

"The commission, however, are unanimously of opinion that when the practical benefits of the plan are appreciated, the benefits being substantial to the communities, to the surface owners and to the mining companies, that all parties will be led, not only through selfish interest, but also through a regard for the public welfare, to exercise that self-restraint that will be necessary to render the plan substantially and permanently effective.

"That the plan may occasionally work a hardship is undoubtedly conceivable, but no solution of so complex a problem could presumably be without that defect.

"That the benefits are mutual and substantial is the well considered belief of the commission, and that they may be the more easily and clearly comprehended, they are herewith set forth.

"Speaking broadly, all the parties—the communities, the individual and the mining companies—are benefited, obviously, by any prolongation of their basic industry, and therefore, as far as compatible with community and individual rights and necessities, this principle was acknowledged and kept in view. It was recognized in the classification of property, under which pillars are not to be left, by the dividing line of value of $5,000 and under; such line not only increasing the total amount of coal to be mined, but also decreasing the burden of making good the surface property of a very large percentage of the total structures of the anthracite regions, inasmuch as the cost of repairing the damage caused by letting down the surface under the structures of $5,000 or under, will average much less than either of the two other methods, namely, the 'leaving of pillars,' or 'flushing.'

"The prolongation of the basic industry is also helped by the suggested permission to mine under highways and streets, except under traffic centers, said highways and streets, however, being restored, in all cases, to their original status and condition, by and at the expense of said mining companies.

"The mining companies, therefore, benefit by such broadened activities, and in consideration of same, they participate in the burden of making good all surface property, such participation taking two forms. First, by paying one-half, at least, of the cost of repairing all structures having a value of $5,000, or under, and, secondly, in selling the necessary pillar supports for all structures exceeding $5,000 in value, at a price that is a distinct concession from the actual value of such pillar coal to them as coal miners. The former burden is estimated in the city of Scranton alone, at say, $3,500,000, while the concessions upon the coal pillars, also in Scranton alone, would probably reach the same figure.

"The benefit to the surface owners, is, therefore, substantial, the companies, roughly speaking, paying one-half of the cost of the ultimate solution of the problem, as regards probably 90 per cent. of the property owners of the anthracite regions and making a distinct contribution wherever pillar support is demanded by reason of the character and value of the remaining 10 per cent.

"The communities are benefited by the prolongation of the industry and by the securing of terms for individual property holders that while burdensome are not considered as being prohibitive. Possibly one of the greatest benefits of the community is the sentimental reassurance that should come from the placing in immediate operation of a practical remedy for conditions that not only menace, but are actually retarding community development. As to the placing of a portion of the cost of supporting private property upon the communities as such, which is, in effect, but changing the form, but not the weight, of the burden, it was felt that such action would be impracticable, owing to the voluntary character of the plan, to say nothing of the inequalities that would be worked through the varying conditions in any given community or of the complications that would arise from increased municipal indebtedness.

"The query very naturally arises as to what will be the attitude of the smaller companies who are not included in the arrangement. The commission can only suggest that it will be difficult for any mining operator, however small may be his field, to decline to acknowledge this reasonable measure of his responsibility so overwhelmingly established by his competitors in trade, unless it be that such operator is indifferent not only to equitable, but also to ethical obligations."

So as to make effective the agreement and plan suggested, the Commission recommended the enactment by the legislature of the two following bills:

AN ACT

To afford additional protection to the public against dangers resulting from the caving in or subsidence of the surface overlying anthracite coal mines.

Sec. 1. Be it enacted by the senate and house of representatives of the commonwealth of Pennsylvania in general assembly met, and it is hereby enacted by authority of the same, that where the owner or operator of any anthracite mine in this commonwealth possesses the right to mine out all the coal without obligation to support the surface, and proposes to exercise that right by removing or materially weakening the support theretofore afforded to the overlying surface by pillars of coal, it shall be unlawful for him to do so until sixty days after he shall have caused to be served, in the manner provided by law for service of the writ of ejectment, a written or printed notice of his intention so to do upon the owner or owners and the occupant or occupants of the surface lands liable to be affected by such action.

Such notice shall specify the time when such pillar mining will, in the operator's opinion, render further occupation of the surface dangerous and shall be served at least sixty days before the date stated therein.

Within the period during which the said occupant or occupants are thus given an opportunity to remove from such place of danger, it shall be his or their duty to do so and remain absent therefrom until the danger from subsidence of the surface has passed.

Sec. 2. The said owner or operator shall cause to be served in the manner aforesaid, a notice of fifteen days upon gas companies and electric light or power companies maintaining pipes and wires in territory under which mining operations are being conducted, which notice shall state when, in the operator's opinion, said mining operations will be liable to disturb said gas pipes and electric wires; whereupon it shall be the duty of said companies to shut off the gas and electric currents and discontinue the supply thereof in the threatened territory until subsidence of surface shall have occurred or the danger to be apprehended therefrom has passed away.

Sec. 3. Any owner, operator, superintendent, or other person having charge of a mining operation who shall wilfully refuse or neglect to give any notice required by this Act, and any official, superintendent or other person in control of the operation of any gas or electric company which has received notice as aforesaid, and shall thereafter wilfully refuse or neglect to perform the duty enjoined upon such company by this act, shall be guilty of a misdemeanor and upon conviction thereof shall pay a fine not exceeding one thousand dollars and undergo an imprisonment for a term not exceeding six months, or both, or either, at the discretion of the court.

AN ACT

Providing for the appointment of arbitrators to settle disputes as to certain facts concerning the damage to public or private property by mine caves and fixing their compensation and providing for the payment of the cost thereof.

Whereas, a joint resolution for the appointment of a commission by the governor of this commonwealth for the purpose of investigating and reporting upon both physical conditions and legal rights in the matter of surface support where anthracite has been removed or the right to remove said coal is vested in others than the owner of the surface; and for the further purpose of suggesting new legislation relative to the same; and making an appropriation to meet the expenses of said commission, approved by the governor, March 24, 1911, and,

Whereas, in pursuance of said resolution said commission has organized and fully considered the matters submitted to it under said resolution and has made its report to the governor as therein required, and,

Whereas, the said commission has reported that there has been a voluntary offer made on the part of mining companies to the effect that upon certain conditions they agree to bear certain proportion of the cost of repairing property and also will repair streets under certain conditions, and further, that under certain other conditions coal for the support of the surface will be sold at rates therein fully set forth or supports will be furnished for the support of the surface, and,

Whereas, it is necessary to enact a law whereby any disputes arising as to the cost of repairing property, ascertaining the quantity of coal left to support the surface and improvements thereon, or the cost of furnishing artificial support, and further as to the repairing of public highways under conditions named in said report.

Now, therefore, it is hereby enacted by the senate and house of representatives of the commonwealth of Pennsylvania in general assembly met, and it is hereby enacted by the authority of the same.

Sec. 1. That whenever any dispute shall arise concerning the matters as herein stated, that such matter of dispute shall be submitted to a board of three arbitrators, one to be appointed by each of the parties to such dispute, and the said two arbitrators to appoint a third and in case of their failure to agree upon a third arbitrator, within a period of thirty days after their appointment, then the said third arbitrator to be appointed by the president judge of the county in which the land is located about which the dispute arises. The decision of a majority of said arbitrators shall be as effective to all intents and purposes as if signed by all of the arbitrators.

Sec. 2. Said arbitrators shall be entitled to receive the sum of five (5) dollars each day actually and necessarily employed in the performance of their duties.

Sec. 3. Either party aggrieved by the award of said arbitrators shall have the right to appeal to the court of equity of the proper county.

Sec. 4. All the cost of said arbitration and appeal shall be borne equally by the parties.

One horsepower is 550 foot-pounds of work in one second, or 33,000 foot-pounds in one minute, or 1,980,000 foot-pounds in one hour.

THE LETTER BOX

Readers are invited to ask or answer any question pertaining to mining, or to express their views on mining subjects in this department. All communications must be accompanied by the name and address of the writer—not necessarily for publication.

The editors are not responsible for views expressed by correspondents.

Method of Mining

Editor The Colliery Engineer:

Sir:—Will you insert the following questions in your Letter Box:

Under normal conditions of roof, floor, and seam, what will be the safe minimum widths of chamber pillar in a flat seam of coal 5 feet thick, 900 feet below the surface when the width of the room is 24 feet? What should be the width of opening chambers on the gangways. This question refers to the Dunmore No. 4 seam.

I would like to have a good explanation of how to rob anthracite pillars for the benefit of the operator and the safety of the men when robbing.

Chas. H. Robinson

Blakely-Olyphant, Pa.

Acetylene Lamps

Editor The Colliery Engineer:

Sir:—I have read the different opinions concerning the acetylene mine lamp, and if some one has not written of the same experience I would like to tell mine.

During the last six weeks I have been employed with a gang of men tearing track, wire, etc., out of workings that have been abandoned for a long time. There has been very little fresh air in circulation at any time since the workings were abandoned, and we found them full of blackdamp. Some of the men used oil lamps and others, including myself, used carbide lamps. Often the oil lamps would go out and we would continue working by the light of the carbide lamps for a long time. We worked up the heading till at last the carbide lamps threatened to go out and then we quit. Afterwards I went up the heading till the carbide lamp became extinguished.

None of us suffered any ill effects, and I am satisfied that a man is safe to work any place that a carbide lamp will burn, so far as blackdamp is concerned.

Foreman

Centrifugal Pumps

Editor The Colliery Engineer:

Sir:—In considering Mr. M. J. Rafferty's answer in February issue to Ques. 4, in Prize Contest, it would appear that he has overlooked the fact that during the past few years centrifugal pumps have been designed which are made very effective against high heads, by reducing the clearance and building in multiple stages. The most interesting installation of this sort that I have seen was at the Centennial Eureka mine in the Tintic district of Utah. This was a Swiss pump of 13 stages, built in two sections, one of five stages and one of eight stages with a 400-horsepower motor between the two, one shaft serving for both sections of the pump and the motor. This pump gave good satisfaction, delivering 500 gallons per minute against a head of 1,700 feet.

In the January 11 issue of *Mining and Engineering World*, is an abstract of a paper on pumping on the Comstock lode, read before the California Miners' Association by Mr. Whitman Symmes, in which he states that at the Ward shaft they had a five-stage Byron Jackson centrifugal pump driven by a 200-horsepower motor which handled as high as 600 gallons per minute against an 818-foot head.

I have seen other installations of a similar nature, but on a smaller scale, which tend to show that in the future the centrifugal pump will find a distinct use as a station pump.

Hay!

Editor The Colliery Engineer:

Hay! "Hay should be dipped in water." You see it was this way. A mine once got on fire and some men were suffocated, all because of a bale of hay. A workman set fire to the hay with his lamp. Some people say that the man was careless with his lamp. Others say that the hay should not have been where it was. Comments are also made on the condition and arrangement of the mine. But the association of ideas is there. Dry hay will burn, wet hay won't. Therefore wet the hay. The mules may not like it. But wet the hay before you take it into the mines and —safety first—avoid mine fires.

A child whose mother never wore earrings and always used plain soap, was picked up into her arms by an aunt. The child examined first one earring, snuggling his nose down into her neck, and then squirming around, examined very carefully the other earring. "Do you like them?" asked the aunt. "Yes, they smell good," was the answer.

It was a perfectly good answer. The child made a logical association of ideas. Earrings were a new sight for him as well as the gentle aroma of powder and good soap. Therefore it was the earrings, which were visible, that produced the smell.

So too an estimable gentleman whose duty it is to write authoritatively, has made an association of ideas. A mine fire—a bale of hay—wet the hay and avoid mine fires.

But how wet shall we wet it? And what tests shall we have to determine how wet it is? Why not a government bureau to determine standards of wetness? For shall we pour one bucket of water over each bale and do we need to wet the bale on the underside? Or shall we turn the hose upon the hay and what size of hose shall we use? Suppose we arrange that the whistle should blow a signal of two longs and three shorts whenever a bale of hay was to be sent down into the mine? Then the fire crew could turn out for practice and instead of attempting to squirt water over everything and a few friends, accidentally of course, would perform their function of fire prevention. An ounce of prevention is worth a pound of water cure.

To be sure the barn boss might object to wet hay. He generally does make remarks whenever any one allows the bales to stand in the rain for a minute. Says that the mules don't like it; talks about using different lights around a bale of hay and keeping the hay dry. But why pay attention to a barn boss or cater to mules?

It is a shame to pick a man up on one sentence in one report. But hay—wet it! Barn Boss

Humidity of Mine Air

Editor The Colliery Engineer:

Sir:—In the July, 1912, Alabama examination for first-class mine foremen's certificate, one question had reference to the quantity of aqueous vapor air will carry or support: My answer which may be of some value to others is given herewith.

The amount of water vapor that the air will carry or support varies with its temperature.

To explain I will give figures but not attempt to give them accurately as I have not the books to refer to.

Say that 3,300 cubic feet of air will support 1 pound of water at freezing, or 32°, that at 62° it will support 3 pounds, then a current of air of 33,000 cubic feet per minute entering a mine at 32° will absorb moisture up to its capacity at 62°, or whatever the temperature is. Thus the current of air takes up and carries away 20 pounds per minute, or about $2\frac{1}{2}$ gallons per minute, which would make 150 gallons per hour or something like 3,500 gallons per day. This goes on for months, the mine getting dryer and dryer.

No ordinary sprinkling systen will entirely correct this, for the air will only absorb moisture as it becomes heated, expands, and dries.

On the other hand, air at 92° will carry or support about 14 pounds of water vapor for 3,300 cubic feet, thus it will be seen when the air enters the mine at 92°, by the time the temperature is reduced to 62° it has given off 11 pounds of water. Assume now, as before, an air-current of 33,000 cubic feet, then instead of drying out the mine, it is depositing moisture in every part of it where the air enters, on the walls, roof, in the gob, and everywhere, creating the condition that exists in the summer time, when the walls and roof sweat from the condensation of the water vapor that the air refuses longer to support, owing to its lower temperature.

I have always doubted the efficiency of sprinkling, not that I have discouraged it, but when the air is increasing in temperature, it will take up moisture, if it has the opportunity, and carry it outside.

Notice in the winter time the frost formed on the trees, timbers, etc., when the warm air from the airshaft precipitates the water vapor it is carrying as it encounters the cold air on the outside.

The same conditions must be created artificially in the winter that exist naturally in the summer.

This can be done.

The intake at some suitable point in the shaft or elsewhere should be heated up to 90° or 100°, then wet steam supplied or artificial rain, or a pond of water prepared for the heated air to pass through or over, so that it enters the mine workings at about 90° fully charged with water vapor. Then condensation takes place as in the summer time.

This is no original thought of mine, though I do not know of its being applied to coal mines.

I examined the same plan for the ventilation of the Capitol at Washington, D. C., over 30 years ago. The only question is, who will first do it. It is perfectly feasible and practical.

The disastrous losses of life have not been caused by the primary explosion, but by the secondary dust explosions.

So long as we work mines we will have explosions and accidents, but this, coupled with the mine being properly arranged otherwise, will minimize the loss of life.

Waste in Mining

A number of prominent mining men were asked to answer two questions relative to the statement of Dr. J. A. Holmes, that "During the past year (1911) in producing 500,000,000 tons of coal there were wasted or left underground, in such condition that it probably will not be recovered in the future, 250,000,000 tons of coal. The questions were as follows:

1. Does the waste occur in your field?
2. Do you know from observation where such waste occurs, and if so where?

The replies received are well worth reading and digesting. Mr. Frank Haas writes:

"I think that Doctor Holmes statement is rather broad, at least from the observation and experience I have had. In the first place it would be necessary for us to determine what the definition of coal is, whether it is a chemical, physical, or commercial definition. To illustrate the point, I can state that in the Fairmont region, of West Virginia, the loss of coal in mining the Pittsburg seam does not exceed 10 per cent. and is probably less than this amount; there is, however, over a considerable area of the Pittsburg seam in the Fairmont region, a seam which is known as the Sewickley seam. It is about 130 feet above the big seam and will materially suffer in the extraction of this latter seam. Unfortunately, however, the character and quality of this Sewickley seam are such that it cannot be marketed at the present time and consequently no operator in this field has attempted to mine it. Now if this Sewickley seam is called a commercial coal, at the present time it is certainly a waste, but on the other hand it is not fit for consumption and I do not see how it can be called wasteful to mine the other seam first.

"The broad statement of Doctor Holmes would indicate wasteful methods of mining, and assuming all coals which are being mined or are commercial propositions at the present time, I do not believe there is any waste going on in coal mining in the mines with which I am familiar. But I do recall many instances like the one cited above, not only in the Fairmont field, but also in the Georges Creek field of Maryland and the Somerset field of Pennsylvania, and possibly in the new field that is being opened up in eastern Kentucky.

"I am indeed glad that you have undertaken to correct this rather misleading and incomplete statement on the part of Doctor Holmes."

Eldorado Mine Explosion

By Special Correspondent

On the morning of February 19, at 7:25 a gas explosion occurred at the Eldorado Coal Mining Co.'s mine about 1 mile north of Eldorado, Ill., in which four men were killed and three others badly injured. The mine is quite a large one, is worked by shaft, and hitherto has been comparatively free from accidents, no fatal accident having been reported since 1909 when a miner was killed by a blown-out shot which he fired himself on an idle day when the mine had not been examined and the management did not know he was in the mine. This shows good intelligent work because about half the coal is mined by shooting off the solid and half with undercutting machine and then shooting. Like all the coal operations in Saline County it is a shaft mine, and is worked by the pillar-and-room method.

The explosion on February 19 took place just after the last cage of men descended into the mine, and that there were no more killed is due to the accumulation of gas being small and confined to the first, or second north entry, off the second west north entry.

The State Inspectors of this district are constantly in fear of just such accidents as these, for gas explosions occurred at Rend City, November 5, 1908, in which four shot firers lost their lives, and on November 19, 1908, an explosion occurred in which three out of six shot firers lost their lives. On December 12, 1908, three shot firers were killed from the same cause as the accident of November 5. On February 16, 1909, an explosion occurred at the Dering Coal Co.'s No. 18 mine while four shot firers were in the mine. The explosion at Zeigler, January 10, 1909, is not in the same class as the others, which caused the State Inspectors of Mines and the Mining Board to recommend to Governor Deneen that where coal was undercut by machines the cuttings should be collected and carried away before any shots were fired.

Mine Manager Ginney of the Eldorado company, asked aid from District Superintendent Bagwell of the O'Gara Coal Co., who responded quickly and requested his company to send the regular helmet crew with their equipment to the mine. This request was received at Harrisburg at 8 a. m. and by the aid of a special Big Four train the crew was at the Eldorado mine at 8:45 a. m., just 45 minutes after the notification.

After organization of rescuing parties, William Taylor and Joseph Robison, who were familiar with the mine and regularly certified rescue men, were equipped with Draeger helmets and sent ahead of the others of the party, who followed with pulmotors, stretchers, etc. At 10:30 the first body was recovered and just after this Thomas Harris of O'Gara No. 11 mine, who was one of the party following the helmet men, rushed into a part of the mine hot with noxious gases and brought two men out on the parting who were severely burned and unconscious. After over one-half hour's work with the aid of the pulmotors they were resuscitated, and had it not been for Mr. Harris there would have been six instead of four deaths. Soon after these two men had been brought to, it was found that three of the rescue party who had rashly rushed into the mine were down from the effects of the noxious gases and it was only by the efficient work of the men in charge of the pulmotors that their lives were saved.

The Successful Mine Foreman From Four View Points

*By H. La Viers**

At the close of a successful or unsuccessful year's business, too often we turn to, and begin the analyzation of an inventory composed of numerous items and figures representing so many dollars, together with a statement of business transacted; and ask the question, what commodities have we exchanged for dollars and cents, and in what amount, have they brought to us either profit or loss (as the case may be); and from such figures and statements, begin to formulate plans that shall guide us in our next year's undertakings, omitting or overlooking perhaps the most important factor—to what extent has the personal equation entered into the results of the past year's work?

A successful year's business in dollars and cents, is purely a mathematical calculation, but it is not conclusive as to mining; for there enter into the operation of a coal mine, considerations other than dollars and cents, which may affect its future profit-paying existence. Such considerations are organization, equipment, and mine condition. In these, we find pronounced the individual equation of the successful or unsuccessful mine foreman, which may be viewed from four points, namely: miner, foreman, engineer, and mine manager; from which view points, the writer has had the privilege of observing, and in a brief way wishes to discuss.

First, View Point of Miner.—The successful mine foreman is he who, through truth and honest dealings, has won the respect and confidence of his men—they knowing that their welfare, financial interests, and personal safety are his daily concern—giving a just remuneration for labor expended, discerning what is right between fellow workmen and so adjudging, and in so governing, bringing about a complete working organization properly disciplined in rules of safety, personal rights and just remuneration that create conditions and an atmosphere that one appreciates and will desire to abide in.

Second, View Point of Mine Foreman.—To be successful, one conceives the idea that he must excel his predecessor in certain things, and jumps at an increased tonnage, with the expectation in so doing to create a lower cost sheet, which he hopes will be the proper road to the desired end.

The two features, or shall I say facts, just mentioned, if obtained, are only the apparent results of success, and to find success, we must look for the forces which create or bring it about. Primarily, we can say it is due to the man on the job, with mind and body from start to finish of the day's work, hearing the needs of this and that party, seeing that they are satisfied, adjusting another's complaint, filling here and there a vacancy, seeing that each party performs his allotted duty, and thereby making it possible to procure maximum results from the entire operating body; eliminating through eternal care and vigilance the unnecessary expense due to waste of material, unnecessary yardage cost, the moving of material that in a few days will require moving again; and when making an improvement, having it made in keeping with the time and extent to which it will be used; bearing in mind that the rank and file are practically what their leader is. He should be a man with a clear conception of justice, few words, kind but positive, always open for counsel, and these with an unlimited power to do, should bring the reward of success.

The successful mine foreman, from an engineer's view point, is one who keeps in mind a plan whereby his mine will be most completely exhausted, and who can forbear the temptation of procuring a few tons today, that a condition of safety may be maintained and a cheaper tonnage procured in the future; one who realizes that straight and well kept entries mean a good road and easy transportation of coal over same; who keeps all the rooms well timbered with no waste of caps and posts due to overtimbering or leaving timber in the gob. Giving greater attention to that part of the work about exhausted and possibly hardest to visit, such as long rooms, pillar drawing, low and wet places, in which places valuable unused material may be left to rust and decay or be covered up in place of being recovered and put into use again, thereby temporarily stopping the inflow of unnecessary new material when old and used will do as well. Above all, avoiding the unnecessary expenditure of money in blasting roof and making haulways, thus averting loss to his company and embarrassment to himself later by finding that had more thought and broader judgment been exercised, a more desirable and much cheaper way could have been opened. In short, letting the day's work be such that it will be the best for the complete exhaustion of the entire property and not for a one day's tonnage; availing himself of every opportunity to use a mechanical device of small cost to eliminate a fixed charge that would in a short time overpay for the piece of machinery. Always maintaining good roads and airways, and when possible taking advantage of gravity in movement of loads.

That of Manager.—From this point of view, there enters more than from any other, the question of safety, harmony, and finances, and very often (or shall I say always) the pronounced personality of the mine foreman which should hold in

* Manager Northeast Coal Co., Paintsville, Ky. A paper read before the Kentucky Mining Institute, December 9, 1912.

a staple condition these three great essentials necessary for the life and success of any business. Here, in the ideal, we look for the foreman to be a leader, broad minded, just, sober, honest and industrious, with a clear conception of right and wrong between employer and employes. A leader, that he may lead and have the respect of his men, broad minded enough to overlook the personal peculiarities of the employe, so long as they do not affect the above mentioned essentials. Just, that he may deal justly between men and employer; sober, honest, and industrious, that he may ask from his men only that which he passes and practices himself, as "like begets like." Having at heart these attributes and principles, we may look for them to go down the line with beneficial results.

Conversely: The many failures of mine foremen, and with them mining companies, can be traced to scrap heaps, waste material, tailings, culm dumps, rust and decay of machinery and material, personal neglect, avoidable accidents and breakdowns, non-punctuality, and wilful absence, then the increased expenditure of money overcoming Nature's difficulties encountered in the ordinary mining proposition of today.

Forestry as Related to Mining

Experience of St. Bernard Mining Co. in Planting Different Kinds of Trees in Kentucky

*By Frank D. Rash**

THE following paper was presented at the December 9, 1912, meeting of the Kentucky Mining Institute:

That the rapid depletion of our timber resources and the consequent necessity for the perpetuation of at least a portion of our forests is now one of the most pressing questions of our national life, is most generally recognized. Taken in their entirety, the effect and influence of forests on the climate, stream flow, and water conditions of a country, is of inestimable value, while the products of the forest go to make up the raw material for, or are in some way necessary to, the greater portion of our useful arts.

Among the many industries closely dependent upon the forest, that of mining stands in the forefront and, although the artisans of steel have taken steps toward a partial replacement of wood in various phases of mining operations, yet timber is, and will remain, vitally necessary in the winning of coal and other minerals. In considering the seeming prodigal use of timber the country over, it is well to draw near to the "Old Kentucky Home" and note the consumption in the mining operations in this field. Based on an experience of a number of years, it has been found that one company in the western Kentucky district has used 3 board feet of timber in raising 1 ton of coal, and, since this figure obtains in a locality where no particular difficulties of top present themselves, it is but fair to assume that this may be considered somewhere near the average for the district. And while the mining operations are requiring a toll of the forest to this extent, yet even this amount is but a small proportion of the total annual cut.

About 2 years ago the United States Geological Survey, in connection with the Kentucky Survey prepared a table showing forest conditions in 54 counties of Kentucky, together with an estimate of the number of years the supply would last. The figures on the conditions in several counties of the western Kentucky mining district are given in Table 1.

These figures but reflect the condition of the timber supply in many of our coal fields; therefore, reforestation should appeal to the mining companies by reason of their ownership of denuded hills and broomsedge fields, particularly as they are peculiarly situated to take the lead in the work so necessary to the country as a whole, and so vital to the mining industry in particular.

Among these Kentuckians who early perceived the necessity for making provisions to replace the increasing annual slaughter of timber, the name of the late John B. Atkinson stands preeminent, and, unlike many who after forming a correct theory fail to put it into practice, this forceful pioneer in the field of tree planting proceeded to prove his faith by his works. In taking up this work, he was actuated by unselfishness and patriotism of a higher order, since he sowed without the expectation of reaping, and conscious of the fact that even while coming generations are enjoying the results of his wise forethought, they may be unmindful of the benefactor. In this article many of the facts in connection with the methods and results in tree growing are gleaned from his observations and experiences.

As managing director and president of the St. Bernard Mining Co., Mr. Atkinson, about 24 years ago began planting walnuts upon the hills and waste lands of that company, and this early planting was

Table 1

	Acres in Forest	Total Stand	Annual Cut	Years Will Last (Not Counting Annual Growth)
Christian County	117,000	178,000,000	14,000,000	12
Muhlenberg County	110,000	204,000,000	36,000,000	6
Hopkins County	147,000	186,000,000	23,000,000	8
McLean County	74,000	197,000,000	62,000,000	3
Webster County	35,000	38,000,000	15,000,000	2
Union County	12,000	15,000,000	4,000,000	3
Henderson County	37,000	56,000,000	11,000,000	5
Daviess County	114,000	220,000,000	13,000,000	17

*Vice-President and General Manager, St. Bernard Mining Co., Earlington, Ky.

quickly followed and broadened to include *Catalpa speciosa*, tulip (yellow poplar), and black locusts. The plantings of this company to date are represented by the following species and figures:

Black walnut (*Juglans nigra*), 1,500,000 (430,000 on 162 acres); *Catalpa speciosa*, 211,000 on 300 acres; black locust (*Robinia pseudacacia*), 314,000 on 440 acres; tulip (yellow poplar) (*Liriodendron tulipifera*), 30,000 on 60 acres. A total of 2,055,000 trees, of which 985,000 are planted on 962 acres. One million seventy thousand black walnuts were planted in many vacant spots in different parts of the property.

The matured black walnut was planted in the autumn, in prepared ground, spaced approximately 4 ft. ×4 ft. This apparently close spacing of the trees was designed to bring about an upward rather than a spreading growth and it has had its effect. As time has passed it has become necessary to occasionally thin out the grove by removing some of the trees, but usually nature may be depended upon to do this by applying the rule of "the survival of the fittest." The largest of these trees now measures about 10 inches in diameter, the smallest 4 inches in diameter.

The *Catalpa speciosa* has been planted extensively and in the majority of instances has proven a hardy and rapid growing tree. Its best growth has been made in good soil, but it has made satisfactory progress on poor land. It is planted 7 ft.×7 ft. or thereabouts, and in order to give it a good start in life, should be cultivated for a few years. According to authorities, the catalpa possesses most of the virtues of the best of our trees, with practically none of their bad qualities.

That the black locust has proven the most satisfactory of any of the plantings of this company may be safely stated. Belonging as it does to the pulse family and drawing its nitrogen from the air and enriching the soil, this hardy tree is flourishing on poor ground as well as on the rich, although it should not be planted in lowlands or damp places. These trees are spaced about the same as the catalpa. The locust usually makes a straight trunk and trims itself, the lower limbs dying and falling off as the tree continues its growth. An interesting comparison of the walnut, catalpa, and locust has been made on one of the farms of the St. Bernard Co. by planting each of the species in the same locality, in the same soil, and under the same general conditions as nearly as possible. The trees have been out for 7 years, and at this time the black locust is apparently the leader in the novel race. The locust, like the catalpa, becomes a perpetual forest, throwing out new shoots from the stump after cutting. It is valuable for mine timbers, fence posts, and many other purposes.

The tulip (yellow poplar) has been planted in good ground 10 ft.×10 ft. apart and shows a satisfactory growth. This is a beautiful tree and the timber is useful in many ways.

Blue grass has been sown in the walnut and locust plantings at several points and a good "stand" made, which affords grazing and throws a safeguard around the young forest by preventing burning over in the dry fall seasons. The locust groves also kill out the heavy broom grass, so frequently seen in our old fields, and this fact, taken in connection with the small size of leaves from these trees, reduces the danger of forest fires to a minimum.

Having thus considered the method and means for reforestation, a process that will require years before fruition, it would seem fitting to sound a note of warning to those companies and individuals who are so fortunate as to find themselves still in possession of timbered lands. In the observations of the late Mr. Atkinson it was ascertained that in producing a tree 12 inches in diameter the various species require the following number of years:

Black locust, 45 years; tulip, 50 years; black oak, 50 years; black walnut, 56 years; sweet gum, 62 years; ash, 72 years; hickory, 90 years; white oak, 100 years.

And so mighty oaks and poplars were not grown in a decade nor yet in a century, and it should be a fixed policy to protect and harvest these wisely and conservatively. Much timber is still wasted in the stump and tops, and younger trees many times are destroyed in the felling of a larger neighbor, all of which evils may be corrected by proper attention. The forest fires, recurring as they do with each fall season, are destructive to young trees as well as to old, and the prevention and proper handling of this menace constitutes one of the serious problems of forestry. Where practicable, forest reserves should be fenced so that the young trees may begin their growth protected from cattle and other destructive agencies.

In concluding, it is to be hoped that mining men may be keenly alert to the dependence of our industry on forestry, and lend their aid in the solution of this national problem, by planting and caring for young trees and by conserving the present supply of timber through wise harvesting and protection from the many ever-present dangers. The situation increases in seriousness and we should do our part in relieving it.

Coal Statistics, 1912

PENNSYLVANIA

Pennsylvania more than retains its distinction as the greatest coal producing territory in the United States, the production for 1912 aggregating the tremendous total of 245,231,555 net tons, one-half of the output of the entire country.

The bituminous coal production was 160,973,428 net tons, an increase of 18,784,099 net tons over 1911 and 11,414,381 net tons over 1907, the year showing the highest previous record.

Along with this great output it is gratifying to note that the number of fatal accidents has been decreased, a matter of sincere congratulation and the direct result in the bituminous region of the enforcement of the new Bituminous Code passed at the Legislative Session of 1911. This

Code during its progress through the Legislature was made the object of bitter attack by the mine workers of Western Pennsylvania and also by some of the operators, and a stubborn fight was made against its passage. It did not meet the views of the mine workers in its provisions relating to safety conditions, which they thought were not drastic enough, and was objectionable to the operators whose point of view was diametrically opposed to that of the mine workers, because its provisions were deemed too drastic and their enforcement would be likely to entail great expense.

The operation of the Code during 1912 has demonstrated that as far as its requirements regarding safety are concerned it is an improvement on previous laws, as the number of accidents was reduced more than 15 per cent., and as far as the increased cost of operation is concerned, it may be said that the operators have met the requirements of the law with a promptness and completeness most commendable.

The number of employes in the bituminous coal region was 182,680; the number of fatal accidents was 437, a decrease of 78 from the previous year.

The tonnage that was produced per fatal accident was 368,360, an increase of 92,264 tons. This production per life lost has not been equaled since 1888. Under the new Code the number of inspectors in the bituminous coal region has been increased and the operators have almost doubled the number of assistant mine foremen, which affords more protection and more thorough inspection of the mines, and will, no doubt, add greatly to the safety of mining operations.

The production in the anthracite region in 1912 was 84,258,127 net tons, a decrease of 6,659,049 net tons from the preceding year, due to the suspension of operations in April and May pending a settlement of the wage agreement. The number of employes was 175,964; the number of fatal accidents was 593, a decrease of 106 from 1911. The number of fatal accidents in 1911, however, was unusual, as 79 lives were lost that year in mine fires. The tonnage produced per fatal accident was 142,088, an increase of 12,021 tons over 1911.

If the proposed Code for the anthracite region to be presented to the present Legislature should become a law, it is believed that it will further add to the safety of mining in that region.

In both regions during the past few years there has been a marvelous advance and improvement in the equipment of the mines. Every approved safety device has been adopted and every intelligent means is being taken to safeguard human life. The equipment of Pennsylvania mines, the facilities for the extraction of coal, and methods of operation, together with the progressive spirit displayed by leading mine officials along the lines of greatest safety to their employes, and the excellent progress made recently in welfare work, place the state ahead of any other coal mining territory in the world.

Fatal Accidents in 1912 in Alabama Coal Mines

Cause	Avoidable	Unavoidable	Per Cent.
Fall of rock	40	14	45.0
Fall of coal	6		5.0
Fall of rock and coal	1		.8
Gas	12		10.0
Powder	1	1	1.6
Electrocuted	7		5.7
Machinery	1		.8

Shaft	3		2.4
Going back on shot	3		2.4
Totals	105	16	
Percentages	87	13	100.0
Total of accidents	121		

MONTANA

The following are the statistics concerning coal mining in Montana for the years 1911 and 1912 as compiled by James B. McDermott, State Coal Mine Inspector:

	1911	1912
Number of mines reporting	45	48
Machine men employed	220	181
Loaders	435	563
Miners	1,715	1,538
Inside day men	764	746
Outside day men	642	570
Total employed	3,776	3,598
Average per day per man	3.3 tons	4.3 tons
Total tonnage produced	2,913,406 tons	3,143,799 tons
Total value, selling price	$4,904,620.83	$5,600,097
Tonnage per life lost	224,108	314,380 tons
Tons per serious accident	58,268	66,889 tons
One life lost for every	290 employed	360 employed
One serious accident every	76 employed	76 employed
Per 1,000 employed, killed	3.44	2.78
Per 1,000 employed, injured	13	13
Black blasting powder used	1,808,745 pounds	1,818,500 pounds
Dynamite	35,220 pounds	25,331 pounds
Hand mined and shot off solid	1,847,318 tons	2,069,540 tons
Machine mined	1,066,088 tons	1,074,258.6 tons

IOWA

The following coal mine statistics for 2 years ending June 30, 1912, are taken from the Sixteenth Biennial Report of State Mine Inspectors, of Iowa:

Dist.	Inside Fatal	Non-Fatal	Production	Inside Employes
1	21	90	5,355,697	6,727
2	23	78	4,893,097	5,047
3	22	126	4,301,708	4,788
Total	66	294	14,550,502	16,562

One fatality for every 220,462 tons mined; one fatality for every 251 men employed in mines; 40, or 60 per cent. of the fatalities due to falls of top or coal; 156, or 53 per cent. of non-fatal accidents due to falls of top or coal; two fatalities due to dust explosions originated by shots. No accidents, fatal or non-fatal, due to gas explosions.

The Cunard Steamship Co. is said to be developing at Morrisdale, Clearfield County, 1,600 acres of a 5-foot thick bed of bituminous coal, which with the adjoining acreage of the same bed leased by the company, will require 50 years to mine.

Modern machinery and electric power and haulage will be installed. Two thousand tons a day will be shipped until the heart of the deposit is reached, when the output will be vastly increased.

Stopping Ventilation at Firing Time

Can It Be Safely Done?—A Discussion of the Dangers Likely to Result From Such a Proceeding

By W. H. Reynolds and Sim Reynolds

To one conversant with Pennsylvania's larger and more dangerous bituminous mines, and the conditions governing them, in so far as concerns the control of gas and dust, the suggestions frequently repeated of later weeks in the contemporary mining press relative to the closing of the mine to all air at firing time seem almost ludicrous, if it were not that beyond those suggestions lie possible death and destruction of property. Personally speaking we have followed bituminous mining for upwards of 30 years but never have we heard or read of a reform idea meriting, in our opinion, more caution in acceptance.

But at the outset we would not be misunderstood. The field from which this still-air idea emanates is not our field. We never worked in that particular country, and base our surprise and criticism anent the promulgation of the idea only on this fact: like our own, the Iowa and Oklahoma coal territory is bituminous, and like ours generates gas and dust in explosive quantities; and it is *(sic?)* to forestall these elements from exploding, that Messrs. Verner and McAllister—as the leaders of The Ventilation Reduction Party—ardently, and no doubt earnestly, advocate the stoppage of the fan, and, where possible, the shutting off of even any slight natural ventilation previous to and at all times while the firing continues.

While we do not for a moment doubt the truth and accuracy of the investigations made by the gentlemen mentioned, yet we cannot convince ourselves that the coals where the tests were wrought to a successful conclusion are in circumstance and condition similarly adjusted with our own. We are reactionaries and "stand patters" in this premise, that's sure, although we are honored with a reputation for advocating and putting into practice—wherever possible—any well-founded reform pertaining to mining. However, we cannot convince ourselves that disaster would not follow on the heels of a forward movement of this character, if essayed in some of Pennsylvania's bituminous mines, or in those rather where one-half to 1 per cent. of inflammable gas is thrown into the mine air every minute of the 24 hours. Stopping the fan, for say only an hour in many entries driving into virgin coal, would certainly be a risky proposition even with permissible explosives used to break down the coal.

The contention of Messrs. Verner and McAllister is that placing steel doors over the upcast, stopping the fan over the downcast, and closing up every opening that could admit air, would so deprive the mine atmosphere of oxygen that it would be practically impossible for an explosion to happen, since there would then be not enough of oxygen for the flame of an explosion to feed on, or else that the stopped air would prevent any outlet to the initial pressure. The natural elasticity of air compressed under pressure from any source, the principle of which is well-known to most schoolboys, is in itself sufficient refutation of that idea. And the other phase of the matter seems equally unfounded on actual facts and natural laws, unless the latter vary in accordance with longitude and latitude. Mine atmosphere so devoid of oxygen as to be incapable of giving body to an explosion would certainly not give the combustion necessary to sustain human life.

Hence the utter incongruity of this statement regarding the non-combustible properties of ordinary mine air just merely stilled. Such cannot be the case, we would think, unless some chemical action took place, or its equivalent in the transpiration of immunizing gases. And there is no record in any of these articles which have come to our notice of anything like that. Therefore we must assume that the contention is based solely on the immunity caused by making the air absolutely still at the face for a certain length of time. And if we understand the matter rightly as above stated, we wouldn't give much for the conservatism—however much we respected bravery bordering closely on foolhardiness—of any shot firer, fire boss, or mine foreman, who would willingly enter any one of a hundred entries now being driven into virgin territory in the Washington-Greene section of the Pittsburg seam, and in a number of other parts of the bituminous region of Pennsylvania, 1 hour only after all natural and artificial ventilation had been cut off, and fire a series of heavy shots. Of course it might be possible, but hardly practicable, to so dilute the mine atmosphere with carbon dioxide or other non-combustible gases that firing could go on safely in so far as concerned the engendering of an explosion. But in that event a corps of shot firers would not live long enough to fire one round of shots, let alone 400 or 500. And how long would it take to reduce an extensive mine to that condition? Certainly longer than all the time that could be allowed between the stoppage of work and the time of firing.

Regarding one phase of this subject, we are fully in accord with our western contemporaries. No man well versed in contemporaneous coal mining will deny that the powerful air-currents met with in many of our modern mines would aid greatly in an explosion, once the start was made; but, would not the velocity and pressure of explosions such as wrecked Darr, Monongah, Harwick, or Marianna, have been quite sufficient in either case for the completion of its tragic purpose: the wrecking of the mine and killing of all living men and animals in it, even if the fan had been closed in and stopped a few minutes previous to the gas, or arc, or powder-engendered flame's inception? Would not the oxygen content of any one of these mines, when of sufficient volume to sustain human life at all, have served for all the combustion needed to complete the job? Let us take a few actual measurements and see.

For the purpose of this article we will assume a newly opened heading in the thicker portion of the Pittsburg bed. The coal, we'll say, is 7 feet thick; the entry is 10 feet wide. Assuming the place is driven in 100 feet, we have an area of 8,000 cubic feet of air space. Gas is transpiring into that heading at the rate of one-half of 1 per cent., a by no means uncommon quantity we have personally experienced. Four other headings, in all essentials the same, take their air from the same split, along which we have a volume of 20,000 feet per minute. Therefore, at the end of 1 hour of still air, there is lying at the face of the heading first referred to 1,200 feet of gas. Assuming the seam to be normally flat, this body is all in near proximity to the point where the shots are to be fired. We have assumed 1 hour as being about the average interval of time between the stoppage of work and the time of firing. Under these conditions, at the moment the shot firer enters this heading on his round of the section, in this short entry alone we have a volume of 5,800 feet of ordinarily pure mine air, 1,200 feet of the 7,000 being crowded out by the amount of gas transpired. Since its oxygen content has not been reduced by any chemical action, this 5,800 feet of air is quite capable of serving as a starter for the 1,200 feet of gas, and whatever dust might be lying near. Thus we have a condition in this one heading alone that on the firing of a shot would have within itself the possibility of engendering approximately 11,000 feet of flame, a body of fire calculated to do quite efficiently the work the same chain of circumstances have done—at Harwick, for instance—where the fan had been stopped "over Sunday." And in this case, while it had been started up shortly previous to the firing of the fatal shot, through the downcast being practically closed with ice, the "blind butt" in which the explosion of that mine started had at that moment no doubt its full length of "still air." For it was proven afterward that the fan shaft at Harwick was practically, if not altogether, closed at least all of Sunday night, thus unintentionally doing the very thing this theory of air stopping would have us do intentionally. In the fatal "blind butt," where the shot was fired about 8 A. M., it has been proved almost conclusively, since the disaster, that a body of gas was lying, owing to the air not being in normal circulation at the time to clear it out. And we mention this instance because of its pertinence to the subject in question, as being unintentionally as near an approximation of what could be expected to happen if the same condition were to be brought about deliberately, in the Pennsylvania field at least. And the pressure of that, seeking, as it would inevitably do, whether the air were still or otherwise, the place of least resistance to get an outlet for itself, would move any doors which might be placed against it.

Let us assume, however, that steel or other heavy doors had been placed over the upcast of that mine mouth out of which there escaped force sufficient to lift the body of a mule clear from the shaft bottom to the surface, high above the tipple, and heave it some 300 feet beyond the shaft. Does it stand to sense that any temporary barrier would have barred the outlet of such increase of pressure as would inevitably follow the explosion of the gas and dust throughout an ordinary mine, even if it did withstand the initial shock incidental to the burning of the gas and dust in the short heading furnishing only 11,000 feet of flame? We believe not, and while we respect the courage of our contemporaries in the middle coal field in giving themselves up to test this theory in their own premises, and have not the slightest doubt as to their truth and earnestness, yet we would be loath to essay the same effort in many mines in Pennsylvania, nor would we like to suggest the trial to any one else. A better plan would be to give the shots no chance of exploding anything except their own constituents.

We would suggest to the reader in search of experiments that he try that which has been proved good, not in one or two unusual environments, but in hundreds of gaseous and dusty mines. Let him dilute whatever marsh gas is generated by a conservative quantity of air. And right here, before we go any further, let us say that in this phase of the subject we are practically agreed with Messrs. Verner and McAllister. The mining man, being only human, is, like all humanity, prone to go to extremes in anything he undertakes. And this matter of ventilation is in many places being radically overdone. We all know that to fire shots against too much pressure is not the safest thing in the world. And despite the production of a large amount of firedamp in some mines there is too much water gauge. Of course this is preventable but the means thereof cannot be discussed here. Many of our "model" mines are victims of this habit. Like the dear ladies, God bless 'em! with their inverted dish-pan and peach-basket hats, their tight corsets, high heels and hobble skirts, we mining men run greatly to "fashions" in reform, avoiding, in many instances, the good and practical because it is old. And while, far be it from us to decry the seeking after new things, or a better way of doing mine work, for only the explorer finds new lands and fairer, yet the wise general looks well to the lines behind him before pushing too far to the front. There is such a thing as the radical mine manager going so far into untried fields as, like Napoleon, to find another Moscow and be compelled to retrace his steps in sorrow and regret. The better plan is, as we have said, to feel one's way cautiously into the newer things and stick meanwhile to those which have been proven practical in his own field, remembering at all times that as circumstances and conditions differ so will vary any method in mining.

And in his effort to strike the proper proportion of air, any up-to-date mine foreman should be able to solve the problem by careful analysis. If he have any doubt the nearest Federal Mine Bureau men will gladly tell him just what to use and how to use it, and will aid him in reaching the proper amount for complete safety. They will aid particularly by making accurate tests of samples of the mine air. This done several times, and taken in its proper co-relation with other conditions, will soon enable the mine foreman to gauge the requisite amount of air that will serve his need best. And we firmly believe the lower this can be reduced, in safety, the better. But this is a matter demanding great caution.

The second essential is to keep the mine as well moistened as possible with water or steam, and particularly the vicinity of every shot within at least 25 yards.

Third, let him have his coal properly mined, and particularly the rib sides well squared up, and demand of the miners and shot firers that no holes be fired which enter the solid at all; and if the bed be more than normal thickness, for instance like Harwick, where two seams come together with a parting of heavy slate or "bone" coal, it were far better that the lower section be blown down separately, rather than the terrifically heavy shooting be allowed which is necessary to blast two seams bound in or near the center with a stratum of from 6 inches to 18 inches of foreign substance.

Moreover, a good idea is the method of having the shots fired from the return end of the current, assuming of course that all the men be out of the mine except the shot firers, which should be the case of course in mines where any necessity exists for shot firers. Chances of a more explosive atmosphere being created through the rapid firing would obviously be lessened in this way, and likewise the firer would have a clearer air in which to inspect and do his work.

These few simple precautions, with the use of an explosive as near flameless as can be found, will, without stopping the fan or any other extreme measure, give to the most naturally dangerous mine as much safety as we at present know how to gain. And in a matter like this, which involves in many mines the lives of hundreds of men and the possible destruction of tens of thousands of dollars' worth of property, the well-proved way to safety is the only way the wise manager will take, even if the more enticing and quicker method of shutting off all air may be easier to put into practice, and show a larger monetary return. And by "well proved" we mean methods of mining which have been tried out under varied conditions in his own field and under circumstances similar to his own. For the good mine manager will only be guided by another man's suggestion in so far as he fully believes it coincides with needs created by the artificial and natural conditions affecting his own particular mine.

There is no trade in which "cut-and-dry" theory or "established practice" is liable to lead a man into more pitfalls, nor any trade where a sound judgment, common sense, and inflexible discipline (which means a perfect willingness to bring suffering, mental and physical, on himself and family if need be) will be more certain to bring ultimate success. Not necessarily at one mine, but sooner or later it is sure to.

And particularly tragic would it be if some misguided man were to lose his own life or the lives of others through misdirected zeal regarding the application of a method which, while conserving life and property in some other field, may be the cause of destroying both in his own. Hence the great need, in these days of radical changes, for caution. "Be sure you're right then go ahead," applies more pertinently to the man in control of a dangerously dusty and gas-producing mine than to any industrial officer we know of. For there exists in all truth every possibility for such misadventure, since many a sensitive man, knowing his mine to be dangerous (and believe us, reader, all the men in control of the Underground are not calloused yet to the possible loss of human life, and will go to any lengths to avoid it), such a man will, with the best of intentions sometimes try out even so extreme a plan as this one of shutting off all the air from his "faces," if he have but a faint idea "it might work."

For many a mine manager, with a mine always in a state bordering the danger line, the "proofs" of this method and the "proofs" of that come like the patent "cure all" to the chronic dyspeptic: as a beacon light warranted to lure him gently but permanently (*sic?*), if he but take enough of bottles, from the possible tragedy which haunts his days with mental torture—fearing always the devilishness of some careless subordinate—and his nights with troublous dreams. Wise is he who finds one that will work and sticks to it until he be sure of a better.

Practical Miners' Course

Prof. C. J. Norwood, Dean of the College of Mines and Metallurgy, State University, Lexington, Ky., announces through his assistant, H. D. Easton, E. M., that the practical course for miners, mine foremen, and managers will begin its session, May 19, 1913, and end July 12.

Persons pursuing correspondence courses will find the 8 weeks of personal instruction beneficial. This course has the authority of the Board of Trustees of the State University back of it, and each man who completes this course will be given a certificate showing the fact.

The equipment used for demonstrating mining at this institution is excellent, and cannot but be helpful to any one studying the course of coal mining. The ground covered is, coal mining, mine gases and testing, explosions and fires, surveying and mapping, mine-rescue apparatus. The fee charged is $10, and room and table board can be had from $2.50 to $3.50 per week. For further information address H. D. Easton, E. M., Lexington, Ky.

PRIZE CONTEST

For the best answer to each of the following questions we will give any books on mining or the sciences related thereto, now in print, to the value of $3.

For the second best answer, similar books to the value of $2 will be given.

Both prizes for answers to the same questions will not be awarded to any one person.

1. The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.
2. Answers must be written in ink on one side of the paper only.
3. "Competition Contest" must be written on the envelope in which the answers are sent to us.
4. One person may compete in all the questions.
5. Our decision as to the merits of the answers shall be final.
6. Answers must be mailed to us not later than one month after publication of the question.
7. The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what books they want, and to mention the numbers of the questions when so doing.
8. In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.
9. Employes of the publishers are not eligible to enter this contest.

Questions for Prizes

17. *Diameter of Collar.*—The diameter of a collar, 8 feet between supports, is 10 inches; what should be the diameter of a collar, 16 feet between supports, the weight increasing in proportion to the length.

18. *Weight of Rope.*—What weight of rope will be required to hoist 7 gross tons from a shaft 400 feet deep.

19. *Blasting Coal.*—Explain the principle involved in the use of powder in blasting coal, stating why common black powder is better for this purpose than high explosives, such as dynamite or other nitroglycerine compounds.

20. *Laying a Cross-Over Switch.* Explain each step in the laying of a cross-over switch between the loaded and empty tracks, on a mine haulage road. Show the method of locating the frog in each track, and give the proper frog angle that should be used, the frog distance, the degree of curvature of switch rails, etc.

Answers for Which Prizes Have Been Awarded

Ques. 9. *Method of Mining.* There is a tract of land containing 840 acres in a nearly square plot, in which at a depth of 630 feet there is 4 feet of clean coking coal lying practically horizontal. The floor of the seam is so soft it creeps; the slate roof rock next to the coal is from 2 to 4 feet thick and liable to fall unless pulled down. It is desired to know what system should be followed when mining the coal and the advantages of the system advocated, using a sketch.

Ans.—Before deciding upon a method of working any coal seam we must have a clear understanding of the conditions under which the seam has to be worked. The chief conditions stated in this question put us up against one of the greatest difficulties in modern mining.

To be brief, the necessary precautions should be taken to guard against thrust and creep; and to overcome this difficulty the longwall retreating method should be adopted. In this method of work, narrow roadways are driven to the boundary line in each district and the coal is worked back by a longwall face, leaving the goaf behind. There is only one objection to this system of work; it requires a large amount of capital to be laid out before there is any return, but when some of the districts reach the line, it is the beginning of a rich harvest, as practically all dead work is left behind.

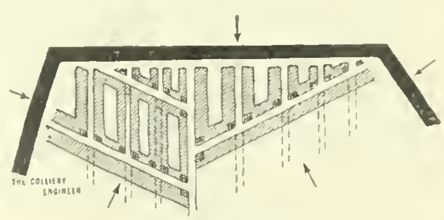

Fig. 1. Longwall Advancing

If the necessary capital was not available I would then adopt the longwall advancing system, as shown in Fig. 1. Under this system the whole of the mineral is usually extracted in one operation with a probable loss of from 5 to 10 per cent. My reasons for selecting this method over pillar and stall or stoop and room are: (1) Because we have the necessary conditions here to build pack walls, therefore all debris is kept in the mine; (2) more adequate and simpler ventilation; as the ventilation travels along the line of face it finds a new course, so to speak, every day, therefore, it will be much cheaper; (3) because a greater percentage of coal can be got from that obtainable. As regards consumption of timber and safety, there is but little difference, but any difference there is, may be in favor of longwall, therefore, longwall would be much more economical, especially the retreating method. I might say that machine-cut coal is another great factor where a top is weak, because the line of face advances quicker and allows a more uniform sinking of the strata, and if this system of work is judiciously carried out the workmen will be working under newly exposed roof every 24 hours.

The machine I would prefer to use would be one of the most up-to-date bar type, as there is no danger of its being held up with the coal setting down on it, as there is only the diameter of the bar plus the length of picks (which may not exceed 8 inches) under the cut.

As the coal is likely to fall, due to the natural conditions, I would put sprags under it to keep it up until the loaders come to work. As the floor is soft and creepy I would prefer to cut in it; this would further increase the percentage of good marketable coal, and would also give more height for tramroads, which in this system will be brought along the face from the road head, as shown in Fig. 2.

As the top is likely to fall, it calls for a good system of timbering; the system I would adopt would be to cross-timber at right angles to the cleats and line of face. The best way to do this is to use cross-timbers sufficiently long to permit one end to rest in a hole cut out in the top of the coal as seen in Fig. 2, and a post under the other end next to the pack wall. This system serves a double purpose; it supports the roadway along the line of face, and it allows the machine to cut without moving any posts. There should be a man there, when machine is cutting, to put a second post up to the cross-timbers just as soon as the machine gets past. I would suggest the length of walls to be 50 or 55 feet, roadways 10 feet wide, pack walls 6 feet along the roadside by 10 or 12 along the face. There will be a space left from the back end of the pack wall on the one road to the back end of pack wall on the next road equal to about 20 feet, and I would support this by putting in two wood pillars or chocks, always keeping two rows of them near to the line of face; and as the face advances I would withdraw the back row and reset them when needed. As the strata overlying the pack walls, etc., are gradually sinking, this causes a locking effect on the strata due to the angular position from the horizontal, and as the packs, or, as we might call them, cushions, become compressed they tend to maintain the height on the roadway by carrying the weight over in to where the greater space has been left unsupported.

The debris required to build the pack walls is got by ripping down the slate roof, which is likely to fall, equal to the width of roadway, which I suggest to be 10 feet; my reasons for making roads that width are because all the ripping can be used in

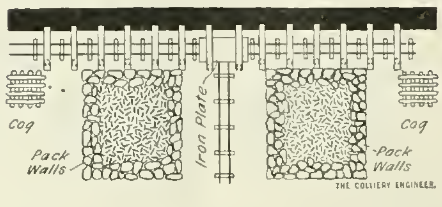

Fig. 2. Plan Showing Packs, Timber and Tramroad

the pack walls or buildings and because the roadways will get narrower, due to compression and strata movement.

Alexander Wilson,
Box 257, New Lexington, Perry County, Ohio.

Second Prize, R. J. Pickett, Shelburn, Ind.

Ques. 10.—*Capacity of Fan.*—What quantity of air in cubic feet per minute will be obtained with a 2-inch water gauge, when a fan 24 feet in diameter makes 90 revolutions per minute under the following conditions: Diameter of the central orifice of intake 12 feet, area of the discharge, 60 square feet; length of the blades, 9 feet; length of the airway, 3,600 feet; area of the airway, 60 square feet.

Ans.—The quantity of air that a fan will yield equals the efficiency multiplied by the centrifugal force and divided by the unit of ventilating pressure multiplied by one-half the acceleration multiplied by 60, or by formula,

$$q = 60\left(\frac{K\,F}{p} \times \frac{f}{2}\right)$$

when K = efficiency of fan;
F = centrifugal force in pounds;
f = acceleration in feet per second;
p = unit of ventilating pressure.

The centrifugal force is found from the formula

$$F = \frac{W\,Vg^2}{g\,Rg}$$

when W = weight of air revolved in pounds;
Vg = velocity of revolved weight (W) in feet per second;
g = force of gravity in feet per second, usually 32.16 at sea level;
Rg = distance of center of gravity from center of revolution in feet.

Breadth $b = \frac{5}{8}\,d = \frac{5}{8} \times 12 = 7.5$ feet. Then for the volume, $V = .7854\,(D^2 - d^2)b = .7854 \quad (24^2 - 12^2) \quad 7.5 = 2{,}544.696$ cubic feet.

Assuming that 1 cubic foot of air weighs .0788 pound, then $W = 2{,}544.696 \times .0788 = 200.522$ pounds.

Solving for the value of $R\,g$, $R\,g = \frac{2}{3}\left(\frac{R^3 - r^3}{R^2 - r^2}\right)$, in which R = outside radius, r = inside radius; then $R\,g = \frac{2}{3}\left(\frac{12^3 - 6^3}{12^2 - 6^2}\right) = \frac{2}{3}\left(\frac{1{,}512}{108}\right) = 9.3$ feet from center of fan shaft. For each revolution of the fan the center of gravity passes over $3.1416\ (9.3 \times 2) = 58.43376$ feet, the fan making 90 revolutions per minute, $58.43376 \times 90 = 5{,}259.0384$ feet per minute. $\frac{5{,}259.0384}{60} = 87.65064$ feet per second.

$$F = \frac{W\,Vg^2}{g\,Rg} = \frac{200.522 \times 87.65064^2}{32.16 \times 9.3}$$

$$= \frac{1{,}540{,}537.234}{299.088} = 5{,}151 \text{ pounds nearly.}$$

The acceleration is expressed by the formula $f = \frac{K\,F}{p\,a}g$. Then assuming an efficiency of 60 per cent.,

$$f = \frac{.60 \times 5{,}151 \times 32.16}{5.2 \times 2 \times 60} = \frac{98{,}793.696}{624}$$

$= 158.323$ feet per second; then

$$q = 60\left(\frac{K\,F}{p} \times \frac{f}{2}\right)$$

$$= 60\left(\frac{.60 \times 5{,}151}{10.4} \times \frac{158.323}{2}\right)$$

$$= 60 \times 29.813 \times 79.1615$$

$= 141{,}602.50797$, or say, 141,600 cubic feet per minute. Ans.

The foregoing shows the correct way of calculating the quantity of air that a fan will yield under the given conditions, although a calculation may be gathered from the following which is near enough for all practical purposes:

The total area $=24^2\times.7854=452.3904$ square feet.

Area of central orifice $=12^2\times.7854=113.0976$ square feet. Then breadth $=\frac{5}{8}d=\frac{5}{8}\times12=7.5$. The volume of air displaced at each revolution of the fan is $(452.3904-113.0976)$ 7.5 $=2{,}544.696$ cubic feet. The efficiency of the fan was assumed to be 60 per cent., therefore, the volume discharged is $.60\times2{,}544.696=1{,}526.8176$ cubic feet for each revolution. The fan making 90 revolutions per minute, $1{,}526.8176\times90=137{,}413.584$ cubic feet per minute, or, say 137,400 cubic feet per minute.

Wm. Holloway,
Box 526, Henryetta, Okla.

Second prize. None.

Ques. 11.—*Hoisting.*—From a coal shaft 650 feet deep, it is desired to hoist 1,200 tons of coal in 8 hours. The engine is 20 in. $\times$ 36 in. first motion and is run so as to give an average speed of 1,600 feet per minute. What steam pressure will be required and what weight of coal should a car contain?

Ans.—Hoisting speed equals 1,600 feet per minute, or $\frac{1{,}600}{60}=26.6$ feet per second.

To make one trip would then require $\frac{650}{26.6}=24.4$ seconds; to this must be added 10 seconds for changing cars each trip; this would then be $24.4+10=34.4$ seconds each trip. Allowing 30 minutes for delays, this will leave $7\frac{1}{2}$ hours actual hoisting, $7\frac{1}{2}\times60\times60=27{,}000$ seconds for 1 day's hoisting.

The trips per day that can then be made equals $\frac{27{,}000}{34.4}=785$.

Then the capacity of car will equal tonnage hoisted divided by number of trips, $\frac{1{,}200}{785}=1.529$ tons.

The actual load on the engines equals the net load plus 10 per cent. of the gross load.

The weight of coal in a car equals $1.529\times2{,}000=3{,}058$ pounds. Assuming weight of empty car 1,200 pounds, and weight of rope 1.8 pounds per foot, and weight of cage 4,000 pounds.

Then, two cages 4,000 pounds each $=8{,}000$ pounds; two cars 1,200 pounds each $=2{,}400$ pounds; two ropes $(1{,}300\times1.8)=2{,}340$ pounds; one lot of material $=3{,}058$ pounds. A total of 15,798 pounds.

Ten per cent. of 15,798 pounds $=1{,}579.8$ pounds. The actual load will then equal $1{,}579.8+3{,}058=4{,}637.8$ pounds. This load has to be hoisted 650 feet in 24.4 seconds, which equals $\frac{4{,}637.8\times60\times650}{24.4}=7{,}412{,}877$ units of work per minute, or foot-pounds.

Then, $\quad H.\ P.\times33{,}000=u$

$u=PLAN$

Then, $\quad 7{,}412{,}877=PLAN$

or $\quad P=\frac{7{,}412{,}877}{LAN}$

The number of strokes per minute is twice the number of revolutions. To get the number of strokes per minute we will have to find the size of the drum required.

Assuming that a $1\frac{1}{4}$-inch rope is used, the drum should then be 100 times the diameter of the rope,

$$100\times1.25=12.5 \text{ feet.}$$

The circumference will then be $3.1416\times12.5=39.27$ feet. The number of revolutions per trip will be $\frac{650}{39.27}=16.55$. The number of strokes per trip $16.55\times2=33.10$. Assuming 3-foot cylinders, the piston distance traveled per trip will equal $3\times33.10=99.30$ feet. Then, $\frac{99.30\times60}{24.4}=244$ piston speed per minute.

Then,

$$P=\frac{7{,}412{,}877}{(20^2\times.7854)\times244}=\frac{7{,}412{,}877}{76{,}655}$$

$=96.7$ pounds.

Assuming the engine has an efficiency of 90 per cent. Then the steam pressure required will be $\frac{96.7\times100}{90}=107.44$ pounds, practically 110 pounds.

Ans.—110 pounds steam pressure; 3,058 pounds capacity of car.

Chase River, Nanaimo, B. C.

Second prize, Thomas F. Kissler, Mammoth, Pa.

Ques. 12.—*Surveying.*—The following data of an underground survey being given, find the course and distance from A to E and give the area of the figure enclosed:

From A to B 35° 18′, 448 feet; from B to C 106° 20′, 565 feet; from C to D 190° 36′, 368 feet; from D to E 160° 31′, 433 feet.

Ans.—In order to get the course and distance from A to E the survey must first be traversed, and to do that it is necessary to transpose the several bearings from azimuth to quadrant courses, and the notes of the survey become as follows:

		Feet
$A-B$	N 35° 18′ E	448
$B-C$	S 73° 40′ E	565
$C-D$	S 10° 36′ W	368
$D-E$	S 19° 29′ E	433

Traversing these bearings give the following result:

Sta.	Bear.	Dist.	North	South	East	West
$A-B$	N 36° 18′ E	448	365.63		258.88	
$B-C$	S 73° 40′ E	565		158.89	542.20	
$C-D$	S 10° 36′ W	368		361.72		67.69
$D-E$	S 19° 29′ E	433		408.21	144.42	
Total....			365.63	928.82 365 63	945.50 67.69	67.69
Difference..............				563.19	877.81	

The connecting bearing can now be calculated by the following rule: Divide the difference between the eastings and westings by the difference between the northings and southings. The quotient will be the tangent of the required bearing, the distance is obtained by dividing the difference between the eastings and westings by the sine of the bearing obtained by the above rule.

Applying these rules to the above example we have the following:

877.81 divided by 563.19 = 1.55863 = tangent of 57° 19′.

As we need a northing of 563.19 and a westing of 877.81 to close our traverse, the bearing is evidently N 57° 19′ W from *E–A* or S 57° 19′ E from *A–E*.

The sine of 57° 19′ = .84167. The difference in eastings and westings 877.81 divided by .84167 = 1,042.94, the required distance.

The area of the enclosed survey, including of course the calculated bearing, can be obtained in two ways: First, by platting the survey to a fairly large scale, say 100 feet per distance of the last course is always equal to the departure of that course.

Having obtained the double meridian distances, multiply the double meridian distance of each course by its latitude, setting the products of the north latitudes in one column and the products of the south latitudes in another. The area of the field is equal to one-half the difference obtained by subtracting the sum of the north products from the sum of the south products or vice versa.

Tabulated in this manner our example shows as follows:

Sta.	Bear.	Dist.	North	South	East	West	Double Mer. Dist.	North Products	South Products
A–B	N 35° 18′ E	448.00	365.63		258.88		258.88	94,654.29	
B–C	S 73° 40′ E	565.00		158.89	542.20		1,059.96		168,417.04
C–D	S 10° 36′ W	368.00		361.72		67.69	1,534.47		555,048.48
D–E	S 19° 29′ E	433.00		408.21	144.42		1,611.20		657,709.95
E–A	N 57° 19′ W	1,042.94	563.19			877.81	877.81	494,373.81	
Totals			928.82	928.82	945.50	945.50		589,028.10	1,380,175.47

inch, which also gives a check on the calculated bearing and distance.

By dividing the plot into triangles and scaling them off, the area can be ascertained with a degree of accuracy that will generally be sufficient for ordinary purposes, but where the ground is very valuable a more accurate method is by latitudes and departures.

The survey is traversed, in the example under consideration, by getting the latitude and departure of the calculated bearing, and from this traverse the double meridian distances of each course are found, the rule for which is as follows: Starting from the station farthest west, the double meridian distance of the first course is equal to the departure of that course, and for any succeeding course is equal to the double meridian distance of the preceding course plus the departure of that course plus the departure of the course being calculated. These additions are algebraic, for as long as the line is moving toward the east the departures are added, but when they start toward the west they are subtracted from the previous courses. As a check on the calculation, the double meridian

1,380,175.47 − 589,028.10 = 791,147.37 = the difference between the sums of the north and south products, and that divided by 2 equals 395,573.68 square feet, and that divided by 43,560 = 9.081 acres, the required area.

The area figured from the plot in this instance comes to 9.102 acres, or a difference of only .021 acre, but where the field is very irregular, containing a large number of triangles or trapezoids, the difference amounts to as much as an acre in some instances, and when coal is selling around $1,000 an acre it pays to make the more exact calculation. In fact in a case of that kind I generally do it both ways as a check.

W. N. Cole,
Engr. Spring Valley Coal Co.,
Spring Valley, Ill.

Second prize, J. H. Sinclair, Calgary, Alberta, Canada.

A Coal Miner in the Cabinet

For the first time in the history of the United States a coal miner holds a cabinet position, and is a member of the advisory board to the President.

William B. Wilson, Secretary of Labor, came to America from Scotland when a small boy. His educational opportunities in youth were limited, as, at an early age he had to seek employment in the bituminous mines of Pennsylvania. Later he became a miner, and took an active part in labor organizations. He became a local leader, and was a member of the committee of United Mine Workers at Harrisburg, when a general bituminous mine law, as well as a number of other measures pertaining to both anthracite and bituminous mining, were before the Pennsylvania legislature. His evident honesty of purpose and his general character won for him the respect of mine owners and mine officials who were his opponents as far as some of the measures were concerned. He had his own views, and while sticking tenaciously to them, he respected the opinions of his opponents, and when convinced that they were wise, he readily admitted it.

Mr. Wilson has a great deal of natural ability. He cultivated it by reading and study, and broadened intellectually. Always loyal to his coworkers in the mines, and always fighting for what he considered was for their best interests, he, at the same time considered the rights of the mine owners, as he saw them.

In course of time he was nominated by the Democratic party for Congress and was elected. He made good as a Congressman and continued to broaden. While still a staunch advocate of union labor he believes in fighting labor's battles within the law, and deprecates violence and incendiary utterances. He has a Scotch conscience and a Scotch respect for law and order. His public life and intercourse with able men, aided by careful reading, have made him a well-educated man. His reputation has been such that when President Wilson chose his cabinet, he selected him for Secretary of the new Department of Labor.

Notes on Mines and Mining

Reports on Conditions and Other Matters of Interest in Various Coal Fields

By Special Correspondents

ALABAMA—Harry Coffin, president of the Alabama Consolidated Coal and Iron Co., was given permission by the Federal Court to reopen Searles mines, which have been idle for several months.

The Tennessee Coal and Iron Co. has contracted for the entire output of the coal, amounting to 1,000 tons per day, the intention being to use it in the by-product coke plant at Corey. The Searles mines are between Jefferson and Tuscaloosa counties.

The Pierce Coal and Lumber Co., Bridgeport, Ala., is developing 24,000 acres of land near Princeton. The first car of coal was shipped in December. It is claimed to be high-grade domestic coal carrying 3 to 4 per cent. ash, low in sulphur but having about 40 per cent. volatile combustible matter. It is therefore a better gas coal than domestic coal.

COLORADO

About 12 miles from Steamboat Springs, Colo., are several coal deposits. The road bed is nearly all coal for a stretch estimated to be at least one-half mile in length. The bed is 4 feet in thickness and the coal is being thrown away to make the grade. A similar thing happened in the Oak Creek as the graders were building the road bed through the coal fields, but not on so large a scale.

ILLINOIS

The first entirely electrical equipped mine in Illinois is that of the Christopher Coal Mining Co., at Christopher, Ill. The coal seam at this mine is 12 feet in thickness and about 593 feet below the surface. The record day's output for this mine is a fraction over 3,075 tons, the average number of men employed being 500.

The Superior Coal Co., of Gillespie, Ill., operates three mines and places on an average of three air stoppings per day. It's officers have been experimenting with concrete block stoppings and have demonstrated that these blocks can be easily and substantially made of cinders and cement if the proper equipment is at hand.

It is claimed that these stoppings have special value as they can be quickly built for emergency stoppings to wall up a mine fire and after the fire is quenched can be easily removed. It is believed that shot explosions which usually destroy other kinds of stoppings will probably separate the blocks but leave them in shape to be reused.

Two were killed and 30 others injured by an explosion in the Latham coal mine near Lincoln, Ill., on February 1. Three hundred men were working in the mine at the time and only two were killed. It is stated that the lamp of Thomas Loomis, the electrician, set off a pocket of gas that caused the explosion. He and Henry Weitkamper, his assistant, were buried under a fall of roof.

The Bunsen Coal Co., one of the subsidiary companies of the United States Steel Corporation, has over 25,000 acres of coal lands in the vicinity of Danville, Ill. The new mines, to be started in February, will be located one-half mile west of that city. Mr. Clay Lynch is general manager.

KANSAS

Strip mining, the process of removing 10, 20, and 30 feet of covering from a coal bed with a steam shovel, is finding investors every week or so in the Pittsburg, Kans., district, where the method is in vogue to the extent of twenty or more shovels. Land dealers are renewing and buying options, as well as coal companies. This is true not only of the shallow beds, but of the deep coal also. The Southwestern Development Co., known as a subsidary of the "Katy" railroad, recently optioned thousands of acres of deep coal land on the western border of the present field. Miller Brothers, on the north side, control 3,700 acres, and many other companies and men have large holdings. The Moka Coal Co., was the last formed in the district for steam-shovel mining. Six men, headed by Oliver T. Jones, a practical coal miner, capitalized at $30,000 and applied for a charter the first of March. Also they leased 165 acres on the Missouri-Kansas line on the north side of the field and will install a shovel in the immediate future. It is said $35,000 will be required to start work. The stripping with shovels started but little over a year ago, and operators say it is in its experimental stage, but they are watching quietly and investing. Several companies are preparing to put in shovels.

KENTUCKY

From 20 to 30 cars of coal a day are now being shipped by the Consolidation Coal Co.'s plant at McRoberts, on Wright Fork, Ky. The shipment goes over the Lexington and Eastern Branch of the Louisville and Nashville. It is expected that, shortly, from 75 to 100 cars will be shipped a day from four of the seven mines.

The Semet-Solvay Co., Syracuse, N. Y., which will put in operation the Ashland, Ky., by-product plant this spring, is negotiating with Rogers-Brown Co., of Chicago, who are operating two pig-iron furnaces at Ironton, Ohio, for the installation of a similar plant for supplying coke to these furnaces. The Semet-Solvay people own their coal property under the name of Solvay Collieries Co.

Messrs. Cunningham & Connor, consulting engineers, Huntington, W. Va., announce that they will commence the construction of 10 miles of standard guage railroad running from Stafford Station, 1 mile below Paintsville on the Big Sandy division of the C. & O., to the mouth of Greenback branch on Jerry Creek in Johnson County. This line will later be extended 20 miles to Quicksand, Ky. All coal tonnage will come to

Paintsville going through the Big Sandy division.

When completed it is expected to be one of the heaviest feeders that the C. & O. will have, because of the fact that it will penetrate a coal tract of 150,000 acres. The road will be known as Big Sandy and Kentucky. Its entire length is through virgin coal and timber land, besides vast coal fields lay all along Paint Creek, Jerry Creek, and Middle Creek, as well as in the upper Licking River. It has been estimated that there are 650,000,000 tons of coal along this line. The entire line when completed will pass through Johnson, Magoffin, and Breathitt counties, and parts of Floyd, Knott, and Morgan counties.

The road will be laid so as to permit the handling of the heaviest class of equipment at any point.

Another large company, termed the Elkhorn Fuel Co., incorporated under the laws of West Virginia, has for its purpose the acquisition and operation of approximately 300,000 acres of coal property in the Elkhorn field of Kentucky. The company has a capitalization of $30,000,000, of which $4,000,000 is represented by five-year five per cent. notes; $6,000,000 of five per cent. accumulative preferred stock, and $20,000,000 of common stock. The management of the company will be vested in a board of fifteen directors. The officers of the company are J. A. Clark, Fairmont, W. Va., president; J. C. Fenhagen, treasurer; and C. T. Williams, vice-president and secretary.

It is reported that a Welsh syndicate represented by D. A. Thomas, of Newport, Wales, contemplates developing a large area of coal land in eastern Kentucky. After opening the mines the intention is to ship the coal by a line of steamers to South America. The Cambrian syndicate, as it is called, expects to ship 4,000,000 tons of coal a year as soon as it gets started.

SECOND OHIO MINE RUN LAW

Operators in Ohio pay their miners on the screened coal basis, that is, for coal passing over screen bars with spaces $1\frac{1}{4}$ inches between them. The miners want to be paid on the run-of-mine basis; that is, for coal as it comes from the mines, and failing to come to an agreement with the operators, had William Greene introduce in the present Ohio legislature, a bill calling for the weighing and payment of all coal before it is screened.

At the annual meeting of the Ohio miners in January they passed resolutions indorsing this law and also demanded the following concessions from the operators:

A uniform working day of 6 hours at the working place for all classes of inside and outside day labor, based on the present price with a holiday on Saturday.

Uniform inside day-labor wage scale with proportionate advances with mine rates.

General substantial advance on machine and pick mining at the basing point; substantial advance on all dead work, deficient work, yardage, day labor, and that all breakthroughs be paid for at entry price.

That the next joint agreement be based on machine mined coal.

The present rate of pick mining was determined on the screened coal basis, that is, $1 per ton for pick-mined coal passed over a screen with bars not to exceed $1\frac{1}{4}$ inches in spaces between.

REPORT ON OKLAHOMA COALS

For more than a year the Oklahoma Geological Survey has been carrying on field work in the coal area of the state. Much of the geology of the area has been worked out in considerable detail in former years, both by the United States Geological Survey and the State Survey. The chief work of the past year has been along economic lines. The main considerations were concerning quality and quantity, questions affecting the cheaper production and supply, and the uses which may be made of Oklahoma coals.

The results along these lines, which have been investigated both in the field and laboratory, together with the geological conditions of the field, will be published as a bulletin.

The report will contain much general information concerning coal, coal mining and coal consumption. Several maps, charts, diagrams, and half-tones will be used. About 150 new chemical analyses and heat tests will be given, and 100 or more other analyses will be included. The analyses are being made from samples collected from the mines and from carloads at the tipples. All samples were taken according to standard specifications adopted by the United States Geological Survey and Bureau of Mines. With each analysis will be stated the condition under which the sample was taken.

The report is intended to show to the consumer the quality and heat value of coals from the various beds and districts, to give some knowledge of the rate situation, transportation facilities and general mining conditions.

Edward Boyle, chief mine inspector of Oklahoma, closed the No. 2 mine of the Great Western Coal and Mining Co., on the grounds that the manways had not been completed. While 150 men were thrown out of employment, there was no other alternative if Mr. Boyle was to live up to his oath of office.

PENNSYLVANIA

The Lehigh and Wilkes-Barre Coal Co. has purchased the holdings, machinery, and good will of the Parrish Coal Co., of Wilkes-Barre. The Parrish company is an old concern with large collieries at Plymouth and Buttonwood, both near Wilkes-Barre. The Buttonwood mine caught fire a few weeks ago and to extinguish the blaze the mine was sealed.

A. D. Lamb, mine inspector of the Thirteenth Pennsylvania District, advocated that the Mine Code Commission embody in its report to the legislature a provision imposing a tax of one and one-half cents on every ton of coal mined. The money to be used for the benefit of the families of the men who are killed or maimed in the mine. Mr. Lamb declared that a greater part of the hard coal is shipped outside the state and that a small tax would not be felt.

Dolan Bros., of Pottsville, have started work on driving a 6,000-foot tunnel at Brownsville, for the Locust Mountain Coal Co., of which Baird S. Snyder, Jr., of Pottsville, is President. The ground will be removed until solid bottom is reached, then the work of driving the tunnel will commence. The main tunnel will be 4,000 feet long and the tunnel to the east basin about 2,000 feet. This is located on ground north of Shenandoah, recently leased from the Girard estate. The contract for the erection of the breaker and foundations has been awarded to H. K. Christ, of Mahanoy City.

The Lehigh Coal and Navigation Co., which has been having trouble with the men, has settled its grievances, and according to reports, loaders in the mine have received an increase of 30 cents a day, and battery men an increase of 40 cents.

Since the suspension in the anthracite field there has been continual friction between the men and the companies, petty strikes occurring in numerous places. The Oakdale, No. 4 colliery, of G. B. Markle & Co., was closed because the breaker boys' pay was in error. 1,000 men at the Henry colliery of the Lehigh Valley Coal Co. went on strike because all men did not wear Union buttons. 700 men struck at No. 7 Susquehanna Coal Co. because the company refused to allow Union officials to examine miners' buttons. 6,000 miners working for the D., L. & W. Coal Co. went on strike because the hoisting engineers were not members of the Union. 1,000 miners of the D. & H. Co. went on strike because of the discrimination in car supply.

The Brookside colliery, belonging to the Philadelphia & Reading Coal and Iron Co., suspended work indefinitely because miners refused to work with a dozen non-union men. The colliery at Williamstown, belonging to the same company was closed down for the same reason. To stop the annoyances resulting from petty strikes, because one or two men at the mine are not affiliated with the United Mine Workers, the Philadelphia & Reading company has adopted a policy that in the future when such strikes are called the operation shall remain idle until the operators get ready to resume.

The development of the hitherto untouched coal fields of Washington and Greene counties, is forecasted in the information that the Pennsylvania Railroad is preparing to extend its line from Washington County south through the central part of the county and probably on into Green County. This branch has been discussed for years. It will give the coal a market route over the Pennsylvania line from northern Washington County. Josiah V. Thompson and his assistants are said to own over 130,000 acres of this coal land.

The Charleroi Coal Works property consisting of 1,200 acres and owned by the Pittsburg Plate Glass Co., has been sold to the Carnegie Coal Co. In 1910 the Charleroi company shipped 400,000 tons of Youghiogheny coal, and it is intended to market all this coal through the Carnegie Dock Co., at Duluth and Superior.

J. D. Boyd is suing the Wharton Coal and Coke Co., at Uniontown, Pa., asking triple damages aggregating $72,000 for coal mined beneath his property. It is alleged by Boyd that 8,000,000 bushels were either mined or made inaccessible between the years 1907 and 1911.

Three men were imprisoned in the Draper colliery by Mahanoy Creek breaking through from the surface. This colliery is near Gilberton, Schuylkill County, Pa. Immediate steps were taken to change the channel, and the men were rescued after spending three days in the mine. The P. & R. C. and I. Co. were able to pump at the rate of one-half million gallons of water per day and so unwater the mine very fast, but the sludge and small coal that washed in made the cleaning in the gangways slow work. So soon as the first shift went to work there was a gas explosion in which several were burned.

Several men were hurt and several others had a narrow escape when a trip of three mine cars ran away down a slope in one of the Susquehanna Coal Co.'s mines at Nanticoke, Pa. The rope that was hoisting the trip broke. There were 17 men in the cars. After going 200 feet the cars were derailed, some of the men saving themselves by jumping.

Recently there has been going the rounds of the press the information that a large coal bed, unknown to the Philadelphia & Reading Coal and Iron Co., had been discovered in Bear Valley. Experts are said to have declared it a new discovery that will yield millions of tons, and will be inexhaustible for hundreds of years. Since 1880 every acre of land owned by the Philadelphia & Reading Coal and Iron Co. in the Schuylkill regions has been cross-sectioned, but the Reading company was not in readiness to work all the coal beds owned, and this bed now stated to be recently found is one of them. There undoubtedly will be a large yield from this coal bed, but it was not newly discovered and has been included in the estimates of the coal in the Schuylkill regions, which already have been given out.

A NOTABLE RECORD

Jenkin T. Reese, mine inspector for the Fourth Anthracite District, called attention to the remarkable record of the National mine in his report to Chief Roderick, of the Bureau of Mines. This mine belongs to the D., L. & W. R. R. Co., and since 1910 there has not been a fatal accident, although 1,000,000 tons of coal have been mined. Superintendent C. E. Tobey in commenting on this record stated that the Manville mine, another of this company's collieries also had a perfect record for 2 years but it did not produce so much coal as the National. John Owens is inside foreman of the National and Frederick Peters is outside foreman.

VALLEY CAMP MINE EXPLOSION

An explosion occurred at the Valley Camp mine, February 26, near New Kensington, Pa., in which two men were said to have been fatally injured and two others badly burned. A searching party had a narrow escape as there was a second explosion which burned four of their number.

The 300 men that work day shift had left the mine before the explosion occurred.

SOMERSET COUNTY DEVELOPMENT

The development of Shade Township, Somerset County, coal lands by an extension of the Windber branch of the Pennsylvania Railroad from Eureka, No. 39 mine, at Foustwell, is now assured. In January last a contract was let to the firm of McMenamin & Sims for the building of 8 miles of railroad on Shade Creek from Foustwell to Reitz. It will mean millions of tons of coal freight more to the Pennsylvania Railroad, who are now hauling an immense daily tonnage from this field. Work was begun immediately, and it is expected by early Summer the road will be in operation. The Loyal Hanna Coal and Coke Co., who bought from 3,000 to 3,500 acres of coal in the field several years ago, in anticipation of the completion of the road, at once let a contract to M. M. Sheesley & Sons, of Johnstown, for the driving of two tunnels to tap the coal at a point affording gravity drainage for a large part of their acreage. Their present development plans include an opening on Shade Creek about 1 mile above the town of Reitz and an opening on Miller Run a mile or so west of Reitz. The mines are to be equipped with every modern device adaptable to this field for the preparation and handling of this coal. A large electric power plant is to be built for furnishing power for cutting coal and the electric haulage system which is to be installed. A tipple is being designed with a capacity of 2,000 tons per day, and all other arrangements now being made for the first opening are for a mine of that capacity.

The new town necessary to house the employes for this development, Cairnbrook, named for John Pitcairn, president of the Loyal Hanna Coal and Coke Co., is now in course of construction.

Arrangements are being made to secure a gravity supply of pure mountain water for mine and domestic use from the headwaters of Beaver Dam Run at a point above the outcrop of the coal measures and above any possible source of pollution or contamination.

The coal to be mined is the Miller or "B" seam, comparing in quality with the Henrietta and other coals of the South Fork district. Because of its low sulphur and ash contents, averaging less than 1 per cent. and 6 per cent, respectively, the coal from that district should find ready sale in the eastern market.

The location of development is at a point in Shade Township where the Berlin basin and Negro Mountain anticlinal run together, with result that the measures are nearly flat with light cover but a firm roof, affording ideal conditions for economical mining.

The Loyal Hanna development is in charge of General Superintendent Joseph Patterson, of Onnalinda, who has long been identified with coal mining in the "B" seam in this district.

The Berwind-White Coal Mining Co. are also arranging for the development of a tract of 1,000 acres lying between the waters of Clear Shade Creek and Beaver Dam Run, which it is understood will be a model and compare favorably with any of their many modern plants in the Windber district.

John Lochrie, the Scalp Level coal operator, has closed a lease for an acreage in the district and will commence the development of it at an early date. With the announcement of the building of this Shade Township extension of the Pennsylvania Railroad there has been a rush of coal speculators to this district, and many other important developments may be expected in the near future.

The Puritan shaft, one of the oldest operations in Cambria County, opened on Martins Branch above Portage, over 25 years ago, and considered by many to be practically worked out, is now under lease to the Forge Coal Mining Co. and has taken on a new lease of life. By a recent addition to the lease they now have from 300 to 400 acres of solid coal just north of the shaft, lying partly to the dip. Failure to provide for proper handling of the water heretofore has delayed the development of that section of the property. By collecting the water from various parts of the mine by gravity to a main sump at the lowest point in the property, where a main pumping station is established, the water is now pumped through a bore hole to the surface. This arrangement had been made with the idea in mind of later collecting all of the water of Puritan shaft, as well as the water of four or five other mines lying above, to this sump, from which point it is to be conducted through a pipe line on the coal seam down the pitch of the seam to a point where the surface is lower than the Puritan sump, thus affecting a gravity drainage plan for many of the mines on the Branch. With this plan in effect, one of the most serious problems to contend with in the operation of slope or shaft properties, the pumping of water, will have been eliminated. They are operating on the "B" or Miller seam of coal, which is unexcelled in quality by any mine of the district. Heretofore, in this or any other mine outside of the Windber district, it has been thought not feasible or profitable to mine the "B" or Miller seam of coal with mining machines. However, this plan has been successfully started at the Puritan shaft. They are now getting from 80 to 85 per cent. machine coal. Because of the differential between the pick and machine mining rate in the district, with this arrangement this mine will soon be one of the cheapest producers in the region. The property is now in excellent shape and is producing 500 tons per day, which will be gradually increased to 1,000 tons per day.

WASHINGTON

Plans are on foot for the development of the new Reserve mine which is owned by the Western Fuel Co., an American company operating on Vancouver Island, in British Columbia. It is expected that by 1914 they will be mining and shipping 1,000,000 tons annually. The company has expended $500,000 in the development of the new colliery, and it is estimated that there is sufficient tonnage proved to last for a period of 50 years with a daily output of 1,500 tons. Thomas Stockett, general manager of the company, stated recently that he expected the main shaft to be down to a depth of 1,000 feet by the end of March, at which point they expect to encounter the coal seams which they plan to mine. Nanaimo is one of the early coal mining districts of British Columbia, and has proven to be a very profitable district. The mines are very extensive, some of them extending out under the sea. A great portion of the coal is shipped to San Francisco, Portland, Ore., and Seattle. It is considered one of the best domestic coals on the Pacific Coast, and finds a very ready market.

COAL TRADE OF NOVA SCOTIA

The coal production of Nova Scotia in 1912 reached the highest figure in the history of the industry. A comparison of the outputs of the larger coal companies with 1911 is as follows:

	1911 (Long Tons)	1912 (Long Tons)
Dominion Coal Co.:		
Glace Bay mines	3,985,000	4,513,000
Springhill mines	266,000	420,000
Nova Scotia Steel and Coal Co.	780,000	842,000
Acadia Coal Co.	370,000	433,000
Other companies	849,000	692,000
	6,250,000	6,900,000

Cape Breton Island produced 82 per cent. of the total tonnage, and will produce an even larger proportion in the future.

A number of new openings and collieries are projected for 1913, but they will not add greatly to production in the current year. In 1914, however, a decided advance in tonnage may be anticipated, under normal trade conditions.

There were no accidents during the year involving serious loss of life. The fatality rate will be less than that of 1912, and will be about 2.5 per 1,000 employed.

The ownership of the coal seams in Nova Scotia is vested in the government, and as a result of this wise reservation, the provincial revenue in 1912 from coal royalties was a little over \$800,000. Some of the operators, including the Dominion Coal Co., pay a royalty of $12\frac{1}{2}$ cents per ton, and the other operators pay 10 cents per ton. It is understood that the government will shortly raise all royalties to the higher figure.

The most striking advance in mining practice during the year has been the extended use of electrical power and the utilization of inferior fuels for raising steam. Groups of collieries are being supplied with motive power from centrally placed generating stations, where unsalable fuels are consumed, in some cases by the latest types of chain-grate stokers, and in one instance by a dust-fired boiler. Several large size electrical winding engines have been installed, and at many collieries the entire plant is electrically operated, including air compressors, ventilating fans, hoisting and screening machinery, and underground pumps. So far, electricity underground has been confined to the operation of pumps and auxiliary haulage motors. It has not been used at the coal face or in trolley haulages, and local opinion does not favor the use of electricity for these purposes.

Pit-Car Cleaning Device for Self-Dumping Cage

The accumulation of slack coal in pit cars in many cases is an item of considerable loss at mines where the coal is paid for by weight and the weighing is done in the cars. Where cars are passed over a dump to an outside track for empties, they can occasionally be cleaned, or an especially bad one can be cleaned when necessary, but it is a more difficult matter to clean cars which are dumped on self-dumping cages.

To meet the latter condition, a cleaning tool like that shown in Fig. 1 is being used successfully at a mine where the loss between mine weights and railroad scale weights ran as high as over 400 tons per month. The device promptly converted a heavy loss in weights to a slight gain.

As seen in the sketch, the tool simply consists of a plate of sheet

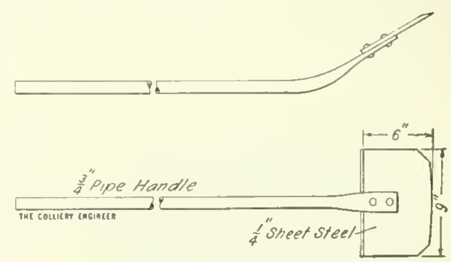

Fig. 1. Car Cleaner

steel 9 in. × 6 in. × 1/4 in., riveted to a handle of 3/4-inch pipe of suitable length, the handle being slightly concave near where it joins the plate, so that the plate can be pushed under the slack which has become packed on the car bottom, especially toward the rear end of the car. It is not uncommon for this slack to extend 3 feet from the rear end of the car, in a bed the full width of the car and tapering down from as much as 2 inches at the rear end to nothing at the front, amounting to as much as three-quarters of a cubic foot in some instances, the weight of which depends upon its compactness and dampness.

It is customary to clean the cars on the self-dumping cages as often as their condition warrants, generally once a month on a "Blue Monday" following a Saturday pay day, as on such a day the little delay occasioned by the stoppage of the cages is not noticeable. The tool is always kept within reach of the dumper so that he can clean any cars that become especially dirty between regular cleaning days. By systematically cleaning the cars, a saving in weight of from 50 to 60 pounds per car has been effected. The magnitude of this saving is partially due to previous undue laxity in keeping cars clean, but it would hardly be an exaggeration to state that at most mines an average of 30 pounds could be effected, which would amount to a ton for every 67 cars of output.—W. F. A.

NEW MINING MACHINERY

New Type Mine Locomotive

The accompanying illustrations show a new type of mine locomotive which has recently been placed on the market by the Baldwin Locomotive Works and the Westinghouse Electric and Mfg. Co. The notable features are the open, cast-steel bar frame and the specially designed commutating pole mine motors.

The frame of this locomotive is designed to give maximum strength and to allow ready access to all parts, so that the locomotive can be inspected or overhauled, when necessary, in the least possible time. The construction is the same as that used on heavy Baldwin steam freight engines.

The open frame gives much better ventilation to the motors and resistance than that obtained by armor-plate frame construction. The motors, brake rigging, brake shoes, and sand boxes are easily accessible. The upper parts of the motors and armature-bearing housings can be removed without disturbing the suspension, so that each part of the motor is exposed for inspection. To remove the grid resistors the only work necessary is to take off the locomotive covers and loosen the bolts and terminals that hold the resistor frames in place.

An attractive feature introduced on locomotives with outside frames is the Vauclain removable gib. To remove a journal box with this gib, it is only necessary to drop the binder and take the weight off the journal box. The journal box may then be slipped out from the side, as shown in Fig. 1. On locomotives with inside frames, the journal box collars are arranged to be easily dropped out for repacking. If it is desired to take out a set of wheels and axle, this may be done without disturbing the motor suspension or connections by simply blocking the motors in place and removing the binders. The wheels may then be dropped.

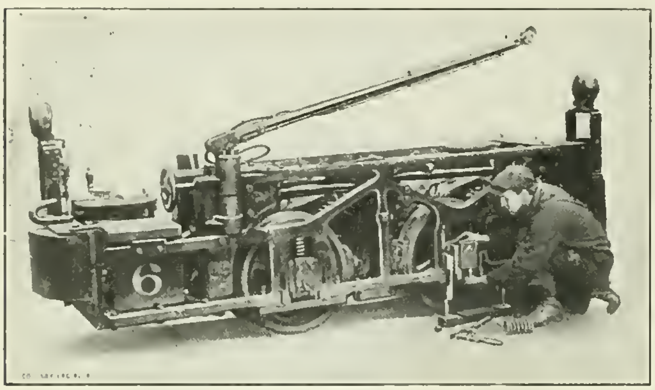

Fig. 1. Locomotive Showing Removable Gib

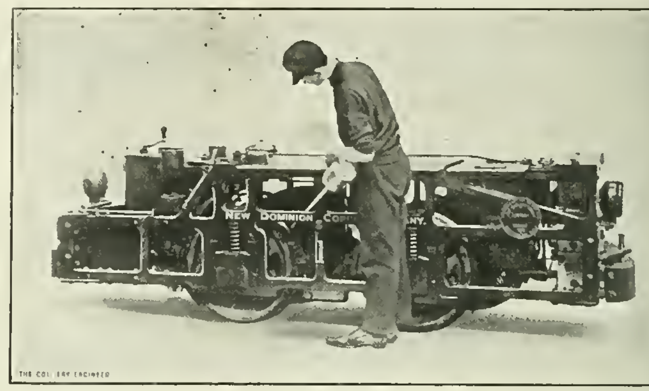

Fig. 2. Another View of Locomotive

The motors used in this locomotive have decided advantages over other types, of which their excellent commutation, due to the use of commutating poles, is of first importance because it increases reliability of operation and cuts down the cost of maintenance. With good commutation, the commutator and brushes require very little attention and brush renewals are seldom necessary. The insulation of armature and field coils remains in good condition for a much longer time than on other types because of the absence of copper and carbon dust.

The frames of the motors are made of cast steel and are split diagonally. The axle bearings and suspension are on the lower half of the frame, so that the upper half, the armature, and bearing housings can be removed without disturbing the suspension or axle brackets. The armature and axle bearings are of bronze and are oil-and-waste lubricated. The armature coils are form wound and are made moisture-proof by means of an impregnating compound. The field coils are impregnated and protected from vibration by heavy cushion springs placed between them and the motor frame. The armature core is mounted on a spider to which it is keyed, making it possible to remove the shaft without disturbing the windings, and also reinforcing the shaft against bonding. Large openings are provided in the spider and through the core to give sufficient ventilation.

Plummet Lamp

Every surveyor in the mines knows the trouble of maintaining a light behind a plumb-bob cord, especially when it is necessary to use a safety lamp with its small light. Probably each surveyor has devised some method in taking sights underground which he thinks is the easiest, quickest, and most accurate; but one of the common methods is to hold a piece of tracing cloth or white translucent paper between the plumb-bob cord and the lamp, so that the cord or, if he likes, the silhouetted point of the plumb bob, is against a white background. Another method is to hold a piece of white paper, often

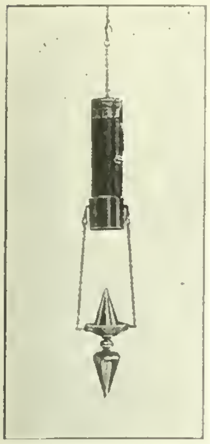

Fig. 3. The Lamp

Fig. 4. As Seen

using an open notebook for this purpose, behind the plumb bob, and at the same time holding the lamp in front in order to light up the cord or plumb bob and also the paper, being careful that the light itself is shaded so that it does not shine toward the instrument.

The latest invention, designed to assist the mine surveyor, is a plummet lamp, which has been patented by Dr. C. V. Martin, mining engineer. It consists of a double plummet, coupled and swung in gimbals by detachable chains from an electric battery lamp. The lamp has a sliding sleeve to cover or expose the lens as desired, and has a hook at the top so that it can be hung from the eye of a spad Fig. 3. The lamp, as shown in Fig. 4, throws a steady light upon the upper point of the plummet.

One great advantage that this lamp possesses is that it can be placed in position and will not require the presence of some person behind it to hold a light, when a sight is being taken. This allows whoever would be called upon to hold a light to assist in other work, such as measuring or taking offsets. Moreover, the lamp is safe in gaseous mines. It is not large and can be carried in the pocket or in a case attached to a belt.

Stine Fan Fitted With Hyatt Roller Bearings

In the design of disk fans there is just one position where the blades must set to enable them to work with the least air slippage, without a loss of power. Moreover there are a fixed number of vanes needed; too many or too few will decrease the output of the fan to a great degree, requiring much nore power. It is only with a thorough understanding of the principles that any disk fan can be built to properly perform its functions.

It is a common statement that disk fans will only work economically and satisfactorily at low speeds, that after reaching a certain peripheral velocity they churn the air, which leaks back through the center.

This is true of many disk and so-called propeller fans, but it is not true in a properly designed fan. Many nanufacturers of this class of machinery finding this trouble in their fans, have added more vanes, presenting a multiplicity of frictional surfaces that set up eddy currents which absorb the greater proportion of the mechanical effort of the driver. Others attach large shrouds to overcome the leakage in the center which is entirely absent in a properly constructed fan. There is a fixed number of blades for each diameter of fan which will give the best results, and one angle of blades combined with the right number which will give the greatest volume. A certain overlap at center and periphery prevents reentries and develops a corresponding water gauge proportionate to the speed of the fan and mine resistance. Two well-defined actions are set up when the fan is in operation; that of a screw in which every blade forces through the casing a definite amount of air at every revolution, and that of centrifugal force, in which a vacuum is set up at the center where the blades are narrower, the air being discharged at the wider tips of the periphery.

A thorough test of a 7-foot J. C. Stine patented disk fan, manufactured by the J. C. Stine Co., Tyrone, Pa., was made by the Meadow Lands Coal Co. at their mines near Pittsburg, Pa., by their general superintendent, Mr. Wilson. This was a standard 7-foot machine, electric driven, the motor and fan both being mounted on one cast-iron subbase, and the armature shaft being connected directly to the fan shaft with suitable insulated coupling. While this test does not show as good results

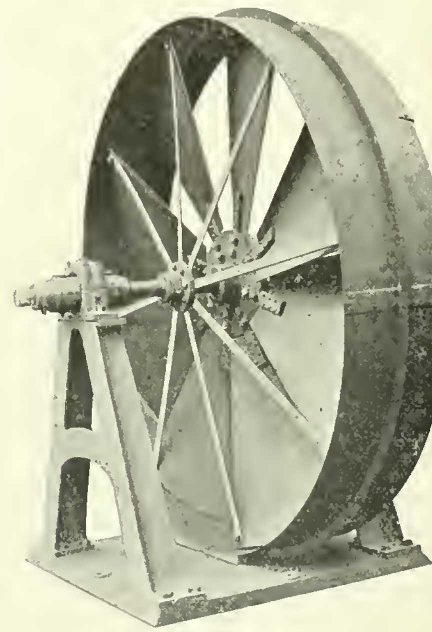

Fig. 5. Stine Fan

as have frequently been obtained at other operations, yet it shows conclusively that there is a volumetric increase of air per revolution, which increases until the fan arrives at maximum speed. At a speed of 262 revolutions per minute the fan moved 151 cubic feet of air per revolution; at 346 revolutions per minute it moved 152 cubic feet per revolution, and at 415 revolutions per minute it moved 165 cubic feet per revolution, a constant gain in feet of air per minute with each increase of speed.

The mechanical efficiency rises steadily with the speed, volume, and water gauge, reaching in many tests 75 per cent. to 80 per cent. of the total expended power, a result not reached by any other fan, regardless of make or cost.

The latest types of these fans are now being equipped with Hyatt roller bearings. This has proven of great value in still further increasing the mechanical efficiency, the saving being from 20 per cent. to 25 per cent. over the best type of ring-oiling bearings, which permits of smaller sized motors or engines being used to produce the same results. The amount of oil required is reduced in similar proportion, actual tests showing a saving of 75 per cent., as they require oiling only once in 2 or 4 weeks.

The Richland Coal Co., of Wheeling, W. Va., writes the following to the manufacturer in reference to these bearings: "Replying to your letter of recent date relative to the new 7-foot roller-bearing fan which you sold us, my report is that this fan is now running at a speed of 348 revolutions per minute; is being driven by a 15-horsepower motor, and is taking about 12-horsepower current. We do not seem to have any notes as to the current consumption by the old fan. Our people are very much pleased with the roller-bearing feature, reporting that the fan only requires oiling once in 2 weeks and runs 22 hours every day; and to show how easily the fan runs, when the belt is off, the current of air produced by the main fan outside causes the fan to revolve. This certainly shows there is not much friction on these bearings."

Fusible Signal Plugs for Air Compressing Machinery

A recognition of the necessity for making machinery automatic, of reducing so far as possible the cost of attendance, has called for the incorporation of devices safeguarding against abnormal operating conditions.

In the air compressor, which has reached a high stage of automatism, various contributory causes might produce unduly high temperatures, which should be vigilantly guarded against and which would not be apparent on the outside. High temperature in air compressing machinery and its appurtenances, such as pipe lines, air receivers, etc., may produce various undesirable conditions, such as increased friction and unequal expansion of the working parts, requiring more power to drive and causing heavy leakage losses, so that the general efficiency of the plant is lowered.

It is essential that lubricating oils be employed in a compressor cylinder to reduce friction and prevent cutting and wear; but it is also a fact that such oils if subjected to high enough temperature will catch fire and burn, and as the interruption of proper cooling, the sticking of valves, etc., will tend to induce such temperature, it is imperative that proper precautions be taken.

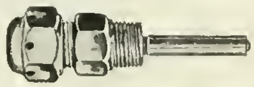

Fig. 6

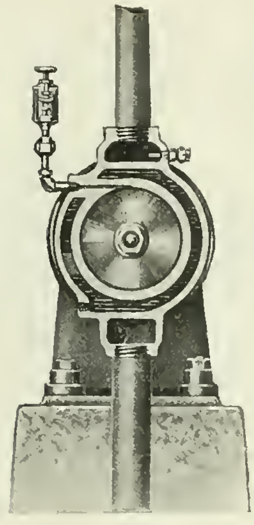

Fig. 7

Products of combustion are foul gases, while partial combustion results in carbon monoxide (CO) gas. One of the most undesirable conditions which might arise is the contamination of compressed air with these hurtful gases—especially is this true in connection with the use of air in closed workings, such as mines, tunnels, caissons, etc., where exhaust from drills and other pneumatic machinery is depended on for the supply of fresh air.

Instances are on record where explosions in discharge pipes and receivers have been traced to excessive temperature, and while the safety of such apparatus is unquestionable under proper supervision, safety devices looking to the prevention of such danger are entitled to serious consideration from users of compressed air.

Devices of a thermostatic nature are manufactured for this duty, but they usually involve other complicated apparatus, such as batteries, bells, wiring, etc.

The Hodges fusible signal plug, which is being marketed by the Ingersoll-Rand Co., is intended to give warning in a positive and unmistakable manner of a rise in temperature to a point which has been previously determined upon as the limit of safety—against the development of excessive strains, or other unnatural conditions.

The device is shown in Fig. 6 and consists of a body formed for readily screwing into a hole tapped for $\frac{1}{4}$-inch pipe thread in the wall of the apparatus to be protected.

As there are no movable parts to the device, no attention is required from the operating engineer. The material used is unaffected by atmospheric conditions.

Fig. 7 shows the device in place in the discharge space of a single-stage compressor. It can also be placed to protect a receiver or other air container. With the device in place, a rise of temperature to a point for which the safety element is set melts it and opens a minute passage through the stem to the head, allowing a small amount of air to pass, producing a distinctive whistle that cannot be overlooked by any one in the vicinity; and this will persist until such a time as measures have been taken to reduce the primary cause of the threatened trouble. It is then but a moment's work to replace the plug with a new one and the machine is again protected against a similar recurring danger.

A few of the removable stems containing the safety element carried in stock will provide protection to a plant of considerable size.

Users of compressed-air machinery can readily understand that this device forms a desirable addition to compressed-air equipment and should be found at every point of possible danger throughout the plant.

The manufacturers supply two

kinds of these signal plugs, with 350-degree and 500-degree blowing point, respectively. The 350-degree plug is suitable for use in the discharge pipe of a single-stage compressor working at 40-pound gauge pressure; in the discharge side of a two-stage compressor working at 100-pound gauge pressure, or in the discharge side of a three- or four-stage compressor, delivering air at 1,000-pound gauge pressure. The 500-degree plug is for use in the discharge pipe of a single-stage compressor working at 100-pound gauge pressure.

Storing and Rehandling Anthracite Under Cover

*By Wm. E. Hamilton**

The ultimate exhaustion of anthracite in Pennsylvania will occur in 104 years, as estimated by Mr. A. D. W. Smith, of Wilkes-Barre, Pa., and Mr. William Griffith, of Scranton, Pa., who have made investigations for the United States Geological Survey. Anthracite will continue to increase in value, and therefore improved and more economical systems of handling, are being sought.

The features most to be desired in a plant to store and rehandle anthracite are the following: The least breakage of the coal, lowest operating cost, low first cost, per ton of storage capacity, least amount of labor employed, least amount of machinery involved, simplicity, and consequent freedom from breakdowns, greatest storage capacity, greatest strength in construction, protection against fire, either accidental or incendiary, protection against the weather.

The system herein described consists of cylindrical tanks having conical roofs and floors, and in the center of each tank a hollow tower containing a spiral chute, and a pivoted bucket conveyer which operates in connection with the chute and a track hopper. Although the plan is new, the details are not, but have been tested and proven. It is a combination of old and well-known ideas and principles, and its simplicity insures its successful operation.

*With the Jeffrey Mfg. Co

The first aim is to reduce the loss in value of the coal caused by degradation. This is an item, which, on a tonnage basis, often amounts to more than the cost of operation, and the cost of interest on plant investment, combined. A great deal of machinery, costly to install, costly to operate, expensive to maintain, and destructive to the coal (through its chipping and flaking by abrasion), is dispensed with by this method of handling. The number of transfers has been reduced to a minimum, and the fall of the coal at these points has been shortened to the least distance. The rolling, or sliding of the coal upon itself is less, by reason of the form of the retainer (see Fig. 8). The coal is carried on pivoted buckets, traveling on self-oiling wheels. The conveyer is 50 per cent. more durable and consumes less power than a scraper conveyer.

The operation is as follows: The coal is received from the mines in cars which are "spotted" over the track hoppers. From these hoppers it is carried by wheeled bucket conveyer to the top of the retainers or tanks, where it is discharged into the large hopper of a covered spiral chute; it glides down and fills this chute; then sliding gates in the chute are opened successively, to allow the coal to flow out into the retainer or tank.

The spiral chute has a capacity greater than that of the bucket conveyer, and may always be kept full. The angle of inclination insures the sliding of the coal, and there is no internal movement or working of coal within the chute, such as would cause grinding or abrasion; but the coal moves down the chute "en masse," sliding on the smooth surfaces, and not grinding on other coal.

The flow of the coal through the gates is regulated so as to keep the spiral chute filled, this being shown by its height in the hopper at the top of the tower The buckets, after discharging into this hopper, travel on guides down through the center of the hollow tower and through the coils of the spiral chute; and passing out of the retainer at the bottom, they return under the track hoppers and are again filled and passed on to their discharge.

At the commencement of the operation of storing coal, all gates of the spiral chute are closed, except the lowest one, the coal flowing out of this and filling the lower part of the retainer. As soon as the coal has reached its level of repose in the tank, this gate is closed and the next higher is opened. The gate-controlled openings are large, and there are eight to each spiral turn, so that the difference in height between one gate and the next is very small, in fact the top of one gate is higher than the bottom of the one next above it, so that there is no falling off of the coal. The gates are opened and closed one after another until the storage retainer is entirely filled, and the coal is stored to the top of the tank in a conical pile, of which the hollow tower is the center, and the steel wall of the retainer is the circumference. Thus in this construction the strains occasioned by this great weight of coal are equally distributed on the outer wall of the retainer.

In reloading out of storage, the preceding operation is reversed. Beginning at the top, the gates in the spiral are opened successively as they are uncovered by the lowering of the coal in the retainer; thus the coal is drawn from the top of the pile, and never from the bottom where it is under pressure of the overlying coal. The only labor required is for opening and closing the gates, and even this can be done mechanically.

The travel of the coal is retarded by the turns of the spiral, so that the pressure at the bottom of the chute, where the coal passes into the pivoted buckets, is very slightly greater than at the top; whereas, if this chute were vertical, straight, and smooth, when full of coal, a pressure of 2,000 pounds per square foot would be carried at the bottom of it, for each 50 feet of its height. The weight of coal in the spiral chute is practically uniform at every turn, as it is divided up and carried by every turn, and not by the coal at the point of discharge; and in reloading the coal, out of storage, there is none moved under pressure.

In this plan of piping the coal from the top of the pile, it is taken out of the center so that the pressure on the wall of the retainer is reduced equally in all directions, and it is uniform at all times and stages of both operations—like the pressure of water in a tank. The "internal working" of a pile of coal when drawn off from the bottom is very apparent. A cone-shaped depression forms at the top and throughout the pile, one piece of coal is grinding against another, chipping and flaking, and breaking off the edges into particles too small to be of much commercial value—forming "buckwheat," "rice," and dust. Such internal working is all avoided in this system.

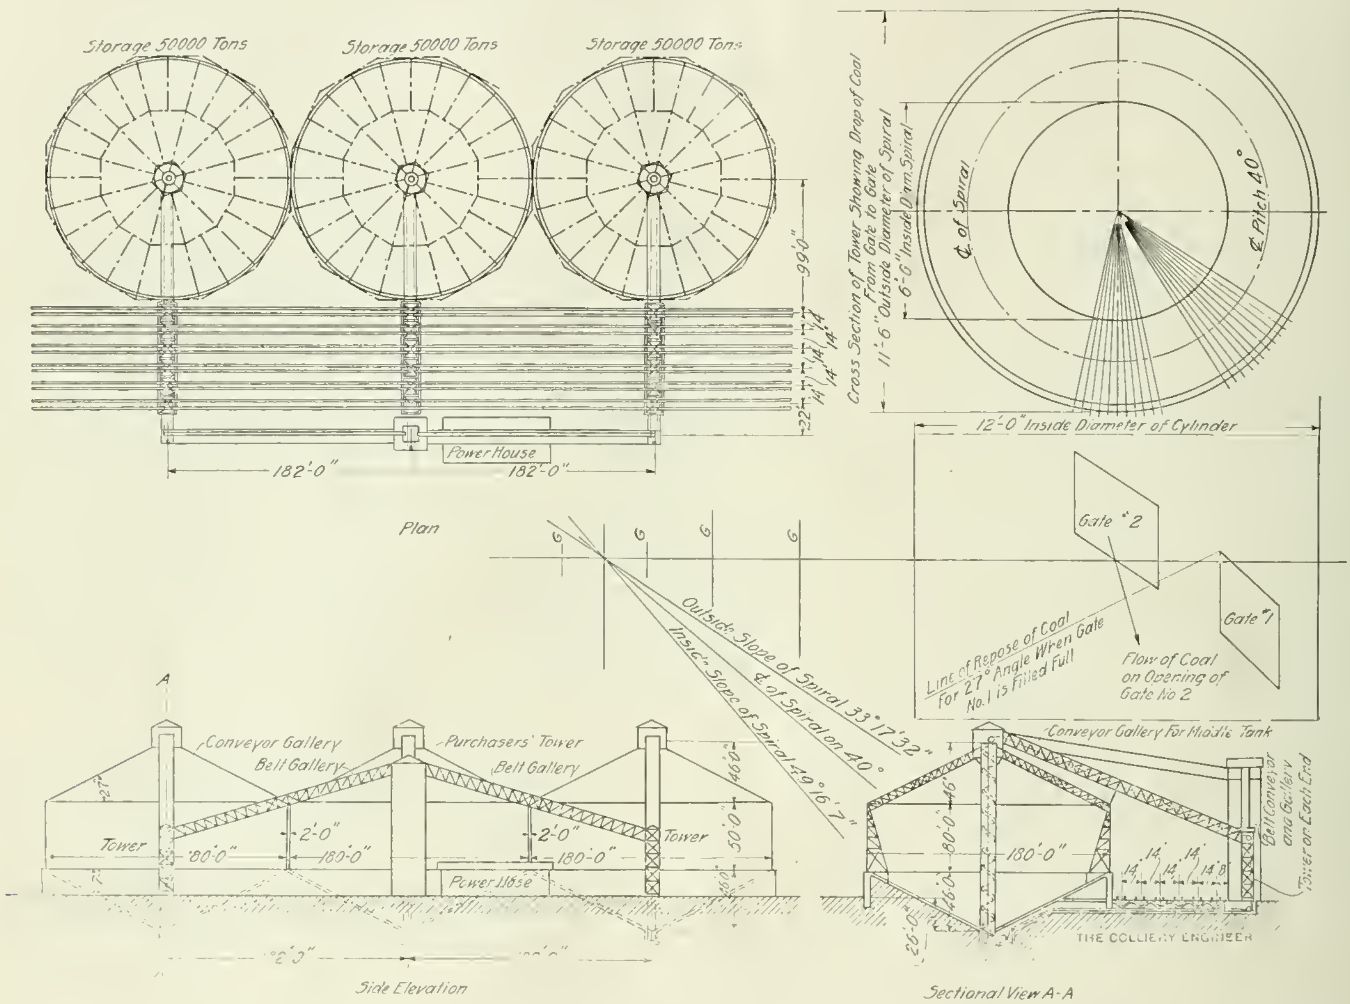

Fig. 8. Plan and Elevations of Coal Storage Apparatus

From records kept at a number of plants, through several years of their operation, the fact is disclosed that neither the first cost nor the operating expense are the principal items to be considered. The loss in value of the coal from its "degradation" is a cost greater than any other. This degradation has not been materially reduced in late years, as the plants which have been installed have followed the original scheme of storing the coal in conical or rectangular piles and drawing it off either by tunnels, under the great pressure and weight of overlying coal, or by conveyers scraping against the side of the coal pile.

The system herein described provides protection against fire, either accidental or incendiary, no sparks nor flying embers can get into the enclosure, and, in case strikes and riots, there are no doors or other openings that give access to the coal where combustible material can be piled and fires started. It would be impossible to communicate any fire from the outside, or from the inside, to the contents of these retainers.

The circular tank or retainer is the strongest construction known. Likewise the cubical content is greater than that of any other geometrical form of building, with the exception of a sphere; and it affords the greatest possible storage capacity for the amount of material entering into its construction.

The London *Times* states that extensive coal deposits have been discovered in Udi, South Nigeria. The test made by the Government, and analyses at the Imperial Institute are said to have given results equal to two-thirds that of the best Welsh coal.

TRADE NOTICES

Current 'o Scope.—Fairbanks, Morse & Co. have gotten out a little device which they call a "Current 'o Scope." It is an arrangement made out of two pieces of celluloid, between which a circular piece can be revolved by the finger. It is marked in such a fashion as to show, when the circular piece is revolved, how the currents travel in a three-phase, alternating-current induction motor, and how the so-called revolving field is produced by the action of the alternating currents. Each phase of the current is represented by a different color, the device being colored with green, red, and black. The top piece has holes punched in it so that the marks on the under piece show through.

The device is accompanied by a description of the action of an induction motor and shows how it may be exemplified by the Current 'o Scope. For any one who is not familiar with an alternating-current, three-phase, induction motor and is desirous of learning about them, this little device can be thoroughly recommended, for it is simple and the directions which go with it are clear.

"Merchant" Weight Pipe.—The National Tube Co. has announced that in the future they will not manufacture "merchant" weight pipe, but will confine themselves to the manufacture of standard weight pipe. The reason given for this is that full weight pipe is suitable for all purposes for which the merchant weight has been used, while the opposite is not true. In the past there have been legitimate uses for merchant pipe, that is, pipe lighter in weight than the standard, but it has been necessary in consequence that the jobber should keep in stock several weights of pipe, which has produced in the mind of the consumer an uncertainty as to the weight of pipe that he was receiving. With a standard weight for all piping there can be no question as to the weight of pipe delivered.

New Dry Battery.—The Western Electric Co. have recently put on the market a new dry battery which is called the Red Label Blue Bell battery. It is designed for intermittent service that requires rapid recuperation, and is intended as a general utility battery, having an initial amperage of 25 amperes on short circuit and being of the low internal resistance type. Some of the uses for which this battery is adapted are for the operation of call bells, for telephone pole changers, for railway telephones in furnishing transmitter current on train dispatching circuits, and as a selective signaling battery; it is also especially fitted for ignition service in general with all types of industrial gas engines, as starting batteries for automobiles, and with slow-speed gas engines, such as are used in motor boats and automobile trucks.

Forty-Fifth Anniversary.—Forty-five years ago, in 1868, the firm of Adam Cook's Sons was founded in Albany, N. Y., as the Albany Lubricating Compound and Cup Co. The first small plant in Albany was outgrown in 4 years, and the business was moved to New York. In 1872 larger quarters were secured along the river front at 231 West Street, New York City, but in 1881 it was found necessary to move to still larger quarters at 313 West Street. Additions were continually made to the plant to meet the growing demands for Albany grease. While the continuous spreading out of the plant provided ample room, it was finally decided that it would be better to concentrate the different departments and plan the manufacturing system according to modern principles and to bring under one roof all of the various departments of the business. After 30 years the West Street plant was abandoned and the present modern commodious plant at 708-710 Washington Street, was placed in service.

New Repair Department.—The Goodman Mfg. Co. announces the opening of a repair and supply department in Pittsburg, Pa., for the convenience of its many customers in the territory nearby. The address will be: Pittsburg Repair and Supply Department, 700 Phipps Power Building. E. Kent Davis is manager, and the electrical repairing done in this shop will be of the same high-grade character as that done in the Chicago shop. A complete stock of parts for the short-wall coal cutter will be carried in stock.

Goulds Mfg. Co.—The annual meeting of the stockholders of The Goulds Mfg. Co. was held at Seneca Falls, N. Y., February 24. No change was made in the board of directors, and the following officers were reelected: President, N. J. Gould; Vice-Presidents, D. V. Colby, W. D. Pomeroy, W. E. Davis, W. E. Dickey; Secretary, H. S. Fredenburg; Treasurer, B. R. Wells; Assistant Treasurer, E. W. Medden.

Refillable Fuse.—Ackley Brake and Supply Co., of 50 Church Street, New York City, are manufacturers of the Monarch Refillable Fuse, for which they are sole agents. It is constructed in all the types and sizes as standardized in the old code type, and it may be refilled in a fraction of a moment by a "filler" adapted to a fuse of a given amperage and voltage. This fuse recommends itself for use in mines because of the impossibility of arcing at the time of a blow-out. The fillers, which are inserted by refilling, are surrounded by powder which suffocates the flame at the instant of arcing, thus obviating any possibility of an exploded cartridge casting out particles of burning fiber and molten metal.

A Flexible Hose That Doesn't "Kink."—Troubles from kinking hose or flexible connectors in steam or pneumatic service have been so common that they are accepted as a matter of course, but many of them are avoided by the new coupling known as the J-M flexible metallic combination hose which has been introduced by the H. W. Johns-Manville Co., of New York.

This consists of a superior grade of durable rubber hose, protected against outward injury by a stout metal armor. The armor is made in the form of a ribbon, with crimped edges, forming, when wound, a continuous, interlocking flexible spiral, which is said to be practically pressure-tight in itself, without the inner tube, and sharp bends are impossible. Consequently the inner tube cannot kink or flatten, and is always open to its full diameter.

Actual service tests show that the armor will resist a crushing strain of 300 to 800 pounds to each four turns of the spiral, while it is capable of withstanding the highest internal working pressures. It is claimed that this hose cannot be put out of service unless both the outer armor and inner tube are punctured at the same time. The inner tube is never subject to any pulling strain, and all the working strain comes on the armor, which is tested to resist an end pull or thrust of 1,000 to 2,000 pounds.

Another advantage of the new hose is that its exterior surface, unlike ordinary single types of hose, does not become excessively hot when used for steam service, drills, blowing out boilers, etc., and can therefore be more conveniently handled. A special booklet describing this will be sent on application.

Temperature Control for Air Compressors

The following is a short description of the automatic temperature control for air compressors, which was described by Thomas W. Dawson, Assistant Chief Engineer of the H. C. Frick Coke Co., in his paper on "Welfare," presented December 18, 1912, at the meeting of the Coal Mining Institute of America.

In Fig. 1, *1* is the compressor; *2*, the steam cylinder; *3*, compressor throttle; *4*, steam pipe leading to

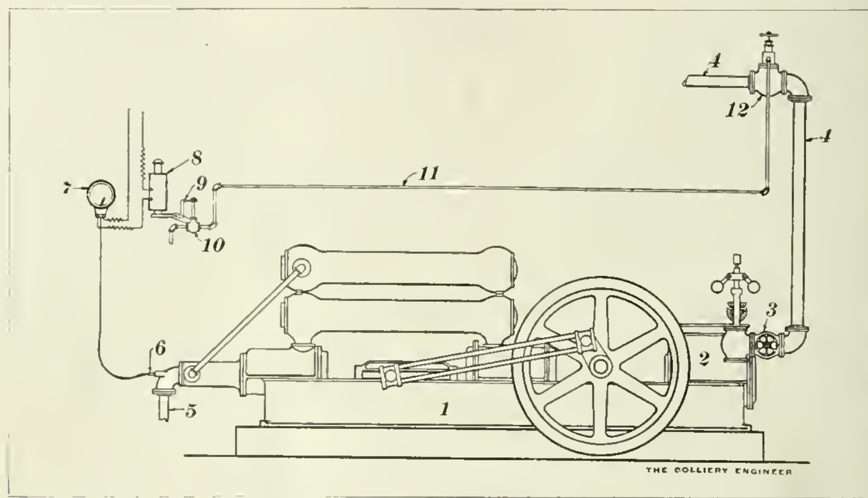

Fig. 1

compressor; *5*, air discharge pipe from compressor; *6*, thermometer fitting; *7*, thermometer recording device; *8*, electrical solenoid; *10*, pilot valve; *11*, small steam pipe; *12*, a quick operating automatic steam valve.

When the temperature of the discharge air in pipe *5* reaches a predetermined abnormal point, it reacts on the thermometer *6* and the recording device *7*, whereby an electrical circuit is closed and the solenoid *8* thereby energized. This energized solenoid in turn, by means of the tripping device *9*, opens the pilot valve *10*, releasing through the pipe *11* the steam pressure upon one side of a piston in the valve *12*, whereby valve *12* automatically closes and stops the flow of steam through pipe *4* to the compressor, and the compressor is thereby automatically stopped.

Address all business communications to THE COLLIERY ENGINEER, Scranton, Pa.

Subscription Rates: $2.00 per year to United States and all possessions, and Mexico; $2.50 to Canada; $3.00 to all other countries. Single copies 25 cents each.

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

THE article on "Safe Timbering" in this issue recalls an incident in Colorado, when two men using a well-designed prop puller recovered 210 mine props. The mine manager was very glad to pay these men at the rate of 4 cents per prop, and 1 cent for caps, as by doing so he made a marked saving in the cost of such mine timber, and the men also made good wages.

Railway Strikes a National Menace

A RAILWAY strike that ties up traffic throughout large areas of territory, not only disastrously affects the entire area involved, but to a greater or less extent it affects the whole country.

If such a thing as a nation-wide railway strike should occur, it would paralyze commerce and industry, and would directly and indirectly bring hunger and suffering to millions.

Any cause that disastrously affects commerce and manufacturing is particularly disastrous to the coal mining industry.

In the case of a railway strike, coal cannot be sent to market, and as a result the mines must be shut down.

The non-movement of freight trains will cut off from large centers of population the regular influx of food stuff, and suffering is sure to follow.

During the severe floods of the latter part of March the temporary interference with the movement of railway trains cut off to a large extent the milk supply of a number of towns, and helpless babes and children suffered. The non-arrival of other food stuffs created a scarcity that forced prices, already high, beyond the reach of thousands of working people.

The Railway Business Association, composed of upwards of 250 of the largest manufacturing concerns of the United States has issued a bulletin on this important subject, showing the immediate necessity of National legislation that will be effective in preventing such calamities as general railway strikes.

In its bulletin the Association says:

"The urgency of the situation leads the Railway Business Association to go outside its main function of conciliation between railways and the public and seek to arouse the public, the railway employes and the railway managers to cooperation and the President and Congress to action at the extra session. The federal Erdman Act, through which until recently strikes causing interruption to train service have been almost wholly prevented, has all but broken down at the point where, media-tion failing, arbitration was attempted in the large-scale dispute involving many roads at once. The Eastern engineers' case was arbitrated outside the Act. In the Eastern firemen's case the roads agreed to arbitration under the Act only after earnest protest and because they believed this to be the only means of averting a strike. The firemen through their officials went on record as favoring amendments which would render the Act more applicable to present conditions.

"The Erdman Act should be amended forthwith or legislation substituted for it providing a form of voluntary arbitration so little open to valid objection as to deprive disputants of all reasonable excuse for declining arbitration under the law. To postpone remedial legislation is to invite widespread and perhaps national disaster at any moment."

The bulletin plainly shows the weakness of the present law in a clear and concise manner, and calls on all classes, railway managers, railway employes, and the general public to cooperate to obtain legislation which will place them squarely on the side of industrial peace.

Copies of the bulletin, known as "Bulletin No. 12," will be sent on request, by Frank W. Noxon, Secretary, Railway Business Association, 2 Rector Street, New York, to all who desire to help the work along by placing it in the hands of their Representatives or Senators, with a request for their aid in the enactment of fair and effective legislation.

The Development of Alaska Coal Lands

If THE coal deposits of Alaska are to be properly developed, the coal mined in such a way as to supply a waiting market, and at the same time assure true conservation of the coal deposits, the United States Government must change the policy of the Interior Department of the two past administrations.

Competent geologists and mining engineers who have examined and reported on the Alaska coal lands agree in the following general conclusions: The strata in the coal fields have been so disturbed by volcanic action that the coal seams lie at all angles to the horizon, from flat to perpendicular. That the coal seams are broken by numerous faults, that in many tracts the coal lies in pockets of greater or less extent, and in some places it has been destroyed by heat from the volcanoes and lava emitted from them. At the same time they unite in stating that there are large bodies of good workable coal. Among the geologists who have so reported are William Griffith, of Scranton, Pa.; Prof. W. R. Crane, of Pennsylvania State College; and George Watkin Evans, of Seattle, Wash.

From the above general statements it is evident to practical mining men that the cost of mining is bound to be higher than it would be if the coal seams were regular in pitch and thickness, and free from numerous faults. The fact that the geological disturbances made the good coal, in many areas, pockety, and that more or less gas has been encountered in drift workings, but a few feet from the entrance, adds to the expense. In addition, the irregularity of the seams and the existence of many faults introduces, to a certain extent, an element of luck in the matter of securing a continuous output from mines that may be opened.

Even in localities where the seams are regular and there are transportation facilities to convenient markets, the mine operators must have sufficient areas of coal to warrant the expense of development and equipment. If there are no transportation facilities to convey the coal to markets large enough to absorb at least a moderately large output, there will be no development.

What the Alaska coal fields require are transportation facilities and such common-sense action on the part of the United States Government as will make it worth while for capitalists to develop and work them.

The federal laws that limit the patenting of Alaska coal lands to a maximum of 160 acres to any one person, and of a maximum of 640 acres to any one corporation, regardless of the number of men in it above four, are in themselves a hindrance. In addition, the price per acre established by the government is excessive. It is as high or higher than the price at which individual coal land owners in several states sell good undeveloped tracts in localities within comparatively easy reach of markets.

Then, to make matters worse, the Department of the Interior has formulated "regulations" governing the details of procedure of citizens patenting Alaska lands that are not in consonance with the enacted law, and which tend to restrict rather than encourage the rational development of the lands. If railroad lines are to be constructed in Alaska there must be assurance of enough business for them to warrant their cost. In the present state of affairs there is not enough freight to be carried to warrant the building of a road to tap the coal fields. If the coal fields were developed, or there was an absolute surety of their being worked on a moderately large scale in the near future, the coal tonnage would be the greatest factor in making their operation profitable. Besides, there must be an ample and continuous coal supply for the locomotives.

In the early development of Alaska's coal resources, and for many years thereafter, the coal tonnage will not be sufficient to yield a paying revenue to one railroad. Therefore, with reasonable restrictions, there should be no encouragement offered to more than one railroad line, until the industry grows to such proportions as to really require additional transportation facilities.

Under existing laws regulating common carriers, one railroad line will not be inimical to the true interests of producers and consumers.

To secure the development of the Alaska coal fields and the working of the coal in a manner that will supply the demand, and at the same time conserve the coal, the mining operations must be conducted by parties having large capital resources. Experience in every coal field in America shows that the working of mines by operators without sufficient capital to employ the services of competent mining engineers and efficient mine officials, to pay for best equipment and machinery, and to pay for proper dead work, has resulted in enormous waste of coal in the ground. Such operators necessarily worked their mines in an unsystematic manner. They took out only the coal that could be mined at least cost, and often a comparatively small percentage of that. When they ceased mining, large quantities of good coal remained which could only be recovered at abnormally high cost, or which could not be recovered at all except at prohibitive cost in money or lives of employes. *Per contra*, operators or mining companies with ample capital and coal areas large enough to warrant the investment of such capital, have worked their mines, particularly in more recent years, in a manner that has resulted in the mining and utilization of from 75 per cent. to 95 per cent. of the coal in the ground, and they have done it with greater safety to the health and lives of the mine workers.

If the utilization and the rational conservation of Alaska's coal resources are to be accomplished, there must be greater liberality in the laws governing the taking up of claims by citizens willing to invest in coal lands in an otherwise unattractive territory, and the detailed regulations as to procedure in filing claims and completing patents must be made to conform with the enacted laws. That the present regulations do not conform to the meaning and spirit of the present narrow laws was recently proved in the United States District Court, in Chicago, by the acquittal of Albert C. Frost, and several associates, who were charged by the officers of the government with an attempt to obtain possession of coal lands by illegal methods.

In 1904, Mr. Frost became interested in the financing of a railroad to run from Seward, on the south coast of Alaska, north, a distance of 483 miles, to Fairbanks. That the road would run near the coal fields of the Matanuska Valley, was the most important factor in attracting investments in its securities. Mr. Frost and his associates realized that such a railroad, without assured coal tonnage of sufficient size, would not be profitable. There was another route into the same field from the Copper River country. To assure for his proposed road a comparatively large tonnage, and to prevent its division with a possible other road from the Copper River country, he, his associates, some of his employes, and some friends, took up claims, and complied fully with the terms of the enacted laws in trying to get patents from the government. But, while complying with the law, they did not strictly comply with the "regulations" formed by the Interior Department, which in a number of points are not in consonance with the law, and are not based on good common sense. Special government agents, acting under the "regulations," reported adversely to the claims of Mr. Frost and his associates. In the meantime, during the Roosevelt administration, these lands were withdrawn from entry, and steps were taken to prosecute Mr. Frost and his associates for conspiracy to obtain possession of the lands, by "dummy" entrymen. On March 16, 1911, they were indicted. The case was tried during the past month, and after a long trial in which the testimony was very voluminous, and eminent counsel argued on both sides, a verdict of "not guilty" was returned by the jury, as the government failed to prove violations of the enacted law.

While the verdict frees the defendants from a serious charge, it does not return to them the money paid the government which yielded them nothing but trouble and expense. Neither does it make possible the construction of the road and the development of the coal lands, as they are still "withdrawn from entry."

The Colliery Engineer is not an advocate of laws that will give away valuable natural resources to a privileged few, but it does advocate laws that will be liberal enough to permit the development, utilization, and rational conservation of such coal lands as the government owns.

In the formation of such laws, and of regulations regarding their enforcement, the officials of the Interior Department should have the assistance and advice of men skilled in coal mining and familiar with the conditions that must be met in developing new coal territory. The Federal Bureau of Mines, which is a part of the Interior Department, has connected with it a number of competent mining engineers and practical mine officials, whose experience and knowledge should be called on in this connection. It is to be hoped that the Alaska coal fields will, in the near future, be again open for entry, on more liberal terms than formerly, and that such terms, and the regulations governing the patenting of the lands will be largely based on advice from the practical coal mining men in the employ of the Bureau of Mines.

Flushing Anthracite Mine Workings

THE illustrated article on another page, which describes in detail the methods employed in flushing mine workings in the Schuylkill region of the anthracite fields, is the first comprehensive description of the methods employed and results obtained ever printed. The value of the system in preventing serious disturbances of the surface, and in making possible the safe extraction of practically all the coal in the seams is such that the article can be read with profit by all engaged in coal mining, whether anthracite or bituminous. There are many localities where surface protection is of small importance, but there are no localities in which the safe mining of the greatest percentage of the coal in the seam is not of prime importance.

In the anthracite regions the large quantities of waste material at the mines provide the material for flushing. In bituminous fields the gob stowed in the mines can be utilized, if supplemented by ashes, sand mixed with loam, and the country rock broken into suitable sizes by crushers, as is the slate, bone, etc., at the anthracite mines where flushing is practiced.

PERSONALS

William A. Sourbrey, Outside District Superintendent for the Philadelphia & Reading Coal and Iron Co., in the Shenandoah, Ashland, and Mahanoy City districts, resigned on April 15. Mr. Sourbrey has been in active service about the mines for over half a century and retires to private life. He has the distinction of being the first man to successfully jig buckwheat coal, and is one of the best posted men in the anthracite regions on the handling of coal on the surface and its preparation for market.

The following candidates successfully passed the recent examinations to obtain certificates as mine foremen and assistant mine foremen in the Fourteenth Anthracite District of Pennsylvania:

Foremen: Frank Pollard, John J. Panko, John J. Boyle, Joseph Yarworth, M. T. Chapman, William B. Motter, of Centralia; William F. Blowbert, Mahanoy Plane; and John Rudd, Shenandoah.

Assistant Foremen: John Hanna, Patrick Whalen, Edward J. Conners, of Shenandoah; John Coleman, Charles Whitmayer, Girardville; Anthony McGinley, Joseph Koch, George S. Wills, Centralia; M. J. Ryan, Luke Hoar, Lost Creek; and John McLaughlin, Connerton.

Charles E. van Barneveld, who for the past 14 years has been Professor of Mining and Metallurgy at the Minnesota School of Mines, has been appointed Chief of the Department of Mines and Metallurgy of the Panama-Pacific International Exposition. Mr. van Barneveld will be at the Headquarters of the Exposition after May 1.

David A. Thomas, chairman of the Cambrian Trust, will shortly return to the complete negotiations for the large tract of coal land in Kentucky that was mentioned in April issue. Mr. Thomas will probably stop for a while in Scranton as before.

Dr. Frederick Schniewind, who improved the Otto-Hilgenstock ovens by combining the underfiring system with the regenerative system, died at his home in Englewood, N. J., in March.

F. Julius Fohs, formerly of the Kentucky Geological Survey, and who, more recently, has been doing special work in the Broad Top field of Pennsylvania, is now making an examination of some of the phosphate mines in middle Tennessee.

Dr. A. H. Purdue, State Geologist of Tennessee, has been inspecting the phosphate field near Mt. Pleasant, and the bauxite deposits near Elizabethton.

Wilbur A. Nelson, Assistant State Geologist of Tennessee, has been correlating the coal seams at Bon Air and Clifton.

Frank Gilday, formerly State Mine Inspector of Kansas, is now connected with the Central Coal and Coke Co. At present he is establishing a first-aid movement in the vicinity of Pittsburg, Kans.

J. A. Jefferies has been appointed General Manager of the Williamsville Coal Co., with headquarters at Springfield, Ill.

J. F. Menzies, General Superintendent of the Northwestern Improvement Co., of the state of Washington, read a paper at the meeting of the Western Branch of the Canadian Mining Institute on mine rescue work as carried on by his company at their several mines in the state of Washington.

P. B. Ashbridge, who has charge of the first-aid work of the Canadian Pacific Railroad, read a paper before the Canadian Mining Institute on first-aid work as carried on by the St. John's Ambulance Society.

James Price, of Nanaimo, B. C., who for 37 years has been in the employ of the Western Fuel Co., was presented with a gold watch by the employes, as an appreciation of respect and good will.

George S. Rice, E. M., addressed the New York Section of the American Institute of Mining Engineers in March on "Flushing or Hydraulic Filling as Practiced in European Coal Mines."

J. B. Hornberger, Controller for the Pittsburg Coal Co., lectured before the students in the School of Mines, University of Pittsburg, on "Coal Mine Accounting and Costs."

Fred R. Thomas, formerly of Wilkes-Barre, Pa., has been appointed Superintendent of all the Northern Pacific Coal Co.'s mines in Kings County, Wash.

George D. McClellan is now Mine Inspector for South Dakota, having been appointed to the position by Governor Byrne. Mr. McClellan has been a resident of the Black Hills district for a number of years.

Governor Cary, of Wyoming, appointed George Blackner, of Uinta County, Coal Mine Inspector of No. 1 district, and W. E. Jones, Sheridan, Inspector of district No. 2.

Benjamin S. Hammil was elected President of the Meadowlands Coal Co. with headquarters at Pittsburg, Pa.

Prof. Arthur Lakes, of Denver, Col., who is well known to readers of The Colliery Engineer for his specially illustrated articles on mining in the West, is now living near Ymir, B. C., where his son is manager of the Wilcox gold mine.

The Kentucky Mining Institute

The next annual meeting of the Kentucky Mining Institute will be held May 16 and 17, at Lexington, Ky. According to the present plan, the first day of the meeting will be devoted to the state-wide first-aid contest, followed in the evening with a banquet and discussion. The second day will be devoted to reading and discussion of papers, on mining topics. Special round-trip tickets at one way fare and 25 cents additional have been granted by the railroads, to be on sale May 15-17 and void after May 19, and it is expected that there will be a large attendance.

Flushing Anthracite Workings

Methods Employed in the Thick and Moderately Thick Seams of the Schuylkill Region of Pennsylvania

Written for The Colliery Engineer

THE filling of mine workings with culm, or fine coal, and other waste materials, by flushing it into the mine and depositing the material by the use of water, serves two main purposes. (1) The flushed material acts as a support to the superincumbent strata and minimizes surface disturbances; and (2) in a number of instances it permits the more complete extraction of the pillar coal.

It is estimated that, under certain conditions in moderately thick seams lying at considerable inclination, only about 50 per cent. of the coal remaining in pillars after first mining can be recovered if flushing is not practiced.

In flat seams more pillar coal can be taken out than in seams having considerable inclination. This is particularly so in the thick seams. In pitching-seam workings the roof rock, when it falls, slides down the pitch and fills up the chambers or other mine openings to a greater or less degree, while in flat seams it remains where it falls, and is removed, if necessary, with less trouble and expense.

When the mined areas have been flushed, enough support is given the roof in both pitching and flat seams to prevent the roof rock breaking in comparatively small pieces. When it does break, it moves in large masses, and finally comes to rest on the flushed material. By flushing the mine workings practically all the coal under towns and villages can be taken out, without causing any great disturbance of the surface. The amount of subsidence in the surface will, if the flushing has been complete, be very slight. That there will be no movement of the surface when the pillars have been extracted and the mine flushed cannot be expected, but the movement that does occur is slight and occurs over large areas. In coal seams lying at considerable inclination, flushing can be made more complete than in flat seams. In the latter there is difficulty in filling the openings entirely, and there is naturally a little space left between the top of the opening and the top of the fill. It is estimated that in such cases where the superincumbent strata move in large masses, the amount of subsidence of the surface is about 10 per cent. of the thickness of the coal seam.

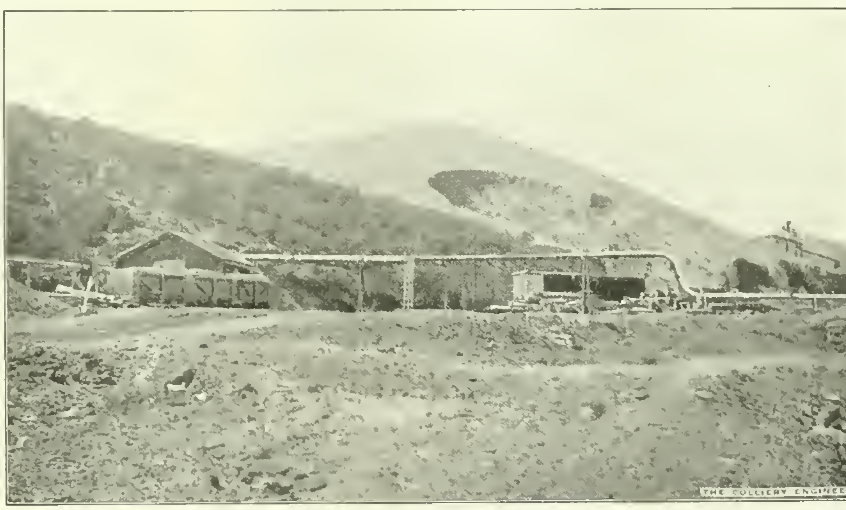

Fig. 1. Culm Pile Being Flushed into Holmes Seam Workings at Tunnel Ridge Colliery

In some sections of the anthracite regions the operation is called slushing and in others flushing. The mixture of water and waste material is usually called "slush."

The first known use of the flushing operation was in the latter part of August, 1884, when the late John Veith, general inside superintendent of the Philadelphia & Reading Coal and Iron Co., employed it to extinguish a fire in the Buck Ridge slope, near Shamokin, Pa.

On August 20 a fire broke out in the main hoisting slope of the Buck Ridge colliery. This slope, which was in the bottom split of the Mammoth seam, had six lifts, three above water level, and three below water level, and was 440 yards long, varying in pitch from 35 degrees at the top to 45 degrees at the bottom. The upper 350 yards was on fire, with flames rising to considerable height above the mouth. The mouth of the slope was with difficulty covered with heavy planks and earth until pumps could be installed to furnish water for flushing. As soon as the pumps were in position and steam and water connections were completed, a small opening was made in the closed mouth of the slope and flushing began. In this instance the proportion of culm to water was very small, about 1,000 gallons of water to a cubic yard of culm, as the intense heat of the fire made necessary a large extra supply of water, and this extra supply naturally had an effect on the fire. Twenty-two thousand five hundred cubic yards of culm were put in the slope by this means, and 22,500,000 gallons of water were used. This extinguished the fire. The culm was then removed, the destroyed timbers in the slope were replaced, and operations at the colliery were resumed.

At the West Shenandoah colliery, Shenandoah, Pa., operated by the same company, a mine fire was extinguished last year by flushing. In this case bore holes were put down from the surface, penetrating the coal seam at a point where it was on fire, and also at points outside the fire zone, and slush was run in through them. The first bore hole was so located as to penetrate a gangway in the midst of the main fire. No attempt was made to control the flow of the slush after it reached the mine workings. It was allowed to flow as it would, an excess of water being used so as to carry it some distance outside the known limits of the fire. The burning area and the workings around it were flushed, so as to block off the fire as completely as possible. When enough of the workings were supposed to have been flushed, openings were made through the flushing, and when evidence of fire or an unflushed space was found, it was immediately flushed full and the fire was entirely extinguished. The slush, being largely fine coal mixed with mud and water, packs solidly when deposited and does not ignite. It is sometimes deposited on burning culm piles to shut off the air and smother the fire.

The credit for the second use of flushing, and for the first use of it to control the overlying strata, belongs to Frank Pardee, of Hazleton, Pa. In 1886, while assistant superintendent of the collieries belonging to A. Pardee & Co., he used the system to stop a squeeze which threatened the slope and breaker of the Laurel Hill colliery, at Hazleton. The squeeze seemed uncontrollable by other means, so he flushed two adjacent breasts full of culm. These breasts were in a thick seam which had a steep pitch. By filling the two breasts, or chambers, he provided

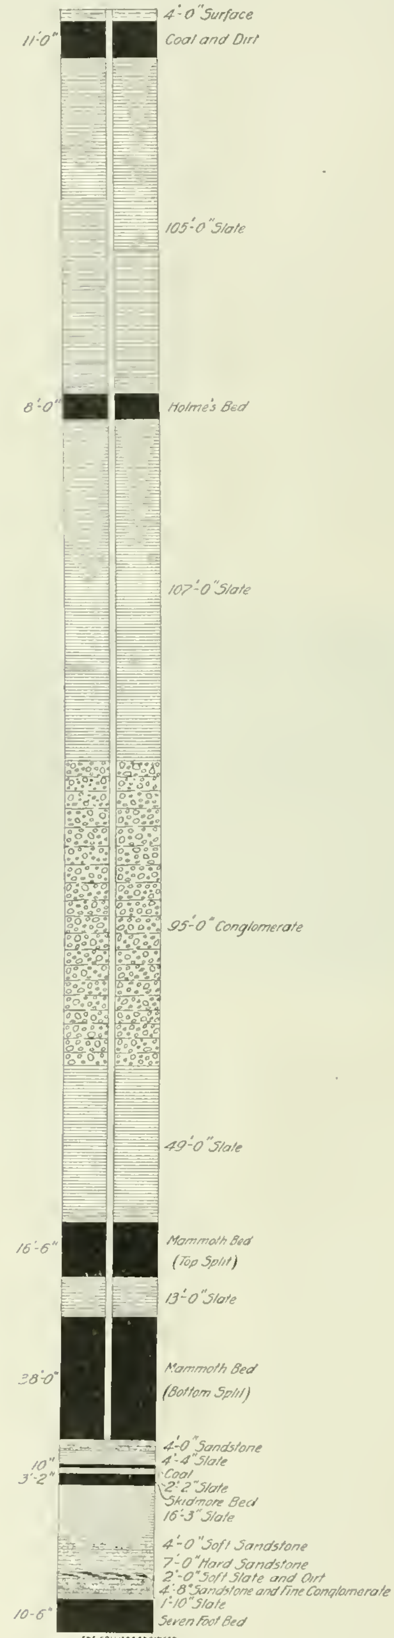

Fig. 2

Scale, 1 in. = 60 ft.

a partly natural and partly artificial pillar consisting of three coal pillars, each 10 yards wide, and two culm pillars, each of the same width, or a solid block of 50 yards. When the squeeze reached this pillar the rock broke and the trouble was averted.

The third, and one of the most extensive uses of flushing, was at the Kohinoor colliery, at Shenandoah, Pa. Previous to 1884 this colliery was operated by R. Heckshcr & Co., and, as was the custom in those days with individual operators working coal lands on lease, there was but little system used in the working of the coal, and the mine surveys were few and frequently very inaccurate.

On January 1, 1884, the Philadelphia & Reading Coal and Iron Co. obtained possession of the colliery. One of the first things done was the making of an accurate survey of the entire mine workings, the engineers carrying tidal elevations to each survey station or point sighted to, as is the present rule in good mine surveying. When the mine map was completed it was an extremely accurate one, and the data on the map and in the note books made it an easy matter to construct accurate geological cross-sections and a contour map of the bottom of the coal seam. At the same time it was found that the workings in the very thick Mammoth seam were in such condition that but comparatively little coal could be mined from them with safety, and that the surface and the improvements located thereon, in a large part of the western section of the town of Shenandoah, were likely to be seriously affected by subsidences of the surface.

The extremely wide openings, made by the former operators, were very irregular, as the chambers followed the varying, but generally very light, dip of the seam. The great thickness of the Mammoth seam (ranging from 40 feet to 60 feet) made it impossible to take the ordinary precautions as to timbering and removing the shattered and loose coal from the sides or ribs of the pillars, and rendered mining exceedingly dangerous to the men employed.

Of course, the removal of the pillars, even if it could be done with safety to the employes, would cause such a disturbance of the surface and destruction of property in Shenandoah, as to be a source of danger and great loss, even though the thickness of the strata from the surface to the top of the Mammoth seam averaged about 400 feet.

These conditions made it necessary to resort to some unusual means to recover at least a portion of the unmined pillars, which, in some places were very large, and to do it in such a way as not to endanger the lives of the workmen, or the surface.

At that time, the late R. C. Luther was Chief Mining Engineer, Geo. S. Clemens, now Chief Engineer of the Northern Division, was Division Mining Engineer, and the late John Veith was the general Inside Superintendent of the company. A general consultation was held by these officials and the late P. W. Sheafer, one of the land owners, and after various schemes were discussed and found impracticable, it was decided to fill the mine workings by flushing the culm into them, from the breaker and the culm piles, with water. At that time neither of the gentlemen named knew of Mr. Pardee's prior use of the system for supporting the roof.

In a report on the flushing at Kohinoor, made by Mr. Clemens in 1898, he says:

"For the purpose of carrying out the scheme, 10 bore holes, each 8 inches in diameter, ranging in depth from 308 feet to 425 feet, were drilled from the surface to the Mammoth seam, at an average cost of $2.30 per foot. The drilling was started in February, 1887, and was done with churn drills. A series of scraper lines or conveyers, comprised of eight sections, having a total length of 2,475 feet, and slush troughs 1,400 feet long, on trestles, which ranged from 0 to 31 feet high, were erected to convey the fine refuse or culm from the West Shenandoah and Kohinoor breakers to the bore holes sunk to the eastern workings of the Kohinoor colliery. In addition, there were three other scraper lines with a total length of 900 feet, and 83 feet of slush trough, erected to carry culm to bore holes penetrating the western workings.

"An engine, 18-inch cylinder and 36-inch stroke, with rope wheels 14 feet in diameter, was erected to run the scraper lines, and a duplex pump with four working barrels each 9-inch diameter by 38-inch stroke, with 2,620 feet of 4-inch to 6-inch column pipe to furnish water for slushing, were also installed. This equipment, with two 90-horsepower boilers to furnish steam, comprised a distinct plant for this special work. There was also an underground slush course in the Holmes seam, overlying the Mammoth seam, from the east end of the scraper lines to the No. 3 bore hole. The relative positions of the Holmes seam and Mammoth seam are shown in columnar section, Fig. 2. This underground slush course was put in to avoid an overground structure through a thickly built portion of the western section of the town.

"On May 2, 1887, the flushing of culm into the first or No. 1 bore hole was started. As the openings to be filled were very large, the slush was run into the adjacent breasts through the gangways and cross-headings driven in the lower benches of the seam, so that comparatively little water was necessary. As these openings filled, cross-headings were driven in the upper benches of the seam to allow the slush to flow longer distances on lighter pitches. This of course required more water. In order to fill the openings as tightly as possible, and above all the lateral openings where the water could run off, still larger quantities of water were used, and it was found practicable to distribute the slush in such places on a dip of about 5 degrees. In the latter cases, approaches to the top of the filling and the bottom of the bore holes were provided by timbered traveling ways against the ribs. These were necessary to permit examinations, and to prevent blocking of the bore holes, so that they could be used for further flushing when the surrounding pillar coal was removed. In some places the top rock had fallen, leaving large spaces above the seam. These were also filled.

Fig. 3. Last Two Sections of Conveyer Line at North Mahanoy Colliery

"In one case, close to No. 1 bore hole, the top rock had fallen for a height of 25 feet above the top of the seam. It was necessary in this case to blow down the rock between the bore hole and the fall, and the entire space was then filled to within 3 feet of the top of the hole, this 3 feet being left open for access to the bore hole.

"As all the water used in flushing had to be pumped from the mine, the filling of such places as required an excessive amount of water was reserved for dry seasons, when the regular pumps could handle the excess in addition to the ordinary drainage. The average amount of culm flushed into the holes was 565 cubic yards per day. The amount of water used varied from 67 to 334 gallons per cubic yard of culm, or an average of 200 gallons per cubic yard.

"At times the entire output of culm from the two nearby breakers (Kohinoor and West Shenandoah) was handled by the scraper lines, and for several months the work was prosecuted day and night, the night shift flushing in culm taken from the culm piles. A total of 700,000 cubic yards of culm was flushed through the bore holes into the Mammoth seam workings at an average cost of $4\frac{1}{2}$ cents per cubic yard.

"It was found advisable to not push the mining of coal too rapidly in the vicinity of the flushing, as the very thick coal seam required that extreme care be taken to avoid accidents to the miners.

"A set of miners worked a few weeks in one place, fired a few shots in the pillars, loaded all the coal available, then worked in another place until the first place became thoroughly quiet again. Large falls of coal frequently occurred in these places while work was temporarily stopped, and when the miners returned to them they frequently found enough loose coal to work a week or two without firing a shot. In this way, there was recovered to date of the report (1898), about 185,000 tons of prepared coal from the portions of the workings that had been flushed, and it is estimated that over four times this amount could still be obtained, making a total of about 1,000,000 tons of prepared coal, most of which would have been lost if the flushing had not been done.*

"Before the flushing was completed on the Fourth Left East Gangway a very serious squeeze occurred, which made it impossible to examine the exact condition of the filling at some of the bore holes, but the filling previously done arrested the squeeze and greatly minimized the damage.

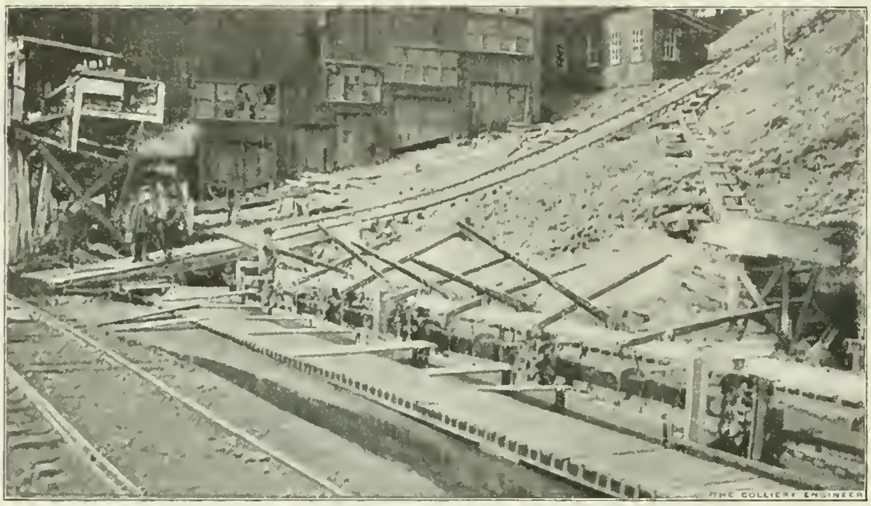

Fig. 4. Settling Tanks at Mahanoy City Colliery

"Later, gangways were driven eastward in the Skidmore seam, shown in Fig. 2 just below the Mammoth seam, to points under the robbing in the Mammoth seam, and chutes from 6 to 7 yards long were driven from them to the Mammoth seam. Through these chutes large quantities of Mammoth seam coal were recovered, and the new openings thus made in the Mammoth seam were flushed full.

"The deposit of slush, or culm, packed remarkably hard and firm. Gangways and headings were driven through it without forepoling, and by timbering with double timber (two legs and a collar in each set) and lagging with slabs or planks, it was not difficult to keep the gangways and headings open."

At the present time the Mammoth seam at the Kohinoor colliery is being mined on a flushing and slicing system. A room is driven in the bottom benches of the seam, and as soon as it reaches its limit it is flushed solidly full. Then, with the top of the flushing as a floor, about 10 feet of the coal is top sliced to the end of the room, after which the room is again flushed and another slice of the top coal is taken. In this manner mining and flushing is alternately carried on until the entire thickness of the seam is taken out. When the chamber is driven on the bottom slate, the track is laid so that the ordinary mine car can be run to the face and the cut coal can be loaded directly in to it. When this opening is flushed full, this is not possible. Therefore, a chute is made at the mouth of the room and the coal is run to it in a buggy, or small car, pushed by hand, and is dumped by way of the chute into a regular mine car.

The total amount of culm so far flushed into the Kohinoor workings is nearly 1,000,000 cubic yards, and through the flushing nearly 53,000 mine cars of coal have been recovered; each car having a water level capacity of 108 cubic feet. Seventy-five per cent. of the coal now being obtained from this mine is from flushed areas.

The success of the flushing at Kohinoor colliery in supporting the surface, and in permitting the extraction of a maximum amount of the coal in the seams was such that the system has been employed by the Philadelphia & Reading Coal and Iron Co. at a number of collieries. As a description of the methods employed at all the collieries would necessarily be repetitions, this article will describe only a few of the typical cases.

The material used for flushing is sometimes the fine screenings from the breaker. At other times specially crushed slate and bone are mixed with the screenings. Sometimes the ashes from the boiler house are flushed in with the broken slate and screenings.

One of the simplest flushing operations in the Schuylkill region is at the Tunnel Ridge colliery near Mahanoy City, Pa., where an old culm bank, shown in Fig. 1, is being washed into the workings in the north dip of the Holmes seam in

* This estimate was a very accurate one, as in subsequent work fully as much coal was recovered as was estimated.

order to protect Mahanoy City. To get this culm into the mine, a slope 200 feet long was sunk and then a gangway was driven so as to strike the tops of the old breasts, down which the slush is poured. One man with a hose washes the culm from the bank into a wooden trough laid along the side of the hill to the head of the slope. From the troughs the slush is discharged into wooden pipes through which it flows into the mine. The building shown at the left of Fig. 1 is the engine house for this slope.

A similar method was used to flush the old Elmwood colliery workings in the south dip of the same seam. This colliery was almost directly across the Mahanoy Valley from the Tunnel Ridge colliery. As, at the Tunnel Ridge colliery, a gangway was driven that ran along the faces of the old breasts, and culm piped in this gangway was allowed to flow down the steep pitching breasts until all were filled.

In contrast to the short distance the slush is carried at Tunnel Ridge colliery and the ease with which it is done, is the distance it is carried at the North Mahanoy colliery, where six sections of conveyers are used to take the culm from the breaker to a distributing point, the last two sections of which are shown in Fig. 3. Here the dirt is elevated dry to the top of a hill where water is added to it and from there it flows through troughs and wooden pipes to bore holes, and down them into the mine.

At the Mahanoy City colliery the screenings as they flow from the breaker are caught in settling tanks (Fig. 4), so that the excess water flows away and only the dewatered culm is elevated to the distributing points. Here water is added and the slush is settled in V-shaped tanks 8 feet deep, placed on each side of a trough. Each tank has a bottom gate opening into the conveyer trough, through which the slush flows to a conveyer in the bottom of the trough. Two men attend to the gates, opening them when a tank becomes full of slush.

Two settling tanks are also used at the West Shenandoah colliery; but here the purpose is to thicken the slush as it flows into the mine. In this case the chambers being filled have a pitch of 45 degrees and not as much water is needed to deposit the slush as if the pitch was less. Moreover, when there is less water to drain away, the pressure on the batteries in the mines is less. The proportion between water and screenings is made as nearly two to one as the men can guess with the eye.

Fig. 5. Conveyer Lines at Shenandoah City Colliery

At the Shenandoah City colliery all the waste material from the breaker is sent into the mine. The slate and screenings are brought out on separate conveyers; the screenings are dumped directly into the first of two flights of conveyers, shown in Fig. 5, which carry them across a railroad track and up to a distributing tower, shown in Fig. 6, where enough water is added to flush them into the mines through several bore holes; the slate is carried from the breaker to a crusher where everything over $2\frac{3}{4}$ inches in size is broken in a No. 3 Williams crusher, and then conveyed back to be mixed with the breaker screenings. The ashes from the boiler house are also mixed with the slate and screenings. When the breaker is running, the ashes are mixed continuously, any clinkers being broken with the slate. A concrete bin has been built into which a week's supply of ashes may be flushed, if necessary, when the breaker is idle, and from which the ashes can be flushed when the breaker is running. The composition of the slush is 50 per cent. screenings, 44 per cent. slate, and 6 per cent. ashes.

About 19 men are employed on the flushing at this colliery; two men take care of the conveyers, two men are employed in the crusher house, and about 15 men are employed underground building batteries and taking care of the pipe lines.

The slush is generally run into the mine through 6- or 8-inch bore holes, though it may flow down slopes or shafts, and where there is a convenient opening on the outcrop it may be carried in through it. One bore hole can be used to flush several seams though it is better to have a separate bore hole for each seam, especially if the breaker is dependent upon the flushing to take care of the waste. Then if one bore hole gets blocked, another can be used. It is also more convenient for the inside working, causing less delays, as the changes in the flow of the slush are controlled by one man at the breaker.

The wooden troughs used to carry the slush to the bore holes may be lined with old sheet iron from the breaker or with split terra cotta pipes. The terra cotta pipes will last the longest of any lining.

The wooden trough branching to the right in Fig. 6 is terra cotta lined. At the end of the trough, the slush can flow two ways, one way leads down a slope where the slush flows in an open trough, the other way leads to a bore hole a few feet away. From the bore hole the slush flows under pressure through a pipe line, 4,000 feet long, in the mine. Where it is necessary to get as much head as possible, or where the grade is too light for slush to flow in troughs, it may be carried in pipes on the surface.

The general practice is to use wooden pipe for conducting the slush inside, though cast-iron pipe is sometimes used. The life of a pipe is dependent upon the kind of material passing through it and the grade on which it is laid. Breaker screenings will not wear a pipe as quickly as ashes and broken slate. A 6-inch wooden pipe line at West Shenandoah colliery, which carried crushed slate for a distance of 1,500 feet on a considerable grade, was worn out after passing about 16,000 cubic yards, whereas wooden pipes carrying breaker screenings have lasted 1, 2, and 3 years. Wrought-iron pipe is often used where ashes are being flushed separately.

As long as the pressure remains in the pipe the slush can be carried up hill and down dale, but the pyrites in the slush is likely to separate and block the pipe where there is a sag and the velocity becomes low.

In flushing any place, the lower end of the chamber or opening is closed with a battery built of props and $1\frac{1}{2}$-inch plank. In building this battery hitches for the ends of the timbers are cut in the bottom rock and in the top rock or top coal. Where the seam is mined all at one time the hitches can be cut in the bottom and top rock, but at places, such as in the Mammoth seam at Kohinoor, the top hitch is necessarily in coal. The depth that is given to the hitches will depend on the weight the battery must support and the character of the rock or coal. When the pitch of the seam is heavy, there is greater pressure upon the battery than where the seam is flat, necessitating the use of heavier props, and putting them closer together. On pitches of 20 or 30 degrees or more, 12- or 14-inch props, or even larger, are used. They are placed 2 feet apart, with braces between to hold them in place. Care must be taken to place the props with their inside faces in line, so that the planks can be securely fastened.

A double layer of $1\frac{1}{2}$ inch plank is placed on the inside of the row of props, and neatly hitched into the coal on each side, the openings or cracks being stopped with hay. Great care must be taken when there is much pitch to the seam, for, a small hole in the battery will allow a large amount of slush to escape.

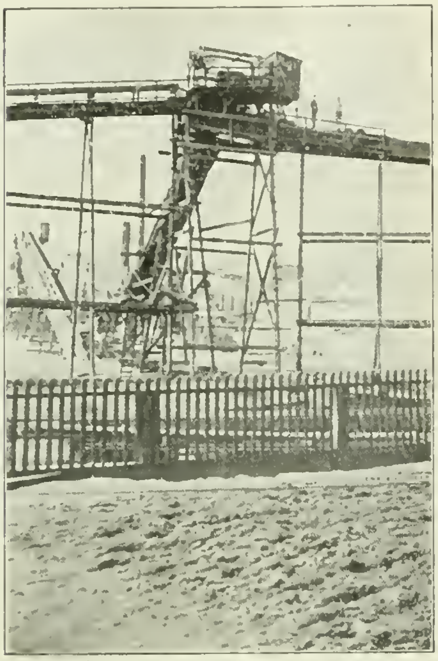

Fig. 6. Distributing Tower at Shenandoah City Colliery

In flat seams the batteries have comparatively little weight against them, and draining the water from the slush is not difficult. An opening a couple of feet wide may be left at the center of the battery across which a board can be placed as the chamber fills up, and over which the water will flow. Besides, the battery for a flat seam, if not too thick, can be made out of 6-inch props and 1-inch boards.

At the Alaska colliery near Mt. Carmel, where the coal seam has a pitch of 15 degrees or more, the slush is discharged alternately into one of two rooms. After flowing for an hour or two into one room, it is shut off to allow the slush water to drain through the cracks in the battery. During this draining period the slush is flowing into the second room for 1 or 2 hours, or, until it is again turned into the first room.

At the Indian Ridge colliery, at Shenandoah, Pa., as well as at other collieries, the water drains off through wooden pipes placed in the batteries. These pipes are made of inch boards and are 4 inches square inside. On their sides saw cuts about a foot long are made, four series of slits being made in each board. These slits allow the water to pass, while holding back the culm. By the use of these, the slush in the chamber is dewatered and there is not so much weight on the battery, the culm at the bottom being packed tight. Three, four, or six pipes may be placed in a battery.

Another method where the seam has not much pitch is to place a couple of square board pipes up a breast and have an upright branch pipe into which the water can flow. When the dewatered material reaches the top of the upright, the pipe is closed with a board.

A chamber having a pitch of 5 degrees or more can be filled if the slush is poured in at the high end. If ashes are used alone a pitch of 10 degrees or more is needed, as ashes, being porous, allow the water to drain away quickly and they will not flow in a stream as readily as breaker screenings. The slush has more or less mud in it, and it is this, with the mixture of various sizes of materials, together with their low specific gravity, that makes it flush so well. Slush can be poured into a caved area and will fill the spaces between the broken rocks.

In filling the Holmes seam at the Tunnel Ridge colliery, no attempt is made to control the flow of the slush by means of batteries. The reason for this is that the gangway from which the breasts were driven has caved so that the mouths of the chambers are not accessible. Moreover it is not desired to rob the pillars there, the main idea being to support the town. Therefore, the slush is allowed to flow as it will. As soon as one breast becomes full, the slush is poured into the next breast.

That there may not be a sudden rush of water which might have become dammed behind the slush, a dam, with a relief pipe, is built in a tunnel leading to the old workings through which the water can escape.

It is easy to reopen a road through caved territory after it has been flushed. For the flushing affords fine support for the ground on each side of the road, as shown in Fig. 8.

Where the seam is flat the flushing pipes are fastened along the roof for the full length of the chamber. Then as the chamber fills and the slush rises up to the pipe, a length of pipe is taken off and the flushing continued In this case the seam cannot be filled completely, a little space always being left between the flush and the roof. The flushing should always be done from the highest point in the chamber.

At collieries where each breast is filled separately, the breakthroughs between breasts are closed with a battery. At Indian Ridge the slush pipe enters the top of a heading in the middle one of three breasts, and as that becomes full up to a breakthrough the slush flows into the breasts on each side until they fill to the breakthrough, when the center breast will begin to fill again. As an average of 592 cubic yards of slush are put into this mine each day. a series of three breasts are filled in about 9 or 10 days.

Screens, generally of $2\frac{3}{4}$-inch mesh, are placed over the mouths of bore holes and pipes. Anything that passes through them will readily flow through 6-inch pipes.

The most common trouble in flushing is to have the pipe become blocked. This will happen if the pipe is not full of clear water without solids before flushing is begun, and if the pipe is not cleaned out with clear water after flushing is stopped. Water must be turned into the pipe and be flowing before the slush enters, and must be kept flowing after the slush is stopped. The slush should be so mixed that there is a constant uniform flow. Sudden rushes of slush are likely to block the pipe. To quickly locate a block, holes are bored in wooden pipes and closed with plugs. The pipe is likely to clean itself out below any block, and by knocking the plugs out the blocks can be located and the pipes need only be taken apart at the block.

Wooden pipes should be turned after being in one position for a certain length of time. On very light grades, it may be necessary to turn them only every 6 months. On steep slopes they had better be turned every few weeks to distribute the wear evenly over the interior and thus lengthen the life of the pipe.

It might be expected that when roadways are cut through the slush it would not stay in place on the sides, but the contrary is true. Enough moisture is retained so that it will stand with a vertical side, and it will not require lagging unless it becomes watersoaked.

In drawing pillars after flushing, regular systems are followed if possible. One method is to take out every third pillar, and it is mined from the gangway advancing. In this case ventilation is maintained by means of a door on the gangway and a brattice up to the working face, as no breakthroughs can be maintained. As soon as the pillar is drawn, a battery is built and the place occupied by the pillar flushed. When one pillar has been drawn the next one is mined, care being taken that the pillars on which work is being done are three apart and that all rooms in between are flushed.

When the pillars are irregular, no system can be followed. Pillars in underlying seams can be taken out without disturbing those in seams above, but it is best to take them out simultaneously and have the rooms flushed in sections one over the other.

The Coal Fields of Ohio

A Description of the Location, Extent, and Quality of the Principal Coal Seams of the State

*By Wilbur Greeley Burroughs**

The coal fields of Ohio are situated in the 30 counties forming the southeastern portion of the state, being included in the Northern Appalachian coal field. Within the Ohio fields, the rocks of the Carboniferous system, in which all the coal seams are included, constitute the surface rocks of about 10,000 square miles. This does not mean, however, that under any given point coal of economic importance can be found, for there are large areas within the general boundary of these coal fields, where, although the rocks are of Carboniferous age, coal seams never were formed; other areas where the coal beds that once existed have been entirely removed by erosion; and still other areas where the coal seams are too thin, or too impure, to possess any commercial value. The Carboniferous formations of these fields are regular and simple of structure, containing few, if any, folds in the strata, only a few low and gentle arches; and the faulting that has taken place has been very slight.

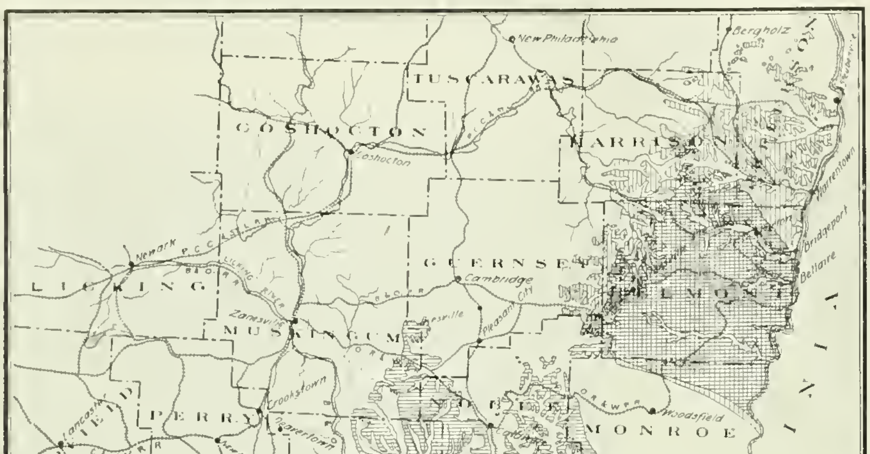

Fig. 1. Map Showing Coal Fields of Ohio

The coal measures of this region are divided into the groups shown in Table 1.

There are at least 16 beds present in the series, and of these the more important ones will now be considered.

Coal No. 1, The Sharon Coal.—R. M. Haseltine in the Twenty-second Annual Report, Part 3, United States Geological Survey, states that this coal occurs chiefly in the northeastern portion of the state, and was probably formed in irregular depressions in the previously deposited conglomerate that forms the base of the Upper Carboniferous. Along the western margin of the coal measures, the No. 1 coal is separated from the conglomerate by about 50 feet of shale. In the northern portion of the field the coal usually has well-defined joints, and comes from the mines in large blocks. It is, therefore, sometimes called Block coal. In Jackson County, No. 1 coal has been mined under the name of the Jackson Shaft coal. Other names applied to this coal are Massillon, and Brier Hill coal.

Coal No. 2, Wellston Coal.—As seen from the accompanying section, Fig. 2, this coal is found between the two divisions of the Massillon sandstone of the Pottsville. Where both No. 1 and No. 2 beds are present the distance between them, according to Haseltine, ranges from 45 to 75 feet. In northern Ohio, No. 2 rarely becomes more than 2 feet thick. At Wellston, in Jackson County, it attains a thickness of 4 feet.

Coal No. 3, Lower Mercer Coal. This coal belongs to the Pottsville

Table 1

	Classification			
	Old		New	Feet
Permian		Upper barren measures	Dunkard	950
Pennsylvanian	4.	Upper coal measures	Monongahela	250
	3.	Lower barren measures	Conemaugh	500
	2.	Lower coal measures	Allegheny	600
	1.	Pottsville conglomerate		300

* Geologist, Oberlin, Ohio.

formation. Where thick enough to justify mining, this seam is generally so mixed with slate as to make an unsatisfactory fuel.

Coal No. 3a, Upper Mercer Coal. This coal is of somewhat better quality than the Lower Mercer, but the quality is unreliable.

Coal No. 4, Lower Clarion (Brookville) Coal.—This seam is included in the Lower coal measures. It is of little importance.

Coal No. 4a, Upper Clarion Coal. This coal of the Lower coal measures, is important in the four counties of Vinton, Jackson, Lawrence, and Scioto. It is occasionally mined to a small extent in other parts of the state. The coal lies directly below the ferriferous limestone, or in some places, is separated from the limestone by a thin bed of shale. This Clarion coal being in the same regions geographically as the Wellston coal, forced it to compete with the Wellston coal, and thus has retarded its development.

LEGEND FOR FIG. 1

Geological Series.—The Pennsylvanian Series comprises the following: *I*, Pottsville Conglomerate; *II*, Lower Coal Measures, Alleghany; *III*, Lower Barren Measures, Conemaugh; *IV*, Upper Coal Measures, Monongahela. The Permian contains *V*, Upper Barren Measures, or Dunkard.

Local Names.—*A*, Coal No. 1, Sharon, Brier Hill, Jackson Shaft; *B*, Lower Massillon; *C*, Wellston, Quakertown; *D*, Upper Massillon; *E*, Lower Mercer, Flint Ridge Cannel; *F*, Upper Mercer, Bruce; *G*, Tionesta; *H*, Homeward, Piedmont; *I*, Lower Clarion, Brookville; *J*, Upper Clarion; *K*, Gray ferriferous, Putnam Hill; *L*, Lower Kittanning, Mineral Point, Leetonia, New Castle; *M*, Middle Kittanning, Hocking Valley, Straitsville, Sheridan; *N*, Upper Kittanning; *O*, Lower Freeport; Hatcher, Steubenville, Whan; *P*, Stilwell, often conglomerate; *Q*, Upper Freeport, Cambridge, Big Vein, Waterloo; *R*, Mahoning; *S*, Grof, Stripe vein, Brush Creek; *T*, Norwich, Patriot; *U*, Pittsburg; *V*, Pomeroy, Redstone in Pennsylvania and West Virginia; *W*, Meigs Creek, Sewickley in Pennsylvania; *X*, Macksburg, Waynesburg.

Strata.—*1*, Conglomerate; *2*, Sandstone and shale; *3*, Fireclay; *4*, Coal No. 1; *5*, Gray shale; *6*, Sandstone; *7*, Shale; *8*, Fireclay; *9*, Coal No. 2; *10*, Shale and sandstone; *11*, Fireclay; *12*, Coal No. 3; *13*, Limestone, with iron ore; *14*, Coal No. 3a; *15*, Shale and sandstone; *16*, Coal No. 3b (Haseltine); *17*, Shale and sandstone; *18*, Coal No. 4; *19*, Sandstone; *20*, Fireclay; *21*, Coal No. 4a; *22*, Limestone; *23*, Shale and sandstone; *24*, Fireclay; *25*, Coal No. 5 (Haseltine); *26*, Gray or black shale; *27*, Limestone; *28*, Fireclay; *29*, Coal No. 6; *30*, Gray or black shale; *31*, Sandstone; *32*, Fireclay; *33*, Coal No. 6a (Haseltine); *34*, Shale and sandstone; *35*, No. 6a (Orton), Coal No. 6b (Haseltine); *36*, Limestone; *37*, Fireclay; *38*, Black band iron ore; *39*, Buff limestone; *40*, Gray shale;

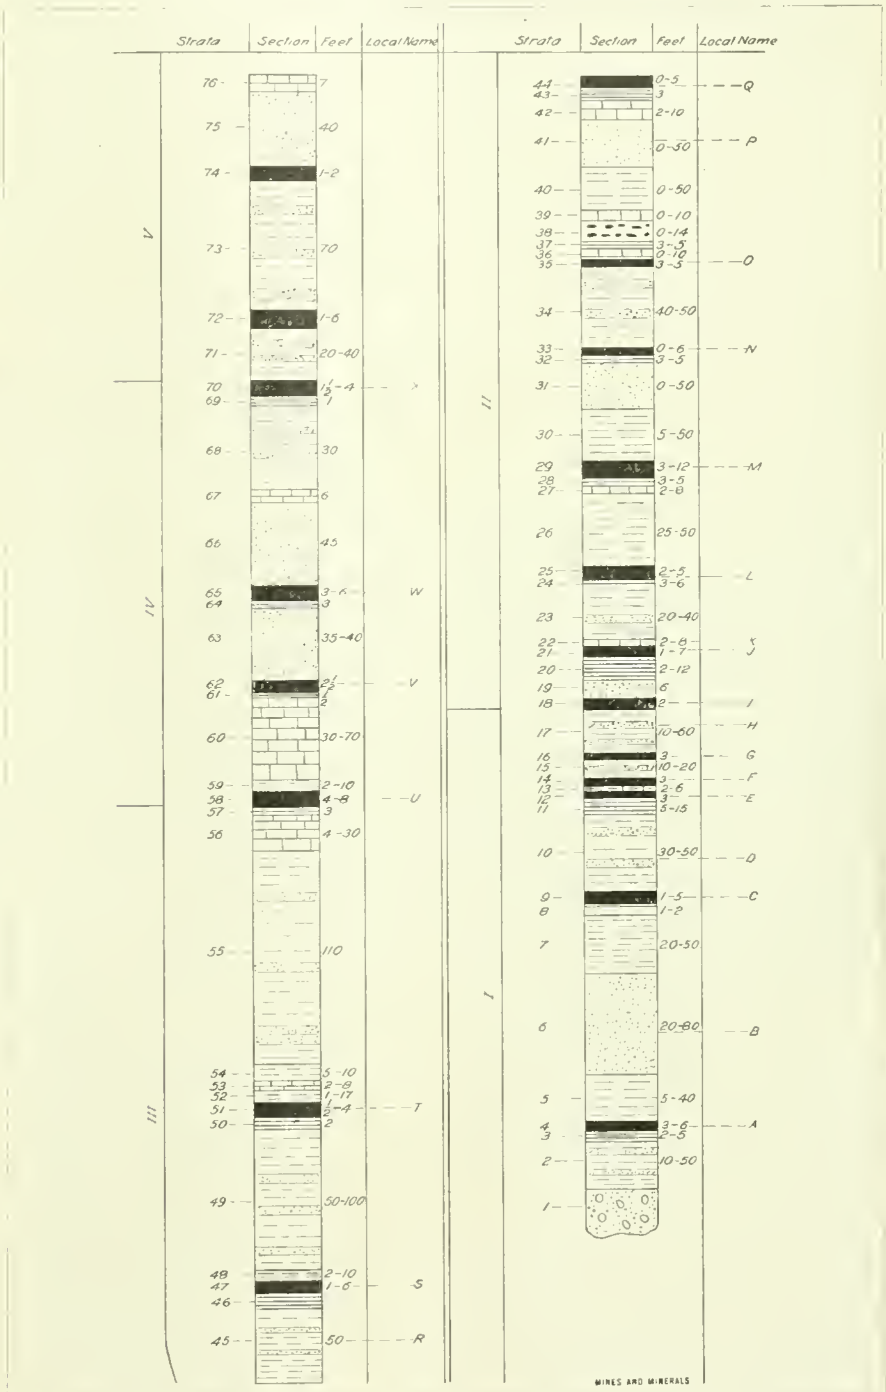

Fig. 2. Section of Ohio Coal Strata. For Significance of Numbers, Letters, Etc., See Legend Accompanying

41, Sandstone; *42*, Limestone; *43*, Fireclay; *44*, Coal No. 7; *45*, Sandstone and shale; *46*, Fireclay; *47*, Coal No. 7a (Haseltine); *48*, Shale; *49*, Shale and sandstone; *50*, Fireclay; *51*, Coal No. 7b (Haseltine); *52*, Shale; *53*, Crinoidal limestone; *54*, Shale: *55*, Shale and sandstone; *56*, Limestone; *57*, Fireclay; *58*, Coal No. 8; *59*, Black shale; *60*, Limestone; *61*, Fireclay; *62*, Coal No. 8a (Bownocker, most recent data), Coal No. 9, Haseltine); *63*, Sandstone; *64*, Fireclay; *65*, Coal No. 8a, (or 10, Haseltine). Coal No. 9 (Bownocker, most recent data); *66*, Sandstone; *67*, Limestone; *68*, Sandstone and shale; *69*, Fireclay; *70*, Coal; *71*, Sandstone and shale; *72*, Coal; *73*, Sandstone and shale; *74*, Coal; *75*, Sandstone; *76*, Limestone.

Coal No. 5, Lower Kittanning Coal. This bed of the Lower coal measures, can be traced from Mahoning County southwest across Ohio to Lawrence County on the western side of which county it is important, being known as the New Castle coal. The Lower Kittanning seam is from 20 to 30 feet above the ferriferous limestone. In thickness this coal is generally less than 3 feet, although in a few places it increases to 4 or 5 feet. It is at its best in the northern part of Columbiana County, especially near Leetonia. The Lower Kittanning is a good coking coal.

Coal No. 6, Middle Kittanning Coal.—The area which this seam, also of the Lower coal measures, covers, coincides nearly identically with that of the Lower Kittanning. Edward Orton, former State Geologist of Ohio, states that so far as Ohio is concerned, this Middle Kittanning coal is in reality the Upper Kittanning seam, but that in the Pennsylvania scale this Middle Kittanning seam is identified as the first seam above the Lower Kittanning coal, while a distinct seam is found there, in some counties, at a somewhat higher place in the scale. Orton traced the outcropping No. 6 seam from the Pennsylvania state line in the Ohio Valley, through the Yellow Creek Valley, under the divide that separates Tuscarawas water from Yellow Creek, to the Little Sandy. It can, also, be directly connected with the Pennsylvania series through the Mahoning Valley, as was first shown by I. C. White.

This No. 6 seam, extending entirely across the state from Columbiana to Lawrence counties is mined in a greater or less degree from the Pennsylvania line to the Ohio River.

The structure of the No. 6 seam in the Hocking Valley field, which field has for its only rival the Pittsburg field of eastern Ohio, is given by Doctor Orton as follows:

"In structure the Hocking Valley coal always has the three benches of the normal Middle Kittanning seam, with some addition of its own. In other words, the great deposit consists of the normal three-bench seam of the Middle Kittanning system covered and reinforced by a Hocking Valley supplementary seam, the latter consisting of one or two, or more benches. The supplementary seam is separated from the original seam by a thin shale parting which is often disregarded in mining, but which is for the most part distinctly recognizable when looked for. The supplementary seam of the Hocking Valley is, in the general view, counted with the upper bench of the normal seam, the whole being known as the top coal. It has a maximum thickness of 10 feet. All the thickness of the Hocking Valley seam in excess of 6 feet, and in many parts of the field in excess of $4\frac{1}{2}$ feet, is to be credited to the supplementary seam. There are numerous irregular partings in this top coal when it becomes thick, only one of which is widely extended and measurably regular. A 4-inch black slate, known as the third slate, and charged with Sigillaria impressions, is found 8 to 9 feet above the bottom of the great deposit, everywhere throughout Monroe Township in the Sunday Creek Valley. As it now appears, it is the same horizon at which a constant layer of cannel coal is found throughout the western portions of the deposit. The coal above the slate becomes a rider seam. It runs too high in ash in most of the field where it occurs to be fairly marketable. It reaches a maximum thickness of 4 feet, but most of it is left in the mines. The composition of the No. 6, coal throughout the Hocking Valley field is fairly uniform. Taken as a whole, it is an open burning coal, but the lower bench, burned by itself, is somewhat cementing. It is distinctly laminated and holds a moderate proportion of mineral charcoal. It ignites easily, swells slightly in burning, and leaves a white or gray ash. It is well approved for steam generation, and also, for rolling mill fuel. To household use it is admirably adapted, rivaling in this line of service the block coals of the Mahoning and Tuscarawas valleys."

The Middle Kittanning coal is of less value in Columbiana County than in any other county of the state in which it occupies as wide an area. Throughout the northern and central portions of this county, it is less than 1 foot thick. In the Ohio Valley, it is known as the Block Bed, and as the Hammondville Strip Bed. About East Liverpool, it is known as the Dry Run coal. Here its quality is so excellent that it is extensively worked in small mines, although but 20 to 32 inches thick, the 32 inches being of rare occurrence.

Coal No. 7, Upper Freeport Coal. The Freeport coal, Lower coal measures, can be traced across the state, and is similar in many ways to the Kittanning coals. It is less persistent in thickness, however, than the Middle Kittanning seam, and is of smaller value. J. A. Bownocker, present State Geologist of Ohio, says in Bulletin 9, of the Ohio Survey, that the best deposits of Upper Freeport coal are found in the eastern and northeastern parts of Ohio. The Cambridge field, including parts of Guernsey and Noble counties, forms one of the most valuable coal deposits in Ohio. In 1906, the output from this field was somewhat over 3,000,000 tons.

In the northeastern part of Lawrence, and the adjacent part of Gallia County, is an important coal bed.

This field is known as the Waterloo field. Due to lack of transportation facilities the coal of this field has been mined, up to that time, only for local use.

Between the Waterloo field and the Cambridge field, the coal seam is irregular. Very little of the coal is shipped, it mostly being mined by the farmers for their own use.

No. 8 Coal, Pittsburg Coal.—The Pittsburg coal of the Monongahela formation, of the Upper coal measures, is the most valuable coal seam in North America. It is important in the states of Pennsylvania, West Virginia, Ohio, and Maryland. White estimated the area of workable Pittsburg coal at from 6,000 to 7,000 square miles. Orton estimated that Ohio alone contains 1,250 square miles, but this included the Pomeroy coal, which Bownocker has determined lies above the Pittsburg seam.

Bownocker in Bulletin 9, of the Ohio Survey, states that the area in Ohio underlaid by the Pittsburg coal, forms two distinct fields, an Eastern field, and a Southern field. The most important of these two fields is the Eastern field which includes nearly the whole of Belmont County, the southeastern part of Harrison, the southern part of Jefferson, the extreme eastern part of Guernsey, the northeastern part of Noble, the northern part of Monroe, and the northern part of Washington counties. The Southern field includes the southwestern corner of Morgan, the eastern part of Athens, the northern part of Meigs, and the southeastern part of Gallia counties.

The Pittsburg coal has a section which is similar over most of the area in Ohio and other states. The section is as follows:

	Feet	Inches
Roof coal	1	
Draw slate		10
Breast coal	2	3
Parting (shale)		½
Bearing in coal		2
Parting (shale)		1
Brick coal	1	5
Parting (pyrites)		1½
Bottom coal	1	3

The above section, taken at the Neff mine, No. 2, near Bellaire, Ohio, may be considered normal, and is found in this order in Pennsylvania, West Virginia, Maryland, and Ohio. Geological Survey of Ohio, Bulletin No. 9.

The order is so persistent that as a general rule, this coal bed may be easily identified. Occasionally, however, the parting between the Brick and Bottom coals is wanting, but even then, there is usually a bedding plane between. Along the Ohio River, in Jefferson and Belmont counties, the Pittsburg seam is at its best for Ohio. Here the section is as given. Farther west, along the western border of Belmont County, and near the western margin of the Eastern field, the section is less regular. The main seam or the portion of it that is considered merchantable is generally from 4 to 6 feet thick.

Coal No. 8a, Pomeroy, or Redstone Coal.—Prior to 1907, the Pomeroy, of the Upper coal measures, was classed as Pittsburg, but this classification has been proven to be incorrect, the Pomeroy seam being shown to be higher than the Pittsburg. Since the Pittsburg coal is known as No. 8, and the Meigs Creek coal as No. 9, Doctor Bownocker has numbered the Pomeroy "8a." The Pomeroy coal is mined in Meigs, Gallia, and Lawrence counties. It is the equivalent of the Redstone coal seam of Pennsylvania, and West Virginia.

Bulletin No. 9, of Ohio Geological Survey, states that the Pomeroy is at its best in Meigs County, where it occurs above drainage, and in the southern part becomes one of the important coal beds of Ohio. In the northern part of this county, the Pomeroy is underlain by the Pittsburg, a thin bed of limestone usually separating the two seams, while further south, the Pittsburg coal entirely disappears.

The Pomeroy seam is overlain by massive sandstone, which sometimes is in direct contact with the coal, and occasionally is separated from the coal by shale beds of varying thickness. The sandstone, however, is very persistent, and is found over wide areas.

Coal No. 9, Meigs Creek Coal.—This coal, of the Upper coal measures, is considered to be the equivalent of the Sewickley of Pennsylvania. The late Prof. C. N. Brown gave this seam its name from the stream that drains the central part of the territory where the No. 9 coal occurs. This coal generally is found from 80 to 100 feet above the Pittsburg seam. Bulletin No. 9, of the Geological Survey of Ohio, states that while the Meigs Creek coal "is due in the hills all the way from Jefferson to Lawrence counties, it is found in workable quantities only in Belmont, Harrison, Monroe, Washington, Noble, and Morgan counties. The coal lacks the persistence and regularity of its neighbor, the Pittsburg, or No. 8, seam. Sometimes, it is divided into two parts or benches by a prominent bed of shale or clay, but more often this structure is wanting. Sometimes the seam is without any parting, but usually one or more bands of shale, clay, or pyrites is found. Both floor and roof are irregular, rising or dipping, and thus modifying the thickness of the seam. Especially is this true of the roof which in a short space may occasionally entirely cut out the coal.

"These features indicate that conditions were not uniform during the deposition of the coal and the rock which forms the roof. Probably these deposits were laid down in coastal swamps or marshes that were partially disconnected, the conditions of deposition being slightly different in the different basins. The absence of the coal where due may be a result of water too deep to permit of the coal plants flourishing, or just the reverse, that the water was so shallow the vegetation after falling was not properly submerged. The later appears more probable, for with deeper waters marine fossils might be expected."

The quality of the coal is inferior to the Pittsburg. In spite of this, however, the Meigs Creek seam is an important one, and its value will increase as the Pittsburg seam below becomes more and more exhausted.

Effect of Coal Mining on the Surface

Experiments Regarding Increase of Volume of Crushed Material and Extent and Direction of Movement of Broken Strata

IN VIEW of the present widespread interest in the effect of coal mining on the surface in various American coal fields, and particularly in the anthracite regions of Pennsylvania, a paper on the subject by M. Fayol, Director of the Commentry Mines, etc., published in the transactions of the Societe de l'Industrie Minerale for the year 1885, translated into English by Mr. H. F. Bulman of the British Society of Mining Students, is of peculiar interest.

In his translation, Mr. Bulman notes the fact that Mr. Fayol reviews the state of the question up to 1885 in an appendix, but that it seemed best to him to put this in the translation.

Mr. Fayol refers to the opinion of a commission of Belgian engineers, in 1839, that the working of a coal seam at a depth of 100 meters (109 yards) would not damage the surface.

In 1868, four engineers were commissioned by the Prussian government to collect information on the question of the "influence that mine workings may have on surface buildings, in the coal fields of England, Belgium, the North of France, and Rhenish Prussia." According to these engineers, it was considered in Belgium that when the coal is entirely removed, the most careful "packing" gives no guarantee against damage to surface buildings; the packing only lessens the sinking; that the surface may be protected by leaving pillars, but in order to make this method effective, only half the area of the coal seams must be removed.

In England, the opinion was (1) that the working of the coal at every known depth may affect the surface, but that at depths greater than 400 meters (437 yards), it can only cause damage to certain buildings, such as cotton mills.

(2) That the surface may be effectively protected by leaving pillars of coal, or in the case of longwall working by "stowing."

M. Von Dechen, Chief Inspector of Mines in Prussia, agreed entirely with this opinion. Regarding what is called "The Law of the Normal," viz., that fracture of the strata takes place in planes at right angles to the inclination of the seam, passes through the perimeter of the area worked, and extends up to the surface whatever the depth, M. Von Dechen thought that with seams having moderate inclinations and regular strata, this was so, but not with highly inclined seams.

Experience at the mines of Montrambert and La Beraudiere, shows that the amount of sinking is about 30 per cent.* of the thickness of the seam The movements produced by the working of a seam 2.10 meters thick (6 feet 10 inches), lying at an inclination of 35 degrees to 90 degrees made themselves felt at an angle of 45 degrees with the horizontal.

At another place the sinking of the surface varied from 25 to 35 per cent. of the thickness of the seam, at a depth of 70 meters (230 feet), of shales more or less hard and compact, covered by 30 or 40 meters (98 feet to 131 feet) of sandstone beds.

M. Fayol gives a summary of M. Dumont's memoir, and refers to the following points, which are not mentioned in the writer's extracts from this memoir in No. 2 of the present volume of the Journal of the British Society of Mining Students.

The inclination of the strata lessens the depth of the subsidence, but increases the area damaged.

Timbering hinders the beds forming the roof of a seam from breaking, and therefore prevents the increase in their volume, which takes place when they break. This increases, rather than diminishes, the subsidence at the surface.

*This is much less than what was found to occur by Mr. J. L. Dixon in his experiments. See No. 2, Vol. XII, of the Journal of the British Society of Mining Students. The difference is probably due to the different systems of working.

The period during which movement of the surface may continue is very uncertain. It is assumed to be from 10 to 12 years in Belgium and at Sarrebruck. In other places it has been as long as 20 and even 50 years.

The draining of old workings, or the flooding of a mine may bring about fresh movement a long time after the original movement has ceased.

The Colliery Owners' Association published a reply to M. Dumont. They agreed with his conclusions as to horizontal seams, but as to inclined seams they thought "The Law of the Normal" would not hold good. The fracture of the lower extremity of the working will occur in inverted steps (gradins renverses) and the fracture at the higher extremity in "gradins droits" (straight tiers). The average inclination of these steps will fall between the normal to the seam and the vertical.

Regarding highly inclined seams, the Colliery Owners' Association stated that the fracture by crushing must be considered, and this, according to Coulomb, takes place at an angle of 45 degrees. Under the action of this new force, combined with that which tends to break the bed by bending, fracture will take place along a line intermediate between these two directions, which will be further from the normal as the inclination is greater.

They agreed with M. Dumont about the effect of faults and vertical strata in altering the direction of the planes of fracture, but they held that soft beds ought to be considered coherent strata, lying unconformably upon the coal measures, and that their effect would therefore be to alter to a vertical direction the planes of fracture. They quoted two examples to prove that this is so.

On the whole they thought that M. Dumont's theory was unsatisfactory, and often of no practical use, and that the only rule to follow was the examination of the special facts which accompany each particular case.

Callon, like Dumont, believed in the law of the normal, which was promulgated in 1858 by Gonot, a leading Belgian engineer.

M. Haton de la Goupilliere, the professor of mining at Paris, expresses much the same opinion as Callon, but with some reservations. He says: "In working by a system which permits the roof to fall (foudroyage) the movement of the strata gradually gets less, and stops at a certain level; with longwall and stowing (remblayage) the movement is almost independent of the depth; the principle of leaving sufficient pillars can alone ensure the absolute safety of the surface. It is impossible that the law of the normal can be found completely verified in practice. . . The knowledge of the laws which govern the occurrence of fractures across strata is still enveloped in obscurity, and that is explained by the great number of conditions on which the result depends, and also by the difficulty and rarity of observations" (Cours d'exploitation des Mines, 1884).

M. Fayol, after long observations and numerous experiments, believes "that the movements of strata are limited by a kind of dome which has for its base the area worked out, and that the amount of movement is less as it is further from the center of the excavation. He describes his observations and experiments which have led him to his conclusion as follows:

BENDING OF PIECES TIED TOGETHER AT THEIR EXTREMITIES

A beam supported at its two ends will bend under its own weight, the deflection increasing as the points of support are further apart. If two similar beams are placed one above the other, the lower beam will bend more, and the upper less than if there was only one. If the number of beams is increased, the lower one bends more and more, but only up to a certain point, after which it remains stationary, whatever the number of pieces added. The lower beam is always bent the most, and the amount of bend gradually diminishes in the upper beams until at a certain height the beam remains horizontal. The limit of the deflected parts of the different superposed beams is a curve, which starts from the points of support of the lower beam, and rises up to the upper beam, which has not participated in the movement.

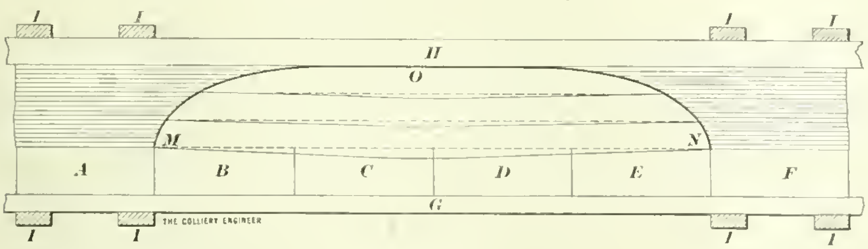

Fig. 1

The following experiments were made: Iron bars 50 millimeters wide by 5 millimeters thick (1.9 in. ×.19 in.) were placed one above the other horizontally on blocks of wood, *A*, *B*, *C*, *D*, *E*, *F*, in Fig. 1. These blocks rested on an iron table *G*. Upon the upper bar was placed a strong iron rule *H*. Then by means of stays *I*, and bolts, the rule and the table, and consequently the iron bars, were strongly bound together.

That done, the wooden blocks *B*, *C*, *D*, *E*, were removed over a length of 4 feet, and the bending of the iron bars was noted.

It was found that the deflection of the lower bar was 5 millimeters (.19 inch), of the tenth 3.25 millimeters, of the twentieth 1.75 millimeters, and that after the thirtieth bar there was no more bending. The limit of the deflections is the curve *M O N* shown in Fig. 1.

The same experiment was tried with flat aloe ropes, and with straps of canvas and india rubber in place of the iron bars.

With straps of canvas and india rubber, the curve of the limits of deflections, that is to say, the limit of the zone of subsidence had a height nearly equal to the distance between the points of support; this height was about one-third of the same distance for the ropes, and one-sixth for the iron bars. Wood and rocks also bend in a manner similar to the materials mentioned.

In the case of a roadway of a mine covered with beds of sandstone and shale, the lower bed may be much sunk and cracked, but the second bed will be less so, and the third still less; the zone of subsidence is very limited.

PLANE OF FRACTURE OF ROCKS

It is generally believed that the fracture of pieces tied together and loaded between their points of support, occurs perpendicularly to the length of the piece, that is to say, along a vertical plane, if the beams are horizontal.

This is an error, and it is this error which has given rise to the theory of the "Normal." In reality the fracture occurs along a plane inclined over the excavation. To prove this M. Fayol made the following experiment: He bound together in the direction of the stratification, blocks of sandstone and shale, so as to leave outside the support about half their length, as shown in Fig. 2. Then upon the projecting portion, a steady and increasing pressure was exerted, until fracture took place. Of the ten blocks tested, eight broke along a plane inclined as shown in Fig. 2.

INCREASE OF VOLUME

After breaking, rocks generally occupy more space. This increased space varies much according to the

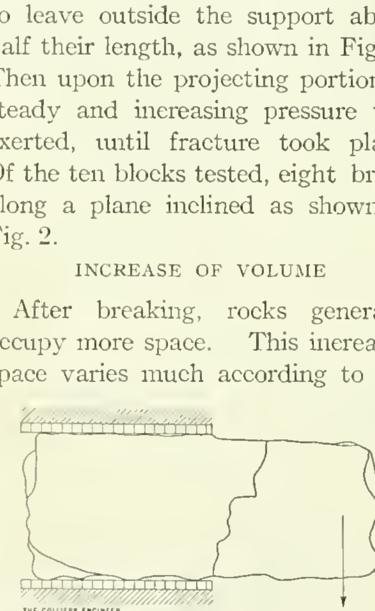

Fig. 2

nature of the rocks, and may be considerable. The results given in Table 1 have been obtained by experiments.

The mixture of sandstone and shale commonly used for stowing, both large and small together, has an increase of about 60 per cent.

COMPRESSION

Strata when broken increase in bulk, which compared with solid strata, varies from 0 to 100, and even 150 per cent. The greater the increase in the bulk, the more easily are the rocks compressed, and their resistance to compression increases rapidly as their volume diminishes. Experiments were made to prove the amount of compression which rocks previously broken or crushed will undergo under various pressures.

The pressures mentioned correspond approximately to the depths of strata of 546, 1,092, 2,730, and 5,460 yards.

Trials were made separately with the rocks reduced to powder, and broken to the size of grains, and with mixtures of grains and powder, but as the state of division of the material did not modify the effect to any extent, the average results are given in Table 2.

The conclusions may be drawn: (1) That the material which ordinarily fills the goaves of mines, always occupies a larger space than it had originally. After an expansion of about 60 per cent., it appears to undergo in workings of from 100 to 300 meters (109 yards to 328 yards), in depth, a compression of about 30 per cent., which leaves a volume about 12 per cent. larger than the volume of the rock *in situ*. The settlement is usually much greater in the middle of the excavations than at their circumferences.

(2) That the cracks and fissures caused by the movement of ground above an excavation remain open in all or in part. The action of water may no doubt considerably modify these conclusions.

EXPERIMENTS ON THE MOVEMENT OF STRATA

Artificial beds of earth, sand, clay, plaster, or other materials were placed in a wooden box, one side of which was glass. The box may have various dimensions. That usually employed was .80 meter (2 feet 7 inches) in length, .30 meter (1 foot) in breadth, and .50 meter (1 foot 7 inches) in depth.

On the bottom of the box were placed, side by side, small pieces of wood of equal thickness, a few centimeters in width, and as long as the breadth of the box. Experiments were made both with one row of these little pieces of wood, and with several placed one above the other.

Upon them were laid successive layers of artificial strata, varying from 1 millimeter to several centimeters in thickness. To note the movement, small pieces of paper, 2 centimeters in length (about ¾ inch), and 1 centimeter in width, were put into the planes of stratification, and on the glass were drawn in ink, strokes covering exactly the lines formed by the paper. These lines enabled the least movement to be followed.

By withdrawing the little pieces of wood, excavations were formed, and movement produced in the artificial strata.

Fig. 3 represents the movements by taking away in the order indicated by the numbers the upper row of wooden pieces, where there were three rows each 1 centimeter (.3937 inch) in thickness.

The first bed (dry sand), which rests directly on the pieces of wood, falls in, as each pillar is withdrawn. The second bed only commences to sink, when a certain number of pillars have been taken away. The sinking is shown at first by a slight curve, which has its greatest deflection toward the center of the excavation. Then the third bed follows the second. The movement gradually extends in depth, and reaches the upper bed after the removal of the twelfth pillar.

After the removal of the seventeenth, the beds have become bent, as shown in the sketch, the limits of the deflection being the curves Z_{13} and Z_{17}. (The index figure of the curves is the number of the last pillar taken away; *e. g.*, the curves $Z_8 Z_4$, indicate the extent of the movements after the removal of pillars 4 and 8).

It is apparent that the zone of sinking is a sort of expanding dome, which grows in proportion as the excavation extends.

The bending of the first bed, hardly observable at first, is considerably increased. The second bed sinks rather less than the first, the third less than the second; the sinking of each diminishes regularly in proportion as it is higher above the excavation. This sinking, in the case of each bed, takes the form of a basin, whose center is on the vertical axis of the excavation.

The lines A_4 A_7 A_8 A_9 A_{11} A_{13} A_{17} are lines followed by the greatest deflections of the sunken beds, after the removal of the pillars 4, 7, 8, 9, 11, 13, 17. These lines nearly coincide with the axis of the domes, which show the limits of the movement.

Throughout the experiments, after the removal of a certain number of the pillars, it was evident that the pressure of the superincumbent mass was strong at the center and weak at the circumference of the excavation.

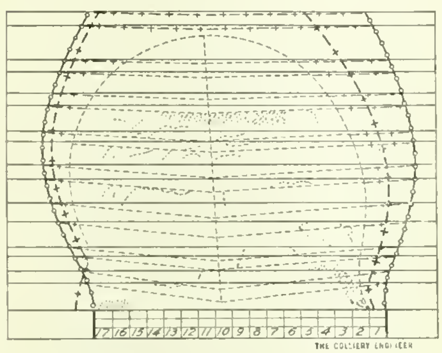

Fig. 5

The second row of wooden pillars was taken away in the order of the numbers on the sketch Fig. 4.

Thus the depth of the excavation was doubled. The lines drawn thus ∘-∘-∘-∘ show the subsidence caused by the removal of the first row of pillars. Those drawn +-+-+-+ show the subsidence produced by the removal of the second row. The shaded portions denote cracks and fissures.

The sinking of the lower beds increased; some of them fell in; the broken ground occupied much more space. The disturbance was greater below, but not at the surface. The line of maximum deflection did not remain vertical, and some of the limiting domes were inclined.

Removal of the third row increased the disturbance caused by the removal of the two former; the fractures of the beds and the spaces between the strata are multiplied; some open more, others close. As before, the movement starts at the lower beds, and reaches the upper, as the excavation extends.

The zone of sinking caused by the removal of the third row as shown in Fig. 5 by the dotted lines is smaller both in depth and width than the two preceding; but in other experiments the settlement produced by the taking of the second and third rows of pillars has been greater than that following the removal of the first.

Figs. 3, 4, and 5 show the position of the beds some minutes after the removal of each row of supports. It is a new state of stability, which continues if no more pillars are taken away.

Similar experiments were made with beds at various inclinations, and it was found that the line of greatest deflection was between the vertical and the normal, and that it departed further from the normal (that is, the perpendicular to the inclination of the beds) in proportion as the beds became more inclined. Whatever the inclination, the subsidence of each bed had always the form of a basin.

When horizontal beds were covered over by beds dipping at various inclinations, that is, resting unconformably on them, the zone of settlement took the direction of the inclination of the beds and its axis tended to become perpendicular to the beds affected.

The lines drawn through the maximum bend of each bed were no longer continuous, but in passing from one set of beds to another were broken and shifted in the direction of the dip of the new set. In all cases the sinking of each bed and of the surface was in the form of a basin.

An experiment was made with horizontal beds, which showed that a block of coal left between two worked-out places, may be of no use to protect the surface above it, because the zones of subsidence due to the excavations on either side, which, as already seen, take the form of domes, may overlap each other between the coal and the surface.

As the area of subsidence increases in proportion as the excavation is extended, it may be asked whether there is any limit in depth to the propagation of the movement, when the excavation extends indefinitely. To answer this, a mass of horizontal beds was isolated round about by a space being left between them and the vertical sides of the box, and then the wooden pillars (in this case .03937 inch thick), were taken away from under the whole area of the mass Being entirely free at the sides, it might be considered to represent a mass of strata lying over the middle of a working of large extent.

On taking away the pillars, the zone of sinking was seen to increase little by little, and to stop at a certain depth; the movement did not reach the surface. The expansion of the lower beds filled the space excavated and the upper beds rested on the fallen rock. The pressure exerted by the upper strata was very much greater in the middle than at the circumference, and in this case, too, the sinking of the strata was in the form of a basin.

The effect of faults was tested, by inserting in a mass of horizontal beds a thin plate of metal, placed at an inclination, and extending the whole width of the beds. This broke the continuity of the beds, and represented a fault without throw. Its tendency was to stop the movement from extending above it, though the sinking occurred as usual on its low side, leaving an opening in the plane of the cut, which extended to the surface.

OBSERVATIONS

The main seam of Commentry, which is generally from 10 to 15 meters (33 feet to 49 feet) thick, is worked by horizontal slices of 2 meters to 2.5 meters (6 feet 6 inches to 8 feet) in height, taken successively in ascending order. Several slices (usually 7 or 8, sometimes only 3) constitute a stage of work (etage); according to circumstances a single stage or several are worked at one time.

The stowing is done, as well as possible, with coal measure rocks procured from quarries.

During the gradual advancement of the face of the working of a single slice or "lift," the roof bends down in a curve from the face, and lays itself on to the stowing behind, and becomes horizontal again where the stowing has quite settled, that is, has been squeezed as far as it will go. This curve moves forward with the advancing face, and somewhat resembles a wave on the surface of water, being very sharp near the face, and gradually coming into line with the horizontal behind. In this movement the roof undergoes at first a drawing out, which cracks it, and afterwards a contraction. The cracks which are formed near the face, close partly behind, where the strata become again horizontal.

When the coal is very tender, the roof no longer bends, with the same regularity. In very hard coal, the movement is neither regular, nor continuous, the roof sometimes stands firm for a long time, hanging over the stowing; then it sinks all at once, and is divided into separate blocks by large fractures.

When several slices are removed in succession one above the other, the coal in the last slice has undergone a good deal of bending before it is extracted, and it is generally broken, the large coal forming a much smaller proportion of the whole than in the first slice. This is a grave defect in the system of working.

Just as in removing a single slice, the roof becomes horizontal, or parallel with the floor of the slice, when the stowing has quite settled, so in the same way, the roof of the seam in the end becomes parallel with the floor, when all the coal has been removed.

EFFECT ON THE SURFACE OF A WORKING OF SMALL EXTENT AND SHALLOW DEPTH

The seam was 1.3 meters (4 feet 3 inches) in thickness, and nearly level. It was worked on a kind of "stall" system, without stowing. Only some band stone, mixed with the coal, was left in the excavation, the roof of which was upheld by nothing but ordinary timbering. When the working had extended to a certain point (the total area being 350 square meters, a sinking occurred, and extended to the surface. The depth was 18 meters (19 yards 2 feet); the strata being composed of sandstone and some thin beds of shale for half this depth, and the rest being artificial ground long since settled.

The working had gone on for 3 months before there was any movement of the roof underground. Then commenced to be heard the ordinary noises which accompany the disturbance of the upper mass. These noises went on increasing; 4 hours afterwards the roof underwent a perceptible lowering, broke the timber over the whole area of excavation, and then fell in with great noise.

At the same time when the fall took place underground, the surface suddenly sunk; a very pronounced basin 50 centimeters (1 foot 8 inches) in depth, and about 30 meters (32 yards 2 feet) in diameter was produced all at once; some cracks appeared at the circumference of the basin. The movement took place rapidly; in 3 minutes the lowering was .5 meter (1 foot 8 inches); during the succeeding 24 hours, it only increased .21 meter (8 inches), and since that, there has been no perceptible movement.

Points to be noticed are:

(1) The settlement in the form of a basin.

(2) The larger area of surface affected than area worked underground.

(3) The irregularity, the discontinuity, and the number of fissures in the ground, following the circumference of the subsidence in a way which as a whole may be considered regular.

(4) The absence of fractures in the middle of the basin.

(5) The inclination of the fractures, which lean toward the center of the basin.

(To be continued)

Standard Mine Doors

In some of the Southern Colorado coal mines a standard size for mine doors is adopted. The idea in adopting a uniform mine door is based on the plan that when a door is of no further use in one part of the mine, it can be moved to another where a standard frame awaits it.

Scientific Management

The Possibility of Its Application to Coal Mining—A Consideration of Some of the Advantages and Difficulties

*By Wm. Archie Weldin**

In the December issue, "Superintendent" inquired as to whether "Scientific Management" has been applied to mining. In answer I would mention the extremely valuable and interesting paper entitled "Efficiency Engineering Applied to Mining," read before the American Institute of Mining Engineers by Mr. Glenville A. Collins, at a meeting held February 17, 1912, at Spokane, Wash.

In this connection, I am reminded of recent conversations with Mr. Fred W. Taylor, the eminent exponent of scientific management, and with Mr. H. K. Hathaway, a prominent efficiency engineer, engaged in introducing the "Taylor system." The following is given with their permission, in the belief that it will be of interest to all progressive mining men.

The question of applying scientific management to coal mining having been mentioned, Mr. Taylor stated that so far as he knew, his system had never been applied to mining, but that he believed it quite possible to so apply it. In fact he stated that great gains are to be made through the introduction of scientific management into the mines, and those who have the courage to go at it properly will find simply enormous profit in the application of these principles. However, there will be great difficulty in introducing it, not only because of the large amount of preliminary work to be done, but because it involves a revolutionary change in the attitude of employer and employe There is also the difficulty that during a protracted period of preliminary work, large sums must be expended for which no results whatever would be apparent. It would only be after such period that results in the shape of reduced costs would begin to appear. He further said that he considered it impossible for the old and new systems to exist side by side. That it would be necessary in order to secure success, to plan to place the entire operation on the new basis.

Mr. Hathaway stated that judging from his experience in manufacturing establishments, and without inquiring particularly into the peculiar needs of mining, he believed that at least 3 years of work would be necessary before the system could be put on a self-sustaining basis. During this period a large sum would be expended, varying, of course, with circumstances, but probably amounting to at least $10,000 per year, for a large operation. He judged that for the first year no benefit whatever would be apparent, and he feared (rightly, I think) that this would discourage most operators. For this reason, the writer was advised, that probably none of the recognized engineers now engaged in introducing the Taylor system would undertake such work unless the management were unanimous in favor of it, and willing to persevere in the face of apparent loss.

As to the method of procedure in introducing the system, it was explained that though certain principles underlie all scientific management, there are no set rules governing it. The system consists rather of the study of the needs of each case, and the development and application of special methods. Heretofore, it has been the practice of the efficiency engineer to proceed to the plant, and inaugurate the necessary studies.

On completion of these, he gradually builds up an organization, preferably of men selected from the employes, to operate the new system.

The writer was advised that in the case of coal mines, on account of special conditions, and the difficulty of securing the services of the well-known efficiency engineers, it would probably be best to detail a man, preferably a graduate engineer, thoroughly familiar with mining methods and management, and send him to study scientific management, under some authority. At the end of a year or more, this man could return to the mine, and himself introduce the system, by methods worked out by his tutors. This procedure would no doubt be far more likely to succeed than any other, but its success would depend very largely on the man selected, his ability to manage, and his tact. It would require exceptional diplomacy, patience, and perseverance on the part of this man, to secure the necessary confidence of the miners and the cooperation of the mine management, and to harmonize his work with existing conditions, without reducing the output of the mine.

As to the possible benefits of scientific management, no doubt they are very great, but the writer is inclined to think that the difficulties in the way of introducing it into mines, at least to the underground workings, are far greater than seems to be supposed. The essence of the system is greatly increased supervision. In one plant visited by the writer, he was informed that the number of so-called "non-producers" was four times greater under scientific management than before the system was adopted. One-fifth of the entire force were office men.

Aside from the difficulty of convincing operators, whose whole effort has been to reduce the proportion of clerks, engineers, etc., the mere physical difficulty to be encountered is great. Instead of large well-lighted rooms full of men working almost within touch of each other, as in machine shops and factories, we have in coal mines, men working in pairs, in separate chambers 100 to 200 feet apart, each surrounded by a small circle of light from his lamp.

These difficulties, however, become less as we look further into the matter. It must be remembered that for the bulk of the operations underground, time and motion studies need be made but once, as the processes are largely stereotyped, and are very simple compared with the work

*Asst. Chief Engineer, Buffalo-Pittsburg. Co.

33—9—4

of a mechanic. Also the mine car forms a ready means of keeping account of the performance of the men, as well as transporting this data to central points. The peculiar bonus plan, which is an integral part of the Taylor system, could as readily be adapted to mining needs as to shop conditions. The men are already accustomed to "piece work," with rather elaborate systems of figuring their pay, and miners are hardly more suspicious and antagonistic to their employers than other workmen.

The writer does not feel sufficiently well versed in scientific management or efficiency engineering to venture an opinion as to how far the science developed by Mr. Taylor and others can be at present utilized in mining, but he feels that in view of the known difficulties, it is advisable to go slow, until the principles are thoroughly understood, and the methods developed. The following quotation from Taylor's "Principles of Scientific Management" will point the moral. He states that the introduction of this system "involves such radical, one might almost say, revolutionary, changes in the mental attitude and habits both of the workmen and the management, and the danger from strikes is so great, and the chances for failure are so many, that such a reorganization should only be undertaken under the direct control (not advice, but control) of men who have had years of experience and training in introducing this system."

From the factory to the mine is quite a long step, and if in the former case, so much danger and difficulty are to be expected with the full benefit of methods and devices perfected during the whole experience of these men, how much more difficult must it be in the mines.

In view of the above, the writer believes there is little to be expected of immediate benefit from the Taylor system as applied to underground processes.

I would suggest that the repair shop be systematized first. This would apply particularly to large central shops, but no doubt even the smallest would be greatly benefited. Here the work would be much more like that already done, and much valuable experience could be gained at minimum risk.

Another line of profitable effort suggests itself in accounting materials. Timber, rail, pipe, oil, etc., are used in enormous quantities at mines. This is not only a large part of the production cost, but it is much more subject to variation with good and bad management than in other industries. In manufacturing, the raw material largely enters into the finished product; there is usually no waste corresponding to the enormous quantities of posts, rail, and pipe lost in the gob of mines, the expensive frogs, switch points, etc., frequently seen lying forgotten "along the rib," or the amount of high-grade oil used where cheap oil would do, and even wasted by spillage and evaporation.

A large increase in the clerical work now done in accounting for this material would undoubtedly result in immediate gain, and this without any risk of precipitating a labor disturbance.

Such a system would begin in the purchasing department, where elaborate records would be kept showing which of several types or grades of certain materials give the most service, for the money, and just what stocks are on hand at each mine or part of a mine. The material would be accounted for by each department in turn at each stage of its career until its final value is extracted as scrap.

This system would hold responsible each man handling material and demand from him an accounting for what is entrusted to his care. One point in particular would be for a certain clerk to record the caving of each working place, and not only note whether track, pipe, and posts were withdrawn, but to credit that place with every piece recovered, and to charge it again to some other place.

This would involve nothing new or strange, but would be simply taking advantage of principles and extending the use of methods of management already well known.

Under the present system, or lack of system, supplies are often not ordered until some emergency discovers a shortage which cannot be made good soon enough to prevent heavy loss. It is generally almost impossible to secure authoritative data on the comparative life and service of different forms of track, wheels, etc. Even the percentage of coal or mineral recovered is hardly ever determined by methods at all reliable.

Many mines are well managed, but in general, it would seem that in coal mining as now conducted there is plenty of opportunity for increased economy, not only by the particular methods whose effectiveness has been so well demonstrated by Mr. Taylor and others, but by increased use of methods already known to us.

In particular, the writer would advocate an immediate and considerable, though gradual, increase in the amount of work done in keeping track of material, equipment, etc. This need not interfere with the introduction of the Taylor system proper; in fact, should be a great help to it, and it will undoubtedly justify itself in reduced costs. The Taylor system may then be introduced gradually, beginning with the shops, tipple, yard, etc. However, any such improvement to be effective must be worked out slowly and patiently.

"It Is to Laugh"

A Chicago trade journal recently published the following news item:

To Open a New Deposit

Scranton, Pa., February 27.—(*Special Correspondence.*)—Following scientific inspection tours about the hills of Port Crane, N. Y., George Yates, a prominent mining engineer of this city, has predicted that that hamlet in a few years will be a hustling mining town and rival Wilkes-Barre and Scranton. According to Mr. Yates the hills which enclose the small village contain rich veins of coal. At present it is understood that only Scranton capital is interested, and that if the coal mining industry is set up in earnest in that village the entire output will be sold to the Delaware & Hudson Railroad Co.

It is the present intention of Mr. Yates to sink a shaft at the most likely place as soon as warm weather arrives. The discovery was made last summer by a son of Mr. Yates who was working for the Delaware & Hudson Railroad Co. at Port Crane. He sent for his father, who immediately went on and remained for several weeks. It is claimed by men who have had occasion to dig wells on farms in that village that in their boring they had penetrated through thick veins of anthracite. Many farms in the neighborhood of the village have been leased by capitalists backing Mr. Yates.

There are only two points in the above "special correspondence" that are wrong. First, neither the Scranton City Directory or the telephone directory lists a George Yates as a mining engineer, and he is unknown to prominent members of the Engineers' Society of Northeastern Pennsylvania. Second, Port Crane is a village in Broome County, N. Y., and the geological formation of that territory is older and lower than the lowest Carboniferous measures. As the measures are those of the Devonian age, it is probable that some farmer, in sinking a well came across a bed of black Devonian shale, imagined he had coal, and somebody is exploiting the discovery (?) to catch suckers.

Specific Gravity Determination of Mineral Oils

By M. Rakousin

When dealing with small quantities of oil, a specific gravity bottle of small dimensions can be used, and the specific gravity of a sample of oil as small as 1 cubic centimeter can correctly be determined. But it may occur that less than 1 cubic centimeter is at the disposal of the experimenter. In such cases, the author recommends the following method: A specific gravity bottle of 5 cubic centimeters capacity is filled with about 4½ cubic centimeters of water, and the weight taken; then the oil is poured into the bottle on top of the water, and the bottle again weighed. Taking d as specific gravity of the oil, n its volume and f its weight, then,

$$d = \frac{n}{f}$$

But n is equal to w (weight of water fully filling the bottle) less e (weight of water partially filling the bottle), while f is equal to p_2 (weight of bottle filled with water and oil) less p_1 (weight of bottle partly filled with water). Thus,

$$d = \frac{w-e}{p_2-p_1}$$

Safe Timbering

Examples of Systematic Placing of Timbers By Which Many Accidents From Falls of Roof Are Avoided

PROBABLY nothing about a mine is so neglected as timbering. For a number of years it was claimed by the miners that the operators would not furnish them timber, consequently a law was passed compelling the mine foreman to see that the workmen are provided with sufficient props, cap pieces, and timbers, of suitable size, "which shall be delivered at the working faces or so near thereto as they can be conveyed in mine cars when asked for by workmen, at least 1 day in advance. If for any reason the necessary timbers cannot be supplied when required the mine foreman shall instruct the workmen to vacate the place until the timber needed is supplied."

Fig. 1. Face of Room Showing Sprag and Timbering

Since the number of deaths and injuries from roof falls do not materially lessen in the coal mines, the inference to be drawn is that miners do not use judgment in ordering timbers, or in placing them.

In England the law requires props to be stood at certain specified distances, regardless of the condition and kind of roof above the coal bed; however, even with this precaution the accidents due to falls of roof are far in excess of accidents due to other causes. James Roderick, Chief of Department of Mines for Pennsylvania, dissects the fatal accident list for 1911, and locates where lives were lost in the mine. From the total of 308 lives lost by falls, 243, or over 79 per cent., were killed at the faces of rooms; 32, or 10 per cent., in entries; and 33, or 11 per cent., while removing pillars.

Of the 206 miners who lost their lives, 78.15 per cent. were killed at the face; 13.11 per cent. while removing pillars; and 8.74 per cent. by falls on entries.

Of the 70 fatalities among loaders, 90 per cent. were killed at the face of the workings; 4.29 per cent in entries, and 5.71 per cent. while removing pillars.

In order to be injured by a fall of coal, there must be carelessness, yet 51 lives were lost in this manner in the bituminous fields of Pennsylvania. In undercutting room coal or pillar coal, sprags should be used. These may be mere blocks 18 to 20 inches long or they may be sprags with a cross-piece as shown in Fig. 1. The coal shown in this cut is about 6 feet thick, known as the Mary Lee bed in Alabama. The timber sprag is used to hold the upper bench of coal which is separated from the lower by a slate parting. The man at the face in a mining position is J. G. Meagher, superintendent of the Sayreton, Ala., mine, belonging to the Republic Iron and Steel Co. It will be noticed that the post and cross-bar over the track are substantial looking timbers. G. F. Morris, general superintendent of coal mines for this corporation, is greatly interested in "Welfare" work, which first of all includes the lessening of mine accidents, and it is to him that the writer is indebted for his methods and for Figs. 1 and 2. According to the timbering rules in operation at the Sayreton mine, timbers must be placed in working places $4\frac{1}{2}$ feet apart whether roof is good or bad Collars are placed on props over roadways and 2 feet clearance must be left on each side between the post and rails. Where the roof is very bad, timbers must be set closer than the $4\frac{1}{2}$ feet specified, but no matter how good the roof may be, the place must be timbered on the $4\frac{1}{2}$-foot rule. This company possibly was the first to practice a definite system of prop setting and road timbering in the United States; it is not the only company, however, which is endeavoring to reduce mining fatalities from roof falls by safeguarding its employes; for instance, Mr. Dawson, of the H. C. Frick Coke Co., read a paper at the Coal Mining Institute of America from which is abstracted the following on prop drawing: The introduction of this method of prop pulling had for its object the lessening of accidents when robbing pillars, which, in Pennsylvania, amounted to the loss of 33 lives in 1911, and the company by the care it has exercised has lessened the number at its mines.

Fig. 2. Showing Regular Timbering

This company in its mining operations requires the miners to stand props at definite intervals which must not be exceeded. The panel system of mining is followed; that is, a certain number of rooms are turned from an entry, and when worked the proper distance the room pillars are drawn. The rooms are narrow, being about 12 feet wide, for the roof above the Pittsburg seam in the coke regions is a weak one, known as "checker." As soon as the last room in a panel is driven its full length, a start is made in drawing the pillars. A breakthrough is driver about 8 feet wide between it and the panel or barrier pillar. This stump is then drawn. The pillars are made generally 30 feet wide, though where the roof is especially weak, the pillars are made wider.

A line of props is placed in the center of each room, the company requiring that the distance between any two props shall not exceed 4 feet 6 inches. A row of props is set on each side of the breakthrough at the same distance apart. In drawing the stumps, the props again are set at definite intervals, a row of props being set along the inside next to the cave, and the others in rotation. A part of the stump is at first taken out so that when the props are drawn a fall will occur, generally this will be an area of about 16 feet square. Then the rest of the stump is taken out and the props drawn so that all the chamber ahead of the pillar is made to cave. In taking a slice 16 feet wide from the pillar and driving a room the same distance, from 35 to 40 props will be used.

About 75 per cent. of these props are recovered by drawing. A prop cannot be expected to hold all the weight of overlying strata; it can only be expected to hold the few feet of roof which lies immediately above a seam and which must be kept in place until mining is finished.

Nor can a prop be expected to stand a long time and remain sound. But where the pillars are drawn so soon as the rooms in a panel are finished, the props which have been used in the rooms will still be good.

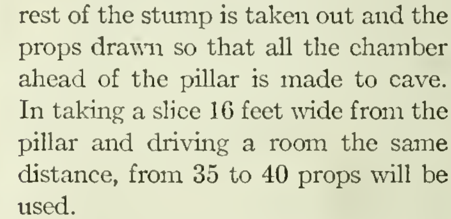

Fig. 3

To be sure, where the largest part of the coal is obtained from pillars, the majority of the props only have to stand a few days before they are drawn.

Fig. 4 shows the method followed in withdrawing a prop by means of the Sylvester prop puller. This is a simple yet powerful device consisting of a notched bar, or rack, from 3 to 5 feet long and a block which slides along the rack when worked by the lever shown in the operator's hands. At the end of the rack is a swivel to which the anchoring chain is attached. When in use, another chain is attached to the block and to the prop to be withdrawn. The block contains a steel dog which engages with the notches of the rack bar and prevents the block from slipping back when pulled forward by the lever. The lever is attached to the block by a short connecting link while the end bolt fits into the slots of the rack when being pulled forward. As soon as the prop is down, it is pulled out from beneath the rock which has fallen or from beneath the dangerous roof. In order to avoid the dangers of going beneath the bad roof, a long-handled pick is provided, as shown in Fig. 3, with which the prop is dragged back. This pick or hook can be made out of an old pick fastened on to the end of a piece of pipe 10 feet long, with a piece of iron welded on to the center of the pick with which hammering can be done. Hooks of this description can also be used to take down roof in order to hasten caving.

Great care is taken to avoid accidents when drawing props and it is a rule at the Frick mines that no props may be drawn except in the presence of a fire boss or pillar boss.

Australian Mine Ventilation

At Broken Hill, New South Wales, Australia, the Broken Hill Junction North Silver Mining Co. hereafter to be known as mine No. 1, is connected with the Broken Hill Junction Lead Mining Co., hereafter to be known as mine No. 2, by rock tunnels whose only object is ventilation.

In due course of time No. 1 installed fans driven by high-power motors, which showed it was progressive, and used the No. 2 mine as an upcast, which showed it had a cheek. As the smoke and impure air from No. 1 was injurious to the men and also interfered with work in No. 2, that company promptly closed the tunnels and prevented the circulation of pure air in No. 1 and impure air in No. 2; thereupon No. 1 became peeved at No. 2 and brought suit to compel No. 2 to open the tunnels so No. 1 could fill No. 2 with bad air. Pending litigation the Inspector of Mines, who is some party in Australia, ordered the obstructions removed from the rock tunnels and No. 1 proceeded to fill No. 2 with bad air which caused No. 2 to become peeved to such an extent it brought counter suit and prayed His Honor for an injunction to restrain No. 1 from using ventilating machinery that fouled the air in No. 2. The use of the "blower fan" was not advisable in this instance, and since the exhaust fan would bring the bad air from No. 2 into No. 1 it was considered inadvisable to have a reversible fan on the premises but to follow out the common plan of taking everything in sight, and having it hold it, possibly in this case on the grounds that it is a dirty bird that fouls its own nest. His Honor suggested before No. 2 suit was entered that the company officials confer with a view to settlement, but counsel were not prepared to do so just then, either because their clients were on their "Bull Dog" or they saw a chance for graft to escape.

Fig. 4. Prop Pulling Machine

As matters now stand honoraria are even if ventilation is poor.

Ode to the Mine Mule

Written for the Colliery Engineer by Coz L. Worker

Here's to the mule, the old mine mule
The "blankety blank, blank, blank'"
Always ready for work, and hard as a nail—
Though often a tough old crank.

He's the subject of jeers and is cussed by the boys
Who clout him with sprags, bars, or whips.
Excluded is he from paternity's joys
But he's always the leader of "trips."

The motors of air, electric, and gas
Have usurped his olden time place—
But only in part, for he is the cuss
That must draw the car up to the "face."

The language, and words that he understands best,
That are lavished on him without stint,
That will make him pull hard, when he yearns for a rest,
Are not those that look "good" in print.

His voice is not pleasant, his song it not sweet,
For beauty he ne'er won a prize,
But as to dynamics in his two hind feet,
No meter e'er measured their size.

L'envoi.—Contributed by an old acquaintance and friend:

His life was not easy, his joys were but few,
He died a hard death as a rule;
Still, we who have used him, misused and abused him,
Feel the loss of that same old cantankerous mule.

WELFARE WORK AT COAL MINES

Hookworm Disease at Southern Mines

*By Dr. J. W. Pryor**

IN presenting this paper upon hookworm disease we must consider first, the symptoms and diagnosis; second, the curative measures; third, the life history of the causative agent and the modes of infection, in order to arrive at what would be called the most practical side of the question; i.e., the means of prevention and the eradication.

The disease which is due to the presence in the intestinal canal of the parasite *Ankylostoma duodenalis*, or that which is found in America, *Necator Americanus* (the American hookworm), has had many titles, among them is that of miners' anemia. With other symptoms of hookworm disease, anemia is usually pronounced. This condition is due to the loss of blood and the presence of a toxin or poison produced by the worms and injected into blood stream. Those infected with hookworm have the appearance of general ill health, pallor of skin, and retarded physical and mental development, when the

Fig. 2. Magnified Head of Hookworm Attached to Wall of Bowels

infection has taken place in early life. Most of the symptoms are not very pronounced in those cases with but little infection. There may be a loss of appetite, or at least it is capricious, occasional pains in the

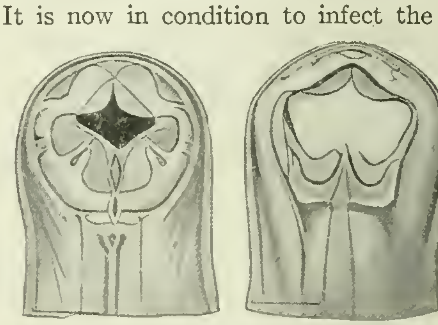
Fig. 1. Development of Hookworm From Egg *a* to Infectious Form *k*

abdomen, headache, lassitude, lack of interest in work, an indisposition to do anything that would require exertion. In what is termed a moderate case these symptoms and others are pronounced, and in a marked case the patient is not only incapacitated for work but the termination is often fatal.

The diagnosis is easily made if the worms are present in sufficient numbers to materially affect the health of the person, and in fact the disease is sometimes easily diagnosed when there are only a few worms present. Such is the case with those who are termed hookworm carriers. Any physician who is familiar with the use of the microscope should be able to detect the eggs in the feces. The technique is very simple, and once becoming familiar with the appearance of the eggs it should not be at all difficult to diagnose the presence of hookworm.

The treatment is as simple as the method of diagnosis, and is thoroughly effective in the majority of instances. I take it you would prefer to leave this part of the subject to the discrimination of your physician.

Now as to something of the life history* of the causative agent, the hookworm. The human is the host of this parasite, and the females lay their eggs in the small intestine. These are expelled with the feces and may be deposited anywhere. The conditions best suited to the development of the eggs are, absence of light, presence of oxygen, a temperature between 71° and 95° F., and a moderate amount of moisture. The eggs have been known to develop in mines at a temperature of 68° F. It is possible for the ideal conditions for development to be found within a mine. Freezing does not kill the eggs in all instances, but they are easily killed by drying. Under favorable conditions the eggs will develop in 24 hours and the larvæ will hatch out; in 2 or 3 days they shed their skins. This is called the first ecdysis. About 5 days from the time they are hatched, the organism passes through the second ecdysis, but this time it remains within the skin, is encysted. It is now in condition to infect the



(a) (b)

Fig. 3. Head of Hookworm, Magnified

human. It will then be seen that the eggs do not develop within the person infected, nor is the person reinfected from this source.

* Professor of Anatomy and Physiology, State University of Kentucky, Lexington, Ky. Paper read before the Kentucky Mining Institute.

* Hookworm Disease, Doctor Bass, 1910.

Fig. 1 shows the newly laid ovum with the usual histologic appearance of other ova, yet having its own characteristic features of identification. Like other ova, when developing, it shortly becomes two cells; to do this it goes through the process of mitosis, then becomes four, then eight, etc., to the stage just preceding the formation of the embryo. A little later we see the embryo within the shell, then shortly after leaving the shell, and later on the larvæ are in condition to infect the human.

The mode of infection is always by the mouth indirectly or directly. It has been said that flies transport the larva to the food and have thus been the means of infection. It is just possible that this is true, but it is the rare exception that hookworm disease is communicated through the medium of flies, but we know that typhoid fever is frequently communicated this way. It would be difficult to exaggerate the conditions of many of the closets to be seen on farms and in fact in many towns. Do you believe that the flies make daily visits between the filth in these privies and your dining room and kitchen? It is a disgusting fact—you have but to examine a fly that you have extracted from your cream pitcher to find that its legs are covered with feces, and can you proceed calmly to drink this mixture? The indirect method of infection is the rule, that is the infection takes place through the skin—this has been demonstrated in the following way: Dr. Claude A. Smith placed mud containing encysted larva on the arm of a man and allowed it to remain 1 hour. In 8 minutes he complained of itching, a dermatitis developed. A section of the skin while inflamed would show the larva present. The dermatitis or inflammation of the skin has been called "ground itch," "dew poison," or "toe itch."

When the larvæ are brought in contact with the skin and remain a sufficient length of time, they bore through the skin and get into the circulation, and finally reaching the lungs they are unable to pass through the capillary blood vessels and they bore through these into the air cells and thus get into the bronchial tubes. They finally reach the mouth by coughing or the natural flow of mucus from the air passages, and many of them are swallowed and, passing through the stomach unchanged, they enter the small intestine, where they undergo complete development; that is, after 4 or 5 days another ecdysis begins and they acquire a buccal capsule which enables them to fasten on the mucous membrane by sucking in a plug of the epithelium. Fig. 2 shows an enlarged view of the head of the hookworm attached to the wall of the bowels. Fig. 3 (*a*) is a view of the head looking directly into the mouth, showing the two jaws, and in the middle is seen the hollow tooth similar to the poison fang of a snake. Fig. 3 (*b*) is the same head at a deeper level and shows the fang-like tooth more plainly.

In 4 or 5 days more the last ecdysis begins and the last skin is shed. The worm is now about one-fifth of an inch long and grows rapidly to its full size and length, that is about five-eighths of an inch. When we take into consideration that in many cases there are thousands of these parasites present, sucking the blood from and injecting their poison into the victim, we can readily understand the gravity of the condition, and when we know that each female may produce thousands of eggs daily, and that in some cases millions of eggs are passed daily with each stool, we can appreciate the tremendous opportunity for infection and the necessity for a realization of the true condition.

Fig. 4. A Hookworm-Afflicted Family. Note Swelling of Face and Legs of Little Girl. Two Deaths Have Been Caused in This Family by This Disease

Now to the more practical side of this question, that is, the means of prevention and the eradication of hookworm disease. The State Board of Health is at present making a campaign in a number of counties against hookworm disease and their health officers are doing a grand work. If you men will give them your hearty support and but carry out their directions, great good will be accomplished, not only in the eradication of the hookworm, but in the prevention of contagious and infectious diseases.

In the first place you must not only believe that these facts concerning this disease are true, but you must realize that the success or failure rests with you, and it will be due only to your continued efforts that the disease will be completely eradicated.

Granting that you have a physician in your camp that can make the diagnosis, every member of the camp and their families should be examined for this disease, and it must be definitely settled. Every case found must be treated and the examination followed up for months, to determine if all worms have been destroyed.

The sanitary condition of the mines and the camp must be carefully guarded. If some part of the mine has been used as a filth room, it must be cleaned and disinfected. If it has been the custom of your men and boys to relieve themselves at any time that nature calls and at any place they have thought convenient, they must understand and be willing to comply with any reasonable rule that you know will meet the circumstances existing and they must be made to understand there are no exceptions.

Sanitary closets must be provided. The State Board of Health will gladly give you full information as to what will be best suited to each locality. The principal point I wish to impress upon you is that hookworm disease may be found in every county in the state; that it is easily diagnosed and easily cured; that you can use positively effective means of prevention and eradication.

This is an economic question of great importance to the state of Kentucky, and you can well imagine what the conservation of life and the increased efficiency of labor would be if hookworm disease were eradicated.

In conclusion I will say to the miners of Kentucky: Believe what the physician tells you in regard to preventable diseases, carry out his instructions to the letter, make an unceasing warfare upon all disease-carrying insects, build sanitary closets, screen your kitchen and dining room, require that your stables be cleaned every day and see that the manure is scattered. See that your garbage cans are made inaccessible to insects—in fact, make it impossible for the propagation of disease-carrying insects, by destroying the breeding places of these pests. In other words, get to the root of these matters, not the surface.

Does this condition seem ideal? It may be, but I think it possible.

Who Is Responsible?

*By William H. and J. T. Reynolds**

THE other day in a mine in which we happened to be, there occurred an incident which is unfortunately of almost daily occurrence in every large mine in the bituminous field. The foreman, who, like many another who will read this, has a little more than a man's job on his hands, and, even with the industrious assistance of a good fire boss, more than he can rightfully or lawfully accomplish in a way he would like to, entered a room in which a miner (?) was loading a car. A glance at the roof above the man showed a slab of slate in a dangerous condition and entirely unprotected. The foreman spoke to the man, and he stopped for a moment, while the official drew his attention to the danger—in English. The workman smiled sycophantly, nodded his head rapidly, and grunted something which the foreman did not understand. Evidently he hadn't grasped a word of what had been said, for he returned to his shoveling. Then ensued a ludicrous pantomime such as is often seen in bituminous plants. The foreman looked about for a sledge and not seeing one went through the motion of setting a post, and pointed to the roof. The miner grunted again, this time in a way to indicate he understood, dropped his shovel, and apparently went in search of the sledge.

The foreman went out, being, as we have said, a man of many parts, and, from what he said later, every one of them was calling him at that moment. He was scarcely a hundred yards away, however, when some one came running after him to tell him the man whose room we had just left was under the slate.

After they had put him in a car and started out, the question came up as to the real responsibility for such accidents as this The foreman frankly acknowledged that in a sense of real justice he was the culprit. "I always am," he added. "The fact that there are a score of other jobs awaiting me this very minute shouldn't cut any figure, of course. I, being foreman, should have stopped in his place and taught him the simple rudiments of mining, which every man, if I had my way, would know before he was set on. But I have my orders and have to obey them. We are behind with our contracts now, and every man who applies gets a job."

"Even if he's never seen a coal mine before?"

"Yes," he continued, as we crawled into another room where another recent vineyard worker was busily engaged digging coal, "because if we don't, the mine above, needing 'em as badly as we do, would set 'em on."

In reply to a more personal question this foreman told us that only a day or two before he had set the injured man on, after casually inquiring of his "cousin," who had brought him with half a dozen other "cousins" to the pit, if he had any experience in coal mining before. "Oh, yes, Meester Boss; oh, yes sir, heem digga coal in my country." "I know of lots of such accidents and worse ones, which I am positive would not have happened if the men had only known how to take care of themselves, but until there's a law to compel every applicant for a job to at least know when, how, and where to set a post, charge and drill a hole properly, care for a safety lamp if need be, and the few simple rules which one at least expects of a miner, we shall continue to have these accidents of ignorance, as well as the list caused by carelessness. And until there shall be some kind of preliminary examination for miners, all who come will continue to be set on as long as men are needed as badly as they are at present."

After having parted from the foreman, the truth of his words, and several other things he had not said, which likewise had bearing on this subject, hammered themselves into our brain One of the most pertinent was that in the formation of such a law as we have mentioned, our present legislative body would have the advantage of its predecessor. It will, when such an act comes up, consider

* Late Member United States Rescue Service.

wisely the state's long and regrettable experience with certain bad features of the anthracite law governing the granting of miner's certificates. This law has filled the mines of the East, which, of all mines need practical and experienced men the most, with Italian and Slavish stock who know but little of mining, and has kept out the sturdy German and English miners whose long experience in the mines of their own countries would be of inestimable benefit in whatever mines they might be employed. The English or Welsh miner, who since a boy has worked in the anthracite and bituminous mines of his own land, and not only understands the best methods known to mining practice, but is one with his superiors in the matter of language and understanding and appreciation of the laws which govern him, is, with his family, a better acquisition for the Commonwealth, than the man whose sole merit lies in the fact of his having left the farm or the vineyard sufficiently long to satisfy the time clause of the examination. But the German or English miner who has spent his life in the pits of his native land has too much independence of character to work for 2 years as an apprentice to a man who knows far less of the trade than he does. The fact that an applicant had learned the trade of coal mining, and could prove to an examining board that he had learned it, should be quite sufficient. But under this act, it is not; hence, this most desirous class emigrate to those parts of our country where experience counts for something, and Pennsylvania's loss is some other state's gain.

The knowledge of these facts should aid in the formation of a better and fairer miner's certificate law for the bituminous as well as the anthracite regions. In a few instances large corporations have found it for their interests and that of their employes to formulate and put into practice for their own mines, what is in substance the same law we suggest as being applicable to the whole bituminous region. Seeing the need, they have applied such rules to their own plants. For the better control of the 99 per cent. who will not, unless compelled by legislative proceedings, take any such measure, this chasm which now stands between safety and danger should be bridged by some definite legal precaution. Either before a board of examiners or else by an elected or appointed committee at each mine, the men who desire to become miners should qualify by answering a few simple questions relating to the timbering of roof, and, if a gas mine, by telling the necessary precautions to be taken to guard against accident to safety lamps, the proper method of placing and charging of shots, and such other questions as might be essential in the particular field in which he desires to labor. In the matter of examination of applicants, there can be no question of the moral right of the miners themselves serving through their elected representatives in this matter, for one ignorant employe, let alone many, passed into service underground, can, where gas and dust are produced in explosive quantities, destroy by a single act not only his own life but those of his fellows. If the carelessly employed ignorant miner stood the chance of killing only himself, that would be bad enough, and worthy all possible precaution to prevent, but when he has in his keeping the lives of every day laborer, miner, and official in the same mine, and the possible destruction of valuable property, too much care cannot be taken.

As matters now stand in the bituminous region the utmost care is taken to safeguard against a noncompetent foreman or fire boss, yet, except in a few instances, we allow anything which has muscle and two arms to work in the same mine, totally regardless of fitness. Yet no matter how scrupulous the fire boss or the foreman, how far can his knowledge and supervision actually extend throughout the entire working day? To one conversant with the conditions of a large mine it is obvious that the only time the general safety can be conserved is before the men are given employment, and even then there will be accidents a plenty. At best the mine officer can devote but a few minutes every day to each working place, and the utmost he can give to individual welfare is a cursory examination and suggestion. If he sees gross carelessness he can discharge or arrest, it is true, but haste and ignorance are creating danger zones in other places while he is looking after one. Take the general safety of a mine as you will, it is a matter of individual care. No mine generating gas or dust is safer than its most ignorant or careless employe will allow it to be, hence, care should be taken against individual ignorance as much as possible.

It is the nature of the miner to take risks, particularly when so doing tends to the increase of his pay; and the time he should devote to taking down or properly timbering his slate is used to take out or load coal; or the better "squaring up" of his bearing-in is left to the chance of a little extra powder and a possible blown-out shot in order to give him time to drill a hole which should go over until the next day. Until the entire subordinate personnel is educated to the great truth that it does not pay to take chances over and above those natural to the occupation, the best we can do is to eliminate the careless and disobedient and remove those chances of accident which come through sheer ignorance, by not allowing any man to work as a miner alone until he shall have proved himself capable of at least looking after his own welfare.

At the Santa Fe water station, at Trinidad, at night, a red lantern is set along side the mark which indicates that the tank is full, say, at 36 feet. Attached to the traveling board, or indicator, is another lantern. As water is pumped into the tank the lantern on the board sinks and when it and the red, fixed lantern are in a horizontal line, the tank is full.

Practical Talks on Coal Mining

For men who desire information on Coal Mining and related subjects presented in a simple manner

Electricity in Mines

The Flow of Electricity—Some Differences Between Static Charges and Currents—Circuits—Electrical Units

By H. S. Webb, M. S. (*Continued from April*)

THE flow of electricity from one terminal of a voltaic battery through a conductor or circuit to the other terminal is known as a continuous current of electricity because it always flows in the same direction and does not vary in an abrupt or pulsatory manner. It is also known as a direct current because it always flows in the same direction through the circuit, that is, from a copper, or carbon, terminal through the conducting wire to the zinc terminal.

A pulsating current is one that flows in one direction only, but is continually rising and falling in value, due to periodic, that is regularly recurring, variations of the difference of potential, or to other regularly varying conditions. Both continuous and pulsating currents are direct currents because they flow constantly in one direction. Alternating currents, which will be considered later, periodically change their direction of flow in the circuit, first flowing in one direction in a given conductor and then in the opposite direction in the same conductor.

Electricity flowing as a current differs from static charges in three important respects: its potential is much lower, its actual quantity is greater, and its motion is continuous.

A substance charged from a strong voltaic battery possesses the property of attracting light substances to a degree detectable only with very delicate instruments. The potential of a current of electricity is comparatively so small that a voltaic battery composed of 10,000 cells is not sufficient to produce a spark more than ½ inch long in air, whereas a small, rapidly moving leather belt in transmitting power may produce static sparks more than 1 inch long. The length of the spark affords a means of estimating potentials, a high potential being capable of producing a longer spark than a low potential; but the length of spark gives no means of estimating the current strength, or the quantity, of electricity flowing. The quantity of electricity produced by a voltaic cell no larger than a thimble would be found greater than that from a large, rapidly moving belt giving static sparks several inches in length.

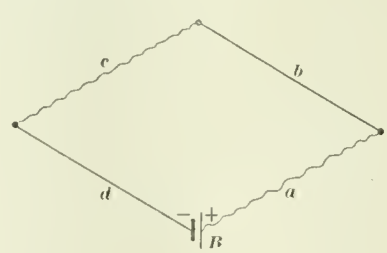


Fig. 1

Circuits.—A circuit is a path composed of a conductor, or of several conductors joined together, and through which an electric current flows. The current may be traced from any point in the circuit along the conducting path back to the starting point.

A circuit is broken, or open, when its conducting elements are disconnected in such a manner as to prevent electricity from passing through the circuit. A circuit is closed when its conducting elements are so connected as to allow electricity to flow through the circuit. A circuit in which the earth, or ground, forms part of the conducting path is called a grounded circuit. An external circuit is that part of a circuit that is external to the source of electricity. An internal circuit is that part of a circuit that is included within the electric source. In the case of a voltaic cell, the internal circuit consists of the two metallic plates and the electrolyte. The external circuit is any conductor and electrical devices forming a conducting path between the terminals of the cell.

Series Circuits.—When two or more conductors are so connected that the same current must pass through all, one after the other, the conductors are said to be connected in series. For example, Fig. 1 represents a closed circuit consisting of a simple voltaic cell B and four conductors a, b, c, and d connected in series. A heavy short and a longer lighter line, as shown at B, are a common method of indicating a voltaic cell. In order that the current, due to the cell B, may pass through any one of the conductors it must pass through all, one after the other. An open circuit, or break, in any conductor or between conductors anywhere in this series circuit will prevent any flow of electricity.

Parallel Circuits.—When two or

more conductors are so connected that each constitutes an independent path by means of which the current can pass between two common points, the conductors are said to be connected in parallel, or multiple. An example of a parallel circuit consisting of two branches *b* and *c* is shown in Fig. 2. The current from the battery *B* flows first through the conductor *a*, then it divides between the branches *b* and *c*, and finally unites and passes back through the conductor *d* to the battery *B*. The two branches *b* and *c* represent conductors or paths that are connected in parallel or multiple. An open circuit in either conductor *b* or *c* will not stop the current through the other conductor, because each conductor constitutes an independent path between the two points where the conductors *b* and *c* are joined to the main conductors *a* and *d*. The arrows indicate the direction of the current. Incandescent electric lamps in residences, stores, offices, and mines are almost always connected in parallel across the main wires that extend to a transformer, to a dynamo, or other source of electricity.

ELECTRICAL UNITS

Quantity of Electricity.—In order to make calculations of any kind, suitable units must be provided. It is not very often that one can tell exactly how much water a tank contains by merely looking at it. To determine the quantity of water in the tank, it must be measured in some manner, such as by drawing off the water into a gallon measure. The number of times the gallon measure is filled until the tank is emptied, gives the number of gallons of water that the tank contains. Thus, the gallon is a unit by means of which any quantity of water may be measured.

Unfortunately, perhaps, we cannot make a vessel in which we can put electricity and see it measured; nevertheless, we can construct devices that will measure electricity by noting the effect that it will produce.

When electricity flows from one piece of silver through a solution of silver nitrate, which is a substance composed of silver, nitrogen, and oxygen dissolved in water, to another piece of silver or other metal, the electricity causes the second piece of metal to gain in weight. It has been experimentally determined that silver is deposited upon the second plate and furthermore that the

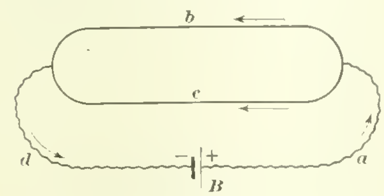

Fig. 2

amount of silver deposited is a measure of the quantity of electricity that is supplied to and passes through the solution. The quantity of electricity that deposits exactly .001118 gram, or .01725 grain, of silver on the one plate is universally considered to be the unit quantity of electricity. This unit quantity of electricity is called, by universal consent, the coulomb, named after Charles A. Coulomb, a celebrated French mathematical physicist, who lived from 1736 to 1806.

If a quantity of electricity passing through a solution of silver nitrate deposits .00559 gram of silver on one of the plates in the solution, then $.00559 \div .001118 = 5$ coulombs of electricity have passed through the solution.

It should be distinctly understood that no reference has been made to the time that it has taken any quantity of electricity to flow through the solution. A coulomb is a certain quantity of electricity and it is still a coulomb whether it takes an hour or a second for it to deposit .001118 gram of silver on the plate.

Strength of An Electric Current.—In electrical work it is generally more useful to know the rate at which electricity is flowing through a circuit at a given instant, rather than the total quantity of electricity that has passed through the same circuit in the given length of time. It is, furthermore, very convenient to have a separate unit with which to measure this rate of flow of electricity. Similar units are used in other branches of science. For instance, the word knot is used to express the rate at which a vessel is moving; for when it passes over 1 nautical mile (6,080 feet) in 1 hour it is said to be making a speed of 1 knot. In a similar manner the one word ampere is the name adopted for the unit with which to measure the rate of flow of electricity. This unit strength of electric current is secured when electricity flows steadily past a given point in the circuit at the rate of 1 coulomb in a second. That is, a steady, or uniform, current produced when 1 coulomb of electricity passes through a circuit in 1 second, is an ampere. Thus, the element of time is involved in the ampere. If a steady flow of current causes the deposition of 1.118 grams of silver out of a silver nitrate solution upon one of the two plates therein in 10 seconds, the amount of silver deposited per second is $1.118 \div 10 = .1118$ gram; and, hence, the strength of the uniform current passing constantly through the solution during this time is $.1118 \div .001118 = 100$ amperes. That is, the rate of flow of electricity is 100 amperes, or 100 coulombs per second.

The ampere is generally defined as the unvarying current, which, when passed through a solution of nitrate of silver in water, made in accordance with standard specifications, deposits silver at the rate of .001118 gram per second. This unit is named after Andre Marie Ampere, a French physicist, who lived from 1775 to 1836.

Example.—If 50 amperes flow through a circuit for 2 minutes, what quantity of electricity has been developed and how many grams of silver would it deposit from a silver nitrate solution?

Solution.— 50 amperes is equal to 50 coulombs per second. 2 minutes are equivalent to $2 \times 60 = 120$ seconds; hence, $50 \times 120 = 6{,}000$ coulombs have been developed. This quantity of electricity would deposit $6{,}000 \times .001118 = 6.708$ grams of silver.

For measuring very small electric

currents, it is convenient to have a smaller unit, in which case the milliampere unit is used. Milli is French for $\frac{1}{1000}$; hence, a milliampere is equal to $\frac{1}{1000}$ ampere. Consequently 1 ampere is equal to 1,000 milliamperes.

An idea of current values commonly used in electrical circuits may be obtained from the following cases: A 16-candlepower incandescent carbon-filament lamp requires a current of about $\frac{1}{2}$ ampere when burning at normal brightness. A 20-foot trolley street car equipped with two motors takes from 20 to 40 amperes, when traveling at full speed on a level. An arc lamp circuit requires from 6 to 10 amperes, depending upon the kind of a lamp used. The current employed in e ectrically welding rails is sometimes as high as 30,000 amperes. An ordinary telegraph line circuit uses from 18 to 30 milliamperes.

Gases Met With in Coal Mines

Three Forms of Matter—Effect of Heat—Thermometers—Gay-Lussac's Law

(Continued from April).

There are three forms of matter—solid, liquid, and gaseous. Which of these forms matter takes depends upon the freedom or ease of movement or motion between the different molecules of which it is made up. In solids the molecules are more or less fixed and there is by little motion between them; in liquids, the molecules move freely but still display cohesion; in gases, the movement of the molecules is greatly increased, cohesion is entirely overcome, and the molecules tend to fly apart from one another; that is, they exert repulsion. Most bodies naturally take any one of the three states of solid, liquid, or gas, depending upon conditions of heat and pressure. Water is an example of the three states matter may assume under changes of temperature. As ice, its molecules do not move at all freely and it is a solid; when heat is applied the movement of the molecules becomes more rapid the force of cohesion is lessened and the ice melts into a liquid known as water; if the application of heat is continued the vibration of the molecules becomes more and more rapid until cohesion is entirely overcome, repulsion taking its place, and the liquid water flashes into gaseous steam. Just the reverse is the case if the heat is removed. Suppose we are firing an outside boiler in the middle of winter. When the fires are drawn, the vibrations of the molecules in the steam lessen until a point is reached where repulsion stops and cohesion begins and the steam condenses into water. If no care is taken, the cold outside air causes a further withdrawal of heat, the motion of the molecules in the water in the boiler becomes less and less, until finally it is so slight that the liquid water freezes into solid ice. It will be seen that in all these states from ice, to water, to steam, and back again from steam, to water, to ice, there has been no change in the substance. It is water, whether we see it as ice or steam or as what is commonly called water. In other words, the change has been among the molecules and is a physical change, and not in the atoms, which would be a chemical change.

Heat is produced in many ways: by friction, as when a brake-shoe bears heavily on the wheel; by percussion or striking as when a blacksmith hammers a bar of cold iron; by chemical action, as when water is poured on lime; by electrical action, as in an electric lamp or in the short circuit of a broken live wire; by combustion or burning (which is really a form of chemical action) as with coal or wood in a fire; by the rays of the sun and stars; by the interior heat of the earth and by living beings, which is known as animal heat. Heat, therefore, does not always mean that there must be flame and smoke.

Heat is transmitted or carried in three ways, known as radiation, conduction, and convection. In the case of a stove the heat is radiated through the air to a person standing nearby, and in the case of a bar of iron stuck in a fire the heat is conducted through the solid iron to the hand of the man holding it. In the first case the molecules of the air and in the second the molecules of the iron are made to vibrate more rapidly than usual, and coming in contact with the body or the hand cause its molecules to vibrate more rapidly and thus give the feeling of heat. In convection, which is shown only when heat is applied to liquids and gases, the process is a little different. Here there is an actual movement of the material being heated, as any one can see when water is boiled in a glass, when the water rises from the bottom near the fire to the top of the glass where the water is cold, and in this movement carries its heat with it.

Temperature is a term used to express the intensity or degree of heat, or the rapidity of vibration of the molecules. Temperature is generally measured by a thermometer which consists of glass tube of small bore, which tube is filled with a metal known as mercury or quicksilver. Mercury is very sensitive to slight changes in temperature and expands or contracts rapidly as heat is applied or withdrawn. There are two thermometers in general use which differ in the way they are graduated or marked. In the centigrade thermometer which is in general use in all countries except Great Britain and its colonies and the United States, although used by chemists and scientific men in both countries, the freezing point of water is taken as zero and the boiling point of water is taken as 100, the distance between these two points being divided into 100 degrees on the scale. The zero point of the Fahrenheit thermometer is taken as that of the lowest artificial temperature the maker, Fahrenheit, could produce. Starting with this as the zero point, or 0°, the temperature of freezing water is 32° and the boiling point of water, 212°.

	Freezing Point	Boiling Point
Centigrade thermometer....	0°	100°
Fahrenheit thermometer....	32°	212°

From experiments and calculations it has been determined that at 460° below zero on the Fahrenheit thermometer scale, or 273° below zero on the scale of the centigrade thermometer, all motion between the molecules of a body ceases. This point is called the absolute zero, and temperatures measured from this point are called absolute temperatures. Absolute temperatures are extensively used in all calculations referring to the volumes of gases and the changes taking place in them under varying temperatures.

For converting ordinary temperatures to absolute temperatures use the following rules:

For the Fahrenheit scale:

Rule I.—Add 460° to the Fahrenheit thermometer reading, and the result will be the absolute temperature, Fahrenheit.

For the centigrade scale:

Rule II.—Add 273° to the centigrade thermometer reading, and the result will be the absolute temperature, centigrade.

Expressed by formulas, these rules for finding the absolute temperature are as follows:

For the Fahrenheit thermometer scale:

$$T_f = 460° + t_f \qquad (1)$$

in which

T_f = absolute temperature (F.);

t_f = ordinary temperature (F.).

For the centigrade thermometer scale:

$$T_c = 273° + t_c \qquad (2)$$

in which

T_c = absolute temperature (C.);

t_c = ordinary temperature (C.).

In ordinary work we deal with one thermometer only, so unless anything is said to the contrary T without a subscript signifies absolute temperature and t without a subscript means the ordinary temperature and should be reckoned according to the scale of the thermometer we are using. In the United States this will be, as stated, the Fahrenheit scale. The words centigrade and Fahrenheit are generally abbreviated to the letters C and F although Cent. and Fahr. are sometimes used. Thus 96° C. means 96 degrees centigrade, or as indicated by a thermometer graduated or marked according to the centigrade system; and 52° F. means 52 degrees Fahrenheit, or as indicated or marked by a thermometer graduated or marked according to the method devised by Fahrenheit.

The volume of any body, whether it is a solid, liquid, or gas, is always changed if the temperature is changed, and nearly all bodies expand or grow larger when heated and contract, or grow smaller, when they are cooled. In this series of articles we are dealing entirely with gases and will not consider the expansion of solids, like iron, or liquids, like water.

The volume of a given weight of gas depends on its temperature and the pressure to which it is subjected. The relation between the temperature, volume, and pressure of a gas is a most important one, and is given in two laws, known as Gay-Lussac's or Charles' law, and as Mariotte's or Boyle's law, which will be considered in order, the former being probably more used.

Gay Lussac's Law.—The pressure remaining the same, the volume of any given quantity of gas is proportional to its absolute temperature.

Expressed as a proportion, this law is,

$$v : v_1 = (460+t) : (460+t_1), \text{ or}$$

$$\frac{v_1}{v} = \frac{460+t_1}{460+t};$$

hence, $$v_1 = v\left(\frac{460+t_1}{460+t}\right)$$

In this formula v is the original volume of the gas at the original absolute temperature, t; and v_1 is the volume of the gas at the higher or lower absolute temperature t_1.

Example.—If while passing through a mine 10,000 cubic feet of air is heated from 30° F. at the intake to 60° F. at the fan, what is the increased or expanded volume of the air?

In this problem the original absolute temperature, t, is 460° + 30° = 490°, and the original volume, v, is 10,000 cubic feet. The higher absolute temperature, t_1, is 460° + 60° = 520°, and the volume at the higher absolute temperature, v_1, is what we have to find. Hence we can use the formula just as it stands and we have,

$$\text{volume at } 60° = v_1 = 10{,}000\left(\frac{460+60}{460+30}\right)$$

$$= 10{,}000 \times \frac{520}{490} = 10{,}612 \text{ cubic feet}$$

Before taking up the second law, that known as Mariotte's or Boyle's law, it will be necessary to say a little about the atmosphere.

The atmosphere, or as it is very commonly called, the air, surrounding the earth is acted on by gravity, causing it to exert what is known as atmospheric pressure. The pressure on each square inch of any surface on the earth, due to the pressure, or as is commonly said, the weight, of the atmosphere, is 14.7 pounds at the level of the ocean and gets less as we rise above that level. As air is a gas, this pressure is transmitted equally in all directions; in other words, the pressure of the atmosphere is not only exerted downward as is weight, but sidewise and upwards as well.

The pressure of the atmosphere is measured by means of an instrument called a barometer, of which there are two very different kinds. The best is the mercurial barometer, which consists of a glass tube about 3 feet long filled with mercury (quicksilver). The upper end of the tube is closed and the tube is turned upside down and the open lower end placed in a bowl or cistern of mercury. When this is done, the mercury in the tube will fall and, at sea level, will come to rest with its surface about 30 inches above that of the mercury in the bowl or cistern. This 30-inch column of mercury in the tube is supported by the pressure of the air on the surface of the mercury in the cistern. When the condition of the atmosphere changes, the pressure of the air upon the mercury in the cistern increases or decreases, and the mercury in the tube rises or falls accordingly. The scale of the barometer is divided into inches, tenths, hundredths, and, by means of a device known as a vernier, may be read to thousandths of an inch. The word barometer is frequently written Bar., and "Bar. 29.986," means that the height of the column of mercury in the tube of the barometer is 29.986 inches.

As a cubic inch of mercury weighs about .49 pound at ordinary temperatures, the pressure of the atmosphere in pounds per square inch may easily be calculated when we know the height in inches of the column of mercury in the barometer. This is commonly called, "height of the barometer," "barometer reading," or, simply, "barometer."

Example.—What is the pressure of the atmosphere in pounds per square inch on the summit of a mountain where the barometer reads 21.500 inches?

As a cubic inch of mercury weighs (approximately) .49 pound, a column of it 21.500 inches high weighs $21.500 \times .49 = 10.535$ pounds. This is also the pressure of the atmosphere, since it is the atmospheric pressure which causes the mercury column to have a height of 21.500 inches.

Water, or any other fluid, can be used in the tube of the barometer just as well as mercury. The reason that water is not used is because of its light weight, which is so much less than that of mercury that it rises, at sea level, to a height of nearly 34 feet in the tube.

As the pressure of the air at sea level is 14.7 pounds, or roughly 15 pounds per square inch, in dealing with steam and other gases it is not uncommon to speak of a pressure of 14.7 or 15 pounds as an atmosphere. Thus a pressure of 3 atmospheres means a pressure of 45 pounds per square inch and one of 6 atmospheres means one of 90 pounds.

(To be Continued)

Mechanics of Mining

An Explanation of the Principles Underlying Calculation Relating to Engines, Pumps, and Other Machinery

By R. T. Strohm, M. E. *(Continued from April)*

Although the lever, in its simple or in its compound form, enables a small force to move a much greater load, it cannot always be used conveniently; for the load moves only a short distance during the time in which the force moves through a correspondingly greater distance. Thus, if a load were to be lifted to a great height, a plain lever could not easily be used, as it would be necessary to lift the load as far as could be done at one setting of the lever, and then

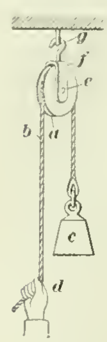

Fig. 10

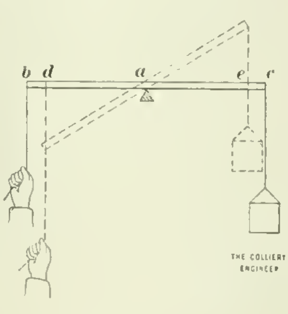

Fig. 11

to block the load in that position while the fulcrum of the lever was being raised to a higher point, so that the lifting could be continued. This repeated process of holding the load and shifting the lever would occupy a great deal of time and require much work, and therefore would be too slow for the lifting usually required to be done.

If a load is to be lifted to a considerable height without stopping, some form of pulley arrangement is commonly used. A very simple case of this kind is shown in Fig 10. The pulley *a* is simply a wheel with a groove in its outer edge in which fits the rope *b* to which the load *c* is fastened and on which the lifting force *d* is exerted. The pulley has an axle *e* that turns in bearings in the frame *f*, which in this particular case is fastened to a stationary overhead support. The pull *d* on one end of the rope is transmitted to the other end and causes the weight to rise. The pulley, meanwhile, turns on its axle. Thus, the whole purpose of the pulley is to change the direction in which the force acts. In this instance the straight downward action of the force *d* is changed by the pulley into a straight upward pull on the load.

In a lever, the lengths of the force arm and weight arm change as the lever swings on its fulcrum. For example, consider the lever shown in Fig. 11, having its fulcrum at *a*. When the lever is level, the force arm is the perpendicular distance *a b* from the fulcrum to the line of direction in which the force acts, and the weight arm is the perpendicular distance *a c* from the fulcrum to the line of action of the weight. When the lever has swung on its fulcrum to the position shown by dotted lines, the force arm is shortened. and is equal to *a d*, which is the perpendicular distance from the fulcrum to the new line of action of the force. The weight arm, in the meantime, has shortened to the distance *a e*.

A pulley may be likened to a simple lever whose force arm and weight arm are always equal and whose lengths never change. For example, take the pulley shown in Fig. 12. Every point on its outer edge, against which the rope bears, is at the same distance from the center *a* on which the pulley turns, because the pulley is circular in shape. Consequently, the perpendicular distance from the center *a* to the point *b* on the line of action of the force is equal to the perpendicular distance from the center *a* to the point *c* on the line of action of the weight; that is, the force arm is equal to the weight arm. No matter to what position the pulley may be turned, this is always the case.

It has been shown that when the force arm and the weight arm are equal, the force must be equal to the load, to balance it. Therefore, as a pulley is a lever with equal arms, it is true that the force must equal the load. In Fig. 10, if a load of 20 pounds is hung at *c*, a pull of 20 pounds must be exerted downwards at *d* to balance it and to keep the pulley from turning.

The kind of pulley shown in Fig. 10 is called a fixed pulley, because the frame *f* that holds it is fastened to a stationary support and therefore does not move up or down With a single fixed pulley supporting a load, as shown in this illustration the pull on each part of the rope is equal to the load or weight. Thus, if the weight *c* is 20 pounds, the part of the rope from the weight to the pulley is under a pull of 20 pounds; also, the part of the rope from the pulley down to the face *d* is under a pull of 20 pounds. Now, if the force *d* pulls

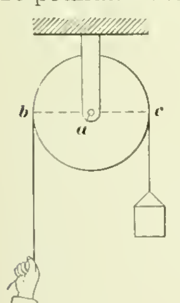

FIG. 12

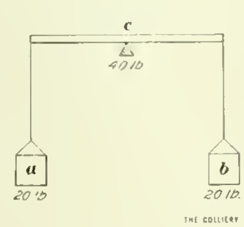

FIG. 13

downwards with a force of 20 pounds at one side of the pulley, and the weight *c* acts downwards at the other side of the pulley, the total downward pull is 20+20=40 pounds; that is, the downward pul of the hook *g* on the stationary support is 40 pounds, or twice the amount of the weight *c*.

This fact may be shown in a different way by considering the fixed pulley as a simple lever with its fulcrum at the middle, as shown in Fig. 13, and with a weight of 20 pounds hung at each end. The weight *a* pulls downwards with a force of 20 pounds, and the weight *b* pulls downwards with an equal force, so that the total force pulling downwards on the lever is 20+20=40 pounds; therefore, the pressure on the upper edge of the fulcrum *c* is 40 pounds. In other words, if a weight is supported by a rope or a chain passing over a single fixed pulley, as in Fig. 10, the pull on the stationary support is twice the amount of the weight.

Suppose, now, that the left-hand part *b* of the rope in Fig. 10 is tied to the ring that supports the weight *c*. The arrangement will then be like that shown in Fig. 14; that is, the weight *a* will be supported by both parts *b* and *c* of the rope, and therefore each will take half of the whole load. The downward pull on the rope *b* will be 10 pounds and the downward pull on the rope *c* 10 pounds, and the total downward pull on the axle of the pulley will then be 10+10=20 pounds, or the amount of the weight *a*. The pull on the stationary support *d* is the same as that on the pulley axle, or 20 pounds.

By comparing Figs. 10 and 14, then, it will be seen that the pull on the fixed support is least when the two ends of the rope are tied to the weight, as in Fig. 14, and that by untying the end *b* and pulling on it with sufficient force to balance the weight, the pull on the stationary support is doubled. This shows that when a sheave is put at the top of a head-gear, with the hoisting rope running down a vertical shaft at one side and straight down to the hoisting engine on the other side, the axle of the sheave and the head-gear itself must be strong enough to stand twice the downward pull due to the load. For the sheave corresponds to the fixed pulley shown in Fig. 10, and the head-gear forms the stationary support.

If the frame of the pulley is fastened to the weight instead of to the stationary support, the pulley is called a movable pulley. An arrangement o this kind is shown in Fig. 15. The weight *a* is hung on the hook *b* attached to the pulley frame *c*. The pulley *d* is held up by the rope, one end of which is tied to the stationary support *e*, the other end being pulled by the lifting force *f*. With this arrangement, the downward pull on the axle of the pulley is equal to the weight *a*. Suppose that the weight *a*

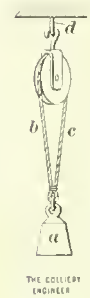

FIG. 14

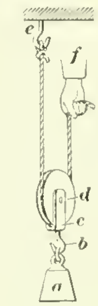

FIG. 15

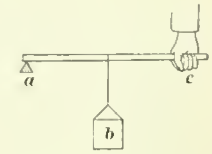

FIG. 16

is 20 pounds. Then the total upward pull required to hold up the weight *a* must be 20 pounds. It is plain that two parts of the rope hold the load, and therefore each takes half of the total pull; that is, the upward pull of the rope fastened to the hook *e* is 10 pounds and the upward pull of the force is also 10 pounds. In other words, with one movable pulley arranged as shown in this illustration, a given weight can be held up by a pull on the free end of the rope equal to half of the weight, and the pull on the stationary support is likewise equal to only half of the weight.

So far as the pull on the stationary support and the strain on the rope are concerned, the arrangement in Fig. 15 is better than that in Fig. 10. For in Fig. 15 the pull on the free end of the rope is just half of the corresponding pull in Fig. 10, and the pull on the support in Fig. 15 is but one-ourth of that in Fig. 10; yet the load is the same in both cases.

This advantage, however, is not gained without a corresponding disadvantage. With the arrangement shown in Fig. 10, the force *d* and the load *c* move at the same rate; that is, if the force *d* moves down 1 foot, the load *c* rises 1 foot. But with the arrangement shown in Fig. 15, the force *f* must rise 2 feet in order to lift the load 1 foot. Thus, although the force required in the second case is only half of that in the first case, it must move twice as far to accomplish the same result.

The pulley in Fig. 15 is like the lever shown in Fig. 16, which has the fulcrum *a* at one end, the load *b* at the middle, and the lifting force *c* at the other end. The fulcrum of the lever corresponds to the fixed end of the rope, the load corresponds to the weight hung from the movable pulley, and the force *c* corresponds to the pull on the free end of the rope. As the force arm is twice as long as the weight arm, the force *c* needs to be only half as great as the weight *b*; but the weight will rise only half as far as the force *c* moves upwards, because it is only half as far from the fulcrum. This shows why, in Fig. 15, the load *a* rises only half as fast as the force *f*.

(To be continued)

BOOK REVIEW

A review of the latest books on Mining and related subjects

Bulletin No. 61. "Characteristics and Limitations of the Series Transformer," by H. R. Woodrow and A. R. Anderson, has just been issued by the Engineering Experiment Station of the University of Illinois. This bulletin presents the results of a theoretical investigation of the characteristics and limitations of the series transformers more particularly in connection with its use in recording transient currents. Copies of Bulletin No. 61 may be obtained upon application to W. F. M. Goss, Director of the Engineering Experiment Station, University of Illinois, Urbana, Ill.

Birmingham District Mineral Land Reference, is a book giving the names of owners of fee simple and mineral lands in the counties of Marion, Winston, Cullman, Blount, Etowah, Fayette, Walker, Jefferson, St. Clair, Tuscaloosa, Bibb, and Shelby, in the state of Alabama. It is compiled and published by Alabama Mineral Map Co., of Birmingham, Ala. Price $100. In addition to the price the company furnishes data and maps to subscribers, somewhat on the order of a mercantile agency.

The South African Mining Directory. Published by S. A. Mining Directory, Ltd., Johannesburg. 200 pages. This directory is published monthly, giving a list of all of the mines of the Rand and Rhodesia and the colliery districts of the Transvaal and Natal, with a full list of the officials of each mine.

The Annual Report of the Superintendent of Coast Geodetic Survey for the Year Ending June 30, 1912, together with Progress Sketches, has just been issued. Aside from Hydrographic Geodetic, Magnetic, and Tidal work, the contents include International Boundaries; Special Surveys; Dangers to Navigation; Triangulation of the Yukon River; and Details of Field Operations. Among the illustrations we find Distribution of the Principal Astronomic Stations occupied to June 30, 1912; Routes of Geodetic Spirit Leveling; Position of Gravity and Tidal Stations; Magnetic Stations; sketch of general progress in Alaska, Hawaii, Porto Rico, Canal Zone, and the Philippine Islands.

Coal Mining Institute of America

The Coal Mining Institute of America expects to make its summer visit to the anthracite regions. The program is not yet completed, but it is roughly as follows: Members will leave the bituminous field from Pittsburg at 8:50 Monday evening, June 16, special sleeping cars being furnished. The train will take up passengers between Pittsburg and Tyrone and will arrive at Wilkes-Barre at 8:59 on Tuesday morning, June 17. Those who desire to make the interesting trip during the day may leave Pittsburg at 7:50, on Monday morning, and arrive at Wilkes-Barre at 7:50 p. m.

The meeting for organization purposes will be held in Wilkes-Barre at 10:30 a. m., June 17. Luncheon will be at 12 o'clock. In the afternoon a trip will be made to nearby collieries, and in the evening, after the Institute banquet, H. G. Davis, district superintendent of the Delaware, Lackawanna & Western R. R. Coal Department, will deliver a lecture on sociological work which has been done by the company. The address will be illustrated by stereopticon.

The following Wednesday, the 18th, the visitors will pass over the scenic Wilkes-Barre & Hazelton third-rail system to the latter town and view the anthracite strippings and collieries in that district. In the evening, the Institute will invite the members of the local District Mining Institutes to meet them at Wilkes-Barre. Addresses will be delivered on soft-coal methods of mining and sociological work in the bituminous region, illustrated by the stereopticon and possibly moving pictures.

On Thursday, the 19th, a trip will be made to the anthracite collieries in the Wyoming Valley, and, if time will permit, the members of the Institute and their wives will be taken by special train on the "Laurel Line" to Scranton to visit the International Correspondence Schools and be entertained with a luncheon as guests of the officers of the International Textbook Co. From 3 to 5 o'clock a session will be held at Wilkes-Barre for a discussion on the impressions received while visiting the anthracite operations.

At 6:20 the train will leave Wilkes-Barre for Pittsburg and other points in the bituminous coal field. It may be added that the members are invited to bring their wives with them if they so desire. Several of the leading anthracite companies have, by their executives, expressed themselves much pleased to have an opportunity to show their hospitality to the members of the visiting institute.

Working Anthracite Culm Piles

The Employment of Hydraulic Methods in Connection With Special Forms of Conveyer Lines

Written for The Colliery Engineer

In the early days of the anthracite industry, lump coal, steamboat, egg, and stove coal, with some chestnut, were the chief products shipped to market. Lump coal was in demand for blast furnace and locomotive use; steamboat coal was considered the only proper fuel for river and sound steamers, and nothing below chestnut would be used by housekeepers, even the mine owners burned pea coal to raise steam.

With the introduction of the Wooten camel-back engine a complete change in locomotive fuel took place; and with the introduction of the McClave grate and argand blower, smaller sizes of coal were used at the mines and in steam-raising generally, until at present, bird's-eye, which passes through a hole $\frac{5}{16}$ inch in diameter, finds a market.

Anthracite is brittle, and the more times it is broken down to produce domestic sizes the greater is the waste. In former years the small, unsalable sizes amounted to about 25 per cent. and these with rock, coal and rock, or small coal, were allowed to accumulate in piles. If it was possible to keep the large rock comparatively free from coal it was stacked by itself in a rock pile, or if there was a way to stack small coal by itself it was allowed to accumulate in culm piles.

Large quantities of culm were lost in preparing coal by the wet method, it going into streams and eventually into the rivers. In some places the culm piles are 100 or more feet high, one-quarter mile in width, and from three-fourths to 1 mile long. Unfortunately a number of these piles have been destroyed by taking fire, but many of them are left, and are being worked for market, and the small sizes, formerly called culm, are being saved at the breaker instead of being stacked as heretofore. The recovery from the culm banks and the small sizes obtained from freshly mined coal constituted about 40 per cent. of the total quantity of anthracite sent to market in 1911, or 20,414,077 long tons. Of this quantity 3,171,678 tons were recovered from culm piles. By further calculations it can be shown that by the use of modern steaming devices 21.3 per cent. of fine coal that would in former years have gone to the culm piles now goes to market.

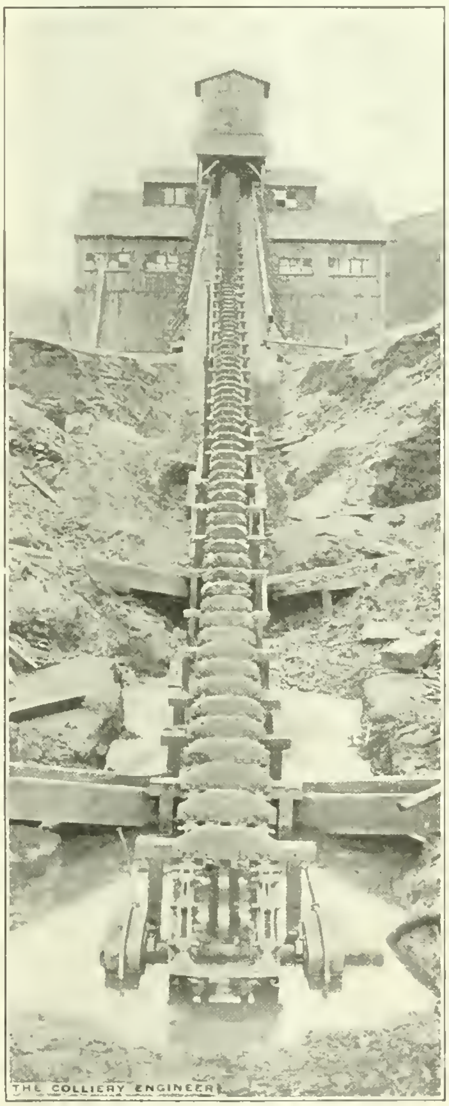

Fig. 1. Scraper Line Near Nanticoke, Pa.

The first washery was installed in 1890 and recovered 41,600 gross tons of coal. In 1907 the output from washeries was 4,301,082 tons.

In some instances the fine material less than five-sixteenth inch is used at the mines under modern water tube or flue boilers, thus effecting a further saving. At one plant the saving due to this procedure amounted to over $10,000 in one year.

There are mines near Scranton where the finest coal and sludge is flushed from the breaker or washery to bore holes going into the mines, and made to fill old workings and support the roof above the excavations. Where no arrangements are made for flushing, the sludge is caught in settling dams to prevent its polluting the streams as heretofore.

Since the reclamation of coal from culm and dump piles in the anthracite regions has been underway, the hydraulic method of excavating and transporting material has proved its superiority over steam shovels.

These old culm and dump piles contain from one-quarter to one-third, in some cases possibly more, good coal, which in former years was considered waste, but which is now being reclaimed by hydraulic sluicing and washing. The method followed is to construct a washery, at some point convenient to the pile, and by means of elevators carry the material to the top, where it is screened into sizes, and freed from slate by jigs and mechanical slate pickers.

In order to do away with the use of steam shovels and cars to load and carry the material to the washery, it is customary to break the culm loose from the banks by streams of water and direct the culm and water through sluice boxes lined with sheet iron to the scraper line leading to the washery. In some cases the scraper line is quite long and horizontal, and made to swing toward the culm bank as that is removed, as shown in Fig. 2; in other cases the sluice delivers material direct to an elevator boot at the foot of the washery; and still again, to an inclined scraper line leading to the top of the washery, as shown in Fig 1. The latter illustration is the washery of the Susquehanna Coal Co., at Nanticoke, where the material is broken loose from the bank by water nozzles, and sluiced to the scraper line. Back of the washery is seen the No. 5 Colliery dump pile, which is 1 mile long and over one-quarter mile wide on the top. The scraper line shown in the illustration serves another large culm bank made up of material from No. 7 colliery and this also is to go through the washery.

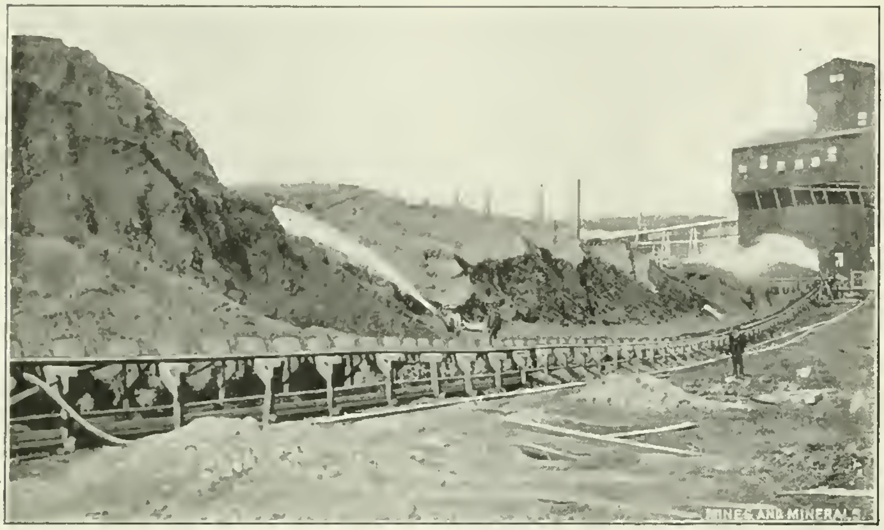

Fig. 2. Hydraulicking Culm to Conveyer Line

Between the centers of the sprocket-wheel shafts of this conveyer there is a distance of 374 feet, with the trough pitched at an angle of 3 inches to 1 foot. The arrangement possesses a number of new features which will appeal to every one who uses or intends to make use of trough conveyers. The trough is of wood, lined with cast-iron plates cast in semihexagonal segments and biased as shown by the heavy lines in Fig. 3. It is well known that when cast-iron plates are bolted inside wooden troughs to act as lining, especially if laid so as to have parallel joints at right angles to the length of the trough as shown by the dotted lines, the fine material will get under and gradually raise them, eventually bringing such pressure to bear on the castings as to crack them. Before the break occurs the plate may be raised sufficiently to have the flights, as they move along, catch on the raised plate, thus putting extra strains on the scraper chains and sometimes causing them or some of the fastenings to break. When the plates are laid in the trough so the joints are diagonal to the length, as shown by the full lines, the flights slide over the joints a little at a time and move the material gradually across the joints, and so do not force it under the plate nor does the flight catch on the joint. The scraper conveyer in Fig. 1 is designed for a capacity of between 1,800 and 2,000 tons of material daily, consequently, the chains must be strong and constructed so that in case of a pin, bolt, rivet, link, or flight breaking it may be quickly repaired. The Cross Engineering Co. have constructed the rivetless chain which is eminently suited for this kind of work, for after 5 months operation not 1 penny has been spent on it for repairs.

The flights shown are backed and bolted to bracket castings, which in turn are constructed so as to fit between two links to which they are rigidly fastened by bolts. The flights are 3 feet apart but only the lower one in the illustration shows a bracket.

Attention is called to the extension of the link pin at both ends because it fits in grooves in the sprocket wheels and all pulling strains due to moving the material and the apparatus come on these projections, a feature which minimizes wear and consequent breakage of links as in cases where the links engage the sprocket-wheel projections and receive the pull of the load. The pin *a*, Fig. 4, has a square shoulder slightly oval which passes through the opening *b* in the links, after which the pin is given a half turn so that the shoulder stands at right angles to the oval opening *b*, and binds the links together, thus making a rivetless joint and completing the chain. Inside the collar the pin is forged square to fit into the recess *d* of the outer link. The pull thus comes on a squared surface and any wear at this place can be compensated by simply turning the pin half way around so as to present a new squared surface to the link recess. The outside links are so extended on each end as to form a "lip," covering the recess formed by the chain when in operating position. This lip prevents dirt or other

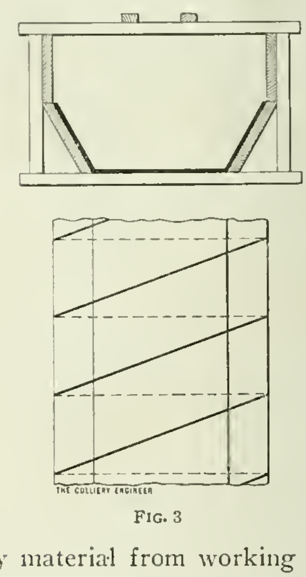

Fig. 3

gritty material from working in on the bearing parts of the inside links and the pins. On the up trip the chain is suspended by the flights resting on the trough floor; on the down trip the chain and flights rest on two shoes bolted near the center of the top of the flights. These shoes slide on rails laid on ties of the framework above the lower flights and are lubricated to prevent wear and reduce the noise caused by friction.

During the last few years considerable attention has been given to dredging for coal and culm that has

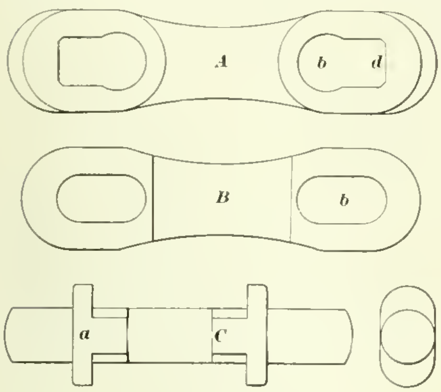

FIG. 4

been washed into the Susquehanna River. The dredges may be noticed by travelers from the cars as far down as Harrisburg. During the year 1912 approximately 80,000 tons of coal was recovered in this way and in 1913 probably 100,000 tons will be recovered.

Speed of Hoisting

Mr. Tom Johnson's paper still affords topics for fruitful discussion at the meetings of the Chemical, Metallurgical, and Mining Society. One of his contentions that has elicited a great deal of difference of opinion was that "it should not be impossible to hoist 5,000 tons of rock per 24 hours through two compartments, 6 ft. × 5 ft., from a depth of 3,000 feet." Some interesting data on this point were brought before the last meeting of this Society by Mr. A. Richardson. To hoist a maximum amount of ore, it is necessary to have quick loading from large and perfectly equipped boxes serving several levels, fast winding with powerful engines, well-maintained shafts, and expert drivers. With those factors granted, the question becomes merely one of winding speed. As far back as 1878 the California Gold and Silver Mining Co. was hoisting from a depth of 2,500 feet in 45 seconds, an average speed of 3,333 feet per minute. The No. III Tamarack has done 4,800 feet in 1 minute 15 seconds, or 3,880 feet per minute, the maximum speed during the wind being over 5,000 feet per minute; this hoist has made forty trips in one hour with three tons of ore per trip. The Calumet and Hecla has wound from 4,900 feet at an average speed of 3,500 feet per minute. At Kimberly, 4,000 short tons have on several occasions been hoisted in a little over 11 hours from 1,560 feet; with this engine the acceleration period occupies 16 seconds, the retardation period 13 seconds, the maximum and constant speed period 13 seconds, equivalent to 3,770 feet per minute, the average speed being 2,230 feet per minute for a winding period of 42 seconds; the loading and dumping together occupy 5 seconds, so that each trip takes 47 seconds.—*S. A. Mining Journal.*

Shaft Sinking

*By Samuel Haines**

I have noticed in MINES AND MINERALS from time to time, different methods relative to drilling holes in drifts to accomplish the greatest amount of work, although it is very seldom that we see anything in regards to shaft sinking. When a company commences work on a new property the main work of that company is in sinking the shaft, and it is up to the superintendent in charge to see that the best results are obtained, and this is only possible when the men working in the shaft do their work in an efficient and practical manner. In my experience in shaft sinking I have seen different methods used in taking out a sink or cut, but none more effective, or accompanied with better results than the "sink" outlined in the following plan:

The plan, Fig. 1, represents a shaft 12 ft.×20 ft., rock measurement. The idea is to get the powder down where it will do the greatest amount of work. A glance at the above illustration will readily show that this is obtained by drilling the holes as represented.

The collar of holes marked No. 1 covers an area of 6 feet square, the holes being drilled at an angle of 65 degrees slanting toward the center of the shaft, and about 7½ feet deep; holes No. 2 are drilled to a depth of 7½ feet at an angle of 65 degrees, also No. 3 are drilled as side holes in same direction and to same depth. Holes 4 and 5 are next drilled to a depth of 6½ feet at an angle of about 75 or 80 degrees, holes 6, 7, 8, and 9 are end holes and are 6 feet deep. Holes 8 and 9 would not be required in a shaft of smaller dimensions than this.

Holes 1, 2, and 5 can be readily drilled without moving the arm on the bar, holes 3 and 4, by simply turning the machine over on the other side of the arm; by swinging the machine over to the other side of the bar, holes 6 and 8 can be drilled, then by swinging the machine over the arm again holes 7 and 9 can be drilled; thus getting the maximum amount of drilling with the

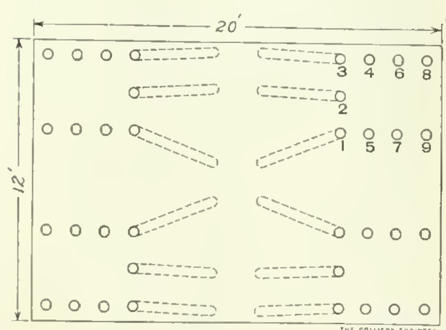

FIG. 1

minimum amount of handling the machine, incidentally saving time. We used this cut or sink regularly in the Negaunee mine shaft, and are using it at present at the Isabella mine, Palmer, Mich., with splendid results in very hard working rock. In my judgment it is one of the best cuts that can be used in shaft sinking, and will accomplish the greatest possible results with least powder, as the powder is placed down where it can be most effective. The four holes numbered one must be blasted with a battery.

*Negaunee, Mich.

THE LETTER BOX

Readers are invited to ask or answer any question pertaining to mining, or to express their views on mining subjects in this department. All communications must be accompanied by the name and address of the writer—not necessarily for publication.

The editors are not responsible for views expressed by correspondents.

Mercurial and Aneroid Barometers

Editor The Colliery Engineer:

Sir:—Textbooks, mining journals, United States Weather Bureau, and others are authorities for the statements that mercurial and aneroid barometers indicate the changes in pressure from 3 to 6 hours in advance of its effect in the mine. The barometer is subject to any changes of atmospheric pressure, and from the principle upon which it is constructed it can only indicate a change that is taking or has taken place, and cannot forewarn of a change that might be about to occur. Now as gases respond immediately to any increase or reduction of pressure, by contracting or by expanding, the question that presents itself is: Why does the barometer indicate the fall in pressure in advance of its effect in the mine when both are subject to the same changes? Not Signed

Note.—The author of the above is referred to a short article on "Use of the Barometer in Mining," by Mr. J. C. Schellenberg, on another page of this issue.—Editor.

Mercurial and Aneroid Barometers

Editor The Colliery Engineer:

Sir:—In regard to the question by "Not Signed" dealing with the statement that instruments for indicating atmospheric pressure show changes 3 to 6 hours in advance of the effect upon coal mines, would reply as follows:

The barometer indicates the existing atmospheric pressure, and the column of mercury changes in height simultaneously with atmospheric pressure variations. In the case of a coal mine, however, a certain amount of lag enters into the case, as some time is required in order to allow the air in the most remote portions of the mine to change in density until it reaches the same condition as the outside air.

When the barometer is high there is actually more air in a mine than when the atmospheric pressure is low, and this can be clearly understood when it is considered that the space within the mine does not change (disregarding mining operations) but the density of the air does.

As an illustration, with the barometer at 30 inches and a temperature of 70° F., the weight of a cubic foot of dry air is .07495 pound, and 13.34 cubic feet of air weigh 1 pound. With the barometer at 29.9 inches, 1 cubic foot of dry air at 70 degrees weighs .0747 pound, and 13.38 cubic feet weigh 1 pound. In other words, when the barometer rises from 29.9 inches to 30 inches, one-third of 1 per cent. more air must flow into the mine in order to permit the density to be increased sufficiently to balance a column of mercury 30 inches in height.

In the case of a mine containing 30,000,000 cubic feet of air a change of $\frac{1}{10}$ inch in the barometric pressure will cause an inflow or outflow of 100,000 cubic feet of air and the rapidity with which the interior of the mine changes to the same condition as the outside atmosphere varies with the size of the mine, the extent of the worked-out portions, and the areas of the various passages.

Detroit, Mich.

Heat Waves Visible

Editor The Colliery Engineer:

Sir:—The following is in answer to the question asked in March number in regard to whether heat waves are visible or not, these being apparently seen when a current of warm air strikes a body of cold air.

The characteristic appearance produced when air at different temperatures is mixed varies in perceptibility in accordance with the difference in temperature. The apparent visibility of transparent hot gases ascending from the top of a chimney is due to the variation in light intensity caused by the refraction of light rays in passing through mediums of different density.

The action is, of course, the same as the apparent bending of a straight stick partly immersed in water, as the portion submerged appears bent out of line, due to the deflection of the light rays when emerging from the water to the air.

The heat waves referred to can apparently be seen issuing vertically from a hot radiator in direct sunlight, but the apparent visibility is due to an optical illusion. The same effect can be noticed upon pouring hot water into a receptacle containing cold water and lined with white enamel. T. Chester

Detroit, Mich.

Afterdamp

Editor The Colliery Engineer:

Sir:—In C. K. Gloman's "Chart Classifying Mine Gases," accompanying The Colliery Engineer for April, I notice that he treats afterdamp as a single gas with the formula $CO_2N_{7.5}$. To quote him: "The symbol of afterdamp is $CO_2N_{7.5}$. There is present, therefore, in each molecule of afterdamp one atom of carbon, C, two atoms of oxygen, O_2, and seven and one-half atoms of nitrogen, $N_{7.5}$. From this it follows that the molecular weight of afterdamp must be the sum of the atomic weight of the atoms comprising the molecule."

As is well known, afterdamp consists of a number of different gases, mechanically mixed, chief among them being carbon dioxide, CO_2; water vapor, H_2O; nitrogen, N_2; carbon monoxide, CO; oxygen, O_2; and occasionally traces of nitrous oxide, N_2O, and unburned marsh gas, CH_4. The kinds and quantities of the gases forming the afterdamp depend on the kinds and quantities of the compounds from which they are produced. The composition of the afterdamp produced by an explosion varies with different mines, as well as with different parts of the same mine.

In the complete combustion of any hydrocarbon, the resulting products are carbon dioxide and water. In the combustion of marsh gas, the gases distilled from coal dust, etc., in a mine explosion; the nitrogen present does not enter into the reaction (except such quantities as may be required to form traces of nitrous oxide) and remains free as before the explosion, and if it did it would not be in fractional parts of an atom. There is no such chemical compound as $CO_2N_{7.5}$.

Carbide Lamp Abuse

Editor The Colliery Engineer:

Sir:—In his recent report for 1912, W. E. Jones, State Inspector of Coal Mines, District No. 2, state of Wyoming, makes the following comment upon the use of carbide lamps, which, in view of what has been said by some of your readers, may be of interest:

"I had made a test of the carbide lamp at the time the last report was submitted and found that while it would burn in an atmosphere that extinguished an oil flame, yet I could and did stay for some little time in an atmosphere that extinguished the carbide light, and conversed with the mine boss without either of us suffering from any noticeable effects. This led me to believe that the danger from the use of this lamp, as alleged by some eastern inspectors, was largely theoretical and imaginary. But during the past year my attention was attracted to abuses of it. Where the air was dull this lamp was introduced as a substitute for air. In one instance I walked into a working place where my oil lamp would have been extinguished had I not retreated immediately. Yet a miner worked there daily, using, of course, a carbide light. There was not enough blackdamp to 'knock him out,' but he must have suffered from the effects, and his health was being steadily and stealthily destroyed. The carbide lamp is a good one if not abused, but a very poor one if undue advantage is taken of it. I would not condemn the lamp on account of its abuse in some cases; on the contrary, I recommend it for general use at the faces where open oil lights are being used. And it must be up to the mine inspector and mine officials to see to it that the abuse is eliminated."

E. W. Jones,
Scranton, Pa.

Use and Care of Safety Lamps

Editor The Colliery Engineer:

Sir:—Two disasters have occurred within recent months, due to defective safety lamps. Now all lamps should have a double gauze, but the objection to the two gauzes is the necessity for taking apart at the end of each shift, the glass, and inner and outer gauzes, and depending for this work on men or boys who only think of how many lamps they can assemble in the shortest time, and then take things easy

After being assembled, all lamps should be carefully tested by blowing around the top of the glass near the top asbestos gasket, and only one gasket should be used, not two or more as is often the case if the glass is too short. With all lamps of this class, dependence is placed entirely on the lamp man and his assistants. These should be intelligent, careful, and above all, sober men, who would be above going into the lamp room in the morning with a swelled head and a muddled brain, to clean and fit the lamps together.

Now I have a lamp of the two-gauze type and glass globe, in which the inner gauze remains stationary after being tightened by the screw plate under the glass cylinder, the same as in the case of a single-gauze Clanny, but my outer gauze can be safely fastened on over the inner gauze. The lamp burns mineral, colza, or pure miners oil. The shield is locked by a spring and cannot be opened until the bottom of the lamp is unlocked and unscrewed. The lock has a lead seal with the company's initials stamped on it before leaving the lamp room, and the lamp man examines each lamp he receives at the end of the shift, to see that the lead seal has not been tampered with. The lamp, on being given out of the lamp room at the commencement of each shift should be carefully examined, cleaned, and lighted, also numbered, and a correct register kept of the person who takes the lamp. Thus:

J. R. Watkins, miner, Lamp No. 1.

The shield need only to be partly fastened until the lamp is again tested by the fire boss. The outer gauze should then be taken off, and the inner gauze examined. It is easier to detect a small flaw in the gauze with a light inside the lamp; therefore, the fire boss can see any defects in the inner gauze or outer gauze. The miner should next test the lamp by carefully blowing around the top and bottom of the glass cylinder, then screwing on the outer shield, which locks with a spring. The lamp is now in a safe condition, having been examined by lamp man, fire boss, and the miner. All men who use safety lamps should be specially trained in their care and use. If the lamp is damaged it should be immediately extinguished, if not damaged it can be relighted in the mine by means of electricity, but no seals should be given to any person outside of the lamp-room staff.

Many locks that pretend to lock lamps can be opened and closed without the management being any the wiser. The lead seal can be easily cut off and the lamp opened, but it cannot be refastened, as the miner has no lead seals and no stamp to put initials on the seal. One man of good standing should be employed as lamp inspector, to carefully examine the locks as each man gives his lamp in at the lamp room, and any marks of any kind found on the lead seal should be recorded, and a careful investigation made. If the seal has been tampered with, then the person should be sent to prison for 2 months without the option of a fine. This punishment would soon cure the lock openers of their habit.

The lamp that has a match igniting arrangement inside, in my opinion, is not a safe lamp, as the average miner, who may have stuck his pick point through the glass, or knocked the lamp from the prop, would immediately on picking it up, begin to turn his match arrangement to get a light, instead of calling for his partner and carefully examining to see if it has been injured. I have seen instances of this kind.

The miner cannot be too careful of the lamp that gives light for him to work by and he should bear in mind that a very small defect can also bring speedy death to himself and coworkers. J. R. Watkins,
Superintendent of the Issaquah and Superior Coal Co.
Issaquah, Wash.

Law Regarding Mine Inspectors

Editor The Colliery Engineer:

Sir:—The matter brought up by Mr. Hooper in the March number is one that has engaged the attention of the coal mining craft ever since the writer can recollect anything about coal mines. Many theories have been advanced by as many interests regarding a method of selecting mine inspectors and determining their qualifications. But like "busting the trusts," the question does not seem so easy of proper solution after all. The miners would perhaps dispose of it to their immediate satisfaction by providing that the inspector be elected by themselves. But this solution, if possible, would be unwise. It is impossible, of course, since this is a government regulated by citizens unaided by aliens. It would be unwise by reason of the fact that the foreigners especially would be unable to discriminate intelligently between conscientious and capable men on the one hand and catering demagogues on the other. An election by the legal voters of the district or state, would be equally unsatisfactory, since the general public is incapable of judging in the remotest degree the qualifications of candidates. The good people of Ohio probably thought the matter properly solved when provision was made whereby the appointments would be equally divided between the two dominant parties, and this scheme has been heralded as a non-partisan arrangement. But the term bipartisan fits it better; in fact, fits it exactly. There is no elimination of partisan politics in this scheme, it is merely a division of the spoils.

Neither does Mr. Hooper's proposed remedy appeal to me as a practical solution. It only prescribes a penalty against the chief without giving him the slightest chance for defense, except as the governor saw fit to grant it. This, indeed, is a most arbitrary method of determining a man's qualifications, unjust, and totally inadequate. For instance, in a certain western district, during the year 1912 the inspector reported a man killed for every 157,150 tons of coal produced. It is generally conceded that this inspector is a clean, conscientious, capable, and strict official. An explosion occurred in his district, killing several, and so far as the writer is aware no one has attached any blame to the inspector. And it is certain that he still retains the confidence and good will of the miners as well as the respect of the mine operators. But if this had occurred in Alabama, with Mr. Hooper's proposed amendment in force, the chief would have been outlawed from office automatically, although innocent of any wrong doing, and the governor would have it in his power to replace him with some other person more to his personal liking or political advantage, as it suited his own purpose, just as the "compromise" gives it to him absolutely. An explosion or other disaster may happen in spite of the vigilance of the chief or even of the district inspector, the cause of which may be clearly beyond either's power to prevent; and it is certainly unnecessary to enumerate here the numerous ways by which they may occur. It would, therefore, be unwise, unjust, and even cruel, to penalize or cast reflection on a public official in no wise responsible for such accident or record.

The proposed law for the anthracite region in Pennsylvania, as explained by Hogan, is a much better plan, though somewhat inconsistent, perhaps, in providing that the majority members shall consist of men less able to examine such applicants than the minority of the board. In my humble opinion two former mine inspectors, themselves sworn not to become candidates for mine inspector, should be substituted for two of the mining engineers, and the five miners should be reduced to three, making a board of seven instead of nine. These ex-mine inspectors will have had actual experience in the particular duties for which the candidates are endeavoring to qualify and they would thus be especially qualified to examine such candidates.

We are surely all agreed that mining laws are made to protect those engaged in mining, and we are equally agreed, I think, that mine inspectors ought to be taken out of the domain of politics, either partisan, bipartisan, or non-partisan. But how to do it is another matter. Neither miners nor operators ought to be permitted to influence an appointment, for both are subject to the mining laws to be enforced by the inspector. And the one is as unwilling at times to abide by the laws affecting him as the other is to obey those affecting himself. The old adage that "familiarity with danger breeds contempt for it" is as applicable to the one as to the other. Both take unwise risks; the one, because, perhaps, proper precaution entails some labor or inconvenience; the other, because it costs time or money. An inspector should therefore be obligated to neither and should be entirely independent of both.

But the personnel of mine inspectors, if I read the signs of the times aright, is gradually improving, just as the standard of mine bosses is looking up. And the methods of selecting mine inspectors are as certainly approaching a proper solution, thanks to the mining journals and a quickened public conscience. Personally, the writer has no better solution for the present than the one mentioned and indorsed by Hogan, together with the amended suggestions herein made. Collier

Rope Turning

Editor The Colliery Engineer:

Sir:—In your March number, "Superintendent" asks how to change a haulage rope end for end. This can be accomplished by running the rope off the drum except turns sufficient to turn the rope. Then make a temporary splice of both ends, and run the splice around through the sheaves to the trip; then run the rope off the drum-fastened end. Afterwards the trip end can be put under or over the bull wheel, as the case may require.

James A. Campbell

Glace Bay, Cape Breton, Can.

Changing the Hoisting Rope

Editor The Colliery Engineer:

Sir:—In your March issue, "Superintendent" asks to be told how to change his hoisting rope end for end with the least trouble and expense. I submit the following as being the best scheme I have seen to do this:

In Fig. 1 a temporary sheave is placed at *c* and another is attached to the front of the car. The *a* end of the rope is threaded through the sheave on the car and passed around the sheave at *c*, and dead ended. Next, as shown in Fig. 2, the car is lowered until only two or three laps of rope remain on the drum *b*. The ropes at *d* are securely clamped together and the *a* end is firmly bound to main rope with soft wire. The next operation, as shown in Fig. 3, is to carefully wind the rope around the drum until *a* reaches that point, after which *a* is again dead ended, and then the clamp is taken off at *d*.

As shown in Fig. 4, the car is then lowered until the drum is nearly empty, after which the car is anchored in some manner so that it cannot move. The *b* end is next detached from the drum, and the *a* end attached; then the rope is carefully wound until the *b* end has been drawn to the car. The sheave is now detached from in front of the car, as in Fig. 5, and the rope attached. Assuming that sheaves of proper size and strength have been placed at *c* and on one end of car, two men should do this job in a comparatively short time and without damage to the rope.

Trinidad, Colo.

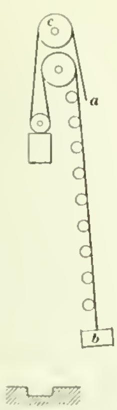

Fig. 1

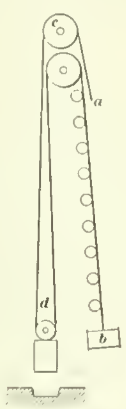

Fig. 2

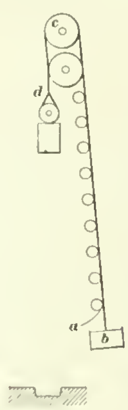

Fig. 3

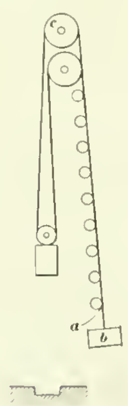

Fig. 4

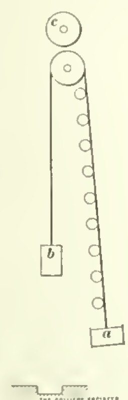

Fig. 5

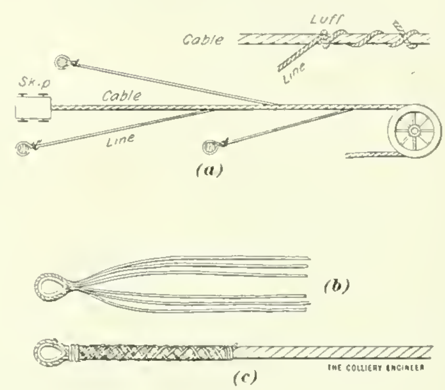

Fig. 6

Editor The Colliery Engineer:

Sir:—In answer to "Superintendent's" query in March issue of The Colliery Engineer, I believe this will fit his case: Procure a strong rope long enough to reach from the hoist to the bull wheel. Lay the coil by the hoist and take one end down to the bull wheel. Now, having the skip at the bottom of the incline and not much cable on the drum, undo the clasp at the end of the cable and taking the end, but leaving enough turns on the drum to hold the strain (about one-half of the drum width, single layer), start the engine to pull the empty skip up the incline and have men take the end out behind the hoist, not coiling but taking it out and laying it straight on the ground.

When the skip is near the top, stop and block it, and then take two or three short ropes and fasten on to the cable and tie to timbers along the shaft, as shown in Fig. 6 (*a*).

Now take the cable off of the skip, and taking three pieces of tiller line about 12 feet long make a loop in the middle or place an eye in, as shown in Fig. 6 (*b*). The eye should be small enough to go through the sheaves. Next place the end of the cable close to the eye, and lattice, or braid, ropes around cable, three going one way and three the other, till the cable is laced back several feet, as shown in Fig. 6 (*c*).

The ends should be finished off by winding around and tucking away. Now fasten the end of a light line into the eye, and with blocks along the way to prevent fouling or rubbing of the light rope, start the engine and pull in the cable with the light rope attached. Having got the end of the light rope to the drum, unfasten it from the end of the cable and run the cable off the drum altogether. Now bring up the other end of the cable and place it on the drum with a few turns put on the way it will run when fixed permanently. Now lattice, or lace, thongs on this end as before, and then taking the other end of the light line take a few turns around the drum in the opposite way to which the cable is running and start the engine, and the cable will again go out through the sheaves. When at the other end, make fast with ropes as before, take off the light rope and fasten to the skip, then lower slowly until bottom is reached, when the cable can be made fast to the drum again, and the change is made. Circumstances alter cases, but according to the sketch shown I do not see any other way to change this. With a rope long and strong enough and the thong latticed, or braided, back far enough, there should be no hitch at all.

The Influence of Drafts in Mine Explosions

Editor The Colliery Engineer:

Sir:—I have read the article by Messrs. Reynolds and Reynolds about "Stopping Ventilation at Firing Time" appearing in the April issue of The Colliery Engineer. The gentlemen have generously designated me a leader of the Ventilation Reduction Party. Had they read carefully my articles regarding dust explosions that have appeared in the past in Mines and Minerals and other mining journals they probably would not have conferred that distinction on me.

I have stated repeatedly and plainly that local conditions must determine whether slowing down or stopping the fan at firing time is permissible or not, and at no time did I advocate the practice for general use. I indorsed the practice in Iowa because conditions permitted it and because I realized that it was based on a sound principle, namely, that combustion is retarded by draft restriction and is promoted by an increase in draft through the improvement of draft facilities of whatsoever kind. I have indorsed the method, not because I considered it a sure prevention of dust explosions, for I knew it was not, but mainly because through its advocacy I hoped to arouse a due appreciation of the dangerous properties of draft in a mine in connection with flame and to hasten the realization of the truth that the magnitude of an explosion is measured by the availability of the air supply rather than the character and amount of the dust present, and if Messrs. Reynolds and Reynolds should see fit to confer upon me the title of leader in that direction I shall accept the honor with thanks.

From my own observations and the experience and experiments of others, I found that the presence or absence of draft largely determined the explosion or non-explosion of the dust. I found also plain and conclusive evidence that in order to produce a dust explosion in a mine the draft produced by the heat from a shot must be sufficiently strong and concentrated to pick up and carry the dust along to the flame. It becomes evident therefore that with the fan stopped and in the absence of natural draft the flame of a shot receives no outside assistance in its production of draft, and consequently there is an increased margin of safety; because a larger flame and one of longer duration would then be required to produce the necessary dust-laden draft toward the flame to make an explosion possible. There are many cases where stopping the fan at firing time may not be permissible, but that does not affect in any way the soundness of the principle involved. I do not object to the rejection of the practice, but I consider it a serious mistake to disregard the principle, known to be correct, because the method of its application may be objectionable under certain conditions.

In my judgment, the final solution of the dust-explosion problem will not be reached until there is a general and full understanding and recognition of the influence of draft in explosions, and I note with disappointment the recently expressed personal opinion by the chief mining engineer of the Bureau of Mines that the movement or non-movement of the air is of relatively small importance in the initiation of a dust explosion. I am disappointed because the opinion appears to me to be an indication that we are moving away from the desired goal and not toward it. Thirty-five years ago Peckham and Peck proved that an increase in draft facilities apparently increased the explosion's force (Mines and Minerals, September issue, 1908) and they showed further that the presence of drafts produced explosion of the dust, and that in the absence of draft such explosion did not occur. Nothing has been developed in the last 35 years to permit us to question the correctness of the findings and conclusions of Professors Peckham and Peck. On page 116 of the Bureau of Mines' Bulletin 25, on the "Explosibility of Coal Dust," the results of experiments regarding the ignition of dust in the absence and presence of draft are given. It is stated there that with the most explosive dust in suspension and in contact with the flame no explosion resulted in the absence of draft; but when draft was supplied and the dust was blown into the flame, explosions resulted. The comment on the experiments is given as follows: "This shows the great importance which the method of introducing the dust can exercise on the character of the explosion." In view of this am I wrong in insisting that the important feature of draft influence should receive immediate and careful attention? Such proofs as the above and the many others that could be cited show that the movement or non-movement of the air is of paramount importance in the initiation of a dust explosion and that therefore the continued ignoring or minimizing of this fact must necessarily defer the solution of the explosion problem indefinitely.

In view of the fact that the fundamental principles governing the occurrence of dust explosions are apparently yet unknown, it seems unprofitable to discuss the merits of methods of prevention at this time. More than a year ago Mr. Rice, chief mining engineer of the

Bureau of Mines, stated that efforts were then being made at Bruceton to determine how and why coal dust explodes. Up to the present, so far as known, the matter has not been determined and it is evident that the value of proposed methods of prevention cannot be judged with intelligence and fairness until that important point is definitely settled.

Chariton, Iowa

Relation of Engineers to Mine Foremen

At the March meeting of the Shamokin and Mount Carmel Mining Institute, John F. Bevan, engineer of the Philadelphia & Reading Coal and Iron Co., delivered an address on the subject "Mining Engineer, Mine Foreman, Assistant Mine Foreman, Their Relation to Each Other and Other Employes." The following is an abstract from his address:

The coal beds in this district are folded, with saddles and basins succeeding each other, and with the intervening strata varying in thickness and quality, thus making coal mining one of the most complicated of problems.

Years ago only one or two seams of coal were mined and so far as output was concerned, the one seam appeared to be inexhaustible.

The continued mining for the last 40 years has brought on conditions where careful thought must prevail in order to secure the best results. The engineer, with the maps showing developments from the infancy of mining, is in a measure able to pierce the undeveloped and anticipate the irregularities to be met. His maps reveal the possible future contour of the gangway; the opening of rooms; the proper precautions needed in connection with them; information as to the advisability of mining at specific points, and the various obstacles that are to be overcome.

The basis of the engineer's information comes from the foremen who are in daily touch with actual developments.

In the entire anthracite field, there is no part more complicated or where the questions of openings, ventilation, and protection, are so vital as in the Shamokin and Mount Carmel field. Foremen schooled where mining conditions are so complex and showing a desire to learn more, cannot belong to any other than the best of their class in the business.

To the foreman and his assistants is entrusted the responsibility of protecting the mine and the mine workers, consequently their eyes are trained to note the defects in top or bottom where openings have been made; their ears are trained to hear and understand nature's warnings. To these responsibilities are added the executive duties of the colliery, which are in themselves no light burden to carry.

The work of the foreman can only be successfully accomplished by the aid and assistance of the mine engineer, and the latter is only of consequence in so far as he is able to assist the foreman. The knowledge gained by both is essential to the science of mining, and it is only valuable when both go hand in hand in the execution of the work. The exchange of ideas and knowledge makes each the wiser, and close business association between these two kinds of mining men will surprisingly advance the welfare of all.

The foreman securing knowledge from the engineer, learns to pierce the undeveloped, and in this he takes pride, when he is able to say this or that is the proper way of doing the work.

It has been my pleasure to instruct assistant foremen in sketching the territory under their supervision, thus enabling them to determine the best method of working. At first they thought this an imposition, and objections were raised by some of them. Those who thought otherwise were encouraged and the progress made was marvelous. Today some of these men are doing excellent work, and with all the labor involved would not discontinue it.

In intercourse, the foreman should remember that the engineer, unless informed, cannot know what is being done, and no other than the ordinary work of mining should be done without his advice, for the data at his command place him in a position where the wisdom or the fallacy of the proposition can be seen.

The engineer should carefully note the information given him and promptly advise to save time and labor. He should study the needs and demands of the mine and should reduce to a minimum by plans, advice, and suggestions, the moves made to accomplish a valuable end. He should remember that a useless move is wasted energy, for neither the operator nor the workman is the gainer.

The foreman should heed the advice of the engineer, and the plans submitted to him should be carried into execution as outlined. Any suggestions given by the engineer to rectify conditions should receive the careful consideration of the foreman, as the latter, being in daily touch with the work, may have some better plan to suggest.

While the greater part of the engineer's time should be devoted to underground matters, the wants of the outside foreman should also receive attention. His tracks should be laid with care, his trough lines on uniform grades, conditions at the breaker should be such as to obtain the best system of handling coal and supplying the cars.

The outside foreman's suggestions should receive immediate attention from the engineer.

While the present relations between the engineer and foreman are close, each should realize his part in mining, and his dependence on the other, so that with clasped hands and ideas they may accomplish greater things than they hitherto have done.

Hoisting Ropes

Causes of Loss of Strength—Proper Tensile Strength of Wire—Protection and Lubrication

*By W. D. Lloyd**

In a paper before the Midland Institute of Engineers, England, W. D. Lloyd gave the following facts: The conclusions drawn from a series of tests with worn wire ropes are that steel wire, however much it is fatigued by constant use, will hold its full load up to the moment when it parts, the only factors which appear to make any difference being actual loss of sectional area by friction or corrosion.

The main factor which determines the life of a winding rope is fatigue. The actual loss of strength caused by wear due to friction is usually comparatively slight, except perhaps in exceptional cases or with badly designed plant. Loss of strength by corrosion should not occur at the majority of pits if the ropes are properly lubricated from the day that they are put on. Fatigue is not caused altogether by the actual lifting of the weight, and imparting to it the required acceleration, but principally by vibration; this may be increased by numerous causes among which may be mentioned uneven coiling of the rope, flats on wooden-lagged drums, variations in the diameter of conical drums, uneven running of engines, valves hanging or sticking, vibrations of the cage due to the conductors (particularly where wooden guides are used), and last, but not least, want of care by the engineman in the handling of the engines. It should be remembered that vibration in a rope travels in waves, which must act in the same way as all other waves; that is, at any point where they are arrested they are reversed and travel back for a certain distance in the opposite direction. In a steel-wire rope, the points where the waves are reversed, and where they meet each other when traveling in opposite directions, are the points where the wire will be most quickly fatigued. This is the reason why a rope generally shows signs of wear in lengths between the pulley and the drum at the start of the wind, and between the rope socket and the pulley at the end of the wind, particularly in the latter, because the waves of vibration of the rope in the shaft as the cage is brought to bank are in a rapidly decreasing length, which may be in some cases reduced at the end of the wind to about 7 feet.

As is well known, the best steel wire may be drawn until it is capable of withstanding a very high tensile strain, but the higher the breaking strain of the wire the less able it is to stand fatigue and bending. In making inquiry into the life of the winding ropes it was thought that the cause of the unsatisfactory working of some particular ropes might be partly due to the wire having been drawn to give too high a tensile strain. On looking into the matter, it was found that until the last few years, owing to the difficulty of obtaining accurate testing machines, the tests of wire used were unreliable; but the following figures for the last few ropes are interesting and confirm this opinion:

Year	Breaking Strain of Wire in Tons Per Square Inch	Torsions in 8 Inches
1904	110	
1905	113	28
1907	114	26
1909	118¾	23

In conclusion the writer is of the opinion:

1. That neither the rope nor the socket that yields the best results in the testing machine will necessarily give the best results for actual work.

2. That, in order to obtain good results, even the best quality steel should not be drawn for winding purposes to more than 105 to 110 tons per square inch breaking strain; that wire of a diameter of .135 inch, No. 9½ standard wire gauge, is the very largest size that can be drawn satisfactorily to over 110 tons per square inch; and that better results and greater safety will be obtained by using more wires of a slightly smaller diameter, made of the best material, but not drawn to over 105 to 110 tons per square inch, even if the factor of safety is nominally decreased to 8 to 1, than to have the wire drawn to 115 to 120 tons per square inch in order to obtain a so-called factor of safety of 9 or 10 to 1.

3. That in testing fatigued ropes the tensile test is of little use, except that probably some information may be gained by observing the modulus of elasticity, as this decreases with fatigue; or, in other words, fatigued wire will generally give a short fracture, while new wire will show a certain amount of elongation at the point of fracture. Of the mechanical tests, bending will give some information when the rope is much fatigued, and is probably more reliable than the torsion test, which is often upset by the wires having lost their uniform section by wear, by corrosion, or by crushing. None of these tests will give any really useful information as to the load which a fatigued rope is fit to carry. By comparing properly prepared specimens of steel wire under the microscope, a practiced observer can detect signs of fatigue by the alteration in the structure of the steel; but it is doubtful whether such examination could be employed by a colliery manager in determining the safe life for a winding rope.

As regards rope sockets, the writer maintains that the old form of socket, though old fashioned, if properly put on, is still the safest; and that, in addition to resocketing ropes every 6 months, the rope ends cut off should be carefully taken to pieces and examined for corrosion and internal broken wires.

A thorough study of hoisting ropes has recently been published in *Glückauf*, which may be summarized as follows:

(1) The protective efficiency of lubrication has not been clearly proved except in dry shafts. This

suggests the conclusion that the present lubrication process for wet ropes leaves room for improvement, though it is certain that all known lubricating agents rapidly disintegrate in shafts with acid or salt water. Future experiments in this direction may provide a remedy. (2) Galvanizing or coating with zinc does not appear to have had a really protective efficiency in wet shafts, the reason being probably that zinc coating has but little power of resistance to salt water. It is also suggested that the wires have suffered by the galvanizing process, for, though it has been proved by Winter and others that that process, when properly and carefully executed, does not unfavorably affect the ropes, it is also well known that it often reduces the tensile strength of the rope by 50 per cent. and even more. (3) The efficiency of ropes in dry shafts stands in the proportion of 100 to 60 or 70 as compared to wet shafts, which, in view of the high prices of ropes, means a substantial economic advantage for dry shafts. (4) Tensile strength between 160 and 180 kilograms per square millimeter does not unfavorably affect the flexibility or hauling strength of the ropes, while ropes of more than 180 kilograms per square millimeter have given substantially lower efficiency figures. (5) The greater or less strain, as expressed by a higher or lower safety factor, put upon ropes has had no influence upon their efficiency. It may therefore be assumed that the advantages of a higher safety factor are neutralized by its disadvantages, namely, greater rope thickness combined with reduced flexibility and greater dead weight.

Units of Measure

Original, or "makeshift," methods of doing things can be seen and heard almost every day in the copper mines of upper Michigan. William was up in the stope at a freshly broken face, from which place he called Tom, standing on the level, "Tom, is there?" "Ase, ase wat do 'ee want?" "Go up top and fe'ch down bit stull." "'Ow long of a stull do 'ee want?" "A middlin' long un." "Can't 'ee measure 'im?" William measured in his own fashion and called back, "Tom, the bit stull I wanted ha measures as long as a pick an' a pick 'andle, a gad an' a gad 'andle, taw bluddy wedges an' a big flat rock."—*Mines and Methods.*

Steam Pipe Hangers

A use which can be made of old scrap rails is that of supporting steam lines. There is a variety of ways in which this may be done, a few of which are shown in the accompanying sketches.

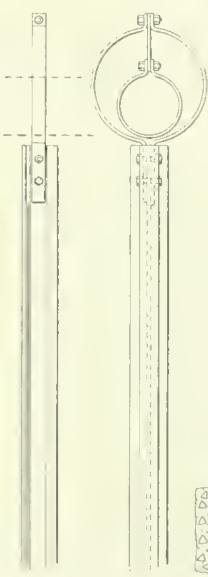

Fig. 1

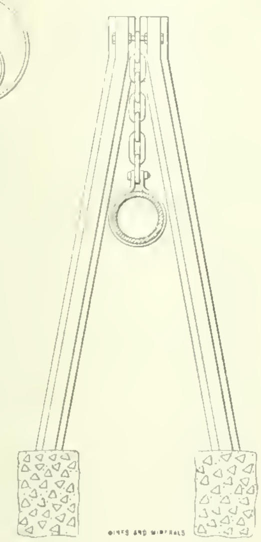

Fig. 2

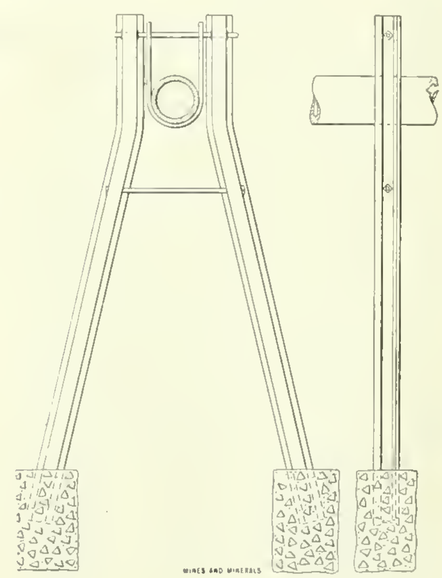

Fig. 3

The simplest form, where the steam line is not heavy, is shown in Fig. 1 where a rail is used as a single post. The rail may be merely set in concrete in the ground or may be placed in concrete so as to stand more firmly. At the top of the rail are placed two semicircular pieces of heavy strap iron with straightened ends, which clamp on each side of the web of the rail and are bolted through the web. At the other end, these pieces are bolted to a straight piece of iron which hangs down and is in turn bolted to the strap which passes around the steam line. In this way the steam line hangs in the circle made by the two semicircular pieces and is thus allowed to move freely with the expansion and contraction.

Another pipe carrier, shown in Fig. 2, consists in making an A frame by bending two rails so that they will be parallel for a few inches at one end. The rails are bolted together at these ends. Sometimes a short piece of pipe is placed between the rails through which the bolt passes and against the ends of which the rails are tightened by the bolt. The steam line is then supported by means of a strap around the pipe and a chain or a bar of iron, which is bolted to the strap and passes around the bolt holding the rails together.

A variation of this latter form can be made by bending a longer part of the end of the rails so that they will be parallel as in Fig. 3. Then the steam pipe is supported by an V-shaped piece of flat iron bored at each end so that the bolt holding the ends of the rails can pass through it.

The use of rails to support steam lines is common in the anthracite region of Pennsylvania where steam is carried sometimes for a distance of a mile through pipes supported in this manner. Any rails which are too poor for track purposes can be used as long as they have the requisite length.

PRIZE CONTEST

For the best answer to each of the following questions we will give any books on mining or the sciences related thereto, now in print, to the value of $3.

For the second best answer, similar books to the value of $2 will be given.

Both prizes for answers to the same questions will not be awarded to any one person.

1. The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.
2. Answers must be written in ink on one side of the paper only.
3. "Competition Contest" must be written on the envelope in which the answers are sent to us.
4. One person may compete in all the questions.
5. Our decision as to the merits of the answers shall be final.
6. Answers must be mailed to us not later than one month after publication of the question.
7. The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what books they want, and to mention the numbers of the questions when so doing.
8. In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.
9. Employes of the publishers are not eligible to enter this contest.

Questions for Prizes

21. In a mine worked by room and pillar in the panel system, do you consider it good mining practice to work a proportion of the pillars along with the solid working? Give the reasons for your answer.

22. Working by room and pillar, what percentage of coal would you leave in the pillars at depths of 300, 500, and 700 feet, respectively?

23. A mule serves a panel of 12 rooms in 6-foot coal. The parting is 100 feet from the first room, and all loaded cars, holding 2 tons each, go to it. Assuming the length of the rooms to be 400 feet when worked out, that the rooms are 20 feet wide, and the pillars 30 feet wide, what distance will the mule travel to collect 160 tons of coal in 10 hours?

24. On a straight track in good condition, having 1-per-cent. grade, a mine locomotive can haul 14 times its weight. The haul is 4,000 feet, and the number of loaded cars to be hauled daily is 600 in an 8-hour shift. (1) How many cars should be in a trip, the total weight of car and coal being 4,200 pounds, and having a frictional resistance of $6\frac{1}{2}$ pounds per ton of 2,000 pounds? (2) What should be the weight of the locomotive? (3) The law allows a speed of 10 miles an hour, what speed will the locomotive require?

Answers for Which Prizes Have Been Awarded

Ques. 13.—*Horsepower of Engine.* Calculate the horsepower of an engine that is capable of hauling a trip of 15 cars, each weighing 1,200 pounds, and having a capacity of 3,000 pounds. The haulage road has a uniform grade of 1 per cent. against the load, and is 4,000 feet long. It is desired to get out 600 cars a day. Assume the coefficient of friction as $\frac{1}{40}$.

No answers to this question were correct, a very essential part being left out. The question is, therefore, left open for better answers than have so far been received.

Ques. 14.—*Tracks in Rooms.* What is the maximum pitch on which tracks can be laid in rooms and cars handled with safety? What methods are adopted for handling the coal in the rooms on steep pitches? Answer briefly.

Ans.—In rooms or chambers where animal power is used for the haulage, the answer to this part of the question is not so much the grade, but how long will the stock do the work without giving out. So it may be more economical to use some kind of mechanical haulage. In moderately thick seams, pitching more than 4 degrees and not more than 18 degrees, the rooms are usually driven across the pitch, securing a grade of track low enough to make easy the haulage of mine cars to the face. Where the pitch does not exceed from 4 degrees to 8 degrees, rooms are turned off the entries or gangways at right angles, using animal power.

In some of the western and northwestern states, rooms are turned off the entries at right angles where the pitch is from 8 degrees to 20 degrees, and the haulage is done with McGinties. The loaded cars going down pull the empty cars up the pitch by means of a rope, the sheave wheels being placed between the rooms, having a face sheave to run the rope around at the face. Another method is to use a rope around a small bellmouth wheel, using some kind of a guard to keep the rope from flying off, and fastened to the motor which works on the entry on the same principle as the reel motor. Sometimes a mule will do this work. Loaded cars are at times let down easy grades by means of a rope which is given one or two turns around a prop at the face, thereby keeping the car under control unless the rope breaks.

I would not say this is the safest plan. In the mining parlance the term "steep" is supposed to mean dips or raises more than 30 degrees, because 30 degrees is about the limit on which rooms can be worked empty. From 35 degrees down to 25 degrees, coal will run by gravity, but not so violently as to require a battery or other obstruction to prevent it from rushing on to the entry or gangway; pieces of planks at times are sufficient to control it. In one part of the eastern bituminous coal fields of Pennsylvania coal would run on a less pitch than is given here, provided it was dry; but as the second part of the question refers only to steep pitches, the miner must have something to stand on to perform his work. Where the coal is soft and the seam thin, so that the top may be propped, mining is sometimes done on platforms or planks, but where solid shooting is done at over 30 degrees, everything would be swept down and out on to the entry, so this is not practical. The breasts must, therefore, be kept full of coal to allow the miner to perform his work at the face and it also acts as a support for the roof. There being two rows of props about 3 or 4 feet from the ribs, they are clad with plank on the inside and used as a manway and as a travelingway to the face and for intake and return airways, the whole width between being kept full of loose coal. The manway is used to get up timber and is supplied with cleats across on one side to get up and down when the pitch is from 40 degrees to 60 degrees to the face Coal is only drawn out by the loader as required to let the miner perform his work. At times these breasts become choked and where booming sticks are not used men known as starters must shoot the pieces which block the breast. At times starting can be done by hammering on the planks of the manway. This starting being very dangerous, only the most experienced men are used to perform this work, for at any time the loose coal may start and rush down the pitch. The coal is prevented from rushing on to the entry by means of a narrow chute, usually driven from 6 to 8 feet wide and 10 or 15 yards long, and rigged with a strong battery built of logs, through which the coal is drawn from the breast. In the Mammoth vein, in the anthracite region, where the coal is hard, these batteries are dispensed with, the chutes being driven very narrow, about 6 feet, one on each side of the breast. A manway is taken up from the gangway to the pillar heading as a travelingway no larger than necessary to get up timber, and is closed by a trap door to maintain ventilation. After the pillar heading is open, the chute heading is used to store timber. The breast is 10 yards wide and 7 feet high. It is driven in the lower bench of the seam. The plan of chutes and batteries is varied to suit conditions due to the pitch, nature of the top coal, the quantity of gas likely to be met with, and the volume of air necessary for its removal.

M. J. RAFFERTY,
Ehrenfeld, Pa.

Second Prize, Joseph Zelinek, Box 227, Alba, Tex.

QUES. 15.—*Size of Airway.*—Are two airways 8 feet square equal to one airway 8 by 16 feet; and which will pass the most air and why, the pressure per unit of area being the same in both cases?

ANS.—Although the combined areas of the two $8' \times 8'$ airways are equal to the $8' \times 16'$ airway, they will not pass as large a volume of air per minute under the same pressure per square foot, assuming the length of all three airways to be the same. This is due to the rubbing surfaces in the two small airways being together more than the rubbing surface in the large airway for a unit of length.

Applying Newton's law, that for a body at rest or in a state of uniform motion, action and reaction are equal and opposite, then at any point in the airways the pressure on the air column is equal and opposite to the resistance offered by its passage. This resistance or friction varies as the area of the rubbing surface and the square of the velocity, or $R = k\,s\,v^2$, in which R is the total resistance; k, the coefficient of friction, or unit resistance of the walls of the airway to the movement of air; s, the area of rubbing surface; and v, the velocity of the air-current.

Let p = the pressure of air per square foot and P the total pressure, then $P = p\,a$, in which equation a represents the area of the airway. Then, by Newton's law,

$$P = R \text{ or } p\,a = k\,s\,v^2 \quad (1)$$

As the pressure per square foot is the same in both cases, the velocity must be greater in the large area if it passes more air in a given time. Let v_1 = the velocity in the small airways and v_2 the velocity in the large airway, then by substituting the numerical values in equation (1),

$$2\,(8 \times 8)\,p = 2\,(4 \times 8)\,k\,v_1^2 \quad (2)$$

$$(8 \times 16)\,p = 64\,k\,v_2^2 \quad (3)$$

Solving equations (2) and (3) simultaneously

$$\frac{v_1^2}{v_2^2} = \frac{48}{64}, \text{ or } \frac{v_1}{v_2} = \sqrt{\frac{48}{64}} \text{ and } v_2 = 1.1547$$

This proves that the velocity of the air is greater in the large airway; and since the quantity of air passing a given point in a minute is equal to the area of the cross-section of the airway multiplied by the velocity in feet per minute, the relative quantities of air passing the airways may be found as follows:

Let Q_1 and Q_2 represent the cubic feet of air passing through the airways having velocities corresponding to v_1 and v_2, then,

$$Q_1 = a_1\,v_1 = 2 \times 64\,v_1 = 128\,v_1$$

$$Q_2 = a_2\,v_2 = 128\,v_2 = 128 \times 1.1547\,v_1, \text{ or}$$

$$\frac{Q_1}{Q_2} = \frac{v_1}{1.1547\,v_1} = Q_2 = 1.1547\,Q_1$$

which proves than an $8' \times 16'$ airway will pass 1.1547 times as much air as two $8' \times 8'$ airways of the same length when the pressure per square foot and lengths of all airways are the same.

DANIEL B. GREGG,
Golden, Colo.

Second Prize, R. S. Cothran, Wrights, Calif.

QUES. 16.—*Standing Props.*—How would you stand a prop in a seam of coal 6 feet thick, which has from 1 foot to 2 feet of slate above it (1) when the seam is flat; (2) when the seam pitches 30 degrees; (3) when the seam pitches 70 degrees? Give details and reasons for your answer.

There were numerous answers to this question, all of which lacked one or more of the essential details to make them correct. This question is therefore left open for another set of answers.

Notes on Mines and Mining

Reports on Conditions and Other Matters of Interest in Various Coal Fields

By Special Correspondents

British Columbia—A meeting of the Western Branch of the Canadian Mining Institute was held on March 4 and 5, at Nanaimo, B. C. Thomas Graham, Chief Inspector of Mines, acted as chairman in the absence of M. E. Purcell, chairman of the Western Branch. Thomas Stockett, general manager of the Western Fuel Co., made the address of welcome, and spoke of the coal mining district of which the city of Nanaimo was the commercial center. Coal mined in this district is bituminous and occurs in the Upper Cretaceous, which is locally called the Cowichan group. The area is extensive and the total tonnage of coal is very large. The coal from the mines is loaded into barges and shipped into various Puget Sound ports, and a considerable portion of it is shipped to San Francisco.

Mr. Stockett, in his address, stated that the No. 1 mine has been shipping continuously for the past 30 years and was good for another 30 years at the present rate of production. Following Mr. Stockett's address, Mr. Geo. Watkin Evans, of Seattle, read a brief paper on the coal field of northern British Columbia, known as the Ground Hog anthracite field. Mr. Evans' paper covered the geology and also the commercial value of the field. He said that some men in discussing the field recently in the public press had compared it with the famous anthracite fields of Pennsylvania, and at the same time mentioned that their estimate of the tonnage in the Ground Hog field was 200,000,000. Mr. Evans called attention to the fact that the Pennsylvania anthracite fields had originally 21,000,000,000 tons, and he wondered where there was any grounds for the comparison. He stated that at present it was impossible to estimate with any accuracy the tonnage of the Ground Hog field. In portions of the field where the geology had been worked in detail, the tonnage could be reasonably guessed at, but for the entire field it was at present a waste of time to give tonnage estimates. He discussed the quality of the coal and also called attention to the severe folding and faulting in some portions of the field. In conclusion he stated that he did not consider the British Columbia field in the same class as the Pennsylvania field, either in quality of coal or probable mining costs. He did believe, however, that in the Skeena, Nass, and Clappan watersheds there would probably be found coal enough to warrant a railroad being built into the district, and that there would be found a sufficient market for a reasonable amount of this grade of coal. He regarded the field as a very valuable asset to the province of British Columbia, one that should be exploited along sane lines, and not be bolstered up by wild and extravagant statements. Some portions of the field looked favorable while other portions were absolutely valueless.

An interesting and valuable paper was read by Mr. E. Jacobs, secretary of the Western Branch, on the "Methods of Mining Coal Under Various Conditions." This paper was prepared by Mr. Alexander Sharpe, who was ill and unable to be present.

The evening session opened with an address by Mayor Shaw, after which a very instructive paper was read by Mr. Henry Clark, of Victoria, the Canadian representative of a well-known English firm, the designers and builders of head-frames and other equipment for modern coal mines. Mr. Clark showed on the slides photographs of head-frames built in Japan, South Africa, Wales, and England. He described each type of head-frame and equipment, and also called attention to correct and incorrect design.

The morning of the second day of the session was devoted to visiting the Reserve mine, which is being opened by the Western Fuel Co. This shaft was then down over 900 feet and expected to reach the coal by the end of March. When equipped and in operation this shaft will hoist 1,500 gross tons in 9 hours, and will be modern in every way. Mr. Matthew Guinness, of Nanaimo, who has taken active part in mine rescue work, read a paper on "How to Prevent Mine Accidents."

Northwestern Canada

The Canmore Navigation Coal Co., Ltd., whose head offices are at 11 Victoria Street, London, E. C., England, is opening a coal area of about 1,300 acres adjoining the property of the Canmore Coal Co., at Canmore, Alberta. Mr. W. H. Wain, 41 The Parade, Cardiff, Wales, is the consulting engineer for this concern. The field work is in charge of Mr. Geo. H. Burd, who is now at Canmore directing the exploration and development. There are a series of veins on the property dipping about 30 degrees to the west. The coal is a steam coal of the following composition:

Proximate Analysis

	Per Cent.
Fixed carbon	81.96
Volatile matter	14.71
Ash	1.90
Moisture	1.43

Ultimate Analysis

	Per Cent.
Carbon	87.33
Hydrogen	4.17
Oxygen and nitrogen	5.42
Sulphur	1.18
Ash	1.90

Specific gravity, 1.34.
Heating value, 8,292 calories.

The installation of a plant for an output of 1,000 tons a day is planned, and a railroad about $1\frac{1}{2}$ miles long to connect with the main line of the Canadian Pacific Railway.

The MacCullough and McGillis Land Co., of Calgary, Alberta, is preparing to open up an area of about 160 acres at Threehills, Alberta, on the main line of the Grand Trunk Pacific Railway from Calgary to Edmonton. It is proposed to install a plant with an output of 250 tons a day. The coal at this point is about 200 feet below the surface. The seam lies horizontal and is a little over 4 feet thick. This coal has a composition as follows: As mined, moisture, 12.43; volatile, 30.75; fixed carbon, 47.35; ash, 9.47; sulphur, .56; British thermal units, 10,066. Dry, volatile, 35.11; fixed carbon, 54.07; ash, 10.83; sulphur, .64; British thermal units, 11,493.

An interesting case is to be tried involving the right of way of railroads over coal lands. The Canadian Northern Railway right of way passes over some coal property of Robert Jackson, at Nevis, Alberta. The seam at this point lies but 20 feet below the surface and the railroad company contends that having paid for the surface rights they are not obliged to pay for coal under their right of way. As a general rule this might hold, but in the present case the attorneys, with the writer as consulting engineer, assert that inasmuch as the property is an ideal one for quarrying by steam shovels, the railway has no right to obstruct this, the cheapest method of mining the coal. The coal mining regulations lease coal lands entirely separate from the surface rights, under a payment of $1 per acre per year and a royalty of 5 cents per ton mined.

The city of Calgary, during the coal strike of 1911 and 1912, went into the coal business, securing $122,119 worth of coal from United States mines mostly, a total of about 29,646 tons. The freight on this amounted to $182,305. The total sales to date have amounted to $194,491. The city is out about $90,000 so far, and has on hand about 1,400 tons, which it is selling with much difficulty. There is considerable sentiment here in favor of the city owning and operating its own mines and this may eventually be done.

The provincial legislature of Alberta, at the session just now ended, has passed a new mines act.

The output of coal of Alberta for the year 1912 amounted to 3,500,000 tons. About 7,000 persons were employed in 1912 in the coal industry, and there are about 246 mines in operation in the province. Large discoveries of coal have recently been made in the Brazeau district of Alberta. This field will be developed very fast.

The government is considering the establishment of mine rescue stations in various parts of the province. They aim to educate the mining public in the operation of apparatus for the saving of life and the protection of property A car has been placed at their disposal for this work by the Canadian Pacific Railway, and with trained men and modern methods it can be rushed to the place of an accident. J. H. S.

ILLINOIS

The miners employed at the Henrietta mine, Edwardsville, Ill., entered the mine at midnight and stripped it, taking out the piping, the mules, coal cars, and even taking up the track. When the company failed to meet the pay roll, the men ran an attachment on the property.

INDIANA

Shot Firers' Bill.—The Indiana Senate refused to pass the shot firers' bill which had passed the House almost without opposition. The coal operators paid no attention to the bill while in the House. In the Senate they had very little difficulty convincing the members that the bill was unfair and that the majority of the miners themselves did not care for it. The legislature adjourned before any bill was enacted that had serious bearings upon the coal industry in Indiana.

Senator Kolsem, of Terre Haute, Ind., introduced a bill in the Indiana Legislature, the object of which was to safeguard the coal miners. Governor Ralston signed this bill which has reference to the number of men who shall work in any mine not having two shafts; and requires that the roads between the two outlets of any mine shall be separated by at least 200 feet of strata; that it is unlawful to erect any inflammable structure or building nearer than 35 feet from the mouth of a mine opening; that the ventilating fan shall not be located directly over the air-shaft, and all fans hereafter installed shall be arranged so as to enable the operator, when desirable, to reverse the air-current.

KANSAS

With two exceptions, all of the coal mines in the state of Kansas have filed declarations with Charles H. Sessions, Secretary of State, that they will agree to the provisions of the Workmen's Compensation law. The exceptions are The Central Coal and Coke Co. and the Cherokee-Pittsburg Coal and Mining Co.

KENTUCKY

The Pond Creek Coal Co. has just issued its annual report for the year ending December, 1912. The company was organized November, 1911, and owns approximately 31,000 acres of coal lands and surface rights. On March 11, 1912, the first mine opening was begun and at present there are seven mine openings. The highest daily capacity of any mine up to date is 200 tons. The properties are in Pike County, Ky., about 10 miles from Williamson, W. Va. The Norfolk & Western Railroad began the construction of a coal road to Pond Creek from Williamson in May, 1912. This road reached the first mine opening November, 1912. The first shipment of coal was made on that date. During the month of November 11,902 tons of coal were shipped; in December, 24,119 tons; in January, 1913, 35,142 tons; in February, 28,313. The coal shipped was the result of development work, the mines not being, as yet, on an operating basis. During the year 1912, 310 dwelling houses and machine shops, blacksmith shops, and temporary buildings were built and mine equipment was purchased The power plant is sufficiently advanced to permit the mines to be operated to some extent by electric power. The coal is from 5 to 7 feet in thickness. During the coming year the shipments from the mines will be materially increased, and it is expected that eventually they will reach 10,000 tons a day.

MONTANA

In 1912 there were 3,598 men and boys employed in and around the coal mines in Montana. In this year 10 fatal accidents occurred, or 2.78 per thousand employed; in 1911, the fatal accidents amounted to 3.44 per thousand employed. There were 66,889 tons of coal mined for each death. The total number of tons mined during the year was 6,057,186. Fifty per cent. of the accidents were due to falling roof; 20 per cent. to moving cars and motors; powder blasting caused 20 per cent. of the deaths; 10 per cent. were said to be due to carbon monoxide.

Among the recommendations made for the good of the industry in Montana by Joseph B. McDermott, inspector, are found the following:

Examination of miners and superintendents, managers, and operators having anything to do with the operation of coal mines.

Two grades of certificates for mine foremen; one grade of certificate for fire boss.

To empower examining boards with the right to revoke certificates for drunkenness or inattention to duty.

To cut out all shooting during working hours when men are in the mines.

To drive at least two entries parallel, and make breakthroughs every 60 feet; escape roads to entries to be made from 1,500 to 2,000 feet apart, or refuge rooms with bore holes to the surface. The refuge rooms to be properly equipped with iron doors and provisioned, with communication facilities installed between refuge room and the surface.

All stoppings, either main or cross-section, to be made of brick, blocks, masonry, or concrete, or any non-perishable material.

NEVADA

A newspaper report states that the Nevada Coal and Fuel Co., at Coaldale, Nev., is shipping coal of good quality. This company secured United States patent for a large area of coal lands and has done considerable development work, going to a depth of 150 feet on a 500-foot slope. At this depth there was a down throw of 30 feet, and then a 7-foot bed of good coal was picked up.

NOVA SCOTIA

The Inverness Railway and Coal Co., of Inverness, Cape Breton Island, Nova Scotia, has ordered a duplex engine whose cylinders are 34 in. ×72 in., and each of the two drums can be operated independently of the other. The load which the hoist is to lift consists of a train of 12 cars, each weighing 1,150 pounds, and containing 2,240 pounds of coal. This load must be pulled up a 10,000-foot incline which varies in slope from 16 degrees at the surface to 35 degrees at the bottom. The stress produced in the hoisting rope by this load is approximately 41,000 pounds, and this, together with the length of the cable, is the feature which makes the hoist probably the largest ever constructed for coal mining.

OKLAHOMA

The Oklahoma legislature passed a law requiring that coal be undermined at least 6 inches beyond length of drill hole before being shot. The law will be effective April 1, 1914, at which time the present contract between miners and coal operators will end. At present the coal is shot from the solid and miners are paid on the mine-run basis.

PENNSYLVANIA

Governor John K. Tener has reappointed James E. Roderick Chief of Department of Mines for Pennsylvania.

Seven miners in Indiana County, Pa., were arrested on the charge of violating the bituminous mine law, and were fined $1 and costs. The violation consisted of negligence in placing sprags under coal when undermining it, and failure to carefully inspect mine roofs after blasts.

To encourage their employes to keep their premises clean and attractive, the Berwind-White Coal Mining Co. proposes to award three prizes to the tenants of the company who have the best and neatest looking place between April 1 and December 1, 1913. The first prize will be $25; the second $15; and the third, $10.

The Connellsville coke production of the first quarter of 1913 was more than the best previous records, as shown by the following tabulation:

First Qr.	*Production*	*Shipments*
1913	5,350,365	5,304,017
1912	4,909,709	4,855,033
1911	4,242,574	4,174,220
1910	5,526,521	5,662,145
1909	3,381,070	3,534,651
1908	2,128,608	2,393,591
1907	5,322,013	5,025,600

WEST VIRGINIA

The Consolidation Coal Co.'s report indicates a prosperous year. After all deductions, including 6 per cent. dividend on the stock, amounting to $1,358,865, the balance to profit and loss was $1,144,492. The net production of coal was 10,347,100 tons, an increase of 1,127,369 tons over the preceding year. President Jerre H. Wheelwright informed the stockholders that the Louisville & Nashville had ordered 3,000 steel railroad cars, and the Baltimore & Ohio 2,000 steel cars to take care of the company's Elkhorn field, of Kentucky. Considering that these companies together spent about $40,000,000 since April, 1911, to reach this field, they are bound to furnish transportation at reasonable rates to this company.

The Pocahontas Consolidated Collieries Co.'s report for the year 1912 is as follows: Total income, $1,246,-166; net earnings, $916,459; surplus after charges, $491,858; preferred dividends, $164,451; common dividends, $180,800; surplus, $146,607; total surplus, $2,233,360. Semi-annual dividend of 2 per cent. and extra dividend of 1 per cent. were declared. Old directors were re-elected and one change in the executive office was the election of George W. Woodruff as secretary in place of J. Walter Graybeal, who becomes assistant secretary.

According to the annua report, the properties of the Island Creek Coal Co., Holden, W. Va., were operated continuously during the year 1912, and produced 2,039,837 tons. Net capital expenditures for the year amounted to $534,522.44. During the year 126 houses were constructed, 38 houses were completed, a new hospital and its equipment installed, new store buildings at mines 7 and 8, and a Catholic church and parsonage were erected, besides new mine equipment including twelve 6-ton locomotives, two 15-ton locomotives, and mine machines, mine cars, etc., were purchased. The expenditures also include payments on account of dock at Superior, Wis., and construction and equipment of a new dock at Duluth, Minn. On August 1, 1912, the first dividend was paid upon the company's stock, at the rate of $2 per share, also an extra dividend of $3 per share. At the same time an opportunity was given the stockholders to reinvest the $3 paid in the company stock at $50 per share. Notwithstanding the large net expenditures at Duluth and elsewhere, the net quick assets of the company remain substantially intact.

The annual shipment sheet of the Pocahontas Flat Top coal field for 1912, published by the Crozer Land Association, Elkhorn, W. Va., shows an increase of 2,207,204 tons in coal shipments and a decrease of 10,584 tons in coke shipments. The total quantity of coal shipped from this field since 1883 is 127,555,046 tons, and the total coke 25,505,573 tons. With the exceptions of the years 1895, 1896, 1897, 1901, and 1908, this field has increased its output of coal. The coke output has gradually decreased since 1909, owing to the United States Coal and Coke Co., which made 721,000 tons of coke in 1909, making but 54,000 in 1912. Eliminating this company, there has been but a slight decrease in coke production in the last 10 years.

The Dixon-Pocahontas coal properties in McDowell County, W. Va., are stated to have been sold to the Lake Superior Corporation, which owns the Cannelton coal properties in the Kanawha field. The sale covers 2,500 acres of Pocahontas coal. The price paid for this land is said to be $500,000. At present there are two mines on the property and a third will be added. The Lake Superior Corporation manufactures iron and steel in the vicinity of Sault Ste. Marie, Canada.

33-10-6

Discipline in Mining

Samuel J. Jennings, mine inspector, of Pittston, Pa., delivered an address to members of the Pittston Mining Institute in which he pointed out the numerous chances for accidents in anthracite mines. To avoid confusion he took one district with which he was familiar and which furnished the following statistics:

In one of the anthracite districts with which I am familiar, the proportion of fatal accidents for the year 1911 is as follows:

	Per Cent.
Falls of roof and coal	59.53
Cars	21.43
Powder and dynamite	14.28

These three causes claimed 95.24 per cent. of all fatal accidents in the district. The non-fatal accidents were of the following proportions:

	Per Cent.
Falls of roof and coal	48.57
Cars	20.00
Powder and dynamite	14.28

The same three causes claimed 82.85 per cent. of the non-fatal accidents. For the year 1912 just closed the proportion of fatal accidents is as follows:

	Per Cent.
Falls of roof and coal	59.53
Cars	14.29
Powder and dynamite	25.00

The three causes claimed 92.86 per cent. of all the fatal accidents in the district during the past year. The non-fatal accidents were of the following proportions:

	Per Cent.
Falls of roof and coal	48.74
Cars	30.00
Powder and dynamite	10.26

The three causes claimed 89 per cent. of all the non-fatal accidents during the year. It is a fact worth observing that only two deaths occurred in the district during the year from other causes than those just mentioned.

Owing to the length of his address only an abstract can be given:

From such records it is plain what class of accidents are most liable to occur and therefore should be made the center of strict discipline. The mine worker places implicit faith in the report of the fire boss, but he should also examine his working place before commencing work. During the mining day, conditions at the face are changing; after each shot gas may be released in dangerous quantities, also roof and sides may have developed conditions that are unsafe unless rectified by prompt timbering.

In the district mentioned 1,414,322 pounds of dynamite and 2,704,300 pounds of powder were used in 1 year. There are 2,800 miners, each of whom on an average fires five shots, or 14,000 shots daily. The serious accidents from explosives occur in a number of the following ways:

The illegal use of a combination of explosives together with a detonator when firing a hole.

Using a needle, for the purpose of saving fuse.

The firing of holes with a short piece of fuse which is lighted before being pushed back into the hole.

Firing with a detonator and common squib.

Tampering with and shortening squibs, to save time.

Failing to give proper warning when firing.

Careless handling of explosives and detonators.

Storing explosives in too large quantities in the mine.

Storing several kinds of explosives in large quantities with detonators in the same box with the tools.

Allowing as many as five or six tool boxes containing explosives in the same small space or cross-heading.

Spreading dynamite on the floor in a cross-heading where persons travel, for the purpose of thawing it.

Approaching, opening, and removing powder from box with lighted lamp on cap, and often with lighted cigarette or pipe in mouth.

Making up charge of powder near lighted lamp.

Storing powder and dynamite along the roadways and chambers, because of not having a box to keep it in according to law.

Carrying detonators in squib boxes with squibs in side pocket at thigh.

Reopening a hole that misfired containing a detonator and mixed powders.

Thawing dynamite with the use of a lighted mine lamp.

Playfully exploding detonator to hear report.

Cleaning out blasting barrel with squib when powder was exposed.

Allowing laborer to use dynamite.

Allowing powder to be carelessly transported inside the mine in cars.

Carrying dynamite on the person for the purpose of thawing it.

Going back to the face after firing a shot with naked light when forbidden to do so.

In the district 7,000 mine cars move along the gangways and into rooms, some of them showing several times a day at the surface. The haulways may become crowded along the sides with material and refuse and so increase the dangers from passing cars.

Persons often ride between the cars and on loaded cars on slopes, all of which is against law and tends to increase the number of accidents. Records of these accidents are as follows:

Allowing gobs too close to roads on haulageways.

Allowing sides of haulageways to become close by allowing an accumulation of refuse.

Riding between cars on haulageways.

Riding upon loaded cars on slopes and planes.

Walking out on slopes and traveling upon them when trips are being hoisted.

Traveling upon slopes instead of using traveling ways.

Sitting upon front bumper of car in motion with foot on rail.

To enforce discipline and familiarize all mine workers with what they must and must not do, is a question too serious to pass over without suggestions. First, the miner must study the mine laws, and then a system must be evolved whereby detection of misdeeds would be sure. When once discovered, the offender should be taught just what the extent of such actions would mean to him if he should continue in the practice.

We are much too sympathetic in dealing with questions of punishment for minor offences. It is on account of these minor actions that most men become the victims of serious or even fatal accidents. There ought to be an existing influence in every mine which would make each man think of the safety of every other man in the mine. There may be a time when an employe, going to his work or even when he is at work, may observe another employe violating the rules and in doing so he is liable to become injured.

Men in some occupations may frequently become so accustomed to doing certain things every day, that they grow away from the idea that danger may accompany their acts. In many instances dangerous practices increase in magnitude at the time when men become familiar with dangerous conditions to such an extent that the danger is lost sight of. In other words, dangerous practices are multiplied and more risks are taken because of the success which they have experienced in taking former risks.

OBITUARY

ALEXANDER FULTON

Alexander Fulton, who died at his residence in Shamokin, Pa., on April 15, was for many years prominently identified with the anthracite mining interests of the Shamokin region as a superintendent and successful operator, until the collieries he was interested in were acquired by the Philadelphia & Reading Coal and Iron Co., nearly 25 years ago. Since that time he lived a retired life in Shamokin where he was regarded as one of the most respected citizens.

He was born at Hamilton, near Glasgow, Scotland, on May 9, 1829. In 1848 he came to America with his parents and settled in Schuylkill County, Pa., and began work in the mines. Shortly after locating in this country as a young man, Mr. Fulton became acquainted with the late Hon. William Connell, of Scranton, Pa., and Andrew Robertson, of Pottsville, Pa., two young men in the same walk of life, who had come to America about the same time. All three remained intimate personal friends until the death of Mr. Connell made the first break in the trio of self-made men, who through their later strong financial positions and high characters were for years leading individual anthracite operators and most prominent citizens of their several communities.

Mr. Fulton was a man of strong physique, and in his younger days was exceedingly active. For a time, in early life, he worked as a miner in western ore mines, and though of a kindly disposition he was a leader in the sports of the camp, and had quite a reputation in friendly fistic bouts. At this time he became acquainted with the late Samuel L. Clemens (Mark Twain).

When Mr. Clemens wrote his "Roughing It" in which is the very humorous account of "Buck Fanshaw's Funeral," he used, and of course exaggerated, Mr. Fulton's old time personality as the original of the character "Scotty Briggs."

Many years ago Mr. Fulton connected himself with the Presbyterian Church, and for nearly or quite 50 years he was a Ruling Elder of the First Presbyterian Church, of Shamokin.

STEPHEN R. KROM

Stephen R. Krom, the originator of the belted high-speed type of crushing rolls, died at his home in Plainfield, N. J., March 21, 1913. To Stephen Krom belongs the credit of being the pioneer in introducing the belted high-speed roll which had its origin and development in this country. This notable contribution to ore dressing consisted in the use of single bedplate supporting the roll shafts, and to which levers holding the movable roll bearings were pivoted. He also made use of steel tension rods to support the crushing strains, and of hammered steel tires for the crushing surfaces.

He was a member at various times of the American Institute of Mining Engineers, the Institute of Mechanical Engineers, and a life member of the American Institute.

Answers to Examination Questions

Questions Asked at the Examination for Fire Bosses and Mine Foremen, Held in West Virginia, 1912

(Continued from April Issue)

Ques. 7.—What dangers arise in dusty mines from the blasting of coal and the lack of judgment in placing holes in blasting in mines? Would you consider it safe to permit blasting to be done in mines generating explosive gases? If so, what per cent. of gas would you consider safe and under what restrictions would you permit blasting?

Ans.—All explosives used in mines give off more or less flame when ignited. Similarly, the dusts of all bituminous coals, especially when in a finely divided state and dry, give off more or less gas when subject even to a low degree of heat. This may be supplied by that of burning or exploding powder, and if sufficiently great and long continued may distil off so much gas from the coal that its rapid burning in the confined passages of a mine will result in what is known as a dust explosion. The amount of flame given off by the exploding powder will depend largely upon its composition and upon the way it is used. The smallest amount of flame and of the shortest duration is given off by the so-called permissible, or safety, powders tested and approved by the United States Bureau of Mines, and the longest and most enduring flame results from the ordinary black powder. A properly balanced shot, that is, one that is so placed and charged that the powder in it is just sufficient to do the work of bringing down the coal, will be more nearly flameless than an ill-placed or overcharged one. Even if the hole is properly charged, if it is placed near a crack, crevice, or joint, the gas will expand into this opening and will burn with a large amount of flame, often sufficient to ignite and explode the fine dust always present in a coal mine. The danger is much greater if the shot is too tight and is so placed that the powder in it cannot bring down the coal. In this case a blown-out shot will result, and any dust in the place will be stirred up and thrown into the air. In this condition the possibilities of an explosion are greater because, being separate and distinct, each grain of dust is surrounded by flame and naturally gives off the greatest amount of gas in the least time.

Even in the best of mines, shot firing is always a dangerous operation, so that it may be said that blasting in gaseous mines is not absolutely safe under any circumstances. However, by proper precautions, the danger may be reduced to a minimum.

The percentage of gas in which shot firing may be carried on depends upon many things, the chief of which is the presence or absence of the finely powdered dry and explosive dust, so common in the mines of West Virginia. If explosive dust is not present (something that is practically impossible), or if the mine is so wet throughout that the dust is in the state of mud, if permissible, short-flamed powder is used, and if the holes are properly placed and properly charged, there is no theoretical reason why shot firing should not be safe(?) until the proportion of gas reaches the burning point of 1 of gas to 17 of air, or about 5.5 per cent.

On the other hand, as explosive dust is always present, theoretical conclusions are of little practical value, and only actual experience is a guide as to the percentage of gas in which shot firing may be safely undertaken when dry dust is found in the workings. Our knowledge of what proportionate mixtures of gas and dust are dangerous is not definite and certain; in fact, it is only of recent years that any information upon this subject has become obtainable. In the light of our present knowledge in dry and dusty mines generating explosive gas the proportion of such gas in the return air-current should be kept well below 1 per cent. by increasing the volume of fresh air supplied to the workings. One per cent. is the limit allowed by several of the large companies under the conditions prevailing at their mines. But, since the explosibility of dust varies with the seam and since the seams vary in different localities, this may be too high under some conditions and comparatively a safe amount under others.

In addition, then, to keeping the proportion of gas at 1 per cent. or below, care should be taken to prevent the formation of dust and to render harmless that which is unavoidably formed. The amount of dust made may be materially reduced by abolishing shooting off the solid, that is, by requiring the seam to be undercut or sheared by pick or machine before it is shot down, by properly placing the holes, and by using in them the proper amount of powder, and by using tight cars which do not leak and allow the fine coal and even lumps to fall on the roadway, where it is soon ground into powder by the feet of passing men and mules. All dust made in mining operations should be loaded out and taken from the mine; the headings, the roof and ribs, as well as the floor, should be thoroughly watered, so that the dust may not be blown about through the workings and may be at the same time so wet that it will not burn; the rooms should be wet down a distance of from 60 to 80 feet back from the face, and short-flamed powder with uninflammable clay tamping should be used in the holes, which should be fired after the men have left the mine either by practical, experienced shot firers, or by electricity. See also the answer to Ques. 6 in the April issue.

Ques. 8.—If you had a large quantity of explosive gas in a gob or worked-out part of a mine that is being carried into another part of the mine where men are working, state how you would control your air-current so that these men would be safe, and if you found it impossible to keep this gob clear of gas, how would you take care of it to make the mine safe? Show this by a sketch as well as by writing.

Ans.—Such accumulations of gas should be removed by a separate split of air when it is possible to do so, as shown in Fig. 1 In this case a common condition has been assumed, one in which a number of rooms near the mouth of the entry have been worked out and have had their pillars drawn back to the entry stumps and beyond which are a number of rooms being worked. Air-tight concrete stoppings are built in the breakthroughs *f* and *g*, between the new work and the old, and similiar stoppings are built at the mouths of the abandoned rooms *d*, *c*, and *b*, along the heading. An overcast is built at *d* connecting the old work directly with the return and a regulator placed at *a* to adjust the amount of air entering the gob, which is thus ventilated by a separate and distinct split, none of the gas in it entering the new workings beyond *d*. After the room *h* is worked out it may be used as a return for the air from the gob by building the overcast at its mouth, by building brattices in the cross-cuts between it and room *k*, and by tearing down the brattice at *f* or any brattice inby *f*. By this means the air will be carried nearer the face of the old workings and their ventilation be more thorough. In some cases, if the gob is packed so tight that air cannot be drawn or forced through it, bore holes may be sunk from the surface, and the gas conducted to daylight through them. Finally, no attempt may be made to remove the gas from the old works either through pipes from the surface or by a separate split of the ven-

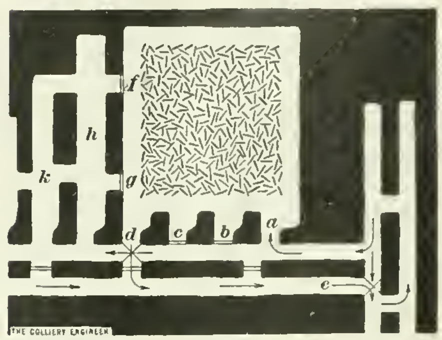

Fig. 1

tilating current. In this case, air-tight stoppings are built at *a*, *b*, *c*, *d*, *g*, and *f*, and a large pipe is placed at *d* connecting the gob with the return. Through this pipe the gas from the abandoned workings slowly passes into the return as it is generated.

Ques. 9.—Under what conditions would the use of open lights be safe in gaseous mines, and under what conditions would you forbid the use of open lights in such mines?

Ans.—The answer to this question depends upon whether the mine is gaseous throughout or only in part. If the mine is ventilated by a number of splits in some of which no gas is found, in such splits open lights may be safely used, as there is no way in which gas can be drawn in upon them. The use of open lights should be prohibited in those splits where gas is found in dangerous quantities, and what is a dangerous amount of gas depends in some measure, as explained in the answer to Ques. 7, upon the amount, nature, and dryness of the coal dust present. Even if gas is not found in a particular split, if it is being driven toward old workings known or supposed to contain gas and which may be tapped unexpectedly, open lights should be forbidden.

This is the common practice, to allow open lights in those splits where gas is not found and to prohibit their use in those splits where gas is found; but common prudence would indicate that safety lamps should be used in all parts of a mine, if explosive gas is found in any part, as it is always possible that a supposedly non-gaseous split may suddenly become a gaseous one. Portable electric lamps for miner's use are now so low in first cost, so low in cost of upkeep and repairs, are so clean, give so good a light and are so eminently safe in explosive mixtures of gas and dust, that their use cannot be too highly recommended under any and all conditions.

Ques. 10.—Why should the circulation of air in mines be maintained continuously, and not during the day only? What special requirements do you consider should be observed in the erection of a ventilating furnace or a ventilating fan? In event of an explosion destroying your ventilating apparatus, state what temporary measures you could take to restore ventilation to permit a rescuing party to enter the mines to recover the injured or dead.

Ans.—Explosive and poisonous gases, if given off at all, are generated as freely by night as by day. When the fan is not running, these gases accumulate in the workings and more or less time is required after the fan is started to restore the mine air to its normal condition. From this it follows that if the fan is shut down over night and only started up a short time before work begins, dangerous amounts of gas, which have accumulated during its idleness, may not be removed before the men enter their working places, and an explosion is possible from a naked light coming in contact with the accumulations of gas.

There are no special requirements to be observed in the erection of either a fan or furnace that do not apply with equal force to all classes of machinery. All ventilating apparatus should be of ample size to perform the work required of it. This work is to supply from 100 to 200 cubic feet of air per minute (the quantity varying with the legal requirements of the different states) for each man employed underground. In addition, there must be a sufficiency for the mules and lights, and enough more "to dilute, render harmless, and carry away all explosive and noxious gases." The apparatus should have ample reserve power so that in event of an emergency or after the workings have been extended, it may be able to supply more air than required when it was first erected. The fan or furnace should be substantially built of good materials and, as far as possible, be situated where it will receive the least damage from an explosion.

The latter part of this question is very comprehensive, opening up as it does the entire subject of rescue work under the very great variety of conditions possible at different mines. In a general way the question may be considered from the view point of when oxygen breathing rescue apparatus is available and when it is not. If "helmets," as they are commonly called, cannot be had, and the afterdamp is suffocating from the presence of carbon dioxide, or poisonous from the presence of carbon monoxide, no rescue or recovery work can be done until the ventilation is restored. If the fan and fan drift are destroyed, the former must be repaired or replaced with a new one, and the drift cleaned of falls. The work of rebuilding the brattices is then undertaken, beginning with the one nearest the fan and proceeding inby. As soon as the rebuilding of a brattice restores the circulation to that point, the work of cleaning up the falls is undertaken; and the work of replacing brattices and cleaning up falls goes on simultaneously. When the rebratticing has enabled the fan to remove the afterdamp, the work of rescuing the living and recovering the bodies of the dead may be begun.

If oxygen breathing apparatus is to be had, the work of exploration and rescue is begun as soon as the helmet crew reaches the mine, and is carried on independently of other crews who are engaged in the work of restoring the ventilation, as just described. In most recent mine explosions the rescue crew wearing helmets and carrying portable electric lamps have located the living long before much more than a start has been made toward restoring the ventilation. In numerous cases where large amounts of carbon monoxide have been present in the afterdamp, the brattices have been rebuilt by men wearing helmets.

QUES. 11.—What is meant by the diffusion of gases and how does it affect the character of gases when they come in contact with each other? How are gases caused to expand out of the strata and at times to overflow the workings in a mine? Explain how the condition of the weather and direction of the wind may affect the production of gases in coal mines.

ANS.—By diffusion of gases is meant the slow and perfect intermixture of two or more gases when they are brought into contact with one another. It does not mean what is called the mechanical mixture of gases, as when they are shaken up together in a jar or swept along by a ventilating current of air, but the slower intermixture which takes place, for example, in the still air of a room in a mine when methane is gradually given off from the pores of the coal. Through the action of diffusion, gases which would naturally arrange themselves in layers in the order of their relative specific gravities are in the end intimately mixed. Thus, the atmosphere is composed mainly of three gases, in the order of their specific gravities and beginning with the heaviest, carbon dioxide, oxygen, and nitrogen. Because of diffusion these gases are uniformly distributed and intermixed throughout the atmosphere, but were it not for this property of diffusion the earth would be surrounded by a shell or layer of carbon dioxide with a specific gravity of 1.529; then with a layer of oxygen with a specific gravity of 1.1056, and finally with a third layer of nitrogen with a specific gravity of .9713. Similarly, methane, which by reason of its very low specific gravity (.559), is naturally found near the roof, is, in the course of time, evenly and uniformly mixed with the mine air; and carbon dioxide, with its specific gravity of 1.529, and so found near the floor, is also intimately mixed with the atmosphere. The velocity with which gases diffuse into one another varies inversely as the square roots of their densities. Thus, the specific gravity of air being 1 and that of methane .559, the relative velocities of diffusion are as $\sqrt{1} : \sqrt{.559}$, or as 1 : .748; that is, 1,000 volumes of methane will diffuse into air in the same time that 748 volumes of air diffuse into methane.

Gases may be liberated in various ways. A certain amount of gas is contained in the pores of the coal, and this is naturally given off as the headings and rooms are driven and fresh faces are exposed. Gas in pockets, fissures, or blowers may be suddenly given off by a shot opening up the cavity containing them. A derangement of the ventilating apparatus in the case of a blowing fan generally tends toward the flow of gas into the workings. This will happen when the fan is slowed or shut down, or when the air is short-circuited through an open door or broken brattice. In any of these cases, there is a lowering of the pressure, as shown by a lower water gauge, and under this lessened pressure gases expand and flow out of the pores and cracks of the coal and from the gobs into the workings.

Any surface conditions of weather which tend to lower the pressure of the air in the mine workings operate to release unusually large amounts of gas not only from the pores of the coal but more particularly from old and abandoned workings. The chief of these weather conditions is a fall in the barometer, which means a decrease in the atmospheric pressure. It is apparent that when the pressure is reduced there is less resistance to the expansion of the mine gases, and increased volumes of them must escape into the workings from the coal and the gob. The Weather Bureau at Washington is now sending out what are called in England, barometer warnings, which call attention to approaching falls of the barometer with attendant influx of gas into the workings, so that means may be taken to increase the ventilating current where necessary. The effect of changes in the direction of the wind upon the escape of gases is not of great importance where there is proper ventilating apparatus. In some cases the wind may blow in such a way across a shaft or drift mouth as to increase the mine pressure and thus force the gases back into the workings; or it may blow in such a way as to help reduce the pressure and thus afford an opportunity for the gas to escape. The effect of the wind is much more marked upon furnace than upon fan ventilation; and upon natural ventilation than upon either.

Ques. 12.—How many years experience have you had in mines generating explosive gases? Give the names of the mines and the companies for whom you have worked in this or any other country where explosive gases are generated in such quantities as required a fire boss or the use of a safety lamp. In what capacity did you work while getting this experience?

Ans.—This question must be answered from the applicant's own experience.

(To be continued)

Coal and Coke in British Columbia

From the preliminary report of W. F. Robinson, Provincial Mineralogist, it is learned that 3,066,000 tons of coal were mined in British Columbia in 1912. This is almost equal to the production in 1910, the production for 1911 being low on account of labor troubles which also affected somewhat the production in 1912. Of this output 1,553,000 tons were from the Vancouver Island mines; 214,000 from Nicola and Similkameen; and 1,299,000 tons from the Crows Nest region. The latter region was the only one to produce any coke, 395,000 tons of coal being made into coke, producing 264,000 tons; the coke yield being about 67 per cent. of the coal.

Use of the Barometer in Mining

By F. Z. Schellenberg

In view of renewed interest in the subject of the barometer in mining operations, I would say that on December 18, 1901, I read a paper on the use of the barometer, before the Central Mining Institute of Western Pennsylvania, now the Coal Mining Institute of America. As that paper will answer some inquiries being made by readers of The Colliery Engineer, I herewith submit it for publication.

I advise the men responsible for safe conditions in the gaseous mines to consult the charts issued daily under telegraphic direction of the Weather Bureau, at Washington, and sent regularly to all postmasters that want them.

Following the map indications day by day will, on experience, teach one the prognostics for his locality. Thus, on the approach of the low barometer area anticipated, there will be no surprise that the coming events cast its shadow before, by increase of gas exudation into the mine working from the newly opened faces of the strata, hours before the local barometer gives a plain sign of lowering atmospheric pressure. Also, the persistence of high barometer makes tense the penning in of the gases in the solid strata and in lurking places, so that a fall of the pressure —and it may be locally sudden with thunder storm and veering of the wind—may give the extra gas, so ready to come, quick release. That the barometer in the mine is slower than the gas, is what has brought it into general disrepute among coal miners; a mercury column barometer or a little, dry, fettered-air barometer, (the aneroid) cannot be as subtle to show changes in the pressure of the air as is the big open gas barometer, which the mine itself is. Now, surely, being posted daily by the map, with its pictured tracts of different densities as parts of the atmosphere, moving across the entire continent, will give to an earnest guardian of the mine, intelligence to become more than merely fitfully weatherwise. Here at 900 feet above sea level, the mercury column ranged in the year 1900 from a normal of 29.1 inches to the extremes of 29.7 and 28.3, the difference between which is equal to 19 inches water gauge or 100 pounds pressure per square foot on all open surfaces. On the weather maps, the readings of all points are marked there as of sea level and 32° F., in order to correlate more simply. The Weather Bureau is under the United States Department of Agriculture, but probably its value thus far has been greatest to those on the coasts, who are concerned in the safety of ships; next, to river men and railroad men, and last to farmers. As I suggest, it would benefit coal miners.

When Morse harnessed the new force, electromagnetism, and invented his alphabetic code, so that a telegraph could be of common use, it was regarded as of importance, first for transmitting intelligence over the country about the weather, particularly the standing of the thermometer at distant points; its great commercial use was not seen. Of course the telegraph had to be brought home to some to tell them anything about it; for instance, the wiseacre on the National pike, who was gazing with others in the village at them stringing the first wire on the poles said: "It may do for small packages, but for large bundles, never!" It took 25 years longer to start the Weather Bureau, in 1870.

Now, it may be in order for the mine foreman to prove his appreciation of such government socialism, by taking others' observations and giving his own. He may invent the means of making practicable the sensitive reaction of his mine with the atmosphere, to tell earlier about the state of this as to pressure than does any present barometric device. But I do not think of him playing with his gas—he may have too much of it, or too little—but rather think of him and the bright ones in the colony around him, devising a pair of large, stationary aneroids, as instruments of precision. There is no telling what new way the men of the coal mines may pioneer in their provisional efforts; they invented the railroad and the locomotive.

An aneroid would read as close as water gauge does, if its divisions of scale corresponding to inches of mercury column, were 13.6 inches long. A semicircular scale the scope of 3 inches of mercury, and as delicate as water gauge, would be about 26 inches in diameter.

It has been suggested to have a large water or glycerine column barometer placed in schoolhouses. For it, a metal tube running up from a cistern in the cellar and having a glass part at the top to be read from the stair landing, would be safe and cheap. It would move feet to the mercury's inches or tenths and its head of column could be reflected on to a convenient scale, within or without the building.

Glycerine does not evaporate ordinarily and would give 26 feet height. The tubes for such liquids must not be small, or capillarity will add to the height of column.

The whole subject of the weather is, of course, not easy in its problems with the ever varying factors of pressure, temperature, and humidity of the air and also the direction and force of prevailing wind, at the scattered points of observation on land. The faithful watchman should have honor and encouragement from thoughtful men against the vacuous scribblers in ridicule, to whom every forming science is both mystery and child's play.

We are coming to replace man's superstitions with the knowledge of the natural laws, even in reckoning with the elemental forces in the grand arena of our universe.

Dumper for Mine Cars

Translated from Glückauf

The arrangement as shown in Fig. 1 consists of a frame constructed of flat bar irons *a* and *b* which are placed longitudinally on the rails so that the tops of the rails are covered, as shown in Fig. 1 (*a*) and (*b*). In order to give the necessary height for the car lifting part of the apparatus, special square bar irons *c* are placed upon flat iron *a*, being tapered at the end, that the car may mount them easily. The end pieces *d* are placed on the frame so that the car will just fit in between them. They are pivoted at *e* and fastened to the frame by a bolt *f* at the opposite side. These end pieces catch the car by means of flat irons *g* which project out from them. When the car is in position it can be raised by means of lever contrivances *h* and *i*. The car then, through the action of the levers *i*, is suspended above the edge of the rail upon a pivot *l* and can be tipped on either side.

This dumper has been in use since January, 1912, in shafts Nos. 2 and 7 of the Bergwerks-A. G. Consolidation Co., and has the advantage over other dumpers in that its position can be easily and quickly changed by only one man. As the end pieces *d* are open when the contrivance is not in operation, the work of hauling is not interfered with. There is another advantage, the center of gravity of the car remains above and between the rails when dumping is going on, (as shown by the dotted lines in *b*). Therefore no special contrivances for support are necessary. This way of dumping prevents, above all, a violent shaking of the timbering and neighboring layers of rock, because the recoil is caught by the frame and track.

The arrangement may be used for seams of any thickness or any angle. Where the dip of the seam is great and the seam is small, the pivot *l* in the end pieces would have to be raised a few centimeters, in order that the contents of the car might be emptied down through the track.

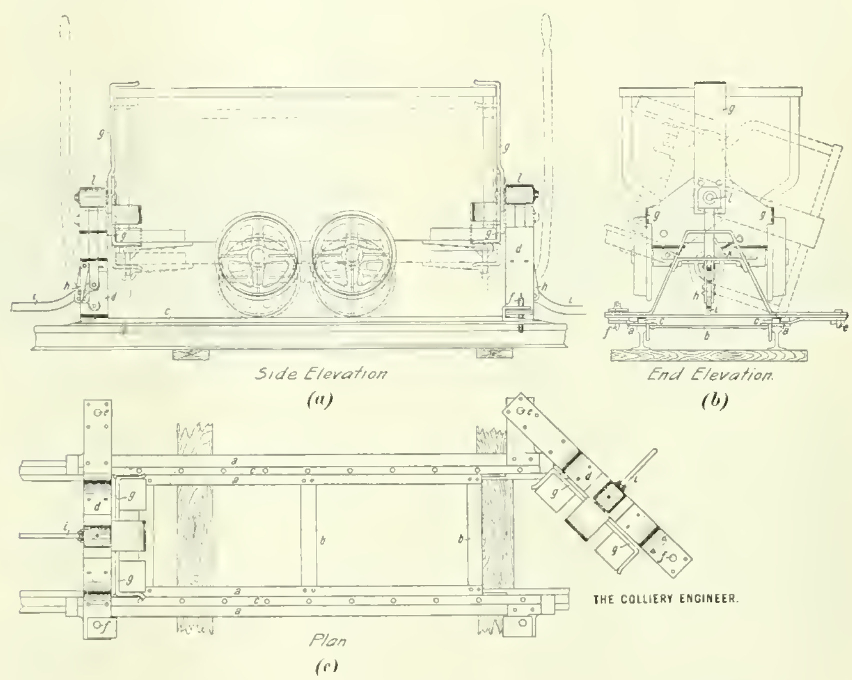

Fig. 1. Dumper for Mine Cars

NEW MINING MACHINERY

Storage-Battery Gathering Locomotives

One of the latest applications of the storage-battery electric haulage locomotive is for gathering work in coal mines. One of these machines manufactured by the General Electric Co. was recently installed in the Glendower colliery of the Philadelphia & Reading Coal and Iron Co. The

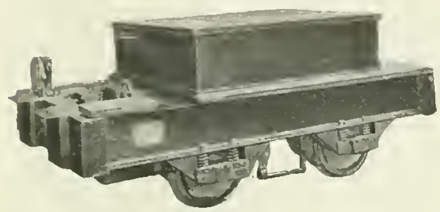

Fig. 1. Storage-Battery Locomotive

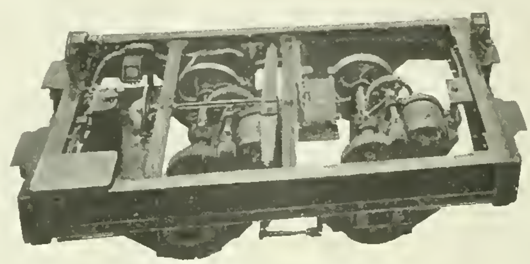

Fig. 2. Locomotive Frame

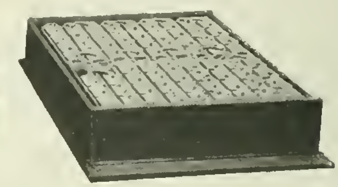

Fig. 3. Storage-Battery Cells

locomotive designed especially for the service and built for hauling six cars is equipped with two 85-volt motors and controller. The batteries employed are Edison 70-cell and have a 300-ampere-hour capacity with a discharge rate of 60 amperes for 5 hours. They will run at the full rated drawbar pull and speed, for 9 miles with one charge of the batteries. Under an assumed car and track friction of 30 pounds per ton on level track, this rating is equivalent to 300 ton-miles on one charge. The machine is fitted with the usual ampere-hour meter indicating the amount of charge and discharge, headlight, and gong.

The locomotive is built to conform to the following specifications:

Total weight	8,000 lb.
Length overall	8 ft. 9 in.
Width overall	5 ft. 3 in.
Height over platform	2 ft. 4 in.
Height over battery compartment	3 ft. 9 in.
Wheel base	44 in.
Diameter wheels	20 in.
Track gauge	44 in.
Rated drawbar pull	1,000 lb.
Speed at rated drawbar pull	3½ m. p. hr.

The batteries are designed for the particular service, and the plates are made specially to give the high service efficiency. The cells are grouped in 18 trays and are mounted on top of the locomotive frame in a wooden case.

The mechanical design of the machine is in accordance with the latest modern practice. The end plates are faced with wooden bumpers, to which suitable couplers are attached. A seat for the operator is provided in the rear.

The journal boxes are fitted with roller bearings, which assures efficient mechanical transmission of power and consequent economy in battery current consumption. The weight of the car is supported from the journal boxes by two coiled springs.

Brake tension is effected by means of a square-threaded brake spindle. A square-threaded nut travels on the spindle and carries an equalizing bar, to the ends of which are connected chains leading from the brake levers. This device admits of locking the brakes automatically in any position left by the operator.

The controller is of the drum type, and with the mechanism, is enclosed in an iron case provided with removable sheet-steel covers.

The motors are series wound, totally enclosed, and of the familiar automobile type. They are designed to operate with the maximum possible economy in the use of battery current. They have high efficiency, large overload capacity and operate with practically sparkless commutation. High efficiency is obtained by designing them with a small air gap and running the iron at low densities. By reason of the latter provision, the speed and torque characteristics are steeper than in the ordinary series motor, thereby tending to limit the overload which can be thrown on the batteries.

The motors are dust and moisture proof, nevertheless are accessible for inspection and repair. One motor is mounted on each axle and drives the axles through double reduction gearing. As slow-speed service is ordinarily required of a storage-battery locomotive, the use of double reduction gearing affords such speeds with minimum rheostatic losses; and due to the large gear ratio from armature shaft wheel tread, very high tractive efforts are obtained at comparatively small current inputs to the motors.

Self-Starting Motor

Electric motors have proven so satisfactory that they have come into universal use as prime movers for driving pumps and fans independently located throughout the mine. In any mine a number of small units may be employed, none of which would be large enough to require constant attendance, so that one man frequently looks after several units, going from one to the other. Under these circumstances a pump will be oiled and started by the runner, who will then go on to the next place, leaving the motor to run unattended for a period of time. One great disadvantage in working the pumps in this manner is the chance that the power may go off, necessitating that the runner go over his route again starting all the motors. Moreover the power may go off at a time when the runner is traveling from one unit to another and not likely to learn the fact, with the result that he finds, on his return to stop the motor, that it has not been running.

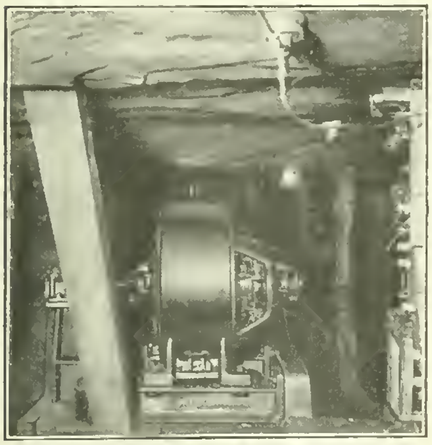

Fig. 4. Self-Starting Motor Underground

Improvement, however, has been made in direct-current motors which overcomes this difficulty, making them self-starting. It has been possible heretofore under some conditions to start motors from the power house, but usually they had to be started by hand.

With the new self-starting direct-current motors, this inconvenience is done away with. When the power fails, the motors stop, it is true, but as soon as the power comes on again, they start automatically and settle down to work as though nothing had happened. Moreover, starting boxes are rendered unnecessary, and the wiring is of the simplest possible character. An occasional visit of inspection is now all they require.

The electrical characteristics of the self-starting motor differ but little from those of the usual type, the only alteration being in the use of a heavier compounding winding which reduces the flow of current when starting. Mechanically, there is no change. Self-starting motors are made by the Westinghouse Electric and Mfg. Co., East Pittsburg, Pa., in ratings up to 20 horsepower for the voltages usually employed in mine work. They can be supplied for all kinds of pump and fan service.

Mining With the Pneumelectric

In order to obtain the advantages of generating and transmitting power by electricity, chain machines have been extensively used under conditions where the puncher method of mining is really preferable. This is because electricity has not heretofore been successfully applied to a machine which strikes a blow by compressed air. Now that an electrically operated compressed-air puncher is available, the benefits derived from the puncher method of mining need no longer be sacrificed for electrical transmission of power. The Pneumelectric Machine Co., Syracuse, N. Y., recently made some calculations and issued a statement regarding work done and the power required by the Pneumelectric Coal Puncher, a machine in which an electric motor and an air cylinder are in the same frame, the air being both compressed and utilized within the same cylinder. Assuming ordinary working limits, the calculation for the Pneumelectric puncher is as follows:

Average width of cut, feet	5
Depth of cut, feet	5
Time of cut, minutes	15
Amperes at 220 volts	25
Watts = 25×220	5,500

These results show that for undercutting an area 5 ft. × 5 ft., or 25 square feet, there will be required 15×5,500 = 82,500 watt minutes. This total reduces to 330 watt minutes per square foot of undercutting. A similar calculation for the chain machine shows that the power for the two types does not differ materially. With the chain machine the cut is uniform, about $3\frac{3}{4}$ inches in height, and the coal thus cut out is very small, almost all of it being unmarketable. To be sure the amount of coal cut out of this kerf is not great, and this is one of the advantages claimed for the chain machine.

With the Pneumelectric the undercut, compared to that of the chain machine, is about three times as high in front and but slightly less at the back. In other words, the amount of coal cut out is about two and one-half times as much as with the chain machine, the power being practically the same, as has been said. But of the coal thus cut out by the Pneumelectric, more than half is $\frac{3}{4}$ inch or over-size coal, all of which is marketable and not "dust." A still greater advantage resulting from the wedge-shaped undercut is the greater space through which the coal can fall when it is shot. With the wedge-shaped kerf, less powder is required to dislodge the coal, and therefore the coal is not as badly shattered as when shot after undercutting with a chain machine. By measuring and inspecting the entire body of coal mined there is found to be a material difference in the results obtained with these two types of machines, the relative amounts of marketable coal showing greatly in favor of the puncher.

A Portable Coal Loader

The accompanying illustration shows a machine that is primarily intended for a wagon loader in retail coal yards. Its efficiency and convenience have been thoroughly proved in actual use. As at many collieries it occasionally becomes necessary, for various reasons, to temporarily store coal, which later must be loaded in cars for shipment, it is evident that this machine can be

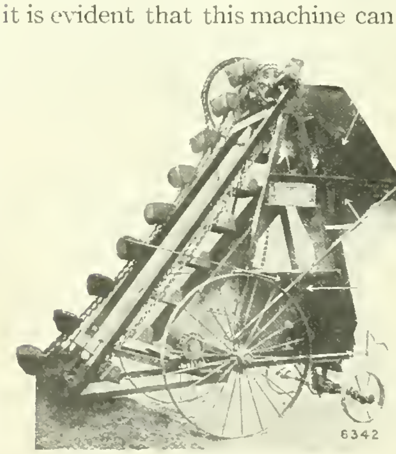

Fig. 5. Portable Coal Loader

used to great advantage when this stored coal is piled on the ground.

In retail coal yards experience has shown that one man operating the loader and helping the coal to the foot of the machine, can load a ton of coal per minute. By increasing the size of the machine there is no doubt but that a similar machine can load coal into a car faster than that, with a great saving in labor as well as of time. The machines are run either by engines or electric motors. They are easily moved from one station to another and handle the coal with least possible breakage.

The Link Belt Co., of Chicago, Ill., are the manufacturers. They have told the story of its advantages in a book "Link-Belt Wagon Loader," and will gladly send a copy on request.

A Spike Puller

A new device for pulling spikes is shown in Fig. 6. Among the advantages claimed for this, are that it does not bend the spike or damage the tie and the spike is in condition to be used again; it is easily applied to the head of the spike and as it pulls straight up it is much more easily operated than the old-fashioned claw bar; it will pull spikes between frogs, guard, and side rails, as readily as on single rails, and on account of its light weight, only 12 pounds, it is readily handled. These advantages and the fact that all the effort applied is exerted on pulling the spike instead of bending it, enable a man to do nearly twice the amount of work possible with the ordinary claw bar. It is patented and manufactured by J. E. Jones, Carneyville, Wyo.

Bristol's Recording Differential Pressure Gauges

A comprehensive new line of recording differential pressure gauges has been developed by the Bristol Company, of Waterbury, Conn. Some of these recorders have been in successful service continuously since the preliminary models were first sent out in 1908, and the design and construction of the line of these latest instruments is based on results obtained in actual service during the last 4 years. These recording gauges are designed for use in connection with Venturi meters, Pitot tubes, orifices, combinations of orifices and Pitot tubes, etc., thereby to record velocities and volumes of air, gas, steam, water, and other liquids flowing through mains and pipes. These recorders may also be used to advantage for recording differences and variations of liquid level in steam boilers, pressure tanks, filter beds, process kettles, etc.

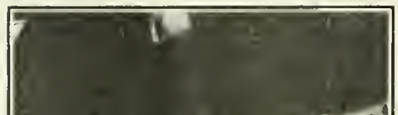

Fig. 6. Spike Puller

The fundamental principle employed in the construction of this differential pressure gauge is that one pressure is applied to the inside of the operating tube while the other is applied to the outside of the same pressure tube within a closed casing. In order to record the movement of the pressure tube it becomes necessary to transmit its motion to the outside of the pressure tube casing.

As the differential pressure to be recorded is usually small as compared with the static pressure, the operative force is correspondingly small, and it is quite evident that it will be impractical to use a stuffing-box around a shaft passing through a pressure casing, on account of the friction which would be produced. To avoid the use of a stuffingbox a unique patented frictionless sealing device is employed, which does not produce appreciable resistance to the rotation of the shaft which operates the recording pen arm, and at the same time leakage of even high pressures from the pressure casing is prevented.

This company also makes a device by which should a pressure causing a differential greater than the gauge is intended to record be accidentally admitted to one side of the tube, a connection is automatically opened that allows the same pressure to act on the other side also, thus preventing the destruction of the tube.

A complete description of any or all of these devices may be obtained by application to the manufacturers.

TRADE NOTICES

Superheating.—As a catalog the Heine Safety Boiler Co., of St. Louis, Mo., has issued the article on "Superheating," by C. R. Meier, which was read before the Engineers Society of Pennsylvania. It contains a number of notes that steam users will be pleased to have in this form and can be obtained from the boiler company.

Steam Scale.—The De Laval Steam Turbine Co., Trenton, N. J., has devised a steam scale to overcome the difficulties in connection with the Mollier diagram. This steam scale is a graduated measuring rule bearing four different scales. The first having a uniform graduation may be applied to an accompanying chart and measure directly the British thermal units available between a given initial and final condition of the steam. The second edge of the rule bears a scale showing the resulting velocity of the steam in feet per second when expanded through a nozzle. The third edge shows the duty in millions of foot-pounds, in 1,000 pounds of steam; while the fourth edge gives the steam consumption in pounds per horsepower hour. Copies of these scales and chart will be sent to those interested by the De Laval Steam Turbine Co. On the back of the chart concise directions are given for its use.

The Bureau of Foreign and Domestic Commerce, of the Department of Commerce, Washington, D. C., has issued a bulletin calling attention to the foreign trade promotion work of the Bureau. The Bureau is charged with the duty of "developing the various manufacturing interests of the United States and markets for their products at home and abroad, by gathering and publishing useful information, or by any other available method." In this work the Bureau has the cooperation of American consular officers. In addition it is provided with a corps of commercial field agents who submit comprehensive reports with respect to foreign markets for specific lines of products. The office is a clearing house for the dissemination of the reports submitted by these officers. Trade reports are published in a daily bulletin, in special monographs, and in circulars. Information concerning foreign customs tariffs, port charges, consular regulations, etc., is collated and published, especial effort being made to keep manufacturers advised of current changes in such rates and regulations.

Statistics relating to imports and exports of this country are compiled by the office, and are published in monthly, annual, and special bulletins. The resources of the Bureau are at the service of American manufacturers and exporters, and its publications are furnished, as far as available, upon request.

Electric Hand Lamp.—The Hirsch Electric Mine Lamp Co., whose electric mine lamp has been illustrated and described in former issues, has put on the market a new hand electric lamp for use in thin coal seams, or any other place in which a hand lamp is more practical than one on the cap. The hand lamp is almost identical with the cap lamp, differing only in the attachment of the lamp and reflector directly to the battery, which is provided with a handle.

Economical Burning of Coal is the title of a catalog recently published by the Valley Iron Works, of Williamsport, Pa. In it the methods of obtaining complete and economical combustion of different kinds of fuel and the importance of having a grate suited to the kind of fuel used are explained. The firm makes shaking and other grates for use with fine or coarse anthracite or bituminous coal, and these are described in the catalog, which also contains testimonials from users of these grates. The catalog contains much of value to fuel users and will be sent on application.

Pipe Information.—A bulletin entitled "Characteristics of 'National' Steel Pipe," recently issued by the National Tube Co., Pittsburg, Pa., contains a large amount of boiled down information about pipe which the average consumer wants to know. The headings are as follows: Uniformity, Chemical Composition, Physical Properties, Bursting Strength, Threading, Improvements, Full Weight Pipe, Spellerizing. Very full information is given under Corrosion, with particular reference to tests that have been made by different persons. Much information is now available relative to the subject of corrosion of wrought iron and steel pipe and from reference to authorities indicated it is seen that steel pipe has been establishing a record for itself.

The specifications given will be of interest to the average user of pipe for they are fair to the manufacturer, at the same time protecting the interest of the consumer. The list of publications is also quite complete and these publications are sub-divided under classification with particular reference to the product. This bulletin is a distinct addition to the literature relative to tubular goods and all using such will find it to their advantage to write to the company for a copy.

Western Electric Co.—Some people entertain the idea that the entire business of the Western Electric Co. consists in sales to the American Telephone and Telegraph Co. and the associate companies. The annual report for 1912, however, states that the company has 24,000 customers other than telephone companies and has wide activities in fields other than the telephone industry. The Western Electric Co. "furnishes equipment for every electrical need" and sells to railroads, electric-power central stations, street railways, electrical contractors and dealers, manufacturers, and now also to a limited extent through its own retail stores, to individual consumers. The line of equipment handled embraces everything electrical, from the largest generating plant to the simplest of electric household devices. The company's sales to customers other than companies of the Bell system have steadily increased during the past 10 years and are in great measure responsible for the addition to the American factory at Hawthorne, Ill., and the Antwerp and London factories abroad.

Centrifugal Pumps for Mine Service.—The Weinman Pump Mfg. Co., of Columbus, Ohio, has ready for distribution a new centrifugal pump bulletin, which contains valuable pumping data. This company has specialized on pumps for mine service for 50 years and is in position to make prompt shipments of mine pumps complete, either steam, electric, or gasoline-engine driven, as they carry a large stock of motors and gasoline engines, in addition to pumps. The Weinman centrifugal pump is built in single and multistage types and is therefore adaptable for extremely high or for low heads. The impeller of this pump is of the enclosed type, which is the means of increased efficiency, and the centrifugal pump is fast being adopted in coal mines, wherever possible. The Weinman pump is reliable and quiet in operation, has no valves or gears, and gives large output with minimum amount of repairs and attention, and requires considerably less space than any other form of pump. A high-grade ball thrust bearing is located in the main bearing oil cellar and is therefore entirely immersed in oil at all times. The engineering department of this company may be consulted freely, either regarding pumps now in operation or new pumps to be purchased, and will be pleased to give customers the benefit of their many years' experience in this field.

Not Damaged By Flood.—A recent letter from an official of the Jeffrey Mfg. Co., of Columbus, Ohio, to the Managing Editor, states that the company's plant was not damaged by the floods that caused so much loss and suffering in the central states a few weeks ago, as the works are located some distance from the points reached by high water. The organization of the Jeffrey forces was, however, crippled for a time on account of the anxiety of the individual members to aid the less fortunate. Every available man in the organization was sent out with the relief crews, some of them working day and night, until the work was well in hand and no known person was without food or shelter.

The letter, dated April 5, stated that "The majority of our men are back at their work again, and we are working full force and are pushing our orders and estimates with every possible despatch; and expect train service, mail, express, and freight shipments to resume their normal conditions within a few days."

Catalogs Received

Roberts & Schaefer Co., Chicago, Ill. Reinforced Concrete, 32 pages.

Chicago Pneumatic Tool Co., Fisher Building, Chicago, Ill. Duntley Track Drill, 8 pages.

New York Blasting Supply Co., 11 Broadway, New York. High Explosives, 4 pages.

Sullivan Machinery Co., 122 South Michigan Avenue, Chicago, Ill. Sullivan Diamond Core Drills, 31 pages; Sullivan Hammer Drills, 31 pages.

Scott Drill Co., St. Louis, Mo. Gasoline Rock Drills, 11 pages.

General Electric Co., Schenectady, N. Y. Index to Bulletins, 11 pages; Type US-13 Roller Bearing Trolley Bases, 1 page; Circuit Breakers for Railway Service, Type MR, 2 pages; Thomson Watthour Meter, Type 1-10, 6 pages; Electrically-Operated Remote Control Switch Type R, Form C2, 4 pages; Price List No. 5268, G-E Steam Flow Meters, 7 pages; Polyphase Induction Motors, 21 pages; Edison Mazda Lamps for Standard Lighting Service, 26 pages; Electric Fans, 34 pages.

The Industrial Instrument Co., Foxboro, Mass. Bulletin 74, Foxboro Recorders; Foxboro Thermometers and Thermographs, 39 pages.

The Goulds Mfg. Co., Seneca Falls, N. Y. Centrifugal Pumps, 8 pages.

Bausch & Lomb Optical Co., Rochester, N. Y. Engineering Instruments, 155 pages.

Cutting Props

Five men are able to cut all the props which are used at a colliery producing 90,000 tons of coal monthly by means of an American circular saw 4 feet in diameter, mounted on a swinging arm. With a saw of this diameter the largest props which are likely to be used, can be cut. The general run of props are from 6 to 10 inches in diameter and a dozen of these are cut at one time.

The power for the saw is supplied by a small steam engine to which the saw is connected by belts and a clutch. The logs are rolled down from the lumber yard, which lies on a gentle slope in front of the saw, on to a platform and placed so that the logs are even with each other at one end. The saw will then cut props of a certain desired length from one end of the logs and, as the logs are unequal in length, odd lengths from the other ends. The platform is marked with the foot marks so that the odd lengths can be quickly marked and sorted. Ten or twelve logs are placed on the platform to be cut at the same time.

The engine also supplies power to drive an endless rope which moves the trucks on which the props are loaded as soon as cut. The trucks run on a track in front of the platform and are moved by means of the rope to a place where the props may be unloaded in piles according to the lengths.

A supply of props is kept on hand so that all orders sent out from the mine can be promptly filled. The five men who do the cutting also do the loading and even have some time to do other work.

Practical First-Aid Work

A short time ago while taking some pictures of an underground stable, the foreman, who set off the flash-light sheets, burned his hand badly. Five years ago he would have had to have waited for a cage and after reaching the surface waited from 1 hour to 5 hours for treatment, depending upon the whereabouts of the company physician. In the case in question a trip to the foot of the shaft, less than 200 feet away, where first-aid materials were handy, enabled the sufferer to care for himself and return in less than 5 minutes. "The world do move."

Statement of the Ownership, Management, etc., of THE COLLIERY ENGINEER, published monthly at Scranton, Pa., required by the Act of August 24, 1912.

Name of	Post-office Address
Managing Editor, Rufus J. Foster	Scranton, Pa.
Editor, E. B. Wilson	Scranton, Pa.
Business Manager, P. G. Moore	Scranton, Pa.
Publisher, International Textbook Co.	Scranton, Pa.

Owners: (If a corporation, give names and addresses of stockholders holding 1 per cent. or more of total amount of stock.)

T. J. Foster	Scranton, Pa.
Rufus J. Foster	Scranton, Pa.
Elmer H. Lawall	Wilkes-Barre, Pa.

Known bondholders, mortgagees, and other security holders, holding 1 per cent. or more of total amount of bonds, mortgages, or other securities:

NONE.

(Signed) International Textbook Company.
Rufus J. Foster,
First Vice-President.

Sworn to and subscribed before me this twentieth day of March, 1913.

Frank Lambader,
[Seal] Notary Public.

TABLE OF CONTENTS

THE one thing wrong with the "minimum wage," as proposed by impractical so-called reformers and politicians, is that it results in a maximum wage for a minimum of ability, and a minimum wage for a maximum of ability.

IMITATION is the strongest proof of the value of an idea, a method or an appliance. Imitations, however, like counterfeit money, are never as good as the originals. If the originals were not good they would not be imitated.

CARBON monoxide can be detected in the mine air by its effect on the flame of a lamp, which, in the presence of the gas, grows brighter and elongates with a slight blue cap. This statement is absolutely true and can be proved to his personal satisfaction by any man, but he probably will die before he can tell any one else of his experience.

A COMMENDABLE campaign, having for its object the decrease in coal-mining accidents in Alabama is being carried on by the Mine Casualty and Mining Institute Committee of the Alabama Coal Operators Association. It consists in issuing monthly a safety pamphlet prepared by the secretary, James L. Davidson, and approved by the committee before publication. The different subjects treated inform the reader how and why accidents occur in particular instances, and the precautions necessary to prevent them. No attempt is made toward technicality other than the statements of fact that accidents are liable to occur from such a cause if such a matter is neglected.

WHEN a prominent mine manager was recently complimented on the arrangement and equipment of a new mine, on which he had spared no expense to secure safety and economy, his friend spoke of it as a "model mine."

The mine manager threw up his hands and exclaimed: "For God's sake don't call it that. Have you never noticed that shortly after a mine gets a reputation as a model mine it is usually the scene of a great disaster?" He then instanced several such cases in recent years. When asked, if he was superstitious on the subject, he replied: "No, not at all. But when a mine gets a reputation as a model one, particularly as regards safety, the officials and workmen are likely to presume too much on the means taken to eliminate danger, forget the personal element, get careless, and an accident follows. I believe in removing or minimizing every source of danger, but I want my subordinates and the mine workers to constantly be on the alert, and to be just as careful as they would be in a less well protected mine."

A Correction

IN THE article on "Flushing Anthracite Workings" in our last issue, credit for the report on the Kohinoor colliery flushing, from which extracts were made, was given to Mr. Geo. S. Clemens. Mr. Clemens informs us that the report was made by Mr. John H. Pollard, then assistant engineer, and now Division Superintendent of the Mahanoy City Division of the Philadelphia & Reading Coal and Iron Co., who was in charge of the work, under the personal supervision and direction of Mr. Clemens.

Cincinnati Mine Explosion

ON APRIL 23 the Cincinnati mine of the Monongahela River Consolidated Coal and Coke Co. was visited with a disastrous gas explosion that caused the death of 96 persons. This is the first great explosion in the coal mines of Pennsylvania since November 28, 1908, when the Marianna mine blew up.

For some time after the accident it was not possible to obtain definite information as to the conditions existing and the cause of the explosion, but all kinds of rumors were freely advanced, such as that there was a leak from a gas well; that a driver with a naked light went into an entry where he should have gone only with a safety lamp; that the fire boss caused the explosion, etc., etc., all usually ending in adverse criticism of the management of the mine.

To make sure of the actual cause being established beyond doubt, Chief Roderick, of the Department of Mines of Pennsylvania, appointed two independent commissions to investigate the explosion. In all, there were five investigations, one made by the Mine Inspector of the district, one by the United States Bureau of Mines, one by the company, and two by special commissioners at the instance of Chief Roderick. Their reports will be found elsewhere in this issue.

It is probable that none of the officials of the company knew the cause of the accident until after the special commissioners appointed by Chief Roderick gave the findings of their investigations to the coroner's jury, but because those in charge at the mines were unwilling to give out guesses for publication, they were severely and unjustly criticized by some of the daily press.

One persistent rumor circulated was to the effect that a driver set off the gas with a naked light. This was based upon the fact that the men in No. 6 butt entry driven from No. 14 face entry used safety lamps, but they were not used elsewhere in this section of the mine; in fact only two entries, which in advancing had cut clay veins, gave off gas. When the driver went into No. 6 butt entry it was his duty to change his open light for a safety lamp, and it was claimed by some that the explosion was due to his not using the safety lamp. The conditions found upon careful investigation, however, showed that the explosion was not so caused.

At the place where a gas explosion originates, comparatively little damage is done, but as the heated gases expand, they rush toward the nearest outlet. According to the report of the second commission of unbiased men the debris was blown from No. 14 face entry toward the face of No. 6 butt entry, which is one reason for believing the explosion did not originate in this entry; but more conclusive is the evidence of force and lingering heat which was found to have prevailed in this entry.

Knowing the phenomena which attend explosions of this kind the special committees, working independently of each other, sought some place in the affected zone where conditions were favorable to the propagation of an explosion. In butt entry No. 12, driven at right angles to face entry No. 14, they found that the miner had broken into a clay vein which, like the one in No. 6 butt entry, gave off gas. This entry was bratticed to force the air past the last breakthrough to the working face and so furnish the miners fresh air. At the face of this entry there was little evidence of heat and no evidence of force to mention, until the explosion got fully under way some distance from the face. As there had never been any gas detected, even so late at 10 A. M. on the day of the explosion, the miner did not use a safety lamp; however, when he broke into the clay vein gas flowed into the entry and naturally the explosion was originated.

It is probable that in Western Pennsylvania and elsewhere care must be taken to prevent miners shooting clay veins, and when such are discovered precautions should be taken against an inrush of gas, for even although most clay veins do not give off explosive gas, it is evident that some do and that they are in places a menace to life.

It would appear from this newly-discovered form of danger that as fast as one cause of accident is guarded against a new one arises; further, that this accident cannot be attributed to imperfect ventilation, and that the management of this mine took every known precaution to guard against accidents.

The Regulation of Oil and Gas Wells in Coal Regions

AT conferences of State Geologists, representatives of the United States Bureau of Mines, State Mine Inspectors, coal mine operators, and oil and gas well operators, held at Pittsburg, Pa., on February 7 and 8 and March 11, a report was formulated in the shape of a proposed law, to be developed in legal form to meet special local conditions in each state.

The suggested law has many points of real value, and if it, or a proper modification of it to suit local conditions, is enacted in each state, with the exception of one part, it will undoubtedly add to the protection of mine workers and mine property. The exception we make, is that part of the proposed law providing for Well Inspectors. Such officials will be of no practical value, will be a source of unnecessary expense, and as they will not be technical mining men, they will be a hindrance rather than a help in carrying out the intention of the proposed law.

All its provisions can be enforced by the Chief Mine Inspectors and their assistants, if the law is so framed as to conserve the rights of the oil or gas well operators.

The dangers incident to oil and gas wells in coal mining regions are familiar to competent State Mine Inspectors, and, given proper laws, those officials can and will see that a maximum of safety is secured.

American Institute of Electrical Engineers

THE recent meeting of this society at Pittsburg was largely attended, and the goodly number of coal miners present were interested in those papers presented by the electrical engineers connected with coal mines. The other papers were of more interest to those engaged in promoting commercial power plants than to miners; in fact, the advocates of central station plants were live wires connected with direct-current generators whose combined amperage had a voltage of such intensity they succeeded in convincing themselves that under certain conditions the power factor could be purchased at the operators' switchboard for less than the cost of production at the central-station switchboard.

The explanation furnished for this anomaly was the same offered by the Baxter Street merchant who could sell goods below cost because he sold so many of them. During the discussion on "the calculation of load factor" the central station advocates were transformed from direct to non-synchronous polyphase alternating currents, each having from one to four methods for the calculation in which the peak-load time varied from 1 minute to 1 hour. The operators, although dazed, were somewhat relieved by Chairman Wood's remark "that coal operators would hesitate to deal with central station men except on the basis of so many mills per ton of coal mined."

The mining industry will be in the future, as in the past, one of the best markets for the electrical engineer's knowledge and the electrical machine manufacturers' wares. However, the latter individuals, by assuming a knowledge of mining conditions which they do not possess, have made bad mistakes which should not be duplicated. This point was brought out in various ways in the meeting by those who knew something of mining conditions, and realized the injury unintentionally done to the industries in the past. At a recent meeting of the Electrochemical Society there were a number of practical men invited whose questions somewhat embarrassed the members. After one paper which dealt with the deposition of metals in grams per square centimeter of surface had been read, questions were invited. The practical man wanted to know how to calculate the cubic centimeters of surface on 4 gross of forks? The question box at Pittsburg did not prove so embarrassing at least to Chairman Wood.

Canaries in Coal Mines

CONSIDERABLE humorous comment has been made on the use of canaries, by the officials of the United States Bureau of Mines, for the purpose of detecting carbon monoxide, or "whitedamp," in mine air, after a mine fire or a serious explosion. But "there's a reason."

It is a well-known fact that chickens, birds, or small animals such as mice, guinea pigs, etc., will succumb to the effects of carbon monoxide, when that gas is present in the mine air in percentages considerably below what is necessary to seriously affect a man.

The effect of carbon monoxide on the flame of a lamp is observable in a laboratory where it is possible for the experimenter to take such precautions as will protect him from inhaling the air containing the small percentage of gas necessary to show increased brightness and length of flame, and the slight blue cap. It can also be detected in the same manner by well-trained men wearing oxygen helmets. But, if a man is unprotected and enters a body of air containing enough carbon monoxide to show its presence in the lamp, he will probably succumb to its effects before he can escape from its dangers.

Therefore the most practical and safest manner of detecting the presence of the gas is to take birds or small animals into the mine and note the effect of the mine air on them. If they succumb, it is time for the men to retreat or to put on helmets, as the probabilities are that if they continue further they will encounter the gas in sufficient volume to cause quick death.

The reason the Bureau of Mines officials use canaries instead of other birds or small animals is because canaries are purchasable in almost every town of considerable size and at comparatively reasonable prices. Other, native, and less valuable birds might be trapped, or mice or guinea pigs might be used. But, it must be remembered the birds or small animals must be kept in the rescue cars so as to be always ready for use. Non-singing birds, mice, and guinea pigs are usually dirtier than canaries, and require as much or more care, and it is natural that the men composing the rescue corps should either be prejudiced against them, or have so little regard for them as to cause them to be neglected. With the canaries, there is a different feeling. The little songsters are attractive. They win the affections of the men and are well cared for. As a result, they are ready when needed, and they have on numerous occasions proved their value in warning rescue corps of the presence of carbon monoxide in the mine air.

Illinois State Mining School

The dedication of the Mining Laboratory of the University of Illinois took place May 9, 1913, on which occasion a large number of invited guests were entertained by the University.

At the Fuel Conference held at the University of Illinois in March, 1909, two resolutions were passed, one favoring the establishment of a Department of Mining Engineering at the University of Illinois, and another calling for other fuel conferences in the future. The dedication of the Mining Laboratory offered a particularly appropriate time for a second conference, which was held on May 8, 9, and 10.

Prof. H. H. Stoek, ably assisted by Messrs. Lincoln, Andros, and Lauder, who drafted the students as demonstrators, succeeded in explaining the different machines for mining and preparing coal for market and ore for metallurgical treatment. The laboratory has excellent facilities for practically teaching young men to become mining engineers. Eastern people who have not visited this institution will be surprised to know that it has 5,000 students, and has a campus about 1 mile long and one-quarter mile wide.

The great state of Illinois is proud of this college and furnishes sufficient appropriations to make it one of the foremost institutions of learning in the United States. Space will not permit going extensively into the advantages supplied for the education of the young men of Illinois, but we wish the legislature of Pennsylvania would send a Commission to examine the Illinois Mining School, for then Pennsylvania State College would have a suitable building for its mining students instead of its present shack.

Professor Stoek taught mining in Pennsylvania State College, afterwards was editor of Mines and Minerals, now The Colliery Engineer, leaving Scranton to occupy the first Professorship of Mining in the University of Illinois. The papers read at this meeting were excellent and the discussions which followed added to their interest. Mr. Francis S. Peabody, President of Peabody Coal Co., Chicago, talked on "Conservation and Commercialism."

Mr. A. J. Moorshead, President Madison Coal Co., St. Louis, which operates in Illinois, discoursed on "Organization as Affecting Mining." Dr. E. W. Parker, Chief Statistician, United States Geological Survey, Washington, D. C., informed the audience with some figures that Illinois was a fair mineral producer.

Mr. R. W. Ropiequet, Past President of the Illinois Coal Operators Association, Belleville, Illinois, discussed "The Transportation Question from the Standpoint of the Coal Operator." The subject, "Safety First," was discussed by Joseph Pope, President United Mine Workers, District No. 12, Ill.; by Thomas Moses, General Superintendent Bunsen Coal Co., Westville, Ill.; and by John Dunlop, State Mine Inspector, Peoria, Ill. The discussion was led by Mr. Martin Bolt, Chief Clerk of the State Mining Board of Illinois.

"Modern Practice In Illinois Mines" included illustrated lectures on the Buckner mine, by President C. M. Moderwell, Saline No. 3 Mine, by General Superintendent W. R. Johnson, Valley Mine No. 5, by S. M. Dazell, President.

A. F. Allard, Chief Engineer Bunsen Coal Co., gave an illustrated lecture on "Concrete in Mine Construction."

Carl Scholz, President Coal Valley Mining Co., well-known as a mining engineer, gave an illustrated lecture on "Steel in Mine Construction," in which he explained a new system of lining shafts with steel timbering and fireproof lagging.

John A. Garcia, Consulting Engineer, Chicago, read a paper on "Modern Steel Tipple Design."

Professor Stoek read H. M. Wilson's paper on "The Fireproofing of Mining Plants," as Mr. Wilson, Chairman of the Mine Fire Committee of the National Fire Protection Association, arrived too late for the meeting. "Fire Protection in Mines," was amply covered by John P. Ruse, General Superintendent Superior Coal Co. Duncan McDonald, Secretary United Mine Workers, Springfield; G. E. Lyman, Mining Engineer, Madison Coal Corporation; James Taylor, State Mine Inspector, Peoria. The discussion was led by E. T. Bent, President Oglesby Coal Co., Chicago. Resolutions were passed to renew the Mining Conferences from time to time, that benefit may accrue to the coal operators of Illinois. The high class of papers read and the general air of satisfaction which prevailed throughout this meeting speak volumes for Professor Stoek's success and the future of coal mining in Illinois.

West Virginia Coal Mining Institute

The West Virginia Coal Mining Institute will hold its summer meeting at Morgantown, W. Va., June 24, 25, and 26. Papers will be read on the following subjects: "Gasoline Motor Haulage in Mines"; a "New Type of Undercutting Machine"; "Welfare Work in West Virginia"; "Qualifications of a General Manager from a Superintendent's Point of View"; "Hydro-Electric Power in Mining, a Description of the Cheat River Installation."

Approximately one-half the session will be spent in visiting different points of interest. On June 25, there will be an automobile trip to Sabraton to inspect the American Sheet and Tin Plate Plant, also the large glass industries. In the evening, the Morgantown Board of Trade tenders a banquet. On June 26, mines in the Connellsville coking district will be visited, a feature which will allow of comparison between Pennsylvania and West Virginia practice in coking and mining.

The committee has made every endeavor to insure the members of the Institute an enjoyable time as well as intellectual feast.

Quarrying Coal at Tofield, Alberta

Methods of Mining Coal From Beds so Situated That They May Be Stripped and Loaded Directly Into Railroad Cars

By Joseph H. Sinclair, M. S.

In the vicinity of Tofield, Alberta, Canada, the coal beds of the Kootanie, Belly River, and Edmonton formations are of unusual interest to the geologist, miner, railroad owners, and inhabitants.

To geologists, because the coal is in a transition state between lignite and bituminous, or what the United States Geological Surveyors have termed subbituminous. To miners, because it offers thick beds, with comparative easy mining and none of the dangers that are encountered in underground mining.

To railroad owners, because it furnishes a cheap fuel that can be stored without much danger of spontaneous combustion and as the moisture evaporates it becomes a better fuel for steam purposes.

To the inhabitants, because the coal can be stored for use in winter in a climate that requires fuel for comfort.

Tofield is located on the Grand Trunk Pacific Railway, longitude 113, latitude about 53° 15′, 40 miles southeast from Edmonton, near Beaver Lake. It has an elevation of 2,200 feet above sea level in what is known as the Great Plains of the Rocky Mountains, the usual features of which are fertile undulating table lands. The rocks in this vicinity belong to the Edmonton series, or Edmonton coal fields, the coal beds being assigned to the Laramie formation, which is either in the upper members of the Cretaceous period or the lower members of the Eocene, Tertiary period. According to the Canadian Department of Mines the Edmonton rock series extend from the International Boundary and have a breadth through Tofield of about 140 miles, covering, so far as known, an area of 35,000 square miles. The Edmonton series is essentially a lignite-bearing formation, which rests comformably on the Pierre shales. To the west of Edmonton at the Pembina River crossing, beds of lignite, show thicknesses of 6, 12, and 13 feet, outcrop in the Edmonton series, and on the Saskatchewan River one bed attains a thickness of 25 feet of workable coal. In the immediate vicinity of Edmonton a persistent bed of lignite, 5 to 6 feet thick, is above the level of the river, and is nearly horizontal.

Fig. 1. The Tofield Coal Bed

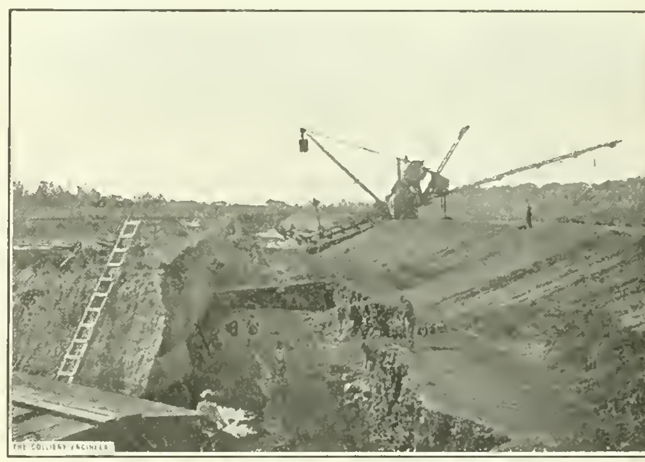

Fig. 2. Stripping Tofield Coal Bed With Scraper Line

The coal in Saskatchewan Province, to the east of Alberta, is lignite and as it goes west becomes subbituminous, and further west coking coal;* evidently it shades imperceptibly from one kind of coal to the next. The Cretaceous formations consist chiefly of sea deposits; there are three horizons which show land conditions and evidences of plant life, and in these coal seams are found.

A marine invasion of the central

*Mining Engineer and Geologist, Calgary, Alberta.
33—11—3

* Mr. Sinclair sent the Editor a sample of Tofield coal which is evidently subbituminous and not lignite, for the following reasons: It does not air slack but dries hard and becomes brittle; it gives a black streak, and while it does not coke it gives off an odor of burning rubber (and no acetic acid is obtained from the volatile matter).

part of the continent during Cretaceous time was preceded in the then existing low trough of the present Rocky Mountain area by an abundant flora, so that the early Cretaceous is coal bearing.

These beds, known as the Kootanie series, were subsequently covered by a series of marine shales deposited by an invasion of the sea; but a shallowing of this sea over the western part also brought about land conditions again in later Cretaceous times, and vegetation spread eastward, and was in turn buried by shales in another invasion of the sea.

The second flora is preserved in the beds of the Belly River formation, and in places forms important coal deposits about in the center of the Cretaceous period.

At the close of Cretaceous times, when the continent finally emerged from this sea invasion, and while the land surface oscillated slightly at or near sea level, another mantle of vegetation covered the low ground which was afterwards submerged. Coal seams were again formed, and in the rocks which succeeded these coal beds, impressions of leaves, stems, and petrified wood, show an increasingly changeable climate, and probably an increasing altitude.

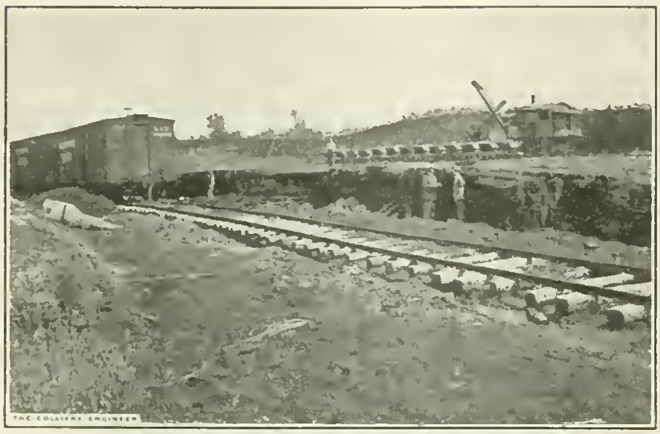

Fig. 3. Loading Coal From Bed into Box Cars

Fig. 4. Stripping Coal for Domestic Use at Tofield

The last deposits of the Cretaceous and the early ones of the Tertiary, form the third coal horizon, and include the Edmonton and the lower Laramie.

The three coal horizons thus found are: Edmonton, Laramie formation; Belly River formation; Kootanie formation.

In the upper of these formations, the Edmonton series, is found the coal seam at Tofield. There is but one seam known, or at least worked, and this has a thickness of about 10 feet.

The analysis of the coal at Edmonton is given in Table 1.

The analysis of the Tofield coal was made from a dried specimen several weeks after it was quarried, so no account was taken of the moisture in the sample. In Fig. 1 is shown the Tofield bed under a rich prairie loam on a dry subsoil, which sometimes is from 12 to 15 feet deep. The coal area immediately about Tofield is estimated at 20,000 acres. Taking a value of 50 cubic feet to the ton with an average thickness of 10 feet, there would seem to be available theoretically 174,000,000 tons. One company, the Tofield Coal Co., owns 1,400 acres of coal land and there are other companies in the field.

Table 1. Analyses of Edmonton Coal

	Moisture	Volatile	Fixed Carbon	Ash	B. T. U.
Parkdale Coal Co.	17.3	28.7	42.8	11.2	8,940
Standard Coal Co.	15.3	31.2	46.0	7.5	9,610
Strathcona Coal Co.	16.1	30.9	41.1	11.9	9,010
Tofield Coal	10.7	53.82	31.3	4.18	

Fig. 2 shows the operation of stripping the coal by means of a scraper line and distributor. Provided the stripped material was loaded into cars which could be hauled so as to fill in back of the coal excavation the same as when a steam shovel is used, the plan has merits, but where the dirt is wasted back of the stacker it becomes only a question of time when it must be rehandled. In this case the coal is broken from the bed as before, loaded into barrows, and wheeled into the car.

Fig. 3 shows the coal with a thick cover being stripped by a steam shovel, at work on top of the coal beds. Here the coal is broken from the bed with bars from above and by picks at the face into sizes which are shoveled into the cars without further preparation. As the face advances the track is shifted in order to make loading economical. As the bed is pure coal a steam shovel could be used to load gondolas were they obtainable, and were it not policy to ship in box cars.

Fig. 4 shows a coal bed where the coal has been stripped for domestic consumption. In this case powder is used to break the coal and coke forks are used to load the lumps into the wagon.

While wages are higher in this new country the cost of stripping per ton of coal is practically the same as in Arkansas, Kansas, and Oklahoma.

According to Barry Scobee, the cost of stripping in Kansas* is about 6 cents per cubic yard where the coal is but 30 inches thick and the covering 20 feet. In Tofield the cost of stripping might be twice as much and the price per ton be reduced on account of the thick coal.

As a commercial proposition, stripping depends upon the thickness of the coal bed and the cover, the facilities for digging and wasting the dirt, and finally on the value of the coal as a fuel.

The cost of stripping 97,854 yards of material over a seam of anthracite at a certain mine in the eastern United States was $1 per ton of material stripped or $.516 per ton of coal obtained. The average depth of the stripping was 75 feet, and about two-thirds of the material removed was rock. The cost of stripping a bank 15 to 18 feet high in Western Pennsylvania was $.30 per cubic yard of stripping. It is fair to assume, therefore, that the coal at Tofield can be placed in the cars at a cost not much over 35 cents per ton.

New Geographical Map of Illinois

This map, 36 in. × 50 in., is mounted on cloth and reinforced top and bottom so it may be hung on the wall or made into a roll as desired. The map has been compiled from a number of sources, and changes will be necessary from time to time in order to make it conform with the geological data being gathered as developments progress. The Illinois Geological Survey invites suggestions and corrections, and if any errors are discovered a favor will be conferred by reporting them to Director F. W. DeWolf, Urbana, Ill.

* The Colliery Engineer, March, 1913, page 406.

Description of Tonnage Map

*By Carel Robinson**

Several years ago after leaving my university and while serving an underground apprenticeship, I served a term as a boss driver. All of the details of the work were then immediately before me, and it was my endeavor to so adjust the several elements of the haulage system as to balance properly. For example, if one of the drivers could haul more coal than he was getting, I would induce more loaders to begin working in that section of the mine. On the other hand, if in some other section of the mine the drivers or motormen were working up to capacity, I would object to more loaders starting in that section unless we could get enough additional tonnage to justify another driver or motor. Knowing the character of the haul, grades, length, condition of track, etc., I could tell pretty closely what a driver or motorman should do in a day. Devoting all of my attention to the haulage in one mine, I could keep posted as to details and adjust the methods of handling the work to the constantly changing conditions.

Later as superintendent of one mine, I delegated the direction of the haulage to a mine foreman and he to his boss driver. With one mine I could supervise the haulage in a general way and keep in fairly close touch with the methods of handling the work. Later, however, with three mines and a good deal of outside work to look after,

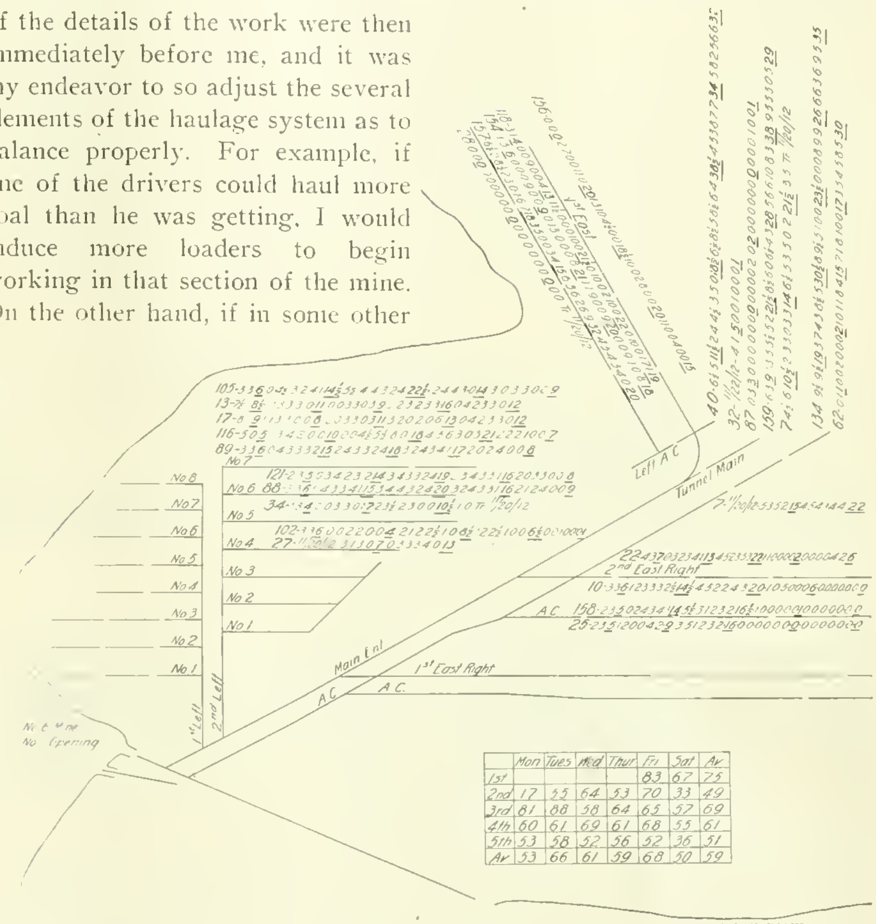

Fig. 1. Tonnage Map

I found it physically impossible to get around over the work and keep in close personal touch with it. I could not possibly check the work performed by the several foremen nor advise with and give them the benefit of my own experience. In the office I could check the total cost, and underground I could follow the general system, but there were many important parts that I could not get completely and accurately as I had done when underground constantly. I therefore wanted some system that would enable me to dig out the details wanted and, at the same time, give a broad view of the situation. To accomplish this we developed what we call our tonnage map.

The straight lines shown in Fig. 1

* Mine Manager.

make a skeleton map of the mine. The large numbers are the check numbers of the men working in the several places, and the small numbers show the number of cars from each place each day, and those underscored show the total on Sundays.

On the first day of each month a draftsman makes the skeleton map of the mines. Also on the first of the month the mine foreman sends in a list of the check numbers working in his mine and the name of the place from which the coal on that check will come. This is entered on the tonnage map. The tipple clerks send in carbon copies of their daily weight sheets and the cars on each sheet are entered on the tonnage map daily just as they are entered on the pay roll by the pay-roll clerk. When no coal is loaded on any check a cipher is marked on the tonnage map. This with the totals each Sunday make it easy to check tonnage produced in any place or any section any day.

In addition to the haulage, we have found these maps very useful for other purposes; for instance, we pay about 3 cents a ton more for coal from narrow places than we do for coal from wide places. The rates for coal that are turned in by the mine foremen are checked on the tonnage map, and several times we have caught mistakes in rates promptly. It also enables us in the office to keep close tab on the pillar work to see that the proper tonnage is coming from the pillars, investigation underground can be made promptly, where otherwise bad practice might go for several days before it would be caught.

Repairing a Large Rope Sheave

Method of Reenforcing the Wheel by Which Breakdown and Delay of Operations Were Avoided

By H. L. Handley

THE New Mexico-Colorado Coal and Mining Co. is operating an endless-rope tramway 1 mile long at Yankee, N. Mex. The grades on this tramway are very irregular, varying from a level grade to a grade of 21 per cent. in favor of the loads. The average grade is 11.2 per cent.

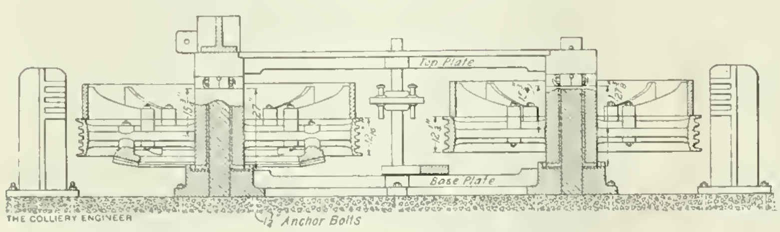

Fig. 1. Longitudinal Section of Rope Sheave

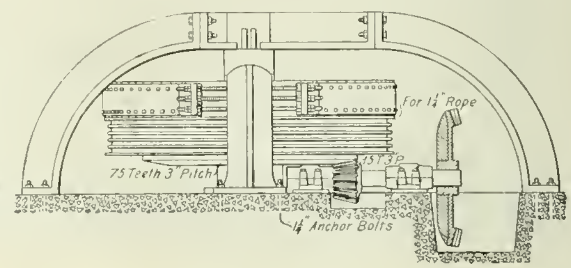

Fig. 2. Rear View

The cars are fastened on to the rope by means of screw grips. Two cars are run in each trip and trips are spaced 400 feet apart. There are 26 loads and 26 empties on the tramway at all times. The empty cars weigh about 1,700 pounds and the capacity of each car is 3,000 pounds of coal, making a load of 61.1 tons traveling with the rope down the hill and a load of 22.1 tons traveling up the hill. The rope is 1¼-inch Hercules patent flattened strand which weighs 14½ tons. The weight of pulling load on the drum is 97.7 tons, making the actual load carried by the drum 10.8 tons.

The drum consists of two cast-iron sheave wheels 81 and 91 inches in diameter, respectively. The front sheave has four grooves and the back one five grooves. The sheaves are mounted tandem, allowing the rope to be wound screw fashion around them, it being fed in on one side of the machine and out on the other. The manufacturers of this machine claim that after 35 years' experience in the manufacture of drums and sheaves for inclined planes they have found this to be the best endless and tail-rope haulage apparatus, and that sheaves mounted with the shafts vertical give much better service than those with the shafts horizontal. This may be the case when the tramway works entirely by gravity, but the writer is at a loss to understand why a machine should be mounted in this way when power is to be applied to the machine at any time. The engineers contended that this installation would need power for its operation at certain times when the conditions were not favorable and it has been demonstrated that power is needed at most times for the purpose of bringing the machine into motion. However, the tramway will operate by gravity when once brought into motion and will work by gravity for several hours when the conditions are very favorable. It is a lamentable fact that the conditions cannot be governed by mere man.

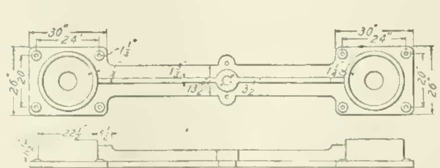

Fig. 3 Base Plate

When received from the factory the machine did not have the large semicircular brace over the top end of the rear shaft shown in Fig. 2 and no means were provided for preventing lateral motion in the rear shaft. It will readily be seen that any motion in the top of the rear shaft would cause the large rack to raise out of mesh; also the bedplate was entirely too light to prevent this wobbling when power was applied. The brace was bought after three teeth had been broken from the rack. A piece of the rack was broken out, new teeth dovetailed in and the piece replaced by means of splices on the back of the rack. The brace was then put on and the gears have given no further trouble.

After the machine had been in use about 3 months a fracture appeared in one of the spokes next to the rim. The machine was kept in use and the second day two other spokes broke at about the same places in the spokes. It was then ordered that the machine be stopped for repairs and triangular pieces of $\frac{5}{8}$-inch boiler plate, *a* Fig. 4, were cut and placed around the circumference of the wheel. These pieces were bolted with their apexes to the spokes and their sides to the lugs on the rim. This formed a wheel of smaller diameter inside the rim and had the effect of transferring the stress from the rim to the spokes closer to the hub of the wheel. The spokes, however, continued to break until there were none left. This did not seem to have any bad effects on the working of the machine, only relieving the internal stress in the rim. The rim had expanded until the fractures in the spokes had each opened up about an eighth of an inch. These cracks opened and closed as the wheel revolved, owing to the shifting of pressure on the rim. It was anticipated that the rim would give way on account of this continual working, but it was desirable to work the machine as long as possible so as to avoid shutting the plant down to change wheels. The wheel was not considered dangerous, as the speed was never more than twenty revolutions per minute.

The machine ran in this way for about 4 months and in the meantime the spokes on the front wheel gave way in the same manner. Similar plates were placed in the front wheel and it has given no further trouble.

When the rim of the rear wheel started to give way it was simply by fracture square across the face of the rim. The machine was put back in motion and in about 2 hours another fracture appeared across the rim about 2 feet from the first. The machine was then shut down for repairs and patches were placed over the breaks. Things then worked nicely for about 6 weeks without mishap. At this time three more fractures occurred in the rim; however, the wheel continued to run and hold its weight. It was deemed advisable to make further repairs on the wheel. Babbitt was poured into the cracks at the ends of two of the spokes when the rim was farthest away from the spoke. This lengthened the rim so that one of the patches was torn off and the wheel went to pieces. No damage was done but the wheel was only a mass of small pieces.

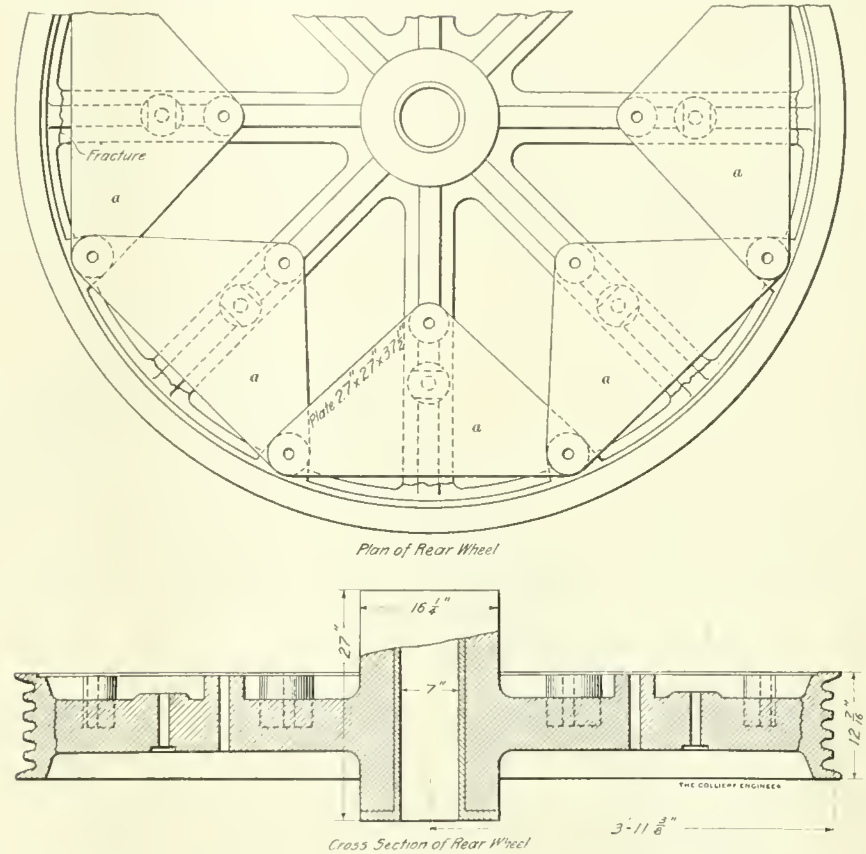

Fig. 4. Showing Braces

A new wheel which was already on the ground was put into place. Before placing this wheel, the rim was sawed square across the face and lugs bolted on. The wheel now acts the same as a split-rim wheel. This tends to relieve the stress between the rim and spokes. The machine is now working without further trouble.

Preventing Timber Decay

At mines where the air is heated and saturated at the intake and in instances where the intake air is saturated by water spray, the life of the entry timbers is shortened to 8 or 9 months and even less in some cases. Timber sets, two legs and a collar, are expensive when the cost of timber, the work, and framing is considered. Therefore, the necessity of treating the timber with some efficient preservative, like creosote, to resist decay is apparent if economy is an item. Warm, dry air induces "dry rot," and warm, moist air induces "wet rot."

Longwall Mining in Illinois

A Description of the Methods in Use at the Mines of the Spring Valley Coal Co.

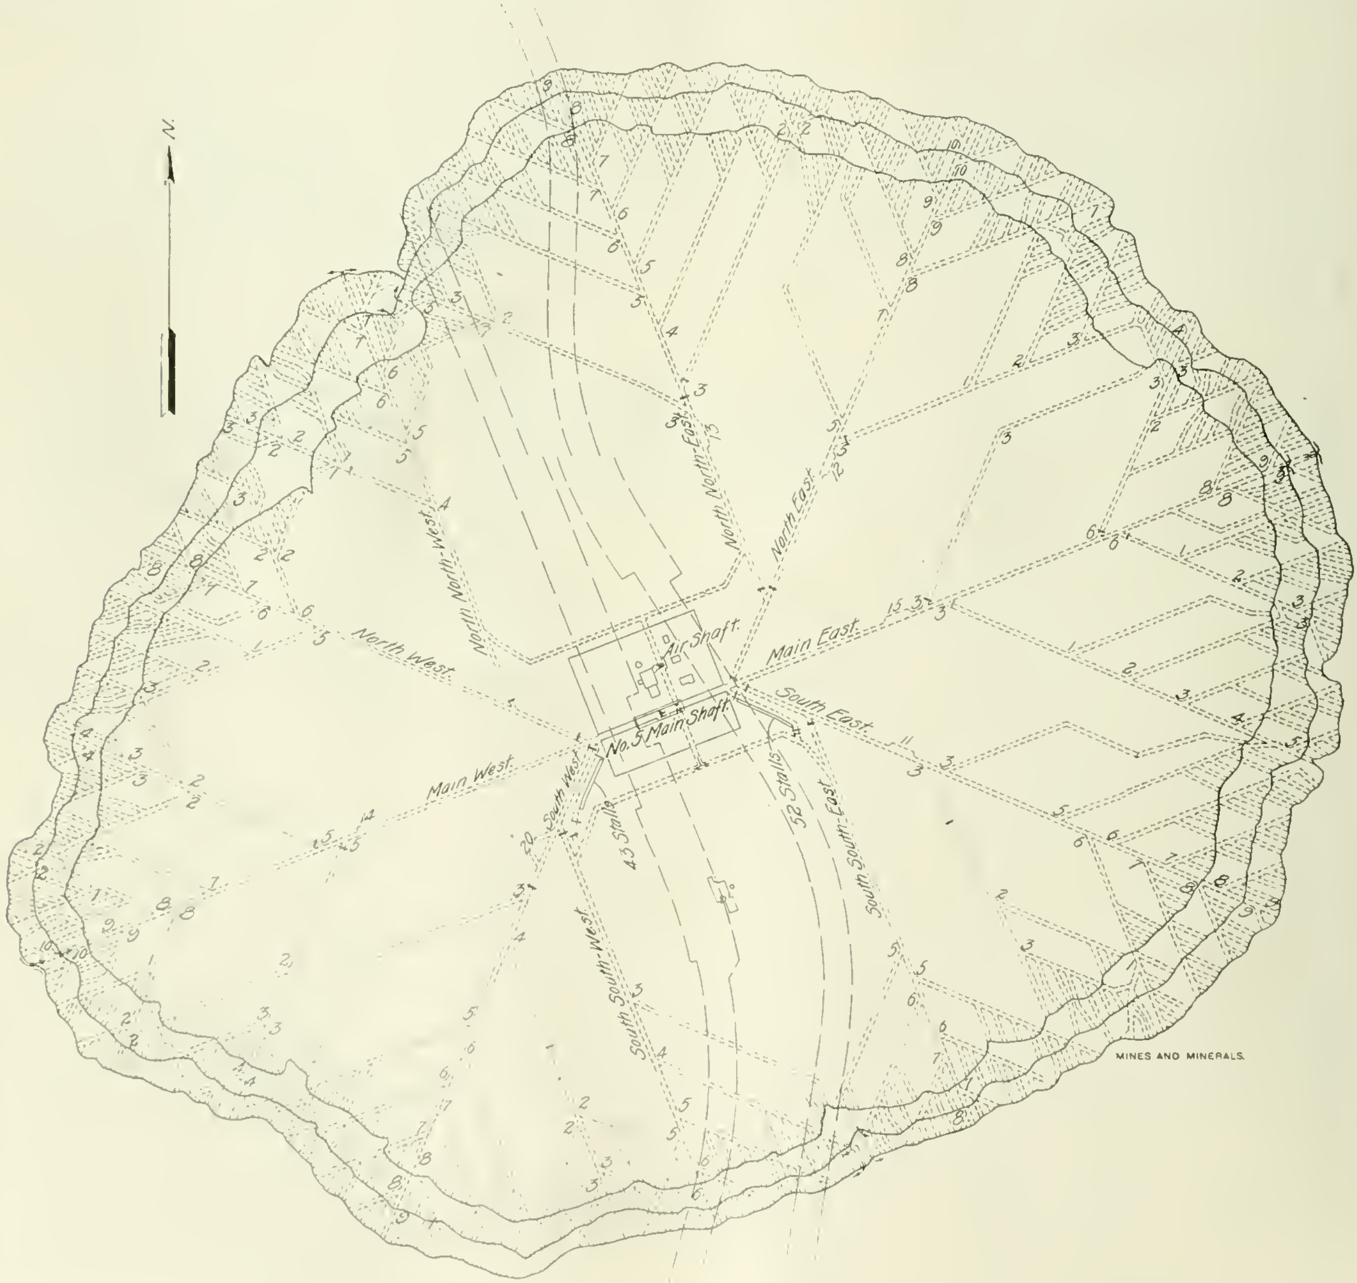
*By S. M. Dalzell**

In the northern coal fields of Illinois, on account of the thin vein, the coal is usually mined by the longwall method. One of the largest and best known coal companies in this field is the Spring Valley Co. This company, whose property comprises over 33,000 acres of coal in Bureau, LaSalle, and Putnam counties, operates four large mines in the vicinity of Spring Valley.

The vein worked is known locally and commercially as the Third vein, but its position in the geological series is that of No. 2. It averages 42 inches in thickness and has no distinct partings, but mines in rectangular lumps, which stand a large amount of rough handling without breaking.

The vein is immediately underlaid with a seam of fireclay from 6 to 24 inches thick, and the coal is undercut in this clay so that the full thickness of the vein is available for commercial purposes. The accompanying plan shows the method of opening the mine, it being known

* General Manager, Spring Valley Coal Co., Chicago, Illinois. Read at the Mining Conference in connection with the dedication of the Mining and Transportation Buildings at the University of Illinois, May 9, 1913.



Plan of Spring Valley Mine

as the Scotch system. The object is to mine the coal in as near a circle as possible. To this end, after leaving the shaft pillar, permanent entries are laid out to the north, east, south, and west; and further divided by entries between at an angle of 45 degrees. As the mine advances, these permanent entries are further subdivided so as to have a permanent road at intervals of from 1,000 to 1,200 feet for the purpose of ventilation and haulage.

From the permanent entries temporary loads are turned off right and left at an angle of 45 degrees, and at intervals of 225 feet. There is no specified distance for the length of these roads. The road advances until it intersects another road from one of the other permanent entries, and at this point one of the roads is stopped, the length of haul, conditions of roadway and other local conditions determining which one is to be advanced.

From these temporary roads rooms are turned off at an angle of 45 degrees at intervals of 60 feet and driven through to the road ahead, or about 200 feet in length. This gives each miner a working face of 42 feet, or 21 feet from the center of his room in both directions.

Longwall mining contemplates the removal of all the coal on the first attack, thus leaving no pillars of coal to be recovered by robbing. In place of pillars, pack walls of gob are built up from refuse in mining, to sustain the roof. As the miner's contract calls for the brushing of 24 inches of roof, there is always plenty of material for this purpose. In fact, the excess of this material accumulated in actual mining, together with that caused by falls in the permanent entries, all of which has to be hoisted on top and dumped, adds considerably to the cost of mining.

In this district, as has been said before, the coal is undercut in the fireclay immediately under the coal. It is only necessary to make this cut from 8 to 18 inches. The miner makes his undercut along his entire face, supports it with sprags and leaves it to stand over night. In the morning the sprags are knocked out, and under normal conditions the roof pressure is sufficient to bring down the coal, it falling out in large blocky lumps. If it does not thus fall, the miner brings it down by means of an iron wedge driven into the face of the coal, so no shooting is necessary.

The road is in the center of the room and the miner has to bring his coal a maximum distance of 21 feet. The mining and rock are thrown back on to the building.

At the angle between the rooms and entries, a cog or cribbing is built of timber, triangular in shape with a base of about 6 feet. About this, the pack wall or building (as it is called locally) is formed and carried ahead as the face advances. Between the building and the face, a row of props is placed to support the roof while the undercut is being made. On account of the roof conditions, this space is not of sufficient width to permit the use of mining machines and consequently none are used by this company. The props are allowed to remain in and the building is built in around them.

The mine is ventilated through the permanent entries as intakes and returns. The air is all carried directly to the face by different splits of sufficient number to give all the working places an equal quantity of air, and travels along the face of the coal to the return. All overcasts are made of brick and steel in a substantial manner and have an area of about 42 square feet.

Ventilation is induced by a 12½′ × 5′ blowing fan, of the Capell patent, direct connected to a 15″ × 15″ engine and furnishing at 140 revolutions per minute 110,000 cubic feet of air per minute at 1½-inch water gauge, equivalent to a ventilating pressure of 7.8 pounds per square foot. All the fans of this company have a recording chart which shows the water gauge for 24 hours. These fans can be used as exhaust fans should the occasion arise and are incased in brick and steel housings.

Each mine is equipped with a complete telephone system of its own, consisting of from 12 to 14 phones. There is also another system connecting all the mines to the central office at Spring Valley; so that in case of serious accident or fire, not only could all the miners in that mine be quickly informed, but help could be immediately summoned from all the other mines.

In order to reduce the danger from fire to a minimum (which is the chief source of danger in this field, there being no gas), all the timbers have been eliminated on the shaft bottoms. Solid masonry walls support the 15-inch I beams forming the roof. These I beams are 15 feet long, 4 feet center to center, and extend to a distance of about 250 feet on each side of the shaft. As a further precaution, the bottoms and stables are lighted with electricity.

As the Third-vein field lies at a depth of about 400 feet, the coal is all hoisted from shafts. At No. 1 and No. 3, double-deck cages are used, but at No. 4 and No. 5 tandem cages are used, the latter proving much better in every way. As in most essential particulars the equipment of all four of the mines is the same, a description of one will do for all. The following applies more directly to No. 5, which is the most modern plant.

The hoisting shaft is 13 ft. 8 in. × 17 ft. 4 in. outside, and 12 ft. × 16 ft. inside. The wall plates are 6″ × 8″ sticks placed skin to skin, with 6″ × 8″ buntons to separate the shaft into two compartments 5 ft. 7 in. × 8 ft. The escapement, or airshaft, 9 ft. × 13 ft., has two compartments; the airway being 6 ft. 3¼ in. × 7 ft. 10¼ in., and the stairway 5 ft. × 8 ft. Between the airway and stairway a partition is constructed of 1-inch rough boards nailed to the buntons and covered with ⅞-inch matched boards.

The top of the hoisting shaft outside of the shaft timbering, is surrounded by a 2-foot masonry wall, which goes down to bed rock.

The cage guides are of standard 60-pound steel rails.

The tower is steel and is equipped with steam transfer tables and Ramsey pushers. To those who are not familiar with the operation of this combination, a short description may be interesting.

The manner in which the cars are moved is as follows:

When either cage, the right one for example, reaches the top with a loaded car, an empty car is already in position on the right transfer table, immediately behind the cage. The tracks on the transfer table and those of the cage are directly in line with those of the tipple. On the same line and directly in the rear of the empty car is the pusher, and as soon as the cage is brought to rest, steam is let into the pusher cylinder. This piston moves forward and pushes the empty car against the loaded one, which is in turn pushed off the cage and the empty car takes its place ready to descend. This arrangement is duplicated for the other cage which is now at the bottom of the shaft, and the transfer table which is at the outer left-hand side of the building, ready to receive an empty car on its return from the tipple. The loaded car which has just been pushed off the cage moves forward with the momentum given by the pusher; passes onto the tipple and is dumped. It then passes over a Phillips cross-over dump and is switched on to one end of the return tracks which pass to the rear on each side of the cage frame. The empty car moves along the track until it passes on to the transfer table, which is now in the lower and outer position near the side of the building. As already stated, the transfer tables are in duplicate, one on each side of the center line of the building which is parallel to the tracks leading from the cage to the tipples. The transfer tables move on tracks at right angles to the tipple tracks. When either transfer table is in the position first described, it is at an elevation of about 3 feet above, and a distance of about 12 feet inward, toward the centers of the building from where it receives the empty car on the return track. The tracks on which the transfer tables move are therefore on an upward grade from each side of the building toward the center.

Both tables are operated by a steam cylinder, underneath the transfer tracks, which has a through going piston rod. A continuous wire cable, to which the transfer tables are attached, runs around a sheave at each side of the building, returning underneath toward the center, and has its end attached respectively to the opposite ends of the piston rod. As the piston moves from one end of the cylinder to the other, the transfer tables are moved one up to its position behind the loaded cage, the other down to its position on the return track.

Both the transfer tables and the pusher are operated from the same position by the cager.

The cars, in passing from the cage to the tipple, pass over a double cross-over or diamond switch, whose latches are controlled by a lever placed near the tipple, so that the man at the tipple can send a car to either one of the two tipples at will. While there are two rock tracks outside of the return empty tracks, the rock is generally sent over on the same track all at one time, as it causes less confusion on the tipple when handled in this manner. The rock is dumped into a special car and hauled up an incline by wire rope and dumps automatically by means of a trip placed in the center of the track.

The cages are hoisted with 1⅜-inch crucible steel rope over 10-foot head-sheaves and furnished with Humble detaching hooks. These hooks are for the purpose of preventing the cage from being pulled over the head-frame in case of an overwinding. They consist of four steel dogs interlocked in a steel frame by means of a copper rivet. To the upper end of the hook the rope is attached, and the cage to the lower dogs. These lower dogs extend out from the body of the frame about 3 inches in the form of a door latch. In action, this hook passes through a circular plate, the diameter of the frame of the hook. The latches or projecting jaws are pressed together by the pull on the rope forcing them up through the circular plate and in coming together they cut the copper rivet. This releases the upper dogs, which in turn open up to release the rope, which passes out over the sheave, this action on the part of the upper dogs throws their lower ends out beyond the sides of the frame in the same position as were the lower dogs in the first position. As the rope releases, the cage drops back but these projections of the upper dogs will not allow them to pass through the hole in the plate and the cage is held there until the rope is again attached. We have had several cases of overwinding and in all cases the hooks worked satisfactorily.

Shaker screens made by the Link-Belt Mfg. Co., are used for the screening of coal, which deliver four sizes of coal known commercially as chunk, lump, egg, and screenings, loading on three tracks and also delivering to a Link-Belt box-car loader when desired.

The hoisting engine is a first-motion, double-cylinder, Corliss engine made by the M. C. Bullock Mfg. Co., of Chicago. The cylinders are 24 in. × 42 in., with an 8-foot oak-lagged drum, provided with a steam brake, steam reverse, and a brake spider 7 ft. 5 in. × 12 in.

The steam plant consists of six 72″ × 18′ return tubular boilers with a rating of 150 horsepower at 125 pounds gauge pressure. They are all connected to a brick stack 100 feet high with an internal diameter of 7 feet. All of the engine and boiler houses are of brick or stone masonry.

In addition to the regular blacksmith and carpenter shop at each mine, the company maintains a well-equipped machine shop capable of taking care of all the necessary repairs to engines, boilers, pumps, etc. This shop, which is located at Spring Valley, is also connected by telephone to all mines; so that no time is lost from when a break-down occurs until the men are on the way to make the repairs.

In connection with the mines, the company operates a coal washer of 1,000 tons daily capacity. The raw screenings from all the mines are shipped there and run through the washer. The washer was built by the Link-Belt Machinery Co., and gives a yield of 65 per cent. washed screenings with 11,000 British thermal units, from raw screenings having 8,876 British thermal units.

The company uses these washed screenings principally for fuel at its own plants and finds them a very satisfactory fuel. They are easily handled and do not clinker badly.

The Spring Valley Coal Co. was among the first to take up first-aid work. They have had a rescue station at Spring Valley for several years, and they sent a team to Washington and to Pittsburg to take part in the national exhibitions in first-aid and mine rescue at those cities. Recently another rescue station has been established at the No. 5 mine and equipped with the latest and most up-to-date apparatus for this work.

The Transportation Problem

From a Coal Operator's Standpoint—Present Conditions and Hoped For Improvements

*By R. W. Ropiequet**

SINCE the prayer of "Bobby" Burns, "Oh wad some Power the giftie gie us, To see ourseles as ithers see us," is so seldom answered, this revelation is generally left to the kind office of friends. "Faithful are the wounds of a friend," says the wise man. And where is friendship warmer and more ardently expressed than that between coal operator and carrier? It may not be amiss, therefore, that at this love feast the operator assume the kind office of a reflecting mirror unto his transportation friends.

For the ardency of the friendship between these two is only exceeded by the reciprocity of their counter estimation. A few years ago the writer was privileged to listen to the frank expression of the transportation fraternity, who, in the spirit of brotherly kindness, expressed the opinion that the untoward conditions prevailing in the mining industry were largely due to lack of management and that if the same ability were applied to this as there is to transportation the result would be more satisfactory.

Whilst the coal operator with the same kindly feeling answers in the words of that popular operetta that moved men's hearts in the days gone by:

"You're very, very good,
And be it understood,
We return the compliment."

For the coal man is perfectly satisfied that if the same business ability and acumen were bestowed upon transportation problems that are necessarily applied to mining, the ills that now beset the mining industry because of those problems would "Fold their tents like the Arabs, and as silently steal away."

Pity 'tis that these abilities should be thus wasted in misapplied channels and that the managements cannot be exchanged. But since 'tis so, it is promising indeed that the great state of Illinois has thus housed them in one structure, so that hereafter the combined intellectual business ability may be unitedly applied to the furtherance of these practically joint interests.

For an Illinois industry with its millions of investments, employing over 80,000 men, an annual tonnage of over 50,000,000 tons of freight (even under the present circumscribed transportation facilities) or almost one-third of the total freight traffic of the state, and which is absolutely dependent upon the carrier for existence, is certainly entitled to the fullest consideration on the part of the carrier, a consideration which, it seems to the coal man, it does not receive.

Here are the great fields of coal, here the mines with their vast investments, here all the facilities for production; yonder the market and the consumer; between these, the only instrumentality by which the products can reach the market, the carrier. And lo! when the demand arises, and with it the opportunity of securing some return on the investment, the facilities for transportation can best be expressed, by what in our school days we called the unknown quantity "*x*," and the algebraic equation is not solved until the demand has ceased, the "period of full car supply" bobs up, and the facilities again become adequate (when they are not required).

As a result, the operator is compelled to be satisfied with a very low per cent. of car supply, his mines are thrown idle a goodly part of the time, his organization demoralized, and the investment becomes a liability instead of an asset.

Brethren, these things ought not thus to be.

His investment has been based largely upon the carrier's promises of adequate transportation facilities. Contracts have been entered into upon the same theory. Or, perchance the operator, unsophisticated as he is, has presumed upon the fact that under the common law, emphasized by statutes of the nation and state, it is the duty of the carrier to provide transportation facilities.

* General Mgr. Royal Coal and Mining Co., Belleville, Ill. Address delivered at the dedication of the Transportation Building and Locomotive and Mining Laboratories of the University of Illinois, May 9, 1913.

And resting upon these, "With hopes triumphant over his fears," he has made his investment, opened up his mines and taken contracts, only at last to realize the full import of, that

"Hope springs eternal in the human breast
Man never is, but always to be, blest."

And that while cars are "the substance of things hoped for" they remain "the evidence of things not seen"; and after many months of weary struggle, "kicking against the goads" he is forced to content himself with a theory of a "non-discriminatory proportionate distribution of available equipment in times of car shortage," and non-discriminatory phase forgotten when applied to specially favored, temporary, whole output mines. 'Tis true that the misery is equalized, but that does not make it less. It simply "rubs the sore where you should apply the plaster." "Misery may love company," a philosophy I am forced to admit quite prevalent amongst coal men, but when you ask for bread and receive a stone, gnawing the stone will not lessen the gnawing pains of hunger; and while the fact that your neighbor is hungry may help you, philosophically, if you are so inclined, it does not remove your own distress, and to this consolation aptly apply the words of Tennyson:

"You say that other friends remain
That loss is common to the race
And common is the common place
And cheap the chaff, though meant for grain."

My friends, when, due to the inadequacy and sometimes well nigh total failure of transportation facilities, the coal industry lies prostrate, thousands are out of employment, dependent communities suffer, and the coal operator stands continually on the brink of the chasm of insolvency with the roar of impending financial annihilation drowning out all their sounds, and feels the very ground crumble under his feet as he impotently struggles to maintain his foothold—is it to be wondered that from his heart and lips there rings the cry that has come down the ages:

"Man's inhumanity to man makes countless thousands mourn."

This is not the portrayal of a nightmare, but an actuality, that so long as the transportation fraternity will hug the delusion that their duty to the coal shipper is to be measured by the single standard of the "Period of full car supply," which, to use the graphic language of Commissioner, now Secretary, Lane, "connotes the period of slack demand," and that at other periods, periods of ordinary business activity, the principle of a "proportionate, (no matter how small the proportion may be) distribution of available facilities" will satisfy the legal and moral responsibility of the carrier, so long can the coal operator look for a continuance of this blessed condition, consoling himself solely with the promise, "Blessed are they that mourn for they shall be comforted."

And the rays of light presaging the coming day of comfort already tinge the horizon.

"The morning light is breaking
The darkness disappears."

The operator who in the simplicity of his faith rested on "ask and ye shall receive, seek and ye shall find," has gone a step further—"Knock and it shall be opened unto you." And he has knocked; and the courts including the highest tribunal in the land are emphasizing the duty of the common carrier to furnish adequate transportation facilities. Whilst the carrier, awakened from his Rip Van Winkle sleep induced by imbibing the potions of legal and economic principles furnished him by the ghosts of yesterday, is arousing himself to meet the necessities of today. To complete the hymn: "The sons of men are waking to penitential tears."

Realizing that the "peak of the load" so far as the coal traffic is concerned, is synonymous with the canon of "no car supply" (and to the operator "slough of despondency" and that the beautifully euphonious "unforseen emergency," cannot fairly be applied to annually regularly-recurring periods of business activity, our friends of transportation have awakened to the fact that to have a maximum of transportation facilities sufficient only to meet merely the minimums of transportation necessities, and these based upon a period of business inactivity, will meet neither their legal nor moral obligations to the shipping public.

And the coal operator, like one of old standing upon the mountain top, can look into the promised land and if, perchance, like him of old, the operator of today may pass away before his foot shall touch the land of promise, he may at least rest in the assurance that those to follow may be able to devote their time and attention to the operation of their industries and not be compelled to wear life away sitting in the anteroom of the mighty, awaiting the opportunity to secure a few crumbs of comfort doled out charitably by the hands of the transportation potentates.

Give unto the coal operator the power of these potentates and this day will be hastened.

What principles would he apply to the adjustment of the transportation problems affecting his own industry?

First, foremost and all the time: Service! Action, action, action, may be the secret of eloquence, but service, service, service, is the fundamental basis of transportation.

The operator would recognize:

"Let him that would be greatest among you be one that serves."

That it is the duty of the common carrier, inherent in the privileges granted it as a quasi-public corporation, indeed, the actual consideration for the granting of these privileges, to supply transportation facilities to meet the ordinary and usual demands of the shippers dependent upon it; and failure in this regard should be called to account by those from whom these privileges have been received, and the carrier be compelled to perform them; and that the victims of this failure and delinquency ought not to be relegated to seeking relief in the courts.

The coal operator wants cooperation not strife, cars not damages, service not law suits. The state has placed upon the operator great burdens in the conducting of his industry. The carriers have received from the state great privileges and with them there has been placed upon them corresponding obligations to meet the transportation necessities of their shippers, including even coal operators.

As the state compels the coal operator to meet the statutory requirements, so the state should also compel the carriers to meet the requirements imposed upon them by statute.

Then, based upon this one all-inclusive principle of service, were he the transportation potentate, the coal operator would furnish transportation facilities reasonably adequate to meet the transportation requirements of the shipper at the times when these requirements usually arise; the duty to furnish these facilities not to be measured or limited by the demands in periods of business inactivity or non-activity.

Second. The principle of "unforeseen emergency" would apply to emergencies that could not and should not have been foreseen; using the bone of "proportional distribution of available equipment in times of car shortage," only as a regulation between and as affecting the victim of the shortage, and not as a cloak of charity to cover the multitude of transportation sins of the carrier.

Third. As a carrier, he would perform the statutory duties of providing the necessary transportation, and if habitually unable to perform these, give back unto those from whence they were received the commission, the trust, the privileges granted by the state, the granting of which were conditioned upon the performance of this duty.

Fourth. Make rates or charges for services based upon scientific principles and not upon a hit-and-miss plan, taking as fundamental if you will "what the traffic will bear"; that is, rates based on giving to the shipper the service to which he is entitled, so as to freely move his product, with the least possible burden on the consumer, and permitting the carrier to secure a revenue commensurate with the cost and character of the service rendered; not however, robbing Peter to pay Paul, and making the low-grade traffic, such as coal, bear the burden of other traffic, and especially not that of the favored traffic shipped by great interests controlling the carrier, nor the frills, fads, fancies, and follies of railroad eccentricities and speculation.

Fifth. Not to place upon the shipper the consequences of the excessive "borrowing" propensities of other carriers, so often used as an excuse by the carrier for its failure to perform recognized duties; which since the remedy lies altogether in the hands of the carrier, should to said carrier be charged; and if unable to remedy this situation, place it in the hands of the regulating bodies of the country for its solution.

Sixth and finally, to use the words of the Interstate Commerce Commission, so far as the coal traffic transportation facilities are concerned, at least, he would nationalize them.

Secure a careful, impartial, and scientific investigation of the actual needs for transportation of the various sections based upon the consumptive requirements of the fields to which these naturally contribute, and the various periods when these needs arise, and ascertain how many cars will be required, approximately, at these various times by each of the different carriers and by all of them unitedly.

This united requirement he would fairly proportion between the various carriers, each to be required to secure and furnish its proportionate number, all of the equipments to move freely, nationally, as in the case of other equipment, and under rules prepared and enforced by the Interstate Commerce Commission; the distribution between the various divisions to be made by one central authority, and based upon the requirements as shown by the investigation and upon the theory of distribution now prevailing in times of car shortage; applying to this problem the same unity of action that is now evidenced in rate making, and which, we are reliably informed is not the result of any combination.

This may be but the dream of an operator, but it would appear to meet some of the conditions, overcome the effects of the borrowing propensities of the various carriers, would demand of each and all of the carriers no more equipment than would be reasonably necessary to move the products of the mines at the time the transportation is required; would obviate to a large extent the waste of idle cars, which must result when the duty is individualized; render stable the productions of coal and its movement to the market; insure to the producers and carriers the placing of the production and movement on foundations of uniformity and stability; permit scientific rate making and a fair return on the investment of both carrier and coal operator, without placing upon the consumer as much of a burden as he is now subjected to because of the speculative conditions inherent in and necessarily produced by the unstable and irregular transportation, and therefore production conditions, as they exist today.

This may be but the vision, the fabric of a dream, utopian, impracticable and non-conducive to the desired result. If so, let the men of transportation, learned in its science and practice, produce the remedy; the present plans certainly are inefficient.

And now, in behalf of the coal operator, permit me to express the wish and hope that the present occasion may be the harbinger of a new day, the commencement of a new era in transportation; and that the housing of the coal industry in the transportation building, by this great state, may be emblematic of the gathering under the all-protecting wing of Transportation, of the coal industry, and that again to invoke the spirit of the Scottish bard:

"That coal and rail the world o'er
May brothers be for a' that."

No. 2 Mine of United Coal Mining Company

*By C. M. Moderwell**

The No. 2 mine of the United Coal Mining Co., is located about 3 miles east of the village of Christopher. This location was selected because, while not exactly in the center of the field which it is to develop, it is as near to the center as the nature of the surface would permit.

The railroad tracks forming the working yard run in an easterly and westerly direction, with the empty storage tracks on the west. The connection from the Illinois Central is made by a spur coming in from the north which forms a Y, connecting both empty and loaded yards. The C. B. & Q. comes in from the south in the same manner. The mining plant is located within this double Y, which makes a convenient arrangement for the handling of empties and loads and also for the receiving of mine supplies.

The tracks are equipped with railroad track scales on the empty side and also with scales for weighing the loads.

The mine was planned both above and below ground to produce ultimately 4,000 tons of coal in an 8-hour day. Each unit of the plant was carefully planned with a view to not only meeting the large capacity required, but to enable this amount of coal to be hoisted, screened, and prepared for the market in the best possible condition and at lowest expense.

The tipple is of the four-track variety and is equipped with a steel rescreening plant with a bin capacity of 1,000 tons and a screening capacity of 1,800 tons daily. The steel tipple is complete with weighing, screening, and loading equipment. A combined power plant includes hoisting engines, electrical equipment, water-tube boilers, boiler house coal conveyer, including overhead steel storage tanks for delivering coal to automatic stokers, ash handling equipment with an ash tunnel under the boilers and steel ash car and hoist for delivering ashes into a hopper located outside of building, the usual repair and blacksmith shops, supply house, etc. There is also an auxiliary air plant in a separate compartment for hoisting men and material during working hours.

The ventilating plant consists of a Clifford-Capell 16-foot fan housed in steel, direct-connected to a Chuse four-valve engine housed in concrete. There is also a complete water system, consisting of a reservoir, electric driven pump, elevated steel tank, and distributing system. The entire plant is of concrete, steel, and brick construction, and is as near fireproof and permanent as possible.

The mine is laid out underground to fit as nearly as possible the conditions found in the No. 6 seam in Franklin County. It is being worked on the panel system and it is proposed to take the pillars in retreating. The seam of coal averages about 10 feet in thickness and about 2½ feet is left up for roof in the first mining. This top coal is taken down when the pillars are drawn.

As the Franklin County field is a comparatively new one, the experience of the operators in that field does not permit of a statement as to the amount of coal recovered, but it is supposed that the total recovery will be about 80 per cent. of all the coal in the ground. If commercial conditions justify, it might be possible to recover more of the coal.

The mine at the present time is producing about 2,500 tons per day, but has something like 200 rooms turned which will be available for quick development when needed.

Underground the cage room on the loaded side is equipped with a Jeffrey car haul which brings the trip down to an automatic car stop which releases the cars one at a time as they are caged. The main haulage roads are laid with 50-pound steel, the cross-entries with 30-pound, and the rooms with 20-pound. A 4-ton car is used and the mine is equipped with electric motors, both haulage and gathering. Overcasts are built of steel and concrete and permanent stoppings are built of brick.

The life of the mine is estimated at 30 years, and in that time it is expected that about 1,500 acres will be worked out. On the basis of 200 working days, it is expected the ultimate capacity of the mine will be 700,000 to 800,000 tons.

Note.—An illustrated description of this mine was published in the issue of this journal for October, 1912.

* President United Coal Mining Co., Chicago, Illinois. Paper read at the Mining Conference held at the University of Illinois, May 9, 1913, in connection with the dedication of the Transportation Building and the Transportation and Mining Laboratories.

Briquet Production in 1912

According to E. W. Parker, of United States Geological Survey, there were 19 briquet plants in the United States in 1912. In 1907 the production was 66,524 tons, in 1912, 220,064 tons. The largest producer is the Berwind Fuel Co., Superior, Wis., which has a capacity of between 35 and 40 tons an hour and last year produced a little over 50,000 tons of briquets. In manufacturing briquets, seven concerns used anthracite culm, nine used bituminous or semibituminous slack, one used oil residue, one mixed anthracite culm and bituminous slack, and one used peat.

Gas Power for Collieries

Use of Coke Oven Gas in Large Engines at Bargoed Colliery—Methods and Apparatus for Cleaning the Gas

*By Sydney F. Walker**

In British collieries the cost of producing and marketing the coal is so steadily increasing, owing to a variety of causes, that colliery managers and mining engineers are obliged to look more and more into costs to economize in production. As in the majority of cases where any product is produced for the market in large quantities, the tendency is not to consider the value of that which is used about the works. This applied particularly to the use of coal for supplying the furnaces of colliery boilers. For many years, no account was kept of the coal used under the boilers, and the only step in the direction of economy was to use the poor coal when there was a brisk demand for the saleable coal. Even this policy appeared doubtful to many colliery managers; because a certain group of boilers, when fed with inferior coal, would not furnish the same supply of steam as when fed with good coal. When the coal with which the boilers were fed was unmarketable, and therefore consisted largely of incombustible material, the effect was serious, and as the boilers were rarely installed to do more than the ordinary work of the colliery, the result was a loss of steam, a loss of power, and a loss of coal output.

All this has been gradually changed; indeed the whole system of marketing the coal has been changed, as 25 years ago small coal, practically unsaleable, ranged in value from 12 cents per ton up to a little over 50 cents; and now, with the revolution that has taken place, small coal is not of much less value than lump coal. The adoption of the mechanical stoker in works where steam power is employed, has largely contributed to this effect. There is also an increasing demand for coke; and a number of collieries in the United Kingdom have constructed modern by-product coke ovens, which use large quantities of small coal.

Among other things, the colliery manager has to examine closely into the cost of the power employed in working his colliery. In the majority of mines in the United Kingdom, electric power has been adopted, partly because of the convenience and economy with which it can be transmitted, and partly because of the greater facilities a central electric generating station affords for economies in the consumption of fuel. In many districts a number of collieries are owned by the same firm, scattered over a moderately wide area, and it is becoming the practice to construct one large central power station to supply electric power to the group, and sometimes to outside collieries situated nearby.

In deciding the question of the most economical source of power for driving the electric generators, steam has to compete with gas in two forms: that produced from coke ovens, and that from producer plants. Coke-oven gas has the advantages, that it is a waste product, and has a much higher calorific value than producer gas. The standard calorific value of coke-oven gas is from 400 to 500 British thermal units per cubic foot. At the Bargoed collieries, belonging to the Powell-Duffry Co., in Monmouthshire, the calorific value of the gas produced is 460 British thermal units per cubic foot. Producer gas ranges from 120 to 150 British thermal units per cubic foot. The difference in the calorific values of the gases is due to the comparatively large quantities of hydrogen and methane present in coke-oven gas; while producer gas depends almost entirely upon carbon monoxide. In the coke-oven gas produced at Bargoed, there is 63.4 per cent. of hydrogen, 23 per cent. of methane, and 5.2 per cent. of carbon monoxide.

Producer gas may be obtained from anthracite, coke, or from the absolutely waste products of the

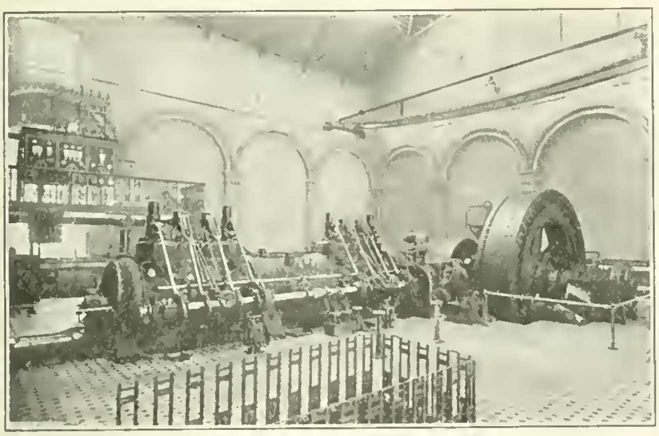


Fig. 1. Tandem Gas Engines at Bargoed Colliery

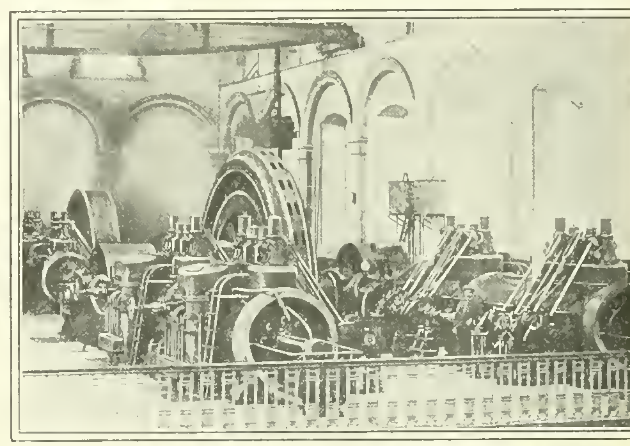

Fig. 2. Twin Tandem Gas Engines 2,400 Horsepower at Bargoed

*Bloomfield Crescent, Bath, England.

colliery. An important question arises here, whether it is better and cheaper to buy anthracite costing from 8 to 9 dollars a ton in the Midland and Northern colliery districts of the United Kingdom, or to use the colliery refuse. Anthracite and coke can be employed in the suction producer; while the refuse can only be used in the pressure gas producer, and only then, when the plant is carefully designed for the purpose. On the other hand, the refuse is as much a waste product, as the surplus gases from the coke ovens.

In the case of the coke-oven gases, about half the total gas which is formed in the coking process, is available for outside use. One-half of the gas is employed in heating the ovens themselves; and the other half is available for power, only when the regenerative method is adopted, that is, when the gases that are to heat the ovens, are burned with preheated air that has passed through brick chambers that have received heat from the combustion of gases in the coke-oven heating chambers.

There are two methods of estimating the money value of the coke-oven gas: By taking its actual cost; and by comparing it with coal used for steam raising. The actual cost of by-product coke-oven gas is the cost of cleaning it. To estimate its value, compared with coal, the management at Bargoed colliery took small coal, such as they would employ in their boiler furnaces, whose money value ranges from $1.25 to $2.50 per ton; and whose calorific value is about 12,000 British thermal units per pound. Approximately, this makes 60,000 cubic feet of the Bargoed gas equivalent in heating value to 1 ton of small coal. But this is on the supposition that the efficiency of the small coal when burnt in the boiler furnace, and when used to produce power in a steam engine, is the same as that of the gas when burnt in the cylinder of a gas engine. As is well known, the efficiency of a gas engine may be taken as 30 per cent., while the combined efficiency of an engine and boiler plant, the boiler using small coal, would rarely exceed 10 per cent. This would make 20,000 cubic feet of the gas, equal in heating value to 1 ton of small coal; and therefore the money value of 1,000 cubic feet of the gas would range from 12 to 24 cents. The actual cost of the gas is a very much smaller quantity. The reason for the high calorific value of the coke-oven gas at Bargoed is, the large quantity of volatile matter contained in the coal from which it is formed.

Two great drawbacks to the working of gas engines with either coke-oven gas, blast-furnace gas, or producer gas, are the possibility of tar depositing on the valve seats, and of acid finding its way into the engine cylinders, and acting chemically upon the cylinder walls, the piston packing, etc. At Bargoed, so thorough has been the removal of the sulphuretted hydrogen, and of the tar, that no trouble whatever has arisen since the plant has been put down, from either of these causes.

Some difficulty was experienced by the management of Bargoed colliery in getting a firm of gas-engine builders to construct engines of the size that were required, to use the gas that contains 63 per cent. of hydrogen, which is a very high figure; and which makes it liable to what is known as back firing but which is really preignition. In the working of the gas engine, compression of the mixture of gas and air is a necessity, so that the molecules of the gas shall have at hand the requisite atoms of oxygen for combination. Experience shows that the power obtainable from any cylinder, increases with the compression. If it were not for the possibility of preignition, compression might be carried very much further than it is. Where the gas, as at Bargoed, is so rich in hydrogen, the danger of preignition, or ignition before the compression stroke is complete, is very much increased. In the engines made for Bargoed, the difficulty was overcome by having a comparatively low compression, six to seven atmospheres; and it is stated that preignition very rarely occurs. On the other hand, the engine will not take any considerable overload. It is well known that the gas engine can rarely be made to accept much overload; that is one point in which it is not so good natured as the steam engine. The steam engine is a willing horse; you can press it very much beyond the power it is made for, in fact up to destruction; the gas engine you cannot.

The first engines made were guaranteed to furnish 1,200 brake horsepower at 100 revolutions per minute, and to drive an 825-kilowatt alternator continuously, with an overload of 9 per cent. When under test, the engines consume 31 cubic feet of the gas at its average calorific value, per kilowatt hour; or 21.3 cubic feet per boiler horsepower. The engine consisted of a pair of cylinders arranged in tandem, as shown in Fig. 1, with the alternator as a flywheel.

It is interesting to note, that it was found quite practicable to run the alternator driven by the 1,200-horsepower gas engine in parallel with an alternator running at another colliery 1½ miles away, driven by a reciprocating steam engine; and also with a third alternator at the same colliery, 1½ miles away, driven by an exhaust steam turbine. For running alternators in parallel, it is absolutely necessary that the two or more machines working together, should be exactly in step; that is to say, that their currents should rise and fall with exact synchronism; and in the early days of gas-engine driven alternators this was found difficult to arrange.

A second engine, shown in Fig. 2, has since been supplied at Bargoed of just twice the power of the first engine. It runs at 100 revolutions per minute, and consists of four cylinders, two cylinders in tandem on each side of the alternator, which acts as a flywheel.

One or two points in connection with the gas engine are worth noting. The cylinders are all horizontal, but their pistons are fitted with tailrods, which run on guides, so that the weight of the piston is taken off the cylinder walls. This again is one of the troubles with both gas and steam cylinders, particularly when of large size, if they are fixed in a horizontal position. The weight of the piston tends to wear the lower part of the cylinder, and create windage in the upper part.

Another interesting case where gas is employed for working the bulk of the machinery, is that at the Aber colliery in the Ogmore Valley, in Glamorganshire. The coal employed is absolutely unsaleable. It contains from 25 per cent. to 30 per cent. of ash; and considerable difficulty has even been experienced in handling it in a producer plant. The coal as it comes from the pit is screened in the usual way by one of the latest modern appliances, the poor fuel being removed, partly by hand picking, and partly by gravity and centrifugal force. This is carried by a conveyer across the valley to a large bunker hopper, above two gas producer furnaces, of the pressure type. A measured quantity of the fuel is fed into a hopper forming part of the cover of the furnace, as shown in Fig. 3, and from the hopper into the furnace, periodically.

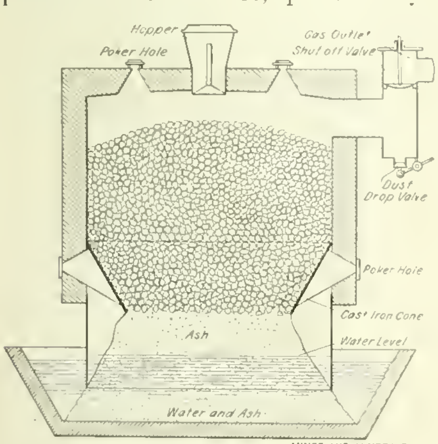

Fig. 3

Combustion is maintained by air forced in at a pressure of 8 inches of water gauge, mixed with steam delivered from a boiler at 80 pounds per square inch. A small steam pipe from the boiler is turned into the air pipe leading to the producer. The furnace is stoked from the top by means of a number of holes, through which pokers can be passed. There are poker holes also below about the level of the grate. The furnace stands in a water seal. From the producer, the gas passes first into a large vertical delivery pipe, having an outlet valve at the top, and a drop valve at the bottom.

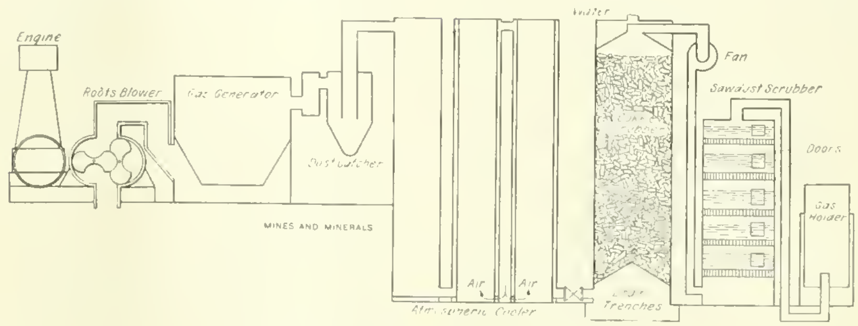

Fig. 4. Apparatus for Cleaning Gas for Engines

One of the greatest difficulties experienced in connection with this gas plant was the large quantity of dust that was made. It is a difficulty which is experienced when converting all inferior coal to gas. All inferior coals contain large quantities of stone, which becomes dust in the furnace, and which has to be removed before the gas can be employed in the engine. The whole of the apparatus between the furnace and the engine is designed to remove the dust, the tar, and the ammonia. As the gas passes from the producer, it will be seen in Fig. 4 that it is made to turn twice at right angles, and that this naturally tends to throw down the dust on to the drop valve below. The drop valve is opened periodically, and the dust allowed to fall into a receptacle. The gas next passes to a dust separator, somewhat similar to those employed in flour mills, but made larger, and with stationary spiral ribs, to give the gas a spiral motion, in place of the fan usually employed in flour mills. The whirling motion given to the gas in the conical-shaped separator throws down a still further quantity of the dust which can be removed through a door at the bottom. The gas then passes out at the top of the conical separator, through the pipe shown, and thence through a series of coolers. They all consist of vertical pipes, but the first pipe is exposed only to the cooling action of the atmosphere; the remaining six having cooling water passing down inside. Each of the other six is of the usual annular form employed in gas works. Each has two concentric tubes, one inside the other; and the gas passes through the annular space between the tubes, water passing down the inside tube, and the outside tube being exposed to the action of the atmosphere. There are two sets of cooling apparatus, one for each producer.

From the coolers, the gas passes to the scrubbers. When the plant was first put down, coke was employed in the scrubbers, as in so many other cases; but it was found to clog so quickly that wooden grids suspended horizontally inside the scrubber, were substituted. A spray of water passes continually down over the wooden grids, and the gas passes up through them. The water absorbs the ammonia and the tar. From the scrubber, the gas passes to a dryer. In the process of cleaning the gas, it naturally takes up a certain amount of water vapor.

Evaporation, as is well known, takes place from water at all temperatures, and depends really only upon the relative vapor pressures, in this case that of the watery vapor already present in the gas, and that of the vapor issuing from the water. Water must not be allowed to enter the engine cylinder, any more than ammonia; and so the drying apparatus is added. The dryer consists of a cylinder about 7 feet high and 7 feet in diameter, at the bottom of which there is usually a certain depth of coke, but sometimes other material such as brick ends may be employed in place of coke. Immediately above the coke are four layers of excelsior, practically wood shavings, separated by perforated diaphragms. Above the wood shavings is a layer of sawdust, and above the whole, a canvas cover, underneath the iron cover of the cylinder. The gas passes through the successive layers of drying materials, emerging, it is claimed, practically free of water vapor. It is then carried into a gas holder by means of a large gas main, to which is fitted a water trap, in case any watery vapor should have escaped. The gas engines draw from the gas holder.

It is well known that at least 30 per cent. of the heat liberated in the cylinder of the engine, passes out with the exhaust, and many attempts have been made to recover this heat by causing it to heat water, or generate steam. At the Aber colliery, a water-tube boiler is connected to each engine, the exhaust gases passing round the boiler tubes while the water inside the tubes is kept in circulation. The boiler is practically a box of tubes, something on the line of a feedwater heater. From the boiler, the gas passes to an expansion and silencing chamber, and thence to a chimney. It was hoped that the steam generated in the boilers heated by the exhaust gases, would be sufficient to furnish that required for the producer. This has not been accomplished, and steam at present is generated in a separate boiler. The calorific value of the gas obtained is given as 140 British thermal units per cubic foot, which is fairly high. The running costs, however, of the plant have not come out very well, for the reason that the power required for the motors employed about the colliery is comparatively low. At present about 32,000 British Board of Trade electrical units are generated per week, at a cost of $.87 per unit. The Board of Trade electrical unit is the kilowatt, 1,000 watts for 1 hour. The cost does not compare favorably with town generating stations, and very unfavorably, indeed, with cases such as at Bargoed, where the gases from the coke ovens are employed.

Rock Dump for Slope

By John Bomling

Some time ago I needed an apparatus for handling, or dumping, rock and bone that comes out of mines, particularly a slope. We have to handle a large quantity of rock and I was anxious to dump it quickly, because it was expensive to handle with a shovel as well as tying up many of our cars. Our master mechanic and I devised an arrangement (I may have gotten the idea from the columns of Mines and Minerals) which answers our purpose very well, as it dumps on either side of the track as well as in front.

The place we had for a dumping ground, was low, so that it was desired to dump on all sides. The dumping service is made out of 40-pound rails, mounted on a turntable *a*, Fig. 1. The part marked *b* is a 2-inch square axle fastened to the part *c* which is a casting that is free to turn in the parts *d* and *f*. The casting *d* is threaded so as to fasten on to the part *f*, which is a piece of 10-inch wrought-iron pipe. The part marked *e* is a casting which fastens on to *f* and also is bolted to the cross-tie *g*. The cross-tie is made of $1'' \times 4''$ wrought-iron and has a clamp *h* which bolts to it on the under side. This clamp can be loosened quickly when it is desired to move the whole arrangement forward.

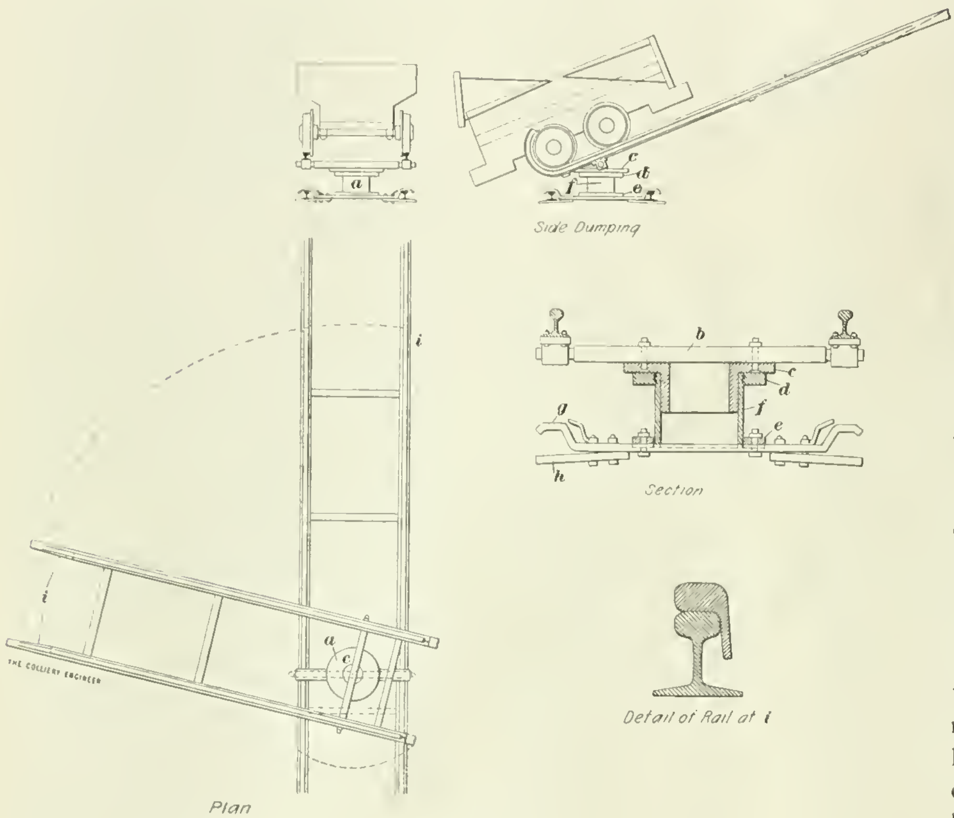

Fig. 1. Rock Dump for Slope

A Long-Lived Leather Belt

A driving belt supplied 32 years ago for driving the machinery at the works of Vernon & Guest, engineers and machine toolmakers, of Smethwick, England, has had a remarkable record. It has been running from 9 to 12 hours a day, at the rate of 1,800 feet a minute, and it is calculated that the distance traveled is equivalent to 74 times round the world. Several other belts, 6 inches to 8 inches in width, running in the neighborhood and supplied by the same firm, have been in practically continuous operation for the past 25 years.

Effect of Coal Mining on the Surface

Experiments Regarding Increase of Volume of Crushed Material and Extent and Direction of Movement of Broken Strata

(Concluded from May)

THE following observations were made in a seam 14 meters (nearly 16 yards) thick, and inclined at an angle of 34°, worked by horizontal slices in ascending order:

The slices, or lifts, were 2.5 meters (8 feet 2 inches) in height, and the stowing consisted of sandstones and shales, as got from a quarry. The depth from the surface of the seam at the level in question was 98 meters = 107 yards. Figs. 6 (*a*) and 6 (*b*) illustrate what occurred.

It was observed:

1. That during the removal of the first slice, the lowering of the surface gradually grew greater, and was further increased considerably by the working of the second.

2. That the movements of the surface were subsidences in the shape of a basin.

3. That the area of subsidence was about four times larger than the area worked.

4. That the maximum sinking was 1.03 meters (3 feet 5 inches) or one-fifth of the height of the excavation.

5. That the movements of the ground appeared at first at a certain horizontal distance in advance of the working face, and that this distance remained nearly constant.

6. That the subsidences increased during a certain time whilst the working proceeded.

7. That the second lift caused a total subsidence almost equal to that of the first lift. This subsidence was .6 meter (1 foot 11 inches) for the second; in all 1.25 meters (4 feet).

8. The area of subsidence cannot be determined, either by normals or verticals to the area worked.

ANOTHER OBSERVATION

An irregular deposit of coal lying at a depth of 58 meters (63 yards) was worked by slices or lifts in ascending order, with stowing, as before. Five lifts were removed and it was observed:

1. That the lowering of the ground was continually increasing in depth and in extent, in proportion as new lifts were taken.

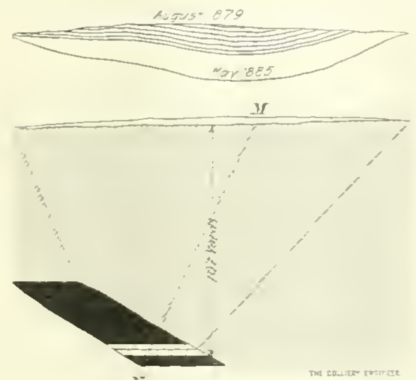

FIG. 6 (a) SECTION THROUGH *C-D* OF FIG. 6 (*b*)

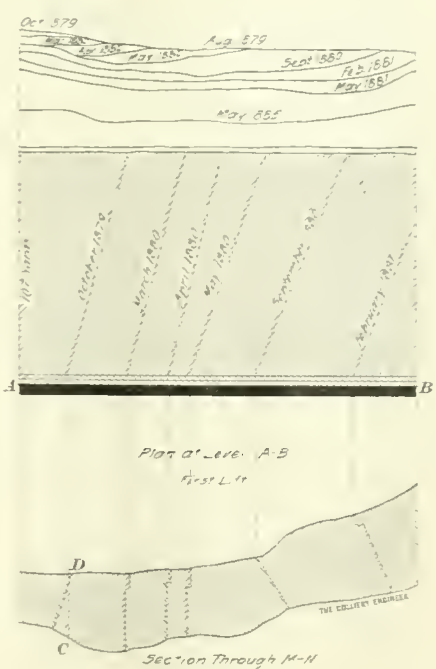

FIG. 6 (*b*)

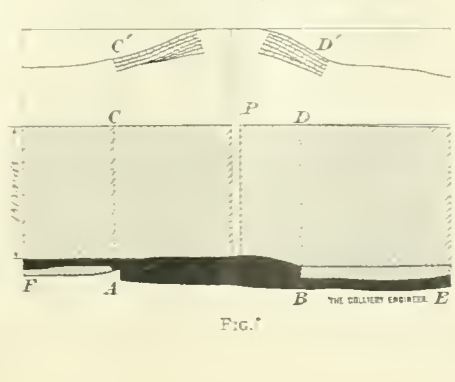

FIG. 7

2. That the area of subsidence was very much greater than the area worked out.

3. That the maximum subsidence was one-tenth of the height of the excavation.

4. That there was no connection between the area of subsidence, and the normals or verticals to the area worked.

THE EFFECT OF LEAVING A PILLAR OF COAL TO PROTECT THE SURFACE

The pillar *A B* shown in Fig. 7, was left to protect the shaft *P*, and the buildings which cover a part of the surface *C D*. The seam has a thickness of 18 to 20 meters (20 yards), a depth 120 meters (131 yards). On the two sides, *B E* and *A F* of the reserved block there has been worked a thickness of coal of 8 meters.

The ground has sunk in the shape of a basin on the two sides and the movement has made itself felt up to the middle of the surface *C D*. Masonry in regular courses and originally horizontal had taken the curvilinear inclination shown at *C′* and *D′*. The curve of the ground in the neighborhood is similar to that of the walls.

The same thing occurs around all pillars which have been left in the midst of areas of goaf, whether to preserve shafts, or for any other reason. Whatever be the inclination and the thickness of the seam, the subsidence occurs in every direction by regular curves around the pillar, and often reaches as far as the very center of the pillar.

Workings Which Have Not Caused Any Settlement of the Ground.—In general, the movement appears at the surface only when the workings have been developed to a certain extent, an extent which must be greater as the excavation is deeper, and the seam thinner. If the area worked is limited, or if, though extended, it is divided by sufficient pillars, the surface is not affected.

The removal of a block of coal

previously left in the middle of an area of goaf had been found to produce serious results on the surface, and at great distances.

FRACTURES OF GROUND, CRACKS, FISSURES, ETC.

These are generally found at the circumference of the surface affected. The basin of subsidence is usually concave at the bottom, and convex at the edges; it is at this convex part, submitted to elongating strains, that the cracks are found. When the subsidence extends, the cracks first formed close, and new ones are formed on the outer edges of the new subsidence. Cracks of the ground are generally disposed in multiple lines, discontinuous, meandering, irregular. They are sometimes very wide. As a rule they are not deep. Long and rectilinear cracks at the surface, and those which continue without interruption from the surface to the excavation are exceptional.

Different kinds of strata cause deviations and alterations of slope in fractures. Generally, the fractures in sandstone are wider, and further from one another than in shales.

CONCLUSIONS

Underground workings have very varied effects on the movement of strata; sometimes the excavation extends considerably before provoking the least subsidence; sometimes the subsidence follows step by step, so to speak, with the excavation; in certain cases the roof falls in all at once in enormous blocks,* in other cases it sinks gradually as it is divided into small fragments, or is lowered without breaking; generally, hard and thick rock roofs fall in large blocks, whilst soft and laminated rocks sink in a slow and regular manner.

When the roof of an excavation sinks, it first bends, and then breaks, if the excavation is of sufficient extent and height. The movement generally reaches a part of the upper mass, and sometimes extends up to the surface. After the cessation of working, the surface soon takes a new state of stability.

ZONE OF SUBSIDENCE

The shape and dimensions of the zone or area which sinks, depend on a number of circumstances; notably on the inclination of the seams, on faults, and other geological peculiarities; on the nature of the rocks; on the thickness of the beds; on the dimensions of the excavation, its depth below the surface, and the manner in which it has been made; on the amount and quality of the stowing put in. The action of water, which may be important, is not here taken into account.

In stratified deposits, the zone of subsidence is generally limited by a sort of dome, which has for its base the area of excavation.

M. Fayol adds in a foot-note that it appears to him probable that the same thing occurs in all rocks. He has proofs of it in soft unstratified deposits, but not in granite and similar rocks. The dome may be regular, irregular, elevated, swollen, flattened, etc.

INFLUENCE OF THE INCLINATION OF SEAMS, OF FAULTS, AND FRACTURES OF STRATA

If the beds are horizontal, the dome is arranged symmetrically round its axis, which is vertical. Each of the beds included in the dome sinks in the form of a basin; the extent of the movement diminishes in proportion as it is further from the center of the excavation. If the beds are inclined the dome is no longer symmetrical, and its axis is inclined.

In proportion as the seams become more inclined, the axis of the dome is inclined also, and tends toward the horizontal; at the same time the height of the zone of subsidence tends toward zero. The axis of the zone of subsidence is quite independent of the vertical and of the "Normal" to the strata. Vertical, "Normal," axis of figure of dome, line of maximum subsidence, all these coincide, when the beds are horizontal; they are distinct, when the beds are inclined.

When the zone of subsidence crosses several groups of beds at varying inclinations, the axis of the dome is deflected in passing from one group to another, and approaches to the normal of the group in which it is. Thus, for example, in beds disposed in the shape of a fan commencing with the horizontal, the axis of the zone of subsidence starting from the vertical arrives by degrees at. the horizontal. The direction of the axis of the zone of subsidence must not be confused with that of the limits of this zone (i. e., the circumscribing lines of the dome). Sometimes the axis of the zone of subsidence approaches in a remarkable manner the perpendicular to the strata, and it is this perhaps which has given rise to the theory known under the name of the "Normal."

This theory is not correct. It rests on the following hypothesis: That the fracture of the beds takes place at the perimeter of the excavation, and perpendicularly to the strata. No working of coal would be possible, if the fracture of the upper beds occurred at the perimeter of the excavation, and continued without weakening up to the surface; no mode of support would

*A striking instance of the truth of the remark occurred at Byer Moor colliery. Pillars 50 yards by 33 yards were worked by "bordways lifts," 8 yards wide, the section of seam averaging 5 feet in thickness; depth from surface about 70 fathoms. The roof is solid "Post" (sandstone) for at least 4 fathoms up from the top of the seam. An area of about 2,500 square yards of goaf was made during a period of 3 months without any fall occurring. One day a very heavy fall took place. Warning sounds were heard about half an hour previously. The mechanical effects of the fall were similar to those of an explosion, but in a much less degree. A hewer 150 yards off had his candle extinguished, and small coals blown about. Sixty yards off two putter boys had their caps blown off, and light extinguished. Nearer at hand an empty tub was blown off the rails; and in another place, which formed a barrier to some extent to the full force of the rush of air, a hewer was driven some 4 or 5 yards by the back rush, and knocked over, and a full tub of coals, weighing at least 13 hundredweight, was moved some distance along the rails. The hewer happened to be a few yards back from the face, and was caught by the back rush. The face of his working place was exposed to the full force of air, as aforesaid, and stopped it, so that the air must have been violently compressed against the face, and therefore the reaction was stronger than elsewhere. Fortunately, there is no gas, and no harm was done. It is worthy of notice that the plane of fracture at the outskirts of the fall, was not vertical, but highly inclined over the excavation, in accordance with M. Fayol's statement.

A similar fall on a much larger scale occurred at the same colliery a good many years ago, but the writer has been unable to obtain particulars about it, beyond the fact that its effects were felt at the bottom of the shaft, where lights were blown out, at a distance of more than 1,000 yards from the fall.

sustain such a load; very fortunately, on the contrary, the roads at the perimeter, those at the working face, are as a rule easily kept open, when the roof has already settled down at a certain distance behind.

Fractures commence rather at the center of excavations; they are multiplied in proportion as the working face advances, and they cut up the superincumbent mass. The upper beds give way one after the other, but they do not break at the same line, as Gonot and Callon supposed.

Faults and fissures, which destroy the continuity of the beds, exert a considerable action on the inclination of the zone of subsidence; they are planes of easy sliding, along which certain movements take place more readily than elsewhere.

INFLUENCE OF THE NATURE OF THE STRATA

The nature of the strata affects the zone of subsidence variously; the hardness, elasticity, plasticity, compressibility, etc., are so many conditions which affect the result; if the ground is hard and brittle, it increases in volume very much more than if it is plastic; if it is firm and cohesive, it only yields under forces very much greater than those which suffice to draw away soft ground; if it has elasticity, it transmits to greater distances the pressures which it receives. The compressibility of rocks, after expansion, is also variable. Therefore, over identical excavation, domes are formed more or less lengthened or heightened, inflated, flattened, etc.

INFLUENCE OF THE DIMENSIONS OF THE SURFACE OF THE EXCAVATION

Above small excavations, confined domes of subsidence are formed, which increase in width and heighth as the empty space extends. If the roof could bend freely in proportion as the area of excavation is developed, the zone of subsidence would grow indefinitely. But allow that, the height of the excavation must be infinite. Now in practice a sinking roof is not long in supporting itself on the floor of the seam; and soon after the zone of subsidence ceases to extend in height; the stoppage takes place when the contact of the roof and floor is established over a certain length.

The height of the zone of subsidence of an excavation of a given height does not extend after a certain point, whatever be the extent of the area of excavation. The height of the zone of subsidence will be 10 times, 100 times, 1,000 times that of the excavation if the average expansion of the upper mass is one-tenth, one-hundredth, one-thousandth; but the upper movement stops, when the total expansion is equal to the space of the excavation.

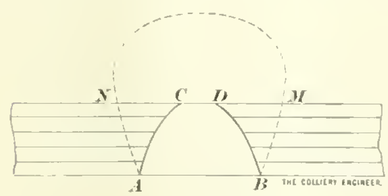

Fig. 8

INFLUENCE OF THE HEIGHT OF THE EXCAVATION

The height of an excavation does not act in a similar manner to the area; whilst the zone of subsidence increases, as far as the limit, in proportion as the excavation extends, it does not always increase when the excavation is of greater height. The subsidence and disturbances which are produced in the upper mass increase, but their area does not always extend.

However, the observations made show, that the zone of subsidence is developed more often in breadth and in height, when the height of the excavation increases, but this extension is far from being in constant agreement with that of the excavation.

An excavation of sufficient height relatively to its breadth or relatively to the depth from the surface, may give rise to peculiarities called in French "cloche" (a bell-shaped cavity), and "fontis" (a conical funnel-shaped cavity).

The "cloche" is a sort of arch more or less irregular, which the roof, in falling, leaves in the upper mass. This occurrence is easily understood; we have seen that the first bed forming the roof breaks usually along a plane inclined over the excavation; the second bed is thus laid bare over a more restricted area, and if it breaks in its turn, it is still along inclined planes, which make smaller still the empty space; the points of support of the roof approach nearer and nearer; finally a bed is reached which does not fall, and the "cloche" is formed. If the ground line cuts the "cloche" one has a "fontis."

In this case the "fontis" may be a sort of frustum of a right cone $ACDB$ as in Fig. 8. If the strata be soft, and the height of the excavation be great relatively to the height of strata covering it, the frustum of the cone is reversed as shown by $ANMB$. A "fontis" may take all shapes comprised between the right cone $ACDB$, and reversed cone $ANMB$.

Instances of this species of fall, a "fontis," have occurred recently at Byer Moor colliery, in working the Busty Bank seam near its outcrop. At the place in question its section is from 9 feet to 10 feet thick, including from 2 feet to 2 feet 6 inches of fireclay in the middle, and there are 10 feet to 14 feet of cover, consisting mostly of clay. In working away the pillars, after removing the timber in a "lift" which has been driven as far as required, a fall usually takes place that reaches to the surface, but it sometimes reaches the surface at a point not vertically over the excavation. The soft strata run into the empty space, and then a clean break occurs, leaving an open hole, like a little pit as shown in Fig. 9.

When a "cloche" occurs above an ordinary excavation, at great depths, its consequences are hardly perceptible in the general subsidence. The material which falls first is the most disintegrated; that at the summit of the "cloche" is sometimes scarcely disturbed.

INFLUENCE OF THE DEPTH OF STRATA WHICH COVERS THE EXCAVATION

In working the same seam, one does not usually notice much difference between the movements of the roof caused by similar excavations at depths of 50, 100, 200, and 400 meters; whether it results in "cloches," falls, or subsidences, the movement of the roof seems to depend very little on the depth of the excavation.

We have seen, however, that the deflection of the first bed increases up to a certain point with the superincumbent load, and that this deflection is generally in direct ratio to the height of the dome of subsidence. But the fracture of the roof is caused more often by the weight of the first beds than the pressure of the upper masses, and much before this pressure can have produced its entire effect. It is probably for this reason that it is difficult to estimate the influence of the depth.

INFLUENCE OF THE MANNER IN WHICH THE EXCAVATION IS MADE

It is known that the subsidence is in proportion to the increase in volume of the superincumbent mass, and that the increase in volume depends on the state of disintegration of the rocks. Now it is plain that the disintegration of the beds forming the roof depends very much on the way in which the excavation is made; the working of a seam 5 meters (16 feet 5 inches) thick, for instance, will not produce the same effects, if all removed at one time, or in successive layers of 1 meter. The zone of subsidence is the most reduced, when the mode of excavation is such as to cause the greatest disintegration of the roof.

EFFECT OF STOWING

If the excavations were completely filled with incompressible material, there would be no subsidence. But ordinary stowing is not in this condition; the material employed is more or less compressible, and never fills the excavations in a perfect manner.

When the roof settles down, the stowing opposes a resistance, which, weak at first, increases rapidly, and soon stops the movement. The influence of the nature of the stowing and its more or less careful execution is easy to recognize in mines.

The following facts have been observed at Commentry:

(*a*) Certain seams, from 3.28 feet to 6.56 feet in thickness, which were very difficult to keep open,

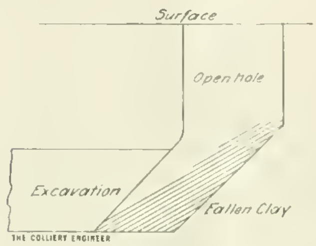

Fig. 9

when worked without stowing, have hardly required timbering, from the time they were stowed.

(*b*) The cost of timbering was high, and the roof always on the move near the working face, in a district of the main seam; for clay rock, which had been used for stowing, was substituted a hard rock not easily compressible; at once the roads became steady, the roof lowered very much less, and the expense of timbering considerably lessened.

(*c*) In the seventh and last lift of a stage of work having for roof the stowing of the stage above, the stowing was done imperfectly; the place was constantly falling, and absorbed a great deal of timber. Great pains were then used with the stowing, no smallest space being left. Soon the pressure was hardly felt at the work face; all the timber put in could be drawn.

With good stowing, one can therefore considerably lessen the movements of the roof.

Let us consider an excavation of 1 meter (3 feet 3 inches), in height. If it is left empty, the first beds of the roof will fall, expanding in volume, and will then support the superincumbent mass. Suppose that the five first meters fall, and fill the empty space at an average expansion of 20 per cent., and that this fallen material retains after the settlement of the upper mass a permanent increase in volume of 10 per cent., i. e., in all .5 meter (1 foot 7½ inches). Suppose again that the upper strata expand, on an average, in settling down, 1 per cent. The height of the zone of subsidence will be $5+50=55$ meters (180 feet).

If it is stowed, the beds will not fall; the upper mass will sink gently upon the stowing. Allow an average expansion of ½ per cent. only, and a compression of .4 meter (1 foot 4 inches) for the stowing. The height of the zone of subsidence will be $.40\times 200=80$ meters (262 feet), that is to say, 82 feet higher than in the case of no stowing.

It is true that to obtain this result, it has been necessary to suppose that the average expansion of the upper mass is 1 per cent. in the former case, and ½ per cent. only in the latter.

If the same average expansion of ½ per cent. is allowed, the zone of subsidence would be 344 feet without stowing, and 252 feet with stowing. Now there is no reason to suppose different expansions in the two cases.

The following calculations appear more probable: The excavation being 1 meter (3 feet 3 inches) in height, if it is not stowed, it may be:

First, that the roof sinks without breaking. Then with a mean expansion of ½ per cent. the height of the zone of subsidence will be 1 meter $\times 200=200$ meters, or 656 feet.

Second, that the roof breaks. Suppose that 5 meters fall, and increase in volume 20 per cent. and that the settlement or compression of this fallen material be .80 meter (2 feet 7 inches), the height of the zone of subsidence will be 5 meters $+.80\times 200=165$ meters, or 541 feet.

If it is stowed, and the stowing squeezes .4 meter the height of the zone of subsidence will be .4 meter $\times 200=80$ meters, or 262 feet.

For a settlement of .3 meter this would be only 60 meters, or 197 feet.

The stowing would diminish by one-half or two-thirds the height of the zone of subsidence, and consequently the extent of the subsidence at a given height.

DAMAGE TO THE SURFACE

On the surface, above underground workings there is sometimes a complete absence of movement, sometimes subsidence more or less considerable.

Above excavations without stowing at depths less than 100 meters (328 feet) and in seams from 1 to 2.5 meters (3 feet 3 inches to 8 feet 2 inches) in thickness, we have seen subsidences varying from 0 to 80 per cent. of the height of the excavation; above excavations with stowing, at depths between 164 feet and 820 feet, we have seen subsidences varying from 0 to 50 per cent. of the total height of the excavation.

At some points, above the main seam at Commentry, where the working had removed from 65 feet to 82 feet thickness of coal, the subsidences of the ground have reached more than 33 feet in depth.

In general the disturbance of the ground is a subsidence in the form of a basin, analogous to that presented by each of the beds included in the region affected. The subsidence is greater as the excavation is nearer the surface.

With horizontal seams, the point of maximum subsidence on the surface coincides vertically with the center of the excavation; the limits of the subsidence are placed symmetrically in relation to this point, sometimes wider, sometimes narrower than those of the excavation.

With inclined seams, the point of maximum subsidence of the ground is no longer on the vertical to the center of the excavation, nor on the line of maximum subsidence of the various beds. Whereas with horizontal seams, the basin of the upper bed coincides with the subsidence of the ground; with inclined beds, there may be a considerable distance between the maximum subsidence of the ground and the greatest deflection of the upper bed.

The theory of the dome, as has been already said, explains different observations sometimes contradictory in appearance, which have been made on subsidences of ground.

In Fig. 10 is shown how the position of surface movements varies with the height of the ground above the excavation.

A B is the excavation; *A B C D* the zone of subsidence.

At the level *S*, the ground is above the zone of subsidence; it undergoes no movement.

At the level S_1, a small subsidence occurs, limited on the right by a Normal *B C*, starting from the highest point of the excavation.

At the level S_2, the limit of the subsidence coincides on the left, with the vertical *A D* starting from the lowest point of the excavation.

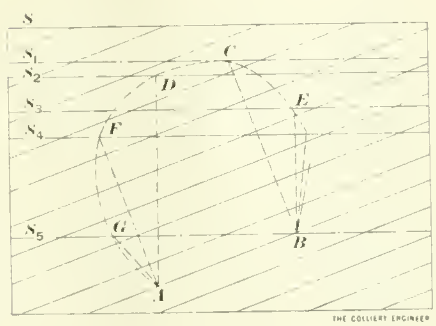

Fig. 10

The limits of the subsidence coincide on the right with the vertical *B E*, at the level S_3; on the left, with the Normal *A F*, at the level S_4; and at the level S_5, with a line inclined at 45 degrees starting from the lower side of the excavation.

CRACKS AND FISSURES IN THE GROUND

The subsidence is generally accompanied by cracks which occur about the perimeter of the depression; they are rare or hardly visible about the middle of the basin.

The fissures usually lean toward the middle of the basin, and therefore over the excavation; they are directed toward the center of the curve of the portion of ground on which they are found. This arrangement allows us to a certain extent to say, on the inspection of fissures, on what side the excavation is; but it does not allow us to fix either its extent or depth.

The cracks are generally discontinuous, numerous, crooked; they are distributed irregularly inside and upon the borders of the zone of subsidence. Rarely do they continue without interruption over a great length either in a vertical direction or horizontal. The width of the cracks may attain several meters. Sometimes between two neighboring cracks, a block of ground, in the form of a wedge, falls in, leaving an enormous gaping hole. Cracks sometimes form the limits of a reciprocating movement caused by subsidence at another point. In place of a subsidence, there is then, on one side, an uprising.

In spite of these various circumstances, one finds nearly always, taking it as a whole, the depression in the form of a basin; and even on ground the most disturbed by underground working, frequently one would not distinguish the subsidence from natural undulations of the ground, if the cracked and damaged buildings did not call attention.

SUBSIDENCES OF GROUND

It results from all that precedes, that subsidences of the ground depend on the area and height of the excavations, and on the depth of these excavations below the surface; that they depend also on the nature of the strata, on the arrangement of the seams, on geological circumstances, and yet other elements, without speaking of the action of water, which we have symmetrically kept apart in this study.

This allows us to understand the difficulty, if not the impossibility, of foreseeing the subsidences of the surface, to which a working may give rise. It is this, which it is most important to know. As already stated, it will probably be arrived at by analogy, after having classified and compared a great number of facts.

M. Fayol then points out, for the special purpose of arousing observations and comparisons, a sort of practical rule to which they have been led at Commentry, in strata where sandstone predominates, and for seams having an inclination of less than 40 degrees.

Height of the Zone Subsidence. (1) When the area worked is vast, so to speak, infinite, the height of the dome does not exceed 200 times the height of the excavation. The height of the excavation is the thickness of the seam in the case of a working without stowing; it is only the squeezing of the stowing or subsidence of the roof, in the case of the goaf being stowed.

(2) When the area worked is limited, the height of the dome is included between twice and four times the breadth of the area worked out; it is about twice for excavations less than 6.56 feet high; greater if the excavations are higher.

Amount of Subsidence.—The surface subsidence is less as the excavation is deeper.

Above a working without stowing, of a seam of 1 meter (3 feet 3 inches) for instance, the subsidence would not make itself felt at more than 200 meters (656 feet) in height; and if the dome of the movement attained this maximum, the subsidence, nil at 200 meters above the excavation, would be about from .40 to .50 meter (1 foot 3 inches to 1 foot 7 inches) at 100 meters (328 feet) height.

If the same seam was worked with stowing, the movement would not extend more than 80 meters (262 feet) in height (supposing a compression of the stowing of 40 per cent.). At 80 meters (262 feet) above the excavation, the subsidence would be nil; at 50 meters (164 feet), it would only be from .10 to .15 meter (4 inches to 6 inches).

If the area worked was reduced to 40 meters (131 feet) in breadth, with or without stowing, the zone of subsidence would not exceed 80 meters (262 feet) in height. But at 50 meters (164 feet) above the excavation, the subsidence would be, in the first case, with stowing, from .10 to .15 meter (4 inches to 6 inches), and, in the second, from .30 to .35 meter (12 inches to 14 inches).

The working of a seam 4 meters (13 feet) thick would produce the following movements:

	Maximum height of the zone of subsidence in yards
Area of excavation unlimited, without stowing	871
Area of excavation unlimited, with stowing (compression 40 per cent.)	350
Area of excavation limited, 164 feet in breadth without stowing	219
Area of excavation limited, 164 feet in breadth with stowing	109

It is not claimed that these figures are precisely accurate. They appear to be only applicable, in some degree, to strata consisting for the most part of sandstone, and having an inclination less than 40 degrees.

MEANS EMPLOYED TO PROTECT THE SURFACE

Subsidences of the ground may be prevented by thoroughly filling the excavations with incompressible material. But this process is costly and sometimes impracticable. It is more easy to protect the surface by leaving pillars in the middle of the portions worked. This process has been recognized everywhere as efficient, and it is the most generally employed. A knowledge of the laws which govern the propagation of the movement of strata, will very much facilitate the determination of the plan to follow in working in order to protect any portion of the surface.

As one penetrates further into the ground, one may increase the dimensions of the pillars worked, and the proportion of the area worked relatively to that of the blocks left, keeping account of the height and breadth of the zones of subsidence, so that the different zones remain distinct, the one from the other.

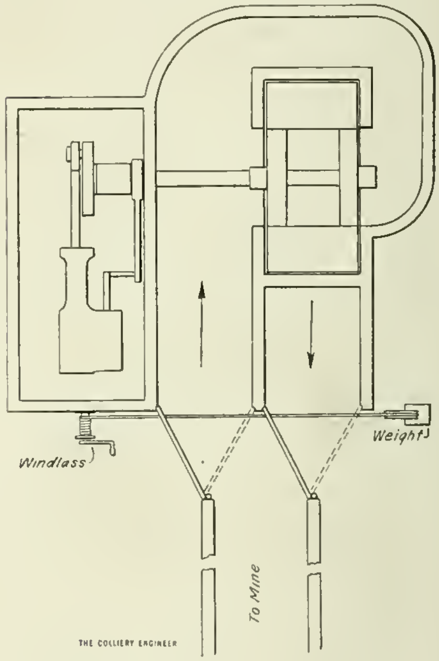
This general rule is susceptible of many combinations according to the thickness, inclination, number, and depth of the seams.

Reversing an Air-Current

By Bert Lloyd

As a rule those fans that have a reversible arrangement in their make-up also have considerable added to their first cost on that account, in return for which a greater efficiency and ease of operation is secured. When the reversing arrangement consists of several doors, including one to throttle the throat of the fan, the cost of installation runs up, and in addition to the inevitable loss by leakage, the fan usually has to be stopped while the change is being effected.

The accompanying sketch is of the arrangement which I think is an improvement over existing methods.



Two doors are built as near the fan as may be convenient and by the aid of a windlass one man may open one door and close the other, thus almost instantly reversing the direction of the air-current, while the fan is going full speed.

A windlass at one end of the chain, or a wire rope, and a weight at the other actuate the doors in either direction. The windlass, being in the open air, is accessible at all times. In addition to the increased efficiency, ease and speed in operation, this system offers a comparatively low cost of installation.

Concrete in Mine Construction

*By A. F. Allard**

Within the last few years a great many important advances have been made at the modern coal plants in the use of concrete for buildings, shaft lining walls, and constructions inside of the mine. The appearance of the up-to-date plant is wonderfully improved with its concrete mine buildings, consisting of the power plant, hoist house, repair shop, miner's bath house, fan house, supply house, powder house, and outside stable. These fireproof structures, with reinforced concrete walls, concrete floors, and cement roof covering, are permanent and involve little or no expense for upkeep during the life of the plant. The boiler house, with its reinforced concrete chimney towering to a great height, is substantial and attractive in appearance as compared with an installation of steel stacks which are subject to deterioration from rust and require frequent painting and attention, while no expense for maintenance after first cost is necessary on a concrete stack. The coal storage bins and water supply tanks erected of reinforced concrete, instead of wood or steel, mark the advance made in the use of concrete for these structures. This material now replaces the wooden walks and platforms of the steel tipple and the members themselves are protected from rust and mine gases with a covering of the same material. Swimming tanks built of concrete prove a source of amusement and recreation for the employes at a coal mining plant. The house site of the miner's home is made bright and clean looking with concrete sidewalks, street curbing, and gutters. House foundations and outbuilding vaults of this material are waterproof and sanitary.

Those who have had to deal with the growing scarcity and steadily increasing cost of large size timbers for inside mine construction, will welcome concrete as a substitute for this material, not only at new plants, but for the renewal of wooden structures at mines in operation. By its selection, the mine owner will be amply compensated for the increased first cost of the installation as compared with wood, when the stability, permanency, and fireproof qualities of the concrete are taken into consideration.

As a fireproof and permanent material for the lining of shaft walls, concrete is without a rival, and its adaptability for this class of work is well recognized, judging by the large number of concrete shafts now being constructed. In fact, we have hoisting and ventilating shafts completed from top to bottom without a piece of timber; the lining walls, cross-buntons, and division wall of the air compartment are of concrete, with guides and stairways of steel. The method of sinking mine shafts by means of the concrete caisson with a steel cutting edge or shoe, through soft and water-bearing strata, has come into prominent use, for by its weight, penetration to great depth is possible, rapid sinking progress is made, the flow of water met with is reduced and a great saving in cost of labor and material is obtained by the omission of timber curbing.

From comparative cost data, I find the price per vertical foot of a completed concrete-lined shaft to be about one-third more than that of the wooden structure; this amount is in the first cost only, for after a few years' time renewal of timbers would be necessary in the latter.

There are numerous designs for concrete shafts including rectangular, circular, elliptical, and the straight sides with circular end walls; the latter is a very economical section, utilizing the end spaces for pipeways or stairways, and reducing to a minimum, excavation and concrete yardage. The circular end walls have great strength to resist the strata and water pressure, forming a continuous concrete arch from top to bottom; the side-wall pressures are taken care of by the thickness of concrete lining, depending upon the nature and depth of strata penetrated. Generally self-sustaining strata, such as rock, slate or good shale require a wall of from 6 to 9 inches in thickness, which is sufficient for the anchorage of the buntons, while a heavy fireclay or wet sand seam would require a much thicker wall.

In the western iron and coal districts, a number of reinforced concrete shafts have been sunk through by means of the pneumatic caisson or compressed air system. This process has proven effective in wet strata for obtaining dry shaft walls; also for making a water-tight joint when the concrete caisson reaches the bed rock. Air pressure is provided in the working chamber to displace the water encountered, and the pressure is maintained until the concrete has set.

The construction of shaft-bottom landings of plain and reinforced concrete includes the single or double-track entry, providing storage room for loaded cars, space for empty car lift back of the shaft, and room for empty car storage track, together with the necessary chutes. For this work, I have used three different designs in concrete construction for supporting side walls and mine roof which have to bear excessive loads and sustain the crushing effect induced by the displacement of the roof strata; they are:

First. The rectangular section supporting I beams on concrete sidewalls and covered with reinforced concrete slabs, having a thickness of 3 or 4 inches. The depth of beam is usually 6 or 8 inches for single track span and from 12 to 18 inches for that of double track, the size and weight of beams selected depending upon the nature and condition of the roof; I have placed the beams on 4-foot centers, covered with slabs 2 feet in width.

*Chief Engineer, Bunsen Coal Co., Danville, Ill. Paper read at Mining Conference in connection with the dedication of the Transportation Building and Transportation and Mining Laboratories, University of Illinois, May 10, 1913.

Second. The poured concrete arch with concrete side walls.

Third. The concrete-block arch, which is composed of concrete blocks previously molded in steel forms with joints cut on true radial lines. The blocks are laid up in the arch crown from each side wall with cemented joints and are supported on a light frame template until the key piece is placed, and one section of the ring is completed. Provision is made in molding to provide blocks of different lengths for breaking of joints on the alternate courses. Blocks 6 inches thick for single and 8 inches for double-track spans and about 18 inches long, make a convenient size for the men to handle. This method of arch construction saves considerable cost over that of the solid poured section, for it eliminates the cost of expensive forms and time necessary for the transporting and placing of the wet mixture.

The rectangular section is a convenient form at back of the shaft where it is necessary to provide clearance room for the empty car lift and where going up into the roof with an arch of large span would prove expensive. The poured arch section is generally adopted for a distance of from 10 to 15 feet on each side of the shaft, the work connecting into and supporting the shaft walls. The continuation of the arch with concrete block construction for the main landing and empty run-rounds, makes an ideal and fireproof shaft bottom. For permanent work inside, we have the mine stables, including the stalls and feed-boxes, pump and motor rooms, overcasts and stoppings, constructed of concrete; this material being especially suitable where an air-tight seal and safe job are necessary, the cement grout completely filling all crevices.

Bore holes are made secure and permanent with cement lining, the pipe casing being subject to rust from mine gases or the discharge of sulphur water.

Wherever possible, all wooden structures in the mine should be replaced with concrete, the most substantial and one of the best known fireproof materials. By its use, the great danger of disastrous mine fires, caused by the ignition of dry timbers, is lessened, and the high standard of the mine is increased by the number of its concrete structures.

Fire Protection of Mines

From the Standpoint of the Mining Engineer—Preventing Start of Fires—Providing Proper Equipment and Organization for Combatting Them

*By G. E. Lyman**

THE subject of fire protection of mines is a matter of such vital importance to every individual connected therewith in any capacity, from the chief executive at the head of the organization to the trapper boy at his door, that it is impossible to draw any line at which the interest of the mining engineer should properly begin or end. The broad, humanitarian features involved will alone make the question command the earnest attention of all, and the engineer realizes that every step taken in this direction is not only in keeping with the spirit of the day, but is a policy that pays well in dollars and cents.

If there is any line of effort in which the energies of the mining engineer should be especially centered, it may be said to lie in these directions:

1. The adoption of every possible means of preventing a fire getting started, both above and below.
2. The planning and installation of the best and most complete fire-fighting equipment possible to obtain, including every possible provision for rescue and escapement, so frequently needed in fires below.
3. The organization of a competent fire-fighting corps whose discipline and efficiency shall be maintained by frequent practice.

The labors of our Commission for the revision of the mining law have given Illinois some advanced legislation in this direction, making compulsory many preventive measures in new developments, and the installation of certain fire-fighting equipment in old mines. The conscientious engineer will recognize that no statute, however broad, can take care of every detail in widely differing conditions of operation, and after satisfying himself that the law is fully complied with, he will make a further careful study of the individual conditions to be met and endeavor to provide such additional safeguards as he can devise for the better protection of life and property.

One of the first things he would consider in planning the surface plant of a new development would be the design of fireproof structures throughout, making them of brick, masonry, or reinforced concrete, with modern structural steel tipples, making the floors of these, as well as the bin linings, concrete or some equally fireproof material, so that it would be well nigh impossible for a fire to occur on top.

The fan would be housed in such a manner as to have nothing inflammable about it, outside of the oil in the journals, and would be set back a sufficient distance from the shaft to eliminate chance of injury even though the entire shaft lining should be burned out.

Boiler and power houses being fireproof throughout, would insure the operation of every detail of the equipment through an emergency which fire alone could cause.

However thoroughly fireproof the plant might be considered, it would yet be the part of wisdom to install a water system with an ample number of fire-plugs at convenient

*Chief Mining Engineer, Madison Coal Corporation. Read at the Mining Conference in connection with the dedication of the Mining and Transportation Buildings at the University of Illinois, May 9, 1913.

points in and about the buildings, with hose connected ready for instant use. Some of the most disastrous fires have been where the contents of fireproof buildings were consumed.

In handling an old plant the need of the water system just mentioned is doubly apparent and altogether too obvious to require comment. Regular fire drills and actual use of the equipment at frequent intervals are essential to its maintenance in proper condition. If possible, the system should be connected to a powerful pump, as well as an independent head, so that it may be thoroughly reliable.

In certain places, like wooden fan houses and tipples, means of flooding the structures through automatic sprinklers, as well as perforated pipes handled by valves outside the buildings, may save great losses.

The value of steel doors to cover the shafts in case of fire is too obvious to dwell on at length.

The practice of allowing waste and other such material to accumulate is extremely dangerous, and the time required in frequent inspections, with the idea of eliminating this practice, is well spent.

The condition of the electrical wiring, above and below, and the cables in the shafts is important.

Within the mine itself much can be done toward preventing fires, by the elimination of everything combustible as far as possible, especially around the bottom and in the stables, oil houses, etc. The replacing of heavy lagging and timbers near the bottom and in permanent entries, with steel and concrete, will be a matter of economy in maintenance in a long-lived property, which justifies the expenditure required entirely aside from its value in eliminating the chance of fires. Such work is required by the Illinois law in new mines, within a certain area near the bottom, but its application to a modern mine can be economically extended much farther.

The fireproofing of shafts is a wise requirement, and one entirely in keeping with modern development.

The fires which cause great loss of life below are generally of fan houses, tipple, shaft linings, stables, or other like critical points, which by their volume and fierceness poison the entire mine atmosphere so rapidly as to render it difficult to get the men out. Here is where the value of good fire-fighting equipment, backed up by organization and discipline, becomes apparent. The first few moments are the vital ones, and in ninety-nine times out of a hundred an organized force, not allowed to grow stale through lack of practice, can quickly extinguish a blaze at the start. In fires of this character the value of adequate and well maintained escapment ways becomes apparent, and they should be made familiar to the men by frequent travel of them.

The writer is a firm believer in the value of perforated sprinkling pipes in the stables and other critical points, to be operated by outside valves, in adition to the automatic sprinklers required by law.

The water supply for the underground system should be not only connected to a standing head on the surface as required by law, but also to the pumps on both surface and bottom, so as to provide for all possible emergencies.

Where the coal seam itself is of such a character as to fire easily, a special study of conditions will be necessary to determine the most practicable precautions to take, and the details of such special methods of shooting, caring for machine cuttings, gob, etc., as may be determined therefrom, must be most rigidly enforced by the management. Fires on the inside, such as gob fires, both local and extended, and fires of the seam itself, generally offer less danger to life than to property, although the dangers to be encountered by the limited number who attempt to control them are often of the gravest character. Opinions as to the proper methods of attacking such fires differ widely, and their discussion can not properly be attempted here, but as to the necessity of the best and most complete equipment for handling them there is no room for argument. Every mine should have available, in addition to the usual small chemical extinguishers, a couple of large capacity mounted on trucks, which can be rapidly taken to the scene of action.

Iron dump cars, to be used in loading out a fire and disposing of it in that way, form useful equipment, and during ordinary operation can be used to advantage in handling dirt and refuse from roads and air-courses, so as not to be idle capital.

When pipe lines run over the mine extensively, as in cases where long distance pumping is done from many sumps, it is an easy matter to arrange the connections so that the pump pressure can be turned into the suction lines. The writer has seen this done to most excellent advantage, and is a firm believer in its desirability. In cases of sufficient emergency, even air transmission lines may be thus pressed into service.

Oxygen helmets will often enable explorations of a fire territory to be made that could not be attempted otherwise, and may even permit of taking lines of hose or chemical extinguishers to the very seat of the trouble. It becomes necessary, therefore, for any mine desiring the most adequate fire protection to have its own equipment of helmets, pumps, supply tanks, and all accessories, including pulmotors and first-aid supplies. The time lost in getting one of the state rescue cars on the ground may allow the fire to make such headway that nothing but walling off the territory can be done. The saving to a company in a single bad fire alone could easily pay for the cost of its own rescue station and helmet equipment, while a group of mines operated by individuals could divide the expense of a common station between them and make the burden very reasonable. Their object would not be to supplant the state rescue cars in any sense, but merely to take advantage of the first vital moments, and often by such action not only avert a serious calamity, but nip in the bud what might otherwise develop into a difficult and dangerous job for the state corps. Such individual stations would, of course, be in charge of competent men who had received thorough training at the state stations.

A frequent and often serious source of trouble in fighting large fires in the workings is the lack of accurate maps, and the consequent difficulty of determining the best way of walling off the territory affected. Only too often it happens that some unrecorded opening into the fire area supplies air sufficient to keep it alive, and at the same time it is very difficult to locate. An accurate map would indicate at once the best way to wall off the fire and lose the least amount of territory thereby.

Where companies maintain their own engineering departments this question of maps should, of course, give no trouble. But where it is the practice to have an outside surveyor extend the map annually to comply with the law, accuracy in details can not be expected. Granted that the man doing the work is thoroughly competent, there will be portions of the mine inaccessible to survey. Accurate, detailed mapping requires frequent extensions, and the remedy for individual operations is for a few to go together and secure the exclusive services of a competent engineer and furnish him adequate help and facilities for handling their work in a manner commensurate with its importance.

Even where an adequate engineering department is maintained and frequent map extensions made, places will frequently be found which cannot be entered for survey. The writer's experience has indicated that this situation can best be met by a system of monthly or semimonthly reports, showing the depth of every working place which has been closed since the last report was rendered, the number of cross-cuts right and left, and other pertinent information. In the writer's practice these reports are not allowed to be used in extending maps unless the engineers are unable to enter the place and measure it themselves. In such cases the desired information is obtained from the reports, and the place shown on the maps in dotted lines, thus differentiating it sharply from the work of the engineering department, and placing before the mine management a visible reminder of their responsibility for that portion of the map. As the average number of places closed monthly in even a large mine is not great, it consumes little time to handle the report carefully, and the writer has found that it is possible to bring about a feeling of joint responsibility for this part of the work with the mine management which is helpful in many ways.

There are few room-and-pillar mines which cannot be advantageously worked on the panel system, or some modification of it, which will permit the walling off of any fire territory with the least possible disturbance to the balance of the mine. The importance of having the maps show faithfully every connection between adjacent panels is obvious, and in the modern mining organization no departure in working plan from the projects furnished the management for their guidance will be permitted without the matter being properly taken up for consideration and authorization if found necessary or advisable.

It is not uncommon to see a mine entirely, or nearly shut down on acount of a fire which should ordinarily have been closely confined in its effects, and this is due to having the workings so cut together that isolation is difficult and the ventilation hard to control. The writer believes that the main air-courses in either direction from the shaft bottom out to the limits of the workings should be considered just as important as the shaft itself, and be just as carefully maintained. This, in connection with a powerful fan, will enable the circulation of a great volume of air at comparatively low velocity and pressure, which will permit a considerable increase in the number of splits, thus reducing the amount of territory affected by a fire in any one portion of the workings. The maintenance of an abnormally excessive amount of ventilation is not advocated, but the use of main air-courses of more than ordinary capacity and excellence is strongly urged, so that the ventilation of the side entries can be treated as individual problems, as much air being diverted into each one from the main air-course—the arteries, so to speak, of the mine—as its individual requirements may demand. With this method of ventilation established, there should be small necessity of ever sealing up more than one entire cross-entry at the most. There are probably very few of us who have not known of instances where large mines were ventilated on two or three splits, and where a comparatively small fire caused the sealing off of perhaps half the workings.

Great emergencies come infrequently to most of us, fortunately, but that very fact is likely to cause us to neglect, or view indifferently the need of a well-disciplined organization to meet the crisis when it confronts us. Organization, discipline, efficiency (both of men and equipment), and all the things connected therewith, form too broad a subject to more than mention the need of here. When a great crisis confronts a mine, be it fire or anything else, and when brave and skilful men are ready to attack it, if organization and all it implies be lacking, the work starts under a terrible handicap.

In concluding, the writer wishes to state he realizes that in the brief limits of this paper he has simply passed in a very superficial manner over some of the many points involved in such a broad subject. The views of all of us are naturally influenced by individual experience, and others may have gathered widely divergent views from their own experience and observation. The more such which can be brought out, however, the greater the light shed on the subject will be.

Organization as Affecting Mining

Importance of Sufficient Capital, Ample Plant, Capable Officials and Enough of Them, and Proper Discipline

*By A. J. Moorshead**

BEFORE touching on the subject matter of his address Mr. Moorshead expressed the satisfaction of those engaged in coal mining in Illinois with the interest shown by the faculty in the establishment of the Department of Mining Engineering; and to emphasize its value to the state he illustrated the magnitude of the coal mining industry with the following figures:

	Tons
Production of coal in Illinois for year ending June 30, 1912	57,514,240
Used for power and wasted at the mines	2,471,326
Taken by railroad locomotives at mine chutes	924,854
Sold to local trade at mines	2,615,678
Leaving a total to be shipped in cars of	51,502,382

Assuming 46 tons to the car, this amount required 1,120,000 cars. Allowing 40 feet for the length of each car, this means a string of loads 8,500 miles long.

Mr. Moorshead gave these data, somewhat amplified, to show the necessity of a thoroughly organized mining department in the State University upon which dependence can be placed to solve the problems of safe and economic mining.—Editor.]

"Organization as affecting mining" is a very broad subject, and so vitally affects the interests of the corporate and operating bodies that it enters into every phase of the business, and upon it hinges the success or failure of all enterprises. Organization is of little value without harmony, and the application of firm and fair discipline must be exercised to secure it. Otherwise the maximum of success is unobtainable, and especially is it true in connection with the dangerous occupation of coal mining. Therefore, organization and discipline must be linked together, and are inseparable for all well-governed bodies.

In order that the student particularly may form a clearer idea of what organization means, the subject must be divided into several classes, and in the order in which they apply to mining:

First. In this great competitive age, when the tendency of all new mining companies is to produce a high tonnage and place a well-prepared product on the market, great care should be exercised in the preparation of complete plans covering both surface and underground construction, and the necessary capital secured not only for the building of a completely equipped plant, but also enough surplus for an easy working fund with which to conduct the business. Otherwise serious embarrassments, if not complete failure, will be certain to follow.

Second. In the selection of a capable working force, care must be exercised in securing supervising officers who not only possess the necessary qualifications for intelligent work, but whose habits will inspire confidence no less among the employes than in the executive. Such officials should be trained in discipline to a degree that will not only demand respect, but when dangers arise and serious disaster is likely to occur, they will be prepared to meet the emergency with organized action, and prevent or minimize what otherwise might become a very serious catastrophe. On the character of the supervising forces and their training and discipline depend the strength of the organization and its success.

Third. A particularly vital necessity in organization, from the standpoint of both safety and economy, is the proper location of the property. All shafts and slope and drift entrances should, together with buildings, be placed well above the highest flood line record, and scarcely too much attention can be given to drainage. Reservoirs must be established where not only good boiler water can be obtained, but of ample size to impound sufficient to take care of the power and washer for a period of not less than 90 days to carry the plants through times of drought, which so often occur in Illinois. Tracks for the railroad cars should be on sufficient grade to move both empties and loads by gravity and of sufficient capacity to take care of the mine's output for 12 hours of operating time.

All power houses, machine, and carpenter shops, as well as supply houses, should be placed on building lines and conveniently arranged together with the tracks to keep cars containing material out of the way of the operating tracks of the mine.

Fourth. In the arrangement of the underground working forces, sufficient supervising officers should be employed to keep in direct contact with the various classes of labor, and the most safely efficient practice will be found in having not to exceed three gangs for work on the roadways—one for track repairs, another for timbering, and the third for keeping the haulageways and air-courses clear. To this must be added special organized gangs for any particular class of underground improvements, such as making concrete stoppings, etc., with a gang leader or foreman to have charge of each of these separate bodies. This plan has, from actual practice, been found by far the most economical, both in point of safety as well as

*President and General Manager, Madison Coal Co., St. Louis, Mo. Address delivered at the Fuel Conference at the University of Illinois during the dedication of the Transportation Building and the Locomotive and Mining Laboratories, May 8 and 9.

service performed, compared with the old method of having many scattered gangs working without leaders, and whom the mine manager or his assistants seldom see.

One or two inspectors on the day shift should be employed (as the size of the mine may require) to travel the haulageways and air-courses for the purpose of inspecting all trap doors, track, switches, electrical circuits, and roof. The inspectors should also test the air and locate defective stoppings, as well as watch for reckless drivers and report all irregularities to the mine manager.

Sufficient assistant managers should be employed, whose duties would require them to be at the face of rooms and entries only, to see that the ventilation is properly maintained and that all the miners are supplied with sufficient timber and that they are properly timbering for their own safety, as well as the proper care of their working places, and they should also, when necessary, give instructions for more effective drilling and shooting, both from the standpoint of safety and the making of the maximum quantity and quality of coal per shot.

It is, I believe, a fair statement to make, that in altogether too many mines the underground managing force is totally inadequate for the number of men employed and tonnage produced, and I have, myself, known of many instances where the mine manager was without assistants, and he became in fact a mere timekeeper and was unable to do much more than keep time and seldom saw an air-course unless a fall baffled the air and interfered with the ventilation, or visited the face except when some trouble called him there.

Wherever such conditions exist, the organization is seriously incomplete, and the owner of the property is permitting an unwise economy to be practiced, because leakages and mistakes must in such cases be bound to occur, and in an indirect manner the mine owner is losing a far larger sum than the yearly salaries of several assistants.

Fifth. It is a waste of money to provide equipment without a properly organized, efficient force to handle it, and this is particularly true of fire fighting and rescue appliances. Each and every man on the surface, and all supervising officers in the mine, as well as all employes working around about and in the vicinity of the shafts in the mine should not only have specific duties to perform, but should, through systematic drilling, be prepared to act in unity, because by quick, energetic action, and complete discipline alone can even a fair degree of success be expected.

Sixth. Harmony, together with firm and fair discipline, is necessary for the success of all institutions, but more particularly is it applicable to coal mining, because most of the men underground are for the greater part of the working time beyond the observation of the managing forces. Consequently, the system to control men, both from point of efficiency, as well as safety, must be most thorough and particularly adapted to the workers in a coal mine.

The views which I have given with reference to underground supervision are practiced by the corporation I represent, and only modified as may be forced by the interpretations of our labor contract.

The points which I desire to make clear are:

That success cannot be expected from any institution undercapitalized.

That a mine must be well equipped in every respect to produce the best economic results.

That all supervising, as well as other employes that can be controlled, must be temperate in their habits.

That efficient and adequate equipment can be of but little value without a skilful and well-organized force to use it.

That systematic drilling is necessary to get the best results and make the force an efficient one.

That discipline is the greatest necessity for the maintenance of a good and dependable organization, and, whenever employed, it is always manifest and plainly observable, but should always be administered with fairness as well as firmness.

That harmony is, for the best results, so necessary that disturbing influences should be removed without hesitation.

That the best of results and greatest success in all things can only be secured, in the conservation of life and property and from the standpoint of investment, by thorough, systematic organization.

In some of the Southern Colorado coal mines a standard size for mine doors is adopted. The size naturally varies at different mines, however, the usual size door is 7 feet wide by 6 feet high. The doors are hung on concrete frames and covered with sheet iron. At the Cokedale works, double doors, 3 feet 6 inches wide, hinged at each side of the entry, are used at the foot of steep grades. In case a trip or even a single car runs away on the slope, these doors, instead of being shattered as a single door would be, are opened by the impact of the car and it passes through them without destroying them. The idea in adopting a uniform mine door is based on the plan that when a door is of no further use in one part of the mine, it can be moved to another where a standard frame awaits it.

Col. R. B. Hutchcraft, of Lexington, Ky., states that what is now called Jellico mountains were originally named Tellico mountains after a tribe of Indians who camped at a place now known as Tellico in McMinn County. When a surveyor made a map of the county he named the mountains Tellico, but the settlers assuming the *T* was a *J* changed the name to Jellico.

Practical Talks on Coal Mining

For men who desire information on Coal Mining and related subjects presented in a simple manner

Electricity in Mines

Measuring Currents—Resistance—Measurements of Sectional Area of Conductors—Resistances of Different Materials

By H. S. Webb, M. S. (Continued from May)

For measuring ordinary electrical currents, instruments called ampere meters, or more commonly ammeters, are used. For measuring small currents milliammeters are used. Ammeters and milliammeters are made in portable forms to carry to any point where it is desired to measure a current, or for permanent connection in a circuit at some one point, as on a switchboard in an electric power station. Ammeters measure the current strength directly in amperes, and milliammeters measure the current strength directly in milliamperes. Current flowing through the coils of wire in such instruments causes small magnetic needles or suspended coils of wire to rotate against either springs or the force of gravity. Most am meters are provided with a light index pointer that moves over a scale, or dial, graduated so that each division on the scale represents 1 or more amperes or a fraction of an ampere. Fig. 3 shows the general form of a portable ammeter. The strength of a current flowing in a circuit can be measured directly, in amperes, by opening the circuit and connecting the two ends thus formed to the binding posts p and p'. The current, in direct-current circuits, must enter the instrument through the binding post marked with a positive sign (+); otherwise the pointer will be deflected in the wrong direction, a condition liable to damage the instrument and cause error in subsequent readings.

Resistance.—It has been stated that all substances resist the passage of electricity, some more than others. Electrical resistance, which is one of the most important properties of an

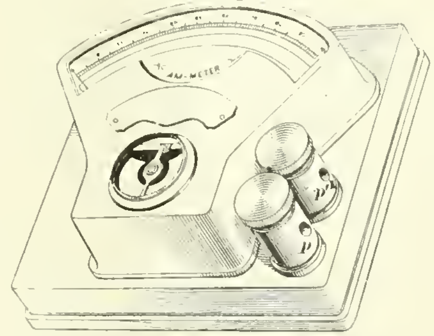


Fig. 3

electric current, is that property of matter, varying with different substances, in virtue of which it opposes or resists the passage of electricity. The unit of electrical resistance is defined as the resistance offered to an unvarying electric current by a column of mercury at the temperature of melting ice (32° F.) weighing 14.4521 grams, of a uniform cross-sectional area and of a length of 106.3 centimeters. Scientific experimenters can accurately construct a column of mercury of the size mentioned and can also construct a resistance of a suitable kind and size of wire exactly equal to the resistance of this column of mercury. Such unit resistances made of wire can be purchased of any reliable maker of electrical instruments. The unit of electrical resistance is called the ohm, after George Simon Ohm, a German mathematician, who lived from 1789 to 1854. A round copper wire 1,000 feet long and having a diameter of .102 inch (known as No. 10 B. & S. gauge) has a resistance of nearly 1 ohm at 68° F. The fine carbon filament of an ordinary 16-candle-power incandescent lamp has a resistance of about 220 ohms when the lamp is lighted.

The resistance of a given conductor at a given temperature is always the same, irrespective of the strength of the current that may be flowing through it or the electromotive force that sends the current through the conductor. The resistance of a conductor is a property of the conductor itself, depending on its length, sectional area, the material of which it is made, and its temperature. In most cases, a continual flow of current through a conductor tends to increase its temperature, at least until the radiation of heat from its surface is equal to the heat produced in the conductor by the current; hence, the conductor tends to become warmer, and on account of their increase in temperature metallic conductors increase in resistance. But if means are provided to keep the temperature constant, neither the strength of the electric current nor its duration will have any effect upon the resistance of the conductor.

Change of Resistance With Change of Length.—If the length of a conductor be doubled, its resistance will be doubled; if its length be halved, its resistance will be halved; an increase in the length of a conductor will cause an increase in its resistance; a decrease in the length will cause a decrease in its resistance.

To find the resistance of a conductor after its length is changed, its original length and resistance being known, use the following rule:

RULE.—Divide the original resistance, in ohms, by the original length, in feet, to get the resistance of 1 foot; then multiply the resistance per foot by the changed length in feet. The result will be the resistance required.

EXAMPLE.—A conductor 1,112 feet long has a resistance of 67 ohms; what will be the resistance of 519 feet of the same conductor?

SOLUTION.—

$$\frac{67 \text{ ohms}}{1{,}112 \text{ feet}} = \frac{67}{1{,}112} \text{ ohm per foot}$$

$$\frac{67}{1{,}112} \times 519 = \frac{34{,}773}{1{,}112} = 31 \text{ ohms.}$$

Measurement of Sectional Area of Conductors.—The sectional area of a conductor is the area of the surface made by cutting the conductor in a plane at right angles to its length. Thus, in Fig. 4, *c* represents the sectional area of a round, solid conductor *a b*. Fig. 5 represents the sectional area of a square metal bar 2 inches by 2 inches; its sectional area is, therefore, 2 in. × 2 in. = 4 square inches.

To find the sectional area of any circular conductor, use the following rule:

RULE.—Multiply the diameter of the conductor by itself, and then multiply this product by .7854.

EXAMPLE.—What is the sectional area of a conductor whose diameter is .114 inch?

SOLUTION.—

.114 in. × .114 in. = .012996 square inch.

.012996 sq. in. × .7854 = .010107 square inch.

In electrical work, it is customary to express the sectional area of conductors in terms of a unit called the circular mil. This unit is the area of a circle of which the diameter is 1 mil or $^1/_{1000}$ inch. One inch equals 1,000 mils; therefore, if the diameter of a conductor is 1 inch, its diameter is 1,000 mils; if the diameter of a conductor is ½ inch (.5 inch) or ¼ inch (.25 inch), it can be expressed as 500 mils or 250 mils.

If a length is expressed in inches or in a fraction of an inch or in

FIG. 4

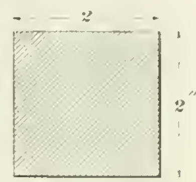

FIG. 5

both, and it is desired to express it in mils, use the following rule:

RULE.—Multiply the value expressed in inches, a fraction of an inch, or both, by 1,000.

EXAMPLE.—Express in mils: (*a*) 5 inches; (*b*) 1.5 inches; (*c*) .75 inch; (*d*) .46 inch; (*e*) .11443 inch; (*f*) .003145 inch.

SOLUTION.—

(*a*) 5	×1,000 =	5,000	mils.
(*b*) 1.5	×1,000 =	1,500	mils.
(*c*) .75	×1,000 =	750	mils.
(*d*) .46	×1,000 =	460	mils.
(*e*) .11443	×1,000 =	114.43	mils.
(*f*) .003145	×1,000 =	3.145	mils.

As inches multiplied by inches gives square inches, so mils multiplied by mils gives square mils. Thus, 2 inches × 2 inches = 4 square inches; but since 2 inches equals 2,000 mils, the expression may be written, 2,000 mils × 2,000 mils = 4,000,000 square mils. The expression .5 inch × .5 inch = .25 square inch, might correctly be written, 500 mils × 500 mils = 250,000 square mils, because .5 inch = 500 mils.

If an area is expressed in square inches or in a fraction of a square inch, and it is desired to express the area in square mils, use the following rule:

RULE.—Multiply the value expressed in square inches, or in a fraction of a square inch, or both, by 1,000,000.

EXAMPLE.—Express as square mils: (*a*) 4 square inches; (*b*) .375 square inch; (*c*) 2.0095 square inches.

SOLUTION.—

(*a*) 4 sq. in. × 1,000,000 = 4,000,000 square mils.

(*b*) .375 sq. in. × 1,000,000 = 375,000 square mils.

(*c*) 2.0095 sq. in. × 1,000,000 = 2,009,500 square mils.

The square mil is not much used as a unit of area, but an understanding of it leads to an understanding of the circular mil.

To find the sectional area of any solid circular conductor in circular mils, use the following rule:

RULE.—Multiply the diameter, in mils, by itself.

EXAMPLE.—The diameter of a trolley wire is .3648 inch; what is its area in circular mils?

SOLUTION.—

.3648 inch = 364.8 mils.

364.8 mils × 364.8 = 133,079 circular mils.

Multiplying the diameter, in mils, by itself really gives the area of a square, one side of which is equal to the diameter of the round wire, expressed in square mils; but the same number gives the square of the diameter which is called the area of the round wire in circular mils. The only reason for using the circular mil as a unit is that most conductors used in electrical work are round, and it is very convenient to have a unit in terms of which to express sectional areas without much calculation. Where circular sectional areas are to be compared with those that are not circular, both must be reduced to either square or circular mils.

(*To be Continued*)

The coal production of West Virginia for the year ending June 30, 1912, was 59,581,774 gross tons, an increase of 5,548,588 tons, or 10.26 per cent. over the preceding year. The coke production was 1,993,697 net tons, a decrease of 701,350 tons.

Gases Met with in Coal Mines

Measurement of Atmospheric Pressure—The Barometer—Mariotte's Law—Diffusion of Gases

(Continued from May)

THE other form of barometer is known as an aneroid barometer, or aneroid, and somewhat resembles in appearance a steam gauge or an old fashioned thick watch with a single hand. On account of its small size and lightness, the aneroid is much used by engineers on exploring work. The instrument consists of a cylindrical metal box from which all the air has been exhausted. The face of the box is of very thin metal, so that when the atmospheric pressure is increased the face is pressed inwards, and when it is decreased it is forced outward. These movements of the face are conveyed by means of a number of levers to an index hand that moves over a scale graduated on the outer rim of the box. This scale is graduated in inches and decimal fractions just the same as the tube of a mercurial barometer, so that the two instruments give readings in inches and fractions.

A vacuum is strictly an empty space, but is commonly taken to mean a space from which all air has been exhausted. It will be plain that if all the air has been exhausted from a space, there will be no pressure to offset the weight of the column of mercury in the tube, and in a vacuum a barometer will read zero. Pressures measured from a vacuum or from a barometer reading of "0.00 inches" of mercury, are called absolute pressures, and the pressure of the air as measured by a barometer is, of course, an absolute pressure.

Another instrument very commonly used to measure the pressures of gases is known as a gauge, a familiar example being the steam gauge used on the boilers at every mine. Pressure measured by a gauge is known as the gauge pressure, and is different from the pressure recorded by the barometer. When there is no fire under the boiler and consequently no steam in it, the steam gauge reads 0, but since the inside of the boiler is always sustaining the pressure of the atmosphere which amounts to 14.7 pounds per square inch, the 0 of the steam gauge really means that the boiler is sustaining a pressure of one atmosphere or 14.7 per square inch. So to reduce gauge pressures to absolute pressures we must add 14.7 pounds to the gauge reading.

Example.—When the steam gauge reads 120 pounds, what is the absolute pressure?

For the reasons stated, the absolute pressure is $120 + 14.7 = 134.7$ pounds per square inch.

We are now able to take up the second law of gases which expresses the relation existing between the pressure and volume of any gas when the temperature is not changed and which is known as Mariotte's or Boyle's law.

Mariotte's Law.—The temperature remaining the same, the volume of any given quantity of gas is inversely proportional to its absolute pressure.

Expressed as a proportion, this law is $v : v_1 = p : p_1$, or $v_1 = v\frac{p}{p_1}$, in which v is the volume of the gas at the original pressure, p; and v_1 is the volume of the same gas at the new pressure, p_1.

Example.—What is the volume of 10,000 cubic feet of air measured originally at the usual atmospheric pressure of 14.7 pounds per square inch, after the pressure has been reduced to 7.35 pounds per square inch, there being no change in the temperature?

As these are atmospheric pressures they are also absolute pressures, and, thence, may be used as given. Hence we have $v = 10{,}000$ cubic feet, $p = 14.7$ pounds and $p_1 = 7.35$ pounds which are substituted directly in the formula, and volume at 7.35 pounds pressure $= v_1 = 10{,}000 \times \frac{14.7}{7.35} = 20{,}000$ cubic feet.

In dealing with gases it most always happens that both the temperature and pressure change, so that both of them have to be reckoned with. By combining Gay-Lussac's and Mariotte's laws it is possible to get a formula that will show the change in the volume of gas when both the temperature and pressure vary. Such a formula is the following:

$$v_1 = v\left(\frac{T_1\,p}{T\,p_1}\right)$$

In this formula v is the volume of the gas at the absolute temperature, T, and absolute pressure p at which it was first measured; and v_1 is the new volume of the gas at the new absolute temperature T_1 and new absolute pressure, p_1.

Example.—A certain gas is found to occupy a volume of 1,000 cubic inches when the pressure is 10 pounds per square inch and the temperature 40°. What will be the volume of the same gas when the pressure is 30 pounds per square inch and the temperature 140°, the pressures being absolute.

The original absolute temperature is $460° + 40° = 500°$, and the new absolute temperature is $460° + 140° = 600°$. Thence we have, $v = 1{,}000$ cubic inches, $T = 500°$, $p = 10$ pounds, $T_1 = 600°$, $p_1 = 30$ pounds, and we have to find the new volume, v_1. For this purpose the formula may be used without change, and substituting $v_1 = 1{,}000 \times \frac{600 \times 10}{500 \times 30} = 400$ cubic inches

By diffusion is meant the gradual intermixing of gases when they are brought in contact. This diffusion is due to the power of the molecules of the gases to move freely among each other. Diffusion must not be confused with mechanical mixture, both of which are commonly displayed in mines. As an illustration of mechanical mixture we have the mixing of carbon dioxide given off by a mine fire with the air as the fumes are driven along by the ventilating current. Here the smoke rolls over and over and the air and gas are mixed just as water and milk may be mixed by shaking them together in a glass. As an illustration of diffusion we may take methane or marsh gas as slowly given off from the working face. Here, while the lightness of the gas causes it to rise to the roof, yet the property of diffusion it possesses causes it gradually to mix with the air in the room without the assistance of any moving ventilating current. This subject will be more thoroughly discussed under the head of chemistry of gases.

Mine Ventilation

Introductory—The Quantity of Air Required—Definitions—Mine Laws and Their Requirements

MINE ventilation is not the difficult and complicated subject many would have us believe, but that it is a subject beyond the understanding of the average man is unfortunately a very general opinion. This belief has arisen from the fact that many text-book writers of little practical experience have buried the important facts that every miner should know under an avalanche of complicated formulas and long drawn-out theoretical discussions. These formulas and discussions, while possibly of interest to the teacher and, in some few cases, to the highly skilled engineer, are of no use to the practical man and only serve to make difficult and distasteful a subject that should be simple and interesting. It is pleasant to note that in recent years most of the boards appointed to examine candidates for the position of fire boss are taking the true and broad view that a man can serve efficiently and faithfully in that capacity, even if he never heard of an equivalent orifice or a mine potential; is incapable of designing a fan; and cannot juggle with fifth powers and cube roots like a professor of mathematics. The questions asked at recent examinations in such advanced states as Pennsylvania (both anthracite and bituminous), West Virginia, Alabama, Utah, and some few others, have been models of plain common sense, the answers to which were within the abilities of any intelligent men. Such examinations are well designed to bring out the practical knowledge and experience of the candidate and indicate the broad training, good judgment, and sound common sense of the examiners. It is unfortunately true, however, that too many examining boards are composed of members who delight in asking useless and even impossible questions; questions which serve to confuse and mislead the candidate, answer no useful purpose, and display the half-baked knowledge and even ignorance of those who ask them.

The Quantity of Air Required for Ventilation.—The quantity of air passing through a mine, is always expressed as a certain number of cubic feet per minute. Thus, if it is said, "the ventilation is 50,000 feet," which is a frequently used, short way of stating the fact, it means that each minute 50,000 cubic feet of fresh air enter the mine at the intake and 50,000 cubic feet leave it through the fan at the mouth of the return. This statement is not quite exact, because the volume of air leaving the mine is a little greater than that entering it, having been increased by that of the gases given off by the workings while the current was passing through them. This quantity of air, 50,000 cubic feet, will occupy about the same space as a two-story house 12 feet wide and 20 feet deep, which gives some idea of the quantity of air used each minute in ventilating a moderate sized mine.

Most all coal mining states have mine laws which, among other things, fix the amount of air which must be circulated each minute through the coal mines within their borders. These laws are by no means uniform in the different states, so that a fire boss leaving a position in, say, Ohio, to take one in Pennsylvania, will do well to secure a copy of the laws of his new state, that he may become acquainted with the regulations under which he is about to take up his duties. These laws determine the quantity of air to be circulated by stating a certain amount that must be supplied per minute for each man, and usually for each draft animal, both when the mine does not generate gas, that is, when it is non-gaseous, and when it generates gas, or is gaseous. While not generally named, the gas in question, is understood to be methane, marsh gas, light carbureted hydrogen, CH_4, by whatever name it happens to be locally known, and which gas, when mixed with air in the proper proportions, forms an explosive mixture known as firedamp.

Definitions.—By mine ventilation is meant the act, process, or method of supplying a mine with fresh air. Its study includes that of the various methods and appliances for producing a current of air in a mine and for conducting a sufficient quantity of air through the entries or gangways and through the rooms, chambers, or breasts. To understand the principles of ventilation a man must have a good practical knowledge of the gases met in mines; of the effect of changes in temperature and pressure upon them; of certain instruments, such as the water gauge, anemometer, etc., used to measure the pressure and velocity of air-currents; of the various systems of mining and the best method of conducting the air-current in each of them; together with a fair knowledge of the machines and appliances used to produce a circulation of air.

The object in ventilating a mine is to supply enough air to the workings to dilute and thus render harmless the injurious, explosive, or poisonous gases given off by the coal and the enclosing rocks, and to sweep away these gases as well as those resulting from blasting and the burning of oil in lamps and those given off by the breathing of men and mules. If this fresh air is not constantly supplied and the bad air carried away, the mine air will rapidly become more and more impure, until the proportion of oxygen in it will be so small that lights will go out and men cannot breathe, or if methane is given off by the coal a gas explosion will result.

Mechanics of Mining

An Explanation of the Principles Underlying Calculations Relating to Engines, Pumps, and Other Machinery

By R. T. Strohm, M. E. *(Continued from May)*

IN the preceding article it was shown that a single fixed pulley simply changes the direction of a force, but that a single movable pulley changes the amount of the force so that the force required to raise a given weight is only half of the weight. There are many possible arrangements of fixed and movable pulleys for lifting loads, but in every case the following law holds good:

The force multiplied by the distance through which it moves is equal to the load multiplied by the distance through which it moves.

To show that this is true, consider the two cases shown in Fig. 17 (*a*) and (*b*). In the first of these, a single fixed pulley is used and in the second a single movable pulley is used. Suppose that the weight in each case is 20 pounds. It has been shown that with a single fixed pulley, the force must equal the weight raised, and also that the force and the weight move at the same speed. The force is then 20 pounds. Suppose that this force moves downwards 1 foot. The weight then moves upwards 1 foot, and $20 \times 1 = 20 \times 1$, which proves the law just stated. In the case of the movable pulley, the force required is only 10 pounds, but the weight is raised at only half the speed at which the force moves. Suppose that the force moves upwards a distance of 2 feet. The weight will then rise 1 foot, and according to the law given above, $10 \times 2 = 20 \times 1$, which again is true.

The cases thus far described are fairly simple, as they include only a single pulley. Very often, however, two or more fixed or movable pulleys are used, and then the matter becomes a little more difficult to understand. For example, take the case shown in Fig. 18, in which the weight *a* is hung from the movable pulley *b*. The rope is fastened to the stationary hook *c*, passes under the pulley *b*, and then over the fixed pulley *d*, and the lifting force is applied at *e*, in a downward direction, however.

The effect of a pull at *e* is to cause an upward movement of the rope at *f*, at the same rate as the downward movement of the force *e*; for, as already stated, the fixed pulley simply changes the direction of a force without changing its amount or its rate of motion. The upward pull at *f* acts on the movable pulley *b* and raises it with the load *a*. But as the pulley is movable, the load rises only half as fast as the rope moves upwards at *f*. The rope moves downwards at *e* just as fast as it moves upwards at *f*; therefore, to raise the load 1 foot, the force *e* must move downwards 2 feet.

The upward pull at *f* is half the weight *a*, and if the weight of the load is assumed to be 20 pounds, there must be an upward pull of 10 pounds at *f*. But the pull at *e* is equal to that at *f*, because the fixed pulley does not change the amount of the force; consequently, a downward pull of 10 pounds at *e* will balance a weight of 20 pounds at *a*. Considered from the standpoint of the pull required, this arrangement has no advantage over that in Fig. 17 (*b*), as the same force must be used in both cases; but in the case in Fig. 18, the force can act downwards, which may be more convenient than having it act upwards.

With the arrangement shown in Fig. 18, the law given previously still holds true. For, with a weight of 20 pounds, a force of 10 pounds is required, and the weight moves 1 foot while the force moves 2 feet; therefore, $10 \times 2 = 20 \times 1$.

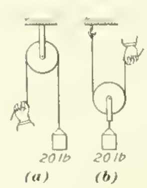

FIG. 17

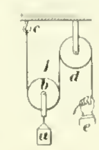

FIG. 18

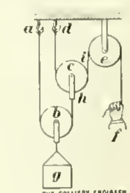

FIG. 19

The combination of pulleys in Fig. 19 includes two movable pulleys instead of one, and there are two hoisting ropes. One rope is fastened to the hook *a*, passes beneath the movable pulley *b*, and is attached to the frame of the movable pulley *c*. The pulley *c* is held up by the second rope, one end of which is fastened to the hook *d*, the other end being carried over the fixed pulley *e*. The lifting force is applied at *f*, and the weight *g* is hung from the pulley *b*.

To illustrate the action of this combination of pulleys, suppose that the load *g* weighs 40 pounds. It is supported by the two parts of the first rope, attached at *a* and *h*, and each part takes half of the load, or 20 pounds; therefore, the downward pull on the frame of the pulley *c* is 20 pounds. The pulley *c*, in like manner, is supported by the two parts of the second rope, and each part takes half of the load on the pulley, or 10 pounds; that is the pull on the hook d is 10 pounds and the downward pull on the rope at i is 10 pounds. To balance the pull at i, the force f must act downwards with a pull of 10 pounds. The force of 10 pounds at f will hold up 40 pounds at g, when two movable pulleys are used, but when only one is used, as in Fig. 18, a weight of only 20 pounds is supported. The effect of adding the extra movable pulley, therefore, is to enable the lifting force to hold twice as great a load.

The advantage of raising a heavy weight by using a small lifting force is obtained at the expense of a slower speed in lifting. Thus, suppose that the force f, Fig. 19, moves downwards 4 feet. The pulley c and its frame will then rise 2 feet. And if the end of the rope attached at h is raised 2 feet, the pulley b and the load g will be lifted 1 foot. In other words, the force must move 4 feet to lift the load 1 foot in the same time; or, the load moves at only one-fourth the speed of the lifting force.

If the same force of 10 pounds is assumed to be applied in Figs. 17 (a), 18, and 19, it will lift loads of 10, 20, and 40 pounds, respectively; but the speed of lifting in Fig. 18 will be only half of that in Fig. 17 (a), and the speed of lifting in Fig. 19 will be only one-fourth of that in Fig. 17 (a). The effect of adding each movable pulley, therefore, has been to cut down the speed of lifting, although it has enabled a smaller force to lift a greater weight. In Fig. 19, as in the other cases, the force times the distance it moves is equal to the weight times the distance it moves in the same time; for $10 \times 4 = 40 \times 1$.

By adding other ropes and movable pulleys, the speed of lifting will be still further lessened, and a smaller force can be used. However, it is inconvenient to have so many separate ropes and pulleys, and the usual way is to use a single rope and to attach the fixed pulleys and the movable pulleys each to a single frame. Such an arrangement is shown in Fig. 20.

The load W is hung from the lower frame that carries the three movable pulleys, and the three fixed pulleys are held in the upper frame attached to the overhead support. The rope is fastened to a hook at

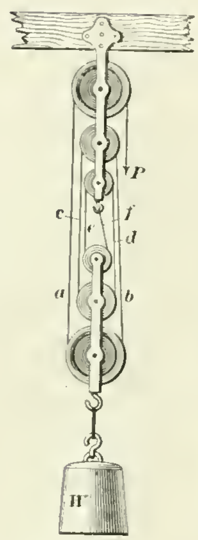

Fig. 20

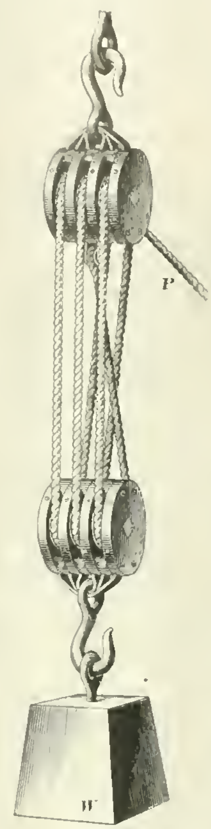

Fig. 21

the bottom of the fixed frame and is then carried around the movable and fixed pulleys, as shown, the lifting force being applied at the free end P, in the direction indicated by the arrowhead.

The load is supported by six parts of the rope, as at a, b, c, d, e, and f, and each part therefore takes one-sixth of the whole load. Suppose that the weight W is 60 pounds. Then the pull in each part of the rope is 10 pounds, and as the upper fixed pulley merely changes the direction of the force, the pull at P is the same as that in the part a of the rope, or 10 pounds. Therefore, with this arrangement of three movable and three fixed pulleys, a load of 60 pounds can be lifted with a force of 10 pounds.

But, as before, the power to lift a load 6 times as great as the lifting force is obtained by having the load rise only one-sixth as fast as the force moves. This can be shown in a very simple way. Suppose that the weight W and the frame of the movable pulleys are pushed up 1 foot. Then each of the parts a, b, c, d, e, and f of the rope will have 1 foot of slack, and there will be 6 feet of slack in the whole rope. To take up this slack, the end P of the rope will have to move downwards 6 feet, when the parts of the rope will again be tight between the fixed and movable pulleys. This means that the force at P must move downwards 6 feet to raise the load W 1 foot; or, the load moves at one-sixth the speed of the lifting force.

The arrangement of pulleys in Fig. 20 takes up considerable space, and the ordinary way is to put the movable pulleys side by side in the same frame, and to arrange the fixed pulleys in the same way. Such a combination is shown in Fig. 21, and is familiarly known as block and tackle. There are three pulleys in the movable block holding the load, and three in the fixed block, so that the combination has the same effect as that in Fig. 20; that is, the weight that can be lifted is 6 times the lifting force applied at the free end of the rope, and the weight rises at one-sixth the speed of the lifting force.

There may be more or fewer than three pulleys in each block; but in any case the force required may be found by the following simple rule:

The force that must be applied at the free end of the rope in a block and tackle is equal to the weight lifted divided by the number of parts of rope leading away from the movable block.

For example, suppose that a block and tackle has five movable and five fixed pulleys, and that a load of 1,200 pounds is to be raised. As there are five movable pulleys, there would be ten parts of rope leading from the movable block, and the force required, according to the rule, would be $1,200 \div 10 = 120$ pounds.

In all that has been given in the preceding paragraphs, the effect of friction has not been considered. To turn each pulley on its axle requires some force, and consequently the lifting force will need to be greater than that found by the rule, to overcome the friction in addition to lifting the weight. The greater the number of fixed and movable pulleys, the greater will be the friction.

(To be Continued)

PERSONALS

F. McN. Hamilton has been appointed State Mineralogist of California State Mining Bureau, with office in the Ferry Building, San Francisco.

George Hill has been appointed Chief Mine Inspector of the State of Missouri. The last legislature in Missouri passed a law creating a Mining Department with a Chief Mine Inspector, and under him six Deputy Inspectors; two for the coal mines and four for the lead and zinc mines. Mr. Hill's office will be at Jefferson City.

J. F. Callbreath, Secretary American Mining Congress, states that a large part of the work of the organization is being done in the Munsey Building, Washington, D. C.

Dr. J. A. Holmes, Director United States Bureau of Mines, delivered the Class-Day address to the graduates of the Michigan College of Mines, Houghton, Mich.

H. W. Scheiler, of Lincoln, Ill., is now County Mine Inspector of Logan County, Ill.

In consequence of the retirement of James Barrowman from the office of Secretary of the Mining Institute of Scotland, the Council have appointed George L. Kerr as Secretary. Mr. Kerr has also been appointed to the office of Treasurer, with offices at 39 Elmbank Crescent, Glasgow.

W. M. Nixon, Secretary of the National Coal and Coke Co., and also connected with the Nixon Mining Drill Co., kept open house during the Confederate reunion at Chattanooga, Tenn., in May. The reunion commemorated the semicentennial of the famous battles of Chickamauga, Missionary Ridge, and the "battle above the clouds" on the heights of Lookout Mountain.

John M. Sherrerd, formerly connected with the Taylor Iron and Steel Co., of High Bridge, N. J., is now with The Titanium Alloy Mfg. Co., of Niagara Falls, N. Y.

Charles T. Malcolmson has organized the Malcolmson Briquet Engineering Co., with offices in Old Colony Building, Chicago, Ill.

The Hon. William C. Redfield, having been appointed a member of President Wilson's cabinet, has resigned his position as vice-president and director of the American Blower Co.

At a recent meeting of the geological members of the American Institute of Mining Engineers, Waldeman Lindgren was made chairman of the Committee on Economic Geology. This committee aims to encourage contributions and promote discussions on the subjects of economic and mining geology.

Eugene Haanel, Ph. D., Director Mines Branch Department of Mines, Ottawa, Canada, announces that the government laboratory for the experimental tests of Canadian ores will be completed about July 1, 1913.

OBITUARY

WILLIAM L. SHEAFER

William Lesley Sheafer, who died at his residence in Pottsville, Pa., on April 23, was one of the most prominent men connected with the mining industry in the Schuylkill region. Though not engaged in actual mining, he was interested in the anthracite industry through ownership in valuable coal lands, and he took great interest in all matters pertaining to the industry as well as in all matters to the benefit of his native county (Schuylkill).

He was born in Pottsville, Pa., on February 19, 1859, and was a son of the late Peter W. Sheafer, who in his life time held a high reputation as a coal geologist and mining engineer.

Mr. Sheafer graduated from Lafayette College as a mining engineer before he reached his twentieth year, then took a post-graduate course of a year and was awarded the degree of Master of Science. He then entered his father's office and was associated with him until the latter's death in 1891, when he became one of the executors of his estate, which consisted largely of valuable coal lands.

Mr. Sheafer was a man of pleasing personality, broad charity, and full of public spirit.

Owing to the absence of necessity for activity as a mining engineer, aside from employing his profession in his own and his family's interest, he did not seek to obtain prominence in it, though he was eminently qualified to rank as a leader, had he so desired, or necessity demanded.

He was a member of the American Institute of Mining Engineers, and was for 20 years a trustee of Lafayette College.

J. Shephard Clark, founder of El Comercio, died in New York City April 26.

Hon. Frank O. Briggs, Ex-United States Senator for New Jersey, and First Assistant Treasurer of John A. Roebling's Sons Co., died at his home on May 8.

Samuel L. Moyer, First Vice-President of the Lunkenheimer Co., died at his home in Cincinnati, on May 3.

The anthracite mines at Russellville, Ark., have resumed operations after being idle for over 2 years. Mr. J. P. Quirk and C. S. Whortley, of Detroit, who bought the property for $183,000, have leased it to Mr. Barrett, of Kansas City, who has put 100 men at work.

The Cincinnati Mine Disaster

Account of the Accident—The Method of Mining—The Rescue Work, and Reports of the Mine Inspector and the Commissioners

By William Z. Price

THE Cincinnati mine, which is one of the oldest bituminous mines in operation, is situated on the west bank of the Monongahela River, about 27 miles southeast of Pittsburg, on the Monongahela Division of the Pennsylvania Railroad.

The explosion at this mine, which resulted in the death of 96 men, occurred April 22, 1913, at about 12 o'clock, noon.

The mine has been operated for about 70 years by various concerns, and about 15 years ago it passed from the hands of C. M. Jutte & Co. into the possession of the Monongahela River Consolidated Coal and Coke Co., the present owner and operator.

There are two entrances to the mine, the Mingo slope, and the main haulage road leading from the pit mouth.

The Mingo slope is near Mingo station on the Pittsburg & Charleroi Street Railway, is about a mile and a half over the hills from the pit mouth, and is used only as a traveling way for men and mules, and as an inlet for the air. It was constructed at the recommendation of Henry Louttit, state mine inspector, shortly before the mine passed over to the present owners. The slope at first was a bad one of a varying pitch, but during recent years it has been graded at a pitch of 20.5 degrees throughout the 500 feet of its length.

The main haulage road is used for head and tail-rope haulage from the pit mouth to the main parting, which is a distance of about 6,800 feet; from there, the mine cars are distributed and collected by motors and mules.

The seam worked is the Pittsburg seam and varies from 5 to 6 feet in thickness. The roof is usually 6 to 7 feet above the rail due to the draw slate above the seam, which is shot down.

No analysis of the coal at the Cincinnati mine could be obtained, but coal from the surrounding mines has the following composition: Moisture, 3.05; volatile matter, 33.50; fixed carbon, 56.55; ash, 6.02; sulphur, .96. Specific gravity, 1.32.

Mining is done by the advance-and-retreat room-and-pillar system, as shown in Fig. 1, which is thus explained. *A*, *B*, and *C* represent the three stages through which the mining passes. There are four parallel face entries driven, and two parallel butt entries, off which the rooms are driven.

A represents the first stage and it shows the rooms being driven on the "advance" and the pillars being drawn back to the entry after the rooms are finished (dotted portion).

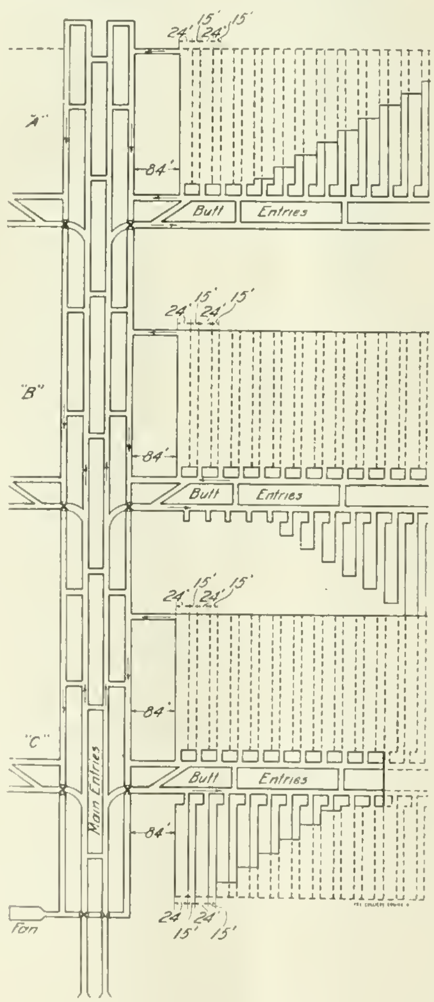

Fig. 1. Method of Mining

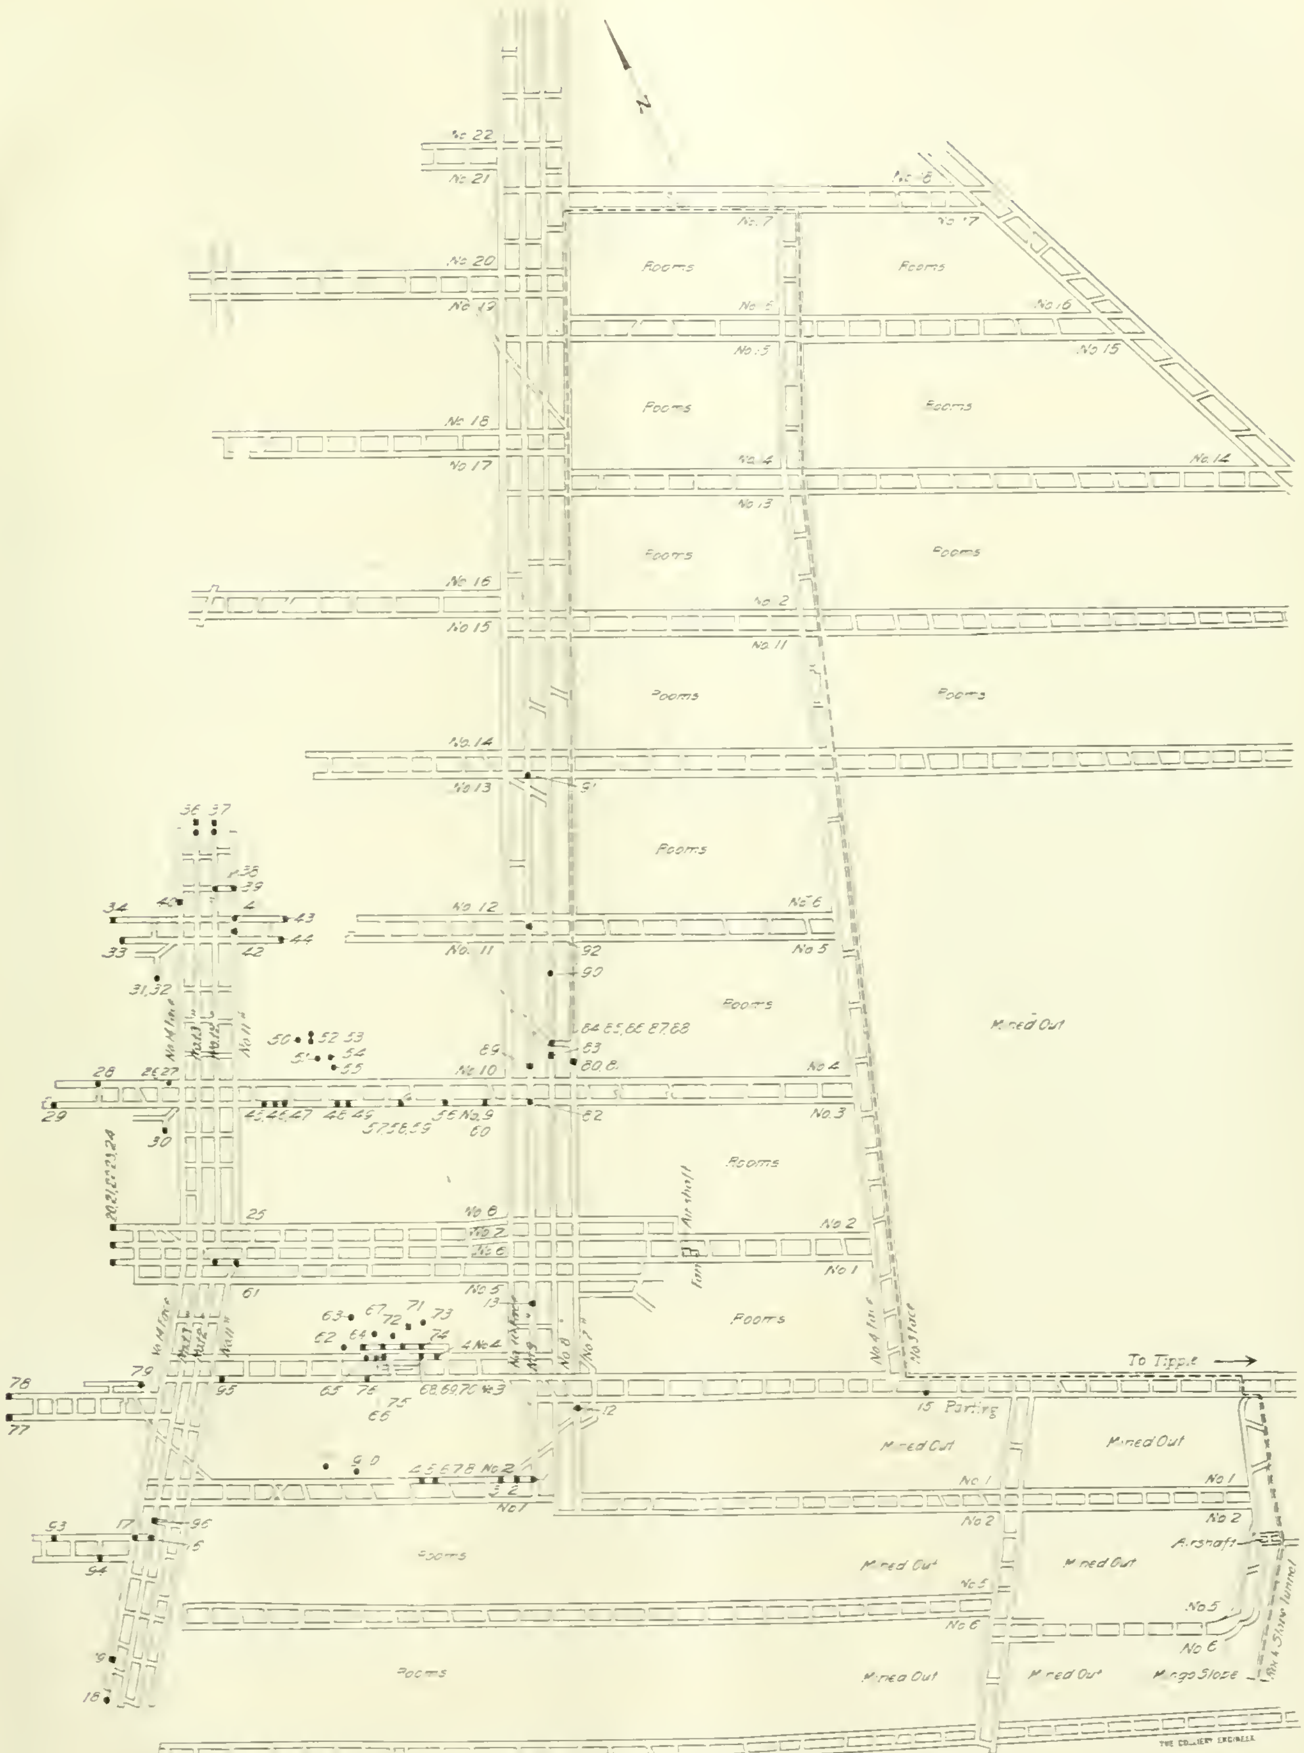
The air-current is indicated by arrows, and after sweeping through the room faces it goes on over the "robbed out" area into the return airway.

B the second stage, shows all the rooms driven their prescribed distance and the ribs drawn back to the stumps on the "advance" entry, and also rooms being driven and rib drawing off the "retreat" entry.

C, the last stage, shows that all rooms have been driven off both entries, and in addition the robbing of all pillar stumps; the ventilation still working as before, the air going to the working faces, then sweeping over the gob into the return. The advantage of this system is that fresh air always goes to the working faces and the gob is always ventilated by the return.

The mine covers approximately 1,100 acres, of which about 590 acres comprise live workings. This, of course, means that an efficient ventilation system is required to circulate the amount of air prescribed by law. It is reported that an explosion occurred at the mine about 20 years ago, but no record of it is in evidence. The mine is ventilated by an exhaust fan of the Capell type, electrically driven by a direct-current motor through gears. The fan is 12 feet in diameter, with blades $3\frac{1}{2}$ feet wide and 3 feet deep, and averages 156 revolutions per minute, developing a water gauge of 3 inches.

According to the latest published report of the State Department of Mines, there was 129,000 cubic feet of air per minute entering the mine, 56,850 cubic feet circulating in all the splits, and 132,000 cubic feet passing out at the outlet. The gob is ventilated, as previously explained, on the advance-and-retreat system and the large quantity of air which enters the mine and does not show in the splits must circulate through some of the mined-out workings. The state mine inspector measures the quantity of air in the different splits at the inside breakthroughs. The fan has



MAP OF CINCINNATI MINE

a capacity of about 200,000 cubic feet, but 129,000 was found to be sufficient.

The coal is mined by machines and by pick work. There are nine electric coal-cutting machines in use. Both open and safety lamps were used in the mine but in all entries wherever gas was found the men worked with safety lamps. In driving rooms the miners used open lamps, but everywhere that pillars were being drawn, the Wolf type of safety lamp was used.

The mine has never been considered a dusty one, but precautions were taken in the shape of two sprinklers and calcium chloride in abundance.

Out of the 96 men killed, a few were killed by the force of the explosion and by burns, but the majority died from the effect of the afterdamp. This afterdamp came back so strong at the intersection of Nos. 9 and 10 butt entries and the face entries, that it overcame 12 men there; these men in their excitement, akin to a stampede, rushed away from friends who escaped by the route indicated by the dotted line on the map and ran right into the foul atmosphere. The accompanying map of the mine workings shows the position of the bodies of these men when found. The numbers on the map indicate the order in which the bodies were found. Two men were found alive in No. 20 butt entry where they had been for about 2½ days. These men were not working there but lost their way and went up the cross-cut from No. 8 face to No. 19 butt. The supposition that more men were alive was not a well founded one, other men would have lived there had they remained, but they escaped across No. 18 butt to No. 4 face and out to the slope.

During the period immediately after the explosion, six state mine inspectors, Messrs. Bell, Cunningham, MacGregor, Pratt, Burns, and Howarth, arrived at the mine to assist the mine inspector of that district, Mr. Alex. McCanch. James E. Roderick, Chief of the Department of Mines, and five other state mine inspectors, arrived the following morning. The company officials, however, were able to cope with the situation and directed all the rescue work and the reconstruction of the ventilation, with the assistance of the state inspectors.

Probably the first intimation of the disaster came to Gorley Stokes, a trip rider. The trip was on its way inside and he was riding in the second car when the explosion took place, he was knocked down but not hurt and his cap and lamp were blown into the third car. He jumped out and gave the signal to the engineer to stop, which he did; then after finding his cap and lamp he started in toward the parting; when he got near the old mine foreman's shanty he heard the telephone ringing and upon answering it found it was the fan runner who said he needed help, that there had been an explosion no doubt, for the explosion doors were blown off the fan house, and the fan was stopped for 8 minutes before it could be started again. Stokes then called up the engine house outside and asked for help. He then found Emil Leroy, his partner, on the parting, *(15)* with his face down and hand fast under a roller, and he was unable to get him loose. Just then four men came by on their way out; they hurried on, however, and bade him do the same. But after finally getting the cable lifted, Stokes released Leroy, only to find him dead.

The mine foreman, one of his assistants, and a miner, were found in No. 6 butt off No. 14 face; each had a safety lamp; the bodies of these men were found close to the face, where they had gone to investigate a report that gas was being generated in that entry.

It is interesting to note that Mine Inspector Alex. McCanch made his last examination previous to the explosion on March 7, 8, and 10, 1913, just 6 weeks prior to the explosion. At that time he found 144,000 cubic feet of air entering the mine and 59,280 cubic feet in the eight splits; he found also that the volume of air per man varied in the different splits from 200 to 700 cubic feet, averaging over 400 cubic feet, an excess of the 200 cubic feet prescribed by law.

Mr. McCanch was at the Ellsworth No. 1 mine at the time of the explosion, and as soon as the mine ventilation was restored and the rescue work finished, made his examination. He claims from his investigations that the point of the initial explosion was on No. 12 butt entry off No. 14 face, it then traveled north to the faces of the face entries and south to all openings on the east and west until it reached the big parting where the force seems to have been spent. There were practically no evidences of an explosion in any other part of the mine.

No. 12 butt entry had been driven about 300 feet and had two breakthroughs; these openings are made about every 120 feet. At the face of No. 12 butt entry, he found a clay vein, running almost at right angles to the course of the entry, exposed by a shot, with a heavy feeder of gas.

Mr. McCanch believes that the miner working in the entry had fired his tight shot in the morning and later in the day had fired the butt shot which evidently exposed the clay vein and allowed the gas to escape. As it was almost noon the miner evidently went back to eat his lunch and then in going back to the face of the entry he fired the gas; the miner's cap and lamp were found about 12 feet from the face and his body about 30 feet from the face.

There were about 15 loaded mine cars out in the face entry, the first car was not damaged, but the coal on the top was blown into the air and by the time the end of the string of cars was reached the force was so violent that the last car was smashed to pieces; the first force having been no doubt augmented by the coal dust blown in the air.

In reviewing the work done by the rescue parties, many deeds of valor were performed, but specific cases cannot be named for fear of slighting many other acts of bravery that were crowded into the succeeding hours of the explosion. When one man came out exhausted, there were 50 eager to take his place. Too much cannot be said in praise of the efficient manner in which the company handled the work; men and supplies were to be had in abundance.

Three helmet men in No. 2 butt entry begun to feel the effects of the afterdamp and one, James McColligan, of Jacobs Creek first-aid corps, collapsed, his companions tried to carry him along, but growing weaker they were compelled to leave him and he died there.

William Lauder, a company mine inspector, had charge of the inside work, and directed gangs of workmen in the construction of stoppings, doors, brattices, etc., as well as participating in the rescue work; the latter was conducted from the Mingo entrance, the rescuing parties being made up of first-aid corps, mine foremen, fire bosses, and miners.

The following is an extract from the report of George S. Rice, Chief Mining Engineer of the United States Bureau of Mines, describing the exploration, made after the explosion:

REPORT OF GEO. S. RICE TO BUREAU OF MINES

Late Wednesday afternoon, April 23, rumors of the disaster reached the Pittsburg station of the Bureau of Mines. Rescue Car No. 6 was immediately sent to Finleyville; George S. Rice, chief mining engineer, and Messrs. Mason, Salisbury, Price, and C. O. Roberts went by train. There were no railroad connections to the Mingo entrance, so the rescue apparatus and supplies had to be taken by wagon several miles to that entrance. Mr. Fritchman, of the Pittsburg Coal Co., who was in charge of that entrance, stated that there were already large parties of rescuers in the mine, and among them the rescue corps of the Pittsburg Coal Co., with breathing apparatus, so that other rescue corps would not be needed for a while. Shortly after 8 P. M. there was a call for a pulmotor to revive some rescue men that had been overcome, and a party of Bureau men went into the mine at 9:05 P. M. with breathing apparatus and a pulmotor. Some of the men who had been overcome soon reached the outside and were given oxygen treatment by another pulmotor of the Bureau's equipment.

The party going underground proceeded to the second butt off the 8th face entry, where the rescue men had been taken who had been overcome. All had recovered but one. He had been given first-aid treatment by two doctors for over an hour without results, and the pulmotor was then tried for an hour and a half, but without success.

The Bureau rescue corps, using breathing apparatus, then made advance explorations in the Nos. 11, 12, 13, and 14 face entries and Nos. 1 and 2 butts off 14th face entry to put out any fires which might have started, and to locate men overcome, or bodies. As the explosion had been strong in this section of the mine there was little chance of men being alive. It was, however, important to determine whether fire existed. A smoldering fire had been put out in the 8th face entry at the mouth of the second butt. In the 14th face group of entries there was much gas, so that if fires existed it was important that they should be put out before ventilation was restored.

Meantime additional supplies had arrived from the Mine Rescue Car, and Messrs. Paul and Deike, the former in general charge of all Bureau rescue operations, also arrived at the Mingo entrance. Mr. Riggs, a volunteer, who had received training with rescue apparatus, Mr. Deike, and two members of the Pittsburg-Buffalo rescue crew, all equipped with oxygen breathing apparatus, together with Messrs. Paul and Rice, entered the mine at 12:05 and proceeded to the second butt entry off the face. Shortly afterwards it was desired to make certain changes in the ventilating current, and the Bureau's rescue corps went out of the mine for a short rest. They were called, and again entered the mine at 3:25 A. M., Thursday. Advance explorations using the helmets were made in the 3d, 4th, 5th, 6th, 7th, and 8th butt entries off the 14th face entry, to insure there being no fire before ventilation was turned into each entry successively.

In order to allow this advance exploration work with breathing apparatus to proceed consecutively it was deemed necessary to call additional men from the Pittsburg station, so that there could be a corps on each shift, and with additional apparatus they reached the Mingo entrance Thursday noon. Thursday at 4 P. M. the Bureau corps in charge of Mr. Paul, together with five others, went into the mine, and proceeded to the mouth of No. 9 butt entry off the 14th face. Exploration was then made to the head of the 9th and 10th entries.

There was considerable difficulty on account of water in these entries, and at different times the crews retreated to the base to adjust the breathing apparatus of three of the men. The latter were slightly affected, but were able to retreat to fresh air with the assistance of other members of the crew. Finally, however, the faces of these entries were reached, and many of the bodies in these entries were located. Finding that there was no fire, brattices were put up in the breakthroughs, and ventilation sufficiently restored to get out the bodies by men not using breathing apparatus. At 10:30 P. M. the exploration having been completed, the air was short-circuited straight up No. 14 face to the 11th and 12th butt entries, which were explored by the men with breathing apparatus. No fire being found, the brattices were carried up into them by men without breathing apparatus, in order to recover the bodies. At this time the oxygen for the apparatus having been exhausted, it was necessary to return to the outside, and during the night, ventilation having been established by bratticing through the entries off the 14th, breathing apparatus was not necessary to complete the exploration in these entries. The entire exploration and removal of bodies in that district of the mine was completed by noon Friday, and then the ventilating current was turned into the entries off the 8th face.

The Bureau's rescue corps and the rescue car remained on hand until the following Thursday (May 1), but there was no further need for their services.

The victims of the disaster were divided by nationalities as follows: Americans, 38 (19 colored); Russian, 21; Italians, 12; Austrians, 9; Scotch, 5; English, 5; Belgians, 2; Hungarian, 1; Lithuanian, 1; Welsh, 1; and French, 1. One hundred and thirty-one children were made orphans, while 51 women became widows. The number of children by families vary from one to 10.

REPORTS OF THE COMMISSIONERS TO CHIEF OF DEPARTMENT OF MINES

In order to ascertain the cause of the explosion at the Cincinnati mine which caused the death of 96 men, on April 23, Chief of the Department of Mines of Pennsylvania, J. E. Roderick, appointed two commissions which examined the workings independently of each other. Through the courtesy of Chief Roderick we are able to give the readers of The Colliery Engineer the conclusions of these commissioners.

The first commission was composed of Thomas K. Adams, I. G. Roby, C. P. MacGregor, Joseph Williams, and Arthur Neale, all mine inspectors, from other districts than the one in which the explosion took place. This commission reported virtually as follows:

"In compliance with your request of April 26, we investigated and examined the Cincinnati mine of the Monongahela River Coal and Coke Co., and submit to you the following report as to what in our belief was the cause of the explosion which occurred at this mine on April 23.

"We have carefully examined that portion of the Cincinnati mine which was affected by the explosion, and also the surrounding parts of the mine not directly or seriously affected thereby. In this instance, as in all other serious and widespread mine explosions it is difficult to determine with absolute surety the origin or the cause of the explosion, but we have concluded that the initial explosion probably occurred in No. 12 butt entry driven off from 14 face entry north, where a shot ruptured a clay vein and allowed the gas back of it, under considerable pressure, to escape. In this instance a tight shot, Fig. 2, had evidently been first fired and loaded out, exposing but not penetrating the clay vein. Subsequently when the butt or second shot, which penetrated the clay vein, was fired a strong gas feeder was tapped. This gas feeder can be heard blowing off even now.

"The man working in No. 12 butt entry was probably using an open

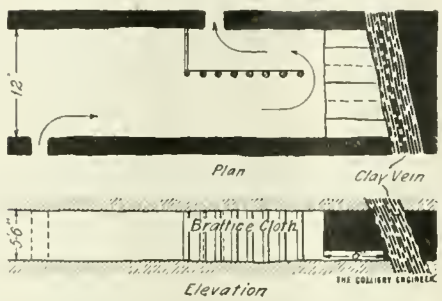


Fig. 2. Face of No. 12 Entry

light, as his working place had not been generating gas before the clay vein was tapped. It is our belief that the gas was liberated by the shot, and being ignited by the miner's lamp, the explosion resulted. We could find no gas being given off in any entries in this section, with the exception of No. 6 butt entry, which had also penetrated a clay vein 3 or 4 yards. We do not think this latter clay vein had anything to do with the origin of the explosion.

"The initial explosion was augmented by the gas driven from the coal by the intense heat which is shown to have existed by the condition of the entries through which the primary explosion passed. The brick air stoppings were built to within one breakthrough of the face of the several entries, and the mine was kept in a clean, orderly condition. We further report that in the area unaffected by the explosion we found the mine in an excellent condition.

"We entered the mine by way of the traveling slope, located near the active workings, and proceeded along the main haulage road. We found the force of the explosion ceased near the mouth of the No. 4 face entry. We found the overcasts blown down on the main haulage road. We traveled up No. 2 butt entry and Nos. 11, 12, 13, 14, face entries and examined them carefully, and noted the conditions existing in Nos. 11, 12, 13, and 14 face entries south, and Nos. 1, 2, 3, 4, 5, 6, 7, and 8 butt entries off No. 14 face entry, and found such evidences of the effects of the explosion as the destruction of the stoppings, doors, and mine cars. We also found coke dust and other evidences of heat on the side walls, from No. 1 butt entry to the face of the several face entries, with little injury to the roads from falling roof.

"On April 29 we went to Nos. 9, 10, 11, and 12 butt entries off No. 14 face entry; to the north face entries Nos. 11, 12, 13, and 14: to butt entries Nos. 9, 10, 11, and 12 off of No. 11 face entry and saw the results of the force of the explosion in those entries, also found much coked dust resulting from the heat between No. 10 butt entry and faces of the north face entries, and face of No. 12 butt entry.

"On the 30th we traveled much of the ground examined on the previous days to make a more minute inspection and note carefully the existing conditions, so as to better ascertain the direction in which the force of the explosion traveled; to determine the point at which it originated, and the cause thereof. We also examined that portion of the mine not affected by the force of the explosion and where a number of the men lost their lives by afterdamp, and also from where a large number of men escaped shortly after the explosion, and in which two men were found alive 55 hours after the explosion had taken place.

"After carefully examining all of the damaged portion of the Cincinnati mine and noting carefully all the evidences of the explosion, we unanimously agree that it originated at the face of No. 12 butt entry being driven west off No. 14 face entry north and was caused by the naked light of a miner igniting a body of gas which had suddenly issued from the clay vein uncovered by the shot, and which had accumulated in the entry.

"The force of the explosion traveled down No. 11 and 12 entries, passed entries Nos. 14, 13, 12, and 11, proceeded southward to Nos. 8, 7, 6, 5, 4, and 3 butt entries, then to Nos. 2 and 1 butt entries, where it cushioned against the faces of Nos. 11, 12, 13, and 14 face entries south, and was exhausted in an easterly direction toward the mouth of the mine. According to our observations there is a probability that a secondary explosion took place, one at the face of Nos. 5, 6, 7, and 8 butt entries, off No. 14 face entry, owing to the fact that much gas was being produced at the face of No. 6 butt entry from the very strong gas feeder. Another explosion seems to have taken place in Nos. 3 and 4 butt entries, off No. 14 face entry; at any rate it is apparent that the explosive force was much increased at these points."

REPORT OF THE SECOND SPECIAL COMMISSION

The second special commission consisted of W. R. Calverly, general manager of the Berwind-White Coal Co., J. H. Sanford, mining engineer, operator and competitor of the Monongahela River Coal and Coke Co., and R. M. McKinney, mining engineer, not connected with any company. These men reported their investigations to Chief Roderick as follows:

"We entered the Cincinnati mine of the Monongahela River Consolidated Coal and Coke Co., April 30, by way of the Mingo rock slope. This slope is driven on about a 20-degree dip to the coal bed, which is about 200 feet below the surface. We proceeded from this slope along the rock tunnel to the main haulage road, which at this point is about 1¼ miles from the river front where the tipple is situated. We proceeded along this haulage road about 7,000 feet to where was found the first evidences of the explosion, and then continued to where the body of the parting boss had been found in a manhole, at the parting. Even beyond this point, a considerable distance, the guards used to protect the men from the trolley wire had not been disturbed, except for a board here and there. Some of the electric bulbs were intact in the course of the explosion, from which it would appear that the force was not great to this point.

"Proceeding to the junction of No. 3 and No. 4 butt entries with the lower north main entries Nos. 7, 8, 9, and 10, evidences of great force and fire were plainly visible. At this point the machine boss had his workshop in a breakthrough which extended from one entry to another, being brick lined with 9-inch walls on each end. These walls were destroyed and it was at this particular junction there was more evidence of fire than in any other of the lower face entries. From this place we proceeded by way of No. 8 face entry to Nos. 5, 6, 7, and 8 butt entries which are driven beyond the main entries, in a westerly direction. We traveled these butt entries 2,000 feet until they intersected with the four upper face entries, Nos. 11, 12, 13, and 14. We then proceeded along No. 11 face entry to butt entries 11 and 12 which are being driven in an easterly direction to meet Nos. 11 and 12, which are being driven from No. 10 face entry. We proceeded to the extreme end and examined carefully the working places of Nos. 11, 12, 13, and 14 face entries. There was no evidence of fire within some 25 or 30 feet of the face of these entries and no disturbance was observed.

"Paper, fuse, and explosives were lying just as the workmen had placed them, even dinner buckets were not disturbed. Going back to where Nos. 11 and 12 butts west start from No. 14 face, there was evidence of fire having played a conspicuous part in coking the face of the coal. The heat must have been very intense at this point and the flame must have lingered some time, because the coking effect was evident almost from the top to the bottom of the coal bed. We proceeded up to the face of No. 12 butt and noticed that the face of the clay vein had evidently been shot and not disturbed afterwards. From this point we retraced our steps and passed through the breakthrough to the face of No. 11 butt entry, then back along No. 14 face, crossed over the face entry and went into Nos. 9 and 10 butts, traveling toward No. 10 face entry. After traveling 1,000 to 1,200 feet we could go no farther on account of an accumulation of water in a swamp, so we went to the faces of Nos. 9 and 10 butts off face entry No. 14, thence back along No. 14 to Nos. 8, 7, 6, and 5 butt entries, where there is an intersection of the north and south face entries.

"We traveled along No. 14 south, walking to the face of Nos. 3 and 4 butt entries east, up the face of Nos. 1 and 2, butt entries, and to the face of Nos. 14, 13, 12, and 11 south face entries. We then traveled to the lower face entries by way of Nos. 3 and 4 butt entries. This was the extent of our travels on Wednesday.

"On Thursday morning we again entered the mine following the same course to the intersection of Nos. 3 and 4 butt entries with Nos. 5, 6, 7, and 8 face entries, proceeding along these face entries to Nos. 9, 10, butt entries, which we traveled until stopped by water which prevented our going through the upper face entries to these entries. Going back down we traveled along No. 10 face entry to the faces of Nos. 11 and 12 butt entries. We were then in a section that had not been affected by the force of the explosion, although afterdamp would have entered and traveled some distance in these face entries. We proceeded, however, to the extreme end of this section of the mine and up Nos. 19 and 20 butts to the face entries, which were being driven off of these two butts north and south at the time of the explosion. Having satisfied ourselves as to the condition of this section, we retraced our steps, again traveling from No. 8 butt to the upper face entry and along No. 11 face north. We examined every detail that we thought might have a bearing upon determining positively where this explosion got its initial start.

"When we arrived at the face of No. 12 butt, off No. 14 face, it was plainly evident that this was the point where the explosion originated, and as previously stated, where the clay vein had been shot and gas had been given off freely evidently the tight shot had been fired and loaded out, exposing but not penetrating the clay vein. When the butt shot was fired it penetrated the clay vein and tapped a strong gas feeder, as gas could be heard blowing out of the fissures when we made our examination, which, of course, was a week after the explosion.

"It is fair to assume that when the butt shot was first fired gas was given off more freely than at the time we made our examination. It would appear to us also that prior to the butt shot being fired the entry was not making any gas. When the workman charged and lighted this shot he would naturally walk back from the face and stand in some protected place until the shot went off. It being noontime, it is probable that the man would sit down and eat his lunch while the smoke was clearing out of his working place. An empty car was standing right up to the face entrance, and it is fair to assume that the man when returning to his working place pushed this empty car ahead of him to the rise. Of course, the man pushing the car would naturally have his head down low, and when he reached the end of the rails and stood erect with a light on his head he would ignite the gas that had accumulated during his absence. His cap and lamp were lying about 10 or 12 feet from the face, but his body was found about 30 or 35 feet from the face.

"The entry was bratticed to within 18 or 20 feet of the face, which appears to have been the custom in most of the entries. (See Fig. 2.) The last 10 or 12 feet of this brattice had evidently not been disturbed by the explosion, while the brattice further out was blown down. There was evidence of fire at the face of this entry where the coal had been blistered, and also where the flame had come in contact with the side of the entry. From this place we traveled back to the breakthrough and passed through it into No. 11 butt, which is parallel to No. 12. In No. 11 butt we examined everything carefully and found that no gas was being given off in this entry. There was no evidence of flame having come in contact with the coal within 20 or 30 feet of the face, while all through the breakthrough and a considerable distance up the entry there had evidently been intense heat and flames. This was plainly evident because on the sides of the entry the surfaces of the coal were coked. It seemed to us to prove, as we traveled away from the face of No. 13 butt, toward No. 14 face entry that the force of the explosion increased and the destruction had become greater.

"At the face of Nos. 9 and 10 entries mine cars were badly wrecked, the line of force having traveled from No. 14 face entry toward the face of Nos. 9 and 10 butt entries. We retraced our steps to No. 8 butt, where we made a thorough examination, because in No. 6 butt gas had been previously reported, 12 feet from the face where a clay vein had been cut, and where in all probability gas was liberated. Here the face had been cut and the tight shot loaded out, and it was evident that coal had been drilled preparatory to shooting out the butt. This entry had been worked with safety lamps, and this is the entry in which, we understand, the mine foreman and his assistant and the men who were working the entry, were found. This would show conclusively that the direction of the force was down the 14 face entry up to the face of these butt entries, as we noticed upon our examination that the debris had been scattered along the entry right up to the working face. From this point we traveled south because the direction of the explosion was certainly toward the face of these entries. We examined this section thoroughly for gas and only discovered it at the face of No. 12 butt where we are positive almost that the explosion started. The face of No. 6 butt, as previously stated, was some 12 feet beyond the clay vein, and water was being given off from this vein, but no great amount of gas, as the gas was escaping through the water, and the noise was more in evidence than the gas itself. We also noticed that a little gas was given off in No. 4 butt entry. The explosive force was in the direction of the lower face entries and the damage appeared similar to that in Nos. 9 and 10 as far as Nos. 3 and 4 butts, where its energy decreased by getting relief up the air-shaft and along the main haulage roads. As previously stated there was no damage done to the lower main section beyond No. 11 butt and it appeared that all the workmen in this section escaped with the exception of a few men who panic stricken rushed along the main traveling road into the afterdamp, against the advice of the assistant mine foreman and others. Two men working at the face of Nos. 11 and 12 butts, off No. 8 face, north, escaped 3 or 4 hours after the explosion occurred by way of the lower return airway.

"In that part of the mine unaffected by the explosion we find the conditions have not been changed from what they were prior to the explosion. There was ample ventilation and it was conducted around all of the working faces. We noticed that brick stoppings were erected in practically every instance to the last breakthrough, except, of course, those used for haulage purposes. The roads were moist and practically free from dust, and clean and free from obstructions. We also noticed in this section that drums of calcium chloride were placed in convenient places and used for sprinkling the roads. In that part of the mine which you might term the 'upper face section' the force of the explosion was very destructive; all of the stoppings were blown out as were the overcasts. These overcasts and stoppings were built of bricks.

"In this section of the mine we also noticed three drums of calcium chloride containing 250 pounds each, which were not opened, and this would indicate that ample quantities of this safety factor had been provided, since some of the drums were partly used. We think we can give to this calcium chloride some of the credit for the explosion not being more destructive than it was, because it seems as if every precaution that must be observed in exploiting our coal fields against dangers which arise, had been taken.

"There is no doubt but that the initial explosion was augmented by the gas given off from the coal by the intense heat. This was shown by the condition of the entries through which the primary explosion passed. We are satisfied, too, that in a brisk air-current some coal dust will be held in suspension, which coming in contact with the flame of the explosion will add to the volume of the gas and increase the energy.

"We are of the opinion that little gas is given off in any of the entries in this section, because at the time of our visit, with the ventilation disarranged and air stoppings and overcasts temporarily built of wood and brattice cloth, the entries were free from gas. As you will notice by reference to the map, Nos. 9 and 10 butt entries are driven a considerable distance from face entry No. 14. The same is true of Nos. 3 and 4 butt entries and the four face entries 11, 12, 13, and 14, north and south, off Nos. 5, 6, 7, and 8 butts. Leaving this section and going to 19 and 20 entries, off the lower face entry 8, north, some distance away, there was no evidence of gas to justify the use of safety lamps. We feel that no one will seek to dispute the fact that the section of the mine unaffected by the explosion was found in excellent condition viewed from every standpoint."

BOOK REVIEW

A review of the latest books on Mining and related subjects

Map of West Virginia Coal Fields.—This map has been compiled by Clark & Krebs, Charleston, W. Va., and shows the property lines, location, and car allotment, of the mines in the New River, Kanawha, Coal River, and Guyandotte River coal fields in West Virginia. The map is large and one which will be appreciated by every operator in West Virginia. Price is $5.

Entropy - Temperature and Transmission Diagrams for Air, by Prof. C. R. Richards, has just been issued as Bulletin No. 63 of the Engineering Experiment Station of the University of Illinois.

This bulletin presents the theory and use of three graphical charts, by the aid of which all problems pertaining to the compression, expansion, and transmission of compressed air may be solved with a minimum of labor and with a degree of accuracy which is satisfactory to engineering work. Copies of Bulletin 63 may be obtained upon application to W. F. Goss, Director of Engineering Experiment Station, University of Illinois, Urbana, Ill.

Virginia Geological Survey. Dr. Thomas L. Watson, Charlottesville, Va., Director, has issued Bulletin No. V on "The Underground Water Resources of the Coastal Plain Province of Virginia." The book is by Samuel Sanford and was prepared in cooperation with the United States Geological Survey.

The California State Mining Bureau, T. McN. Hamilton, State Mineralogist, has just issued Bulletin No. 63, "Petroleum in Southern California." The book covers the Ventura, Los Angeles, Orange, San Bernardino, and Santa Barbara County oil fields. It gives various methods of analysis of the typical oils in the several fields, the history of the development, and describes the operation of the wells in the different localities. The book contains 430 pages, is bound in cloth, and can be had for $1.72 by applying to the State Mining Bureau, San Francisco, Cal.

Gas Power. A recent addition to the Wiley Technical Series is the book termed "Gas Power." The authors of this book, Prof. C. F. Hirsfeld and T. C. Ulbricht, M. M. E., are able to express their knowledge in a way that does not cause the layman a headache when he wants to read about gas engines. Internal-combustion engines are explained, from gas to petroleum, in a way that permits automobile owners, chauffeurs, and attendants at vocational schools to understand the mechanism without having recourse to mathematics.

Chapter I deals with the Heat Problem; Chapter V, Four and Two-stroke Engines; Chapter VIII, with Ignition Systems; Chapter IX, with Carbureting and Carbureters; Chapter XII, with Modern Gasoline Engines; Chapter XV explains the Rating of Internal-Combustion Engines as practiced in this country; Chapter XVIII is on the Practical Operation of Internal-Combustion Engines. In all there are 193 pages and index, 60 illustrations and 18 chapters in the book, and it has been carefully edited by J. M. Jameson, of Pratt Institute. The price is $1.25 net. The publishers, John Wiley & Sons, New York City.

The Mining World Index of Current Engineering Literature, Vol. 2, has just been issued. It represents the second half of the year 1912, and is an international bibliography of mining and the mining sciences compiled and revised semiannually from the Index of the World's Current Literature, which appears weekly in *Mining and Engineering World*, of Chicago. The index has been compiled continuously since the beginning of 1911. There are seventeen chapters in this book, having the following headings: Gold and Silver; Copper; Lead and Zinc; Iron and Steel; Alloys; Tin, Nickel, Cobalt, and Aluminum; Miscellaneous Metals and Ores; Fuels and By-products; Petroleum and Natural Gas; Non-Metals; Prospects and Prospecting; Haulage; Milling and Reduction; Metallurgy and Chemistry; Power and Machinery; Miscellaneous. In addition to the subject index there is an index of authors. The price of the Index is $2.50.

THE LETTER BOX

Readers are invited to ask or answer any question pertaining to mining, or to express their views on mining subjects in this department. All communications must be accompanied by the name and address of the writer—not necessarily for publication.

The editors are not responsible for views expressed by correspondents.

Pulling Pillars

Editor The Colliery Engineer:

SIR:—I should like to hear from those of your readers who can furnish a safe method of pulling anthracite pillars. While the methods will vary in flat and pitching beds, the answers in either case might aid in securing greater safety for the miners and also be of benefit to the operators. CHAS. H. BLEAKELY

Olyphant, Pa.

Location of Regulator

Editor The Colliery Engineer:

SIR:—I would like to have the opinion of some of your readers as to which is the best location for a regulator, at the intake of the split or at its outlet? And which would give the best results, and why?

J. B. WILLIAMS

Carbondale, Pa.

How to Mine

Editor The Colliery Engineer:

SIR:—We are working a coal bed that has bedding and cross-joints. The coal itself has slaty cleavage and practically no cleatage, so that when shot it prefers to break in slabs.

If black powder is used, owing to the joints it is not as effective as it should be.

If dynamite or quick explosives are used the coal is shattered into small parallelopipedons or rhombohedra shaped pieces. I should like to have some of your readers who have had experience with similar coal beds in the Western States tell how they place the holes and what kind of powder they use. J. A. S.

Edmonton, Alberta

The Motive Column

Editor The Colliery Engineer:

SIR:—I wish some information on the Motive Column. What does it mean? How does it originate? What part does it play on the downcast or upcast airway? Does any such thing exist or is it only imaginary? The views of your readers are requested in answer to these questions. COAL MINER

Cape Breton, N. S.

Size of Pillars

Editor The Colliery Engineer:

SIR:—In reply to the question in April issue on width of pillars, by Charles H. Robinson, with reference to Dunmore No. 4 seam, 5 feet thick, 900 feet below surface, width of room 24 feet: First, a knowledge should be obtained of the geological features of the strata both overlying and underlying the seam, and the nature of seam. However, under fair conditions two-thirds of the solid coal should be left for pillar coal. That is to say, for every room width of 24 feet, a pillar 76 feet wide must be left to support the roof. Of course, this is only approximate. If the top is strong and bottom soft, or bottom strong and top soft, or both soft, or both top and bottom strong and unyielding and coal soft and tender, larger pillars are needed. As this seam is 900 feet deep there is great pressure on the pillars, and as the pressure increases to the dip, pillars 90 feet wide will be safe. That is to say, 90 feet wide by 100 feet long, longest side parallel to the dip or right angles to the strike of the seam.

PAT. J. LYNCH

New Waterford, N. S., Canada

Carbon Monoxide

Editor The Colliery Engineer:

SIR:—Will you kindly inform me through your journal, which of the following statements is correct:

In the I. C. S. pamphlet instruction paper on "Mine Gases," page 2, paragraph 3, the statement is made that "carbon monoxide is combustible, but of itself does not support combustion."

In the book "Examination Questions and Answers," the answer to Ques. 312 states: "It is combustible and also supports combustion."

This question was brought up in the Mining School of the Wilkes-Barre District Mining Institute, and we will be very glad to have the matter explained. E. C. L.

West Pittston, Pa., April 17.

The statement quoted from the I. C. S. Instruction Paper that carbon monoxide does *not* support combustion is correct.

The contradictory statement was made in the first 1,000 copies of "Examination Questions and Answers," but was corrected in all subsequent issues. A similar incorrect statement was made in some editions of "The Coal and Metal Miners' Pocketbook." Previous editions of the pocketbook stated that carbon monoxide is *not* a supporter of combustion. The statements that it is a supporter of combustion were made by a writer formerly in the employ of the publishers of The Colliery Engineer, who, while an able mining writer, and as a rule accurate, in this instance expressed an opinion of his own, which is in direct opposition to the actual experience of chemical authorities whose works are regarded as standards all over the world.

Editor

Use of the Barometer in Mining

Editor The Colliery Engineer:

Sir:—I have received the following letter relative to my paper on the use of "The Barometer in Mining," published in your May issue:

Mr. F. Z. Schellenberg, C. E.,
Pittsburg, Pa.

Dear Sir:—I have read with interest your paper on the use of the barometer in mining, as read before the Mining Institute, and as a former official of the Weather Bureau, it has had special interest to me.

You suggest the use of an aneroid with very open scale, and I do not know but such an instrument would prove useful if kept in a place where temperature changes are very slight. But of course you know that it is very difficult to make an accurately compensated aneroid. The temperature error is also very marked in all forms of liquid barometers and in many of them the vapor tension in the vacuum chamber vitiates the reading. This is probably the reason that glycerine is so frequently used for an open-scale liquid barometer as you suggest.

The Germans have a style of mercurial barometer that can be read very accurately. It is a siphon instrument with a hole in the tube at the bend, to which is attached a leather sack. This is suspended by an inverted screw and by raising or lowering the screw the open end of the siphon can always be brought to the same level. The tube is so bent that the open end is directly underneath the vacuum end of the instrument and of identically the same size. In use, the setting screw is turned until the meniscus of the open end meets a setting gauge at the zero point and this setting gauge is identical with the one at the top of the scale. The upper setting is made with a micrometer screw passing around the case containing the tube and graduated to hundredths of a millimeter. With similar fittings above and below, the personal equation is removed and the instrument is capable of very accurate use, the greatest errors being due to irregularities in the temperature of scale and mercury, which are practically unavoidable. The instrument is called the Fuess and is made in Berlin.

Prof. C. F. Marvin designed a very ingenious and accurate instrument in the shape of a recording mercurial barometer, but it is expensive and some care is necessary to adjust it to work properly. It operates on the principle of the platform scale. A lever is balanced on a fulcrum in a manner similar to a platform scale or steelyard, and from the point where the object is to be weighed there is suspended a glass tube an inch in diameter made and filled in a manner similar to a mercurial barometer, the open end of which dips into a cistern on the floor underneath. A counterpoise weight is on the long arm of the lever which is fed out to make a perfect balance. In the recording instrument, an electrical connection is made which thus feeds the weight out on the arm, and a pen attached to the weight records the movement on a revolving cylinder similar to those used in a chronograph. The instrument would be simplified, however, to thus weigh the barometer tube without the recording device. You will observe, of course, that this gives the direct weight of the barometer column and thus avoids the temperature correction, and by proper adjustment of the position of the lever and size of the counterpoise weight, as open a scale can be obtained as may be desired.

The one I saw in operation made a very perceptible movement by the swinging of a door in a room. I think this style of instrument would be much more desirable for mining use than anything else I could suggest.

For the construction of such an instrument, I would suggest using the upright support of a platform scale, and from the point where a connection is made to the platform, suspend a large mercurial tube, and whenever a reading is desired, balance the tube suspended in the mercury cistern by the counterpoise on the beam. All errors by this means due to impurities in mercury and temperature will apparently be obviated.

W. H. Hammon

Pittsburg, Pa.

Use for Old Wire Rope

Editor The Colliery Engineer:

Sir:—There are few coal mines that do not have more or less old wire rope that is listed as "scrap," which is absolutely useless for anything but fencing. I think this rope could be made most valuable by stringing it through all the traveling ways throughout the mine.

By attaching it to props alongside the traveling way, say 3 feet from the floor, excepting where it passed across haulageways and would be placed underneath the rails, a definite guide would be provided even to the greenest of men, to show them either into or out of the mine.

In some mines, the traveling ways are veritable labyrinths, through which a stranger to the mine cannot expect to find his way, unless accompanied by a guide. Signs along the road, pointing the way out, are all right so long as they can be seen, but should a man's light become extinguished and he have no means of relighting it, the rope then may easily be the means of keeping him from wandering into places where CO_2 would quickly overcome him.

In the month of February, this year, two men met death in a mine in Las Animas County, Colo., by wandering in old workings, looking for the air-shaft.

A new man could be directed to "follow the rope" either going into or coming out of the mine and he would be dull witted, indeed, if he allowed himself to become lost, no matter how many turns he had to make or how many old workings he had to pass in his journey.

Bert Lloyd

Trinidad, Colo.

PRIZE CONTEST

For the best answer to each of the following questions we will give any books on mining or the sciences related thereto, now in print, to the value of $3.

For the second best answer, similar books to the value of $2 will be given.

Both prizes for answers to the same questions will not be awarded to any one person.

1. The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.
2. Answers must be written in ink on one side of the paper only.
3. "Competition Contest" must be written on the envelope in which the answers are sent to us.
4. One person may compete in all the questions.
5. Our decision as to the merits of the answers shall be final.
6. Answers must be mailed to us not later than one month after publication of the question.
7. The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what books they want, and to mention the numbers of the questions when so doing.
8. In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.
9. Employes of the publishers are not eligible to enter this contest.

Questions for Prizes

25. The capacity of a room is 6,548 cubic feet and it has the following atmosphere: Air, 92.90 per cent.; marsh gas, 7.06 per cent.; carbon dioxide, .04 per cent. How many cubic feet of oxygen, nitrogen, marsh gas, and carbon dioxide will there be in this room, the temperature being 65° F. and the barometric pressure 29.925?

26. It is desirable to remove all the coal from a 5-foot seam below a concreted reservoir, containing water for public purposes. Indicate a system of working the coal to do as little damage as possible to the reservoir. Seam is 560 feet below reservoir.

---

27. In boring a hole through a coal barrier 140 feet wide in a 5-foot seam, what is the greatest difficulty you would expect to meet, and how would you overcome it, the head of water being 120 feet?

28. An entry 3,600 feet long falls 350 feet 6 inches. (*a*) What is the gradient of the road? (*b*) What kind of haulage would you install on such a road to get up 800 tons a day? Give reasons for and describe the salient points of the installation.

Answers for Which Prizes Have Been Awarded

Ques. 17.—*Diameter of Collar.* The diameter of a collar, 8 feet between supports is 10 inches; what should be the diameter of a collar 16 feet between supports, the weight increasing in proportion to the length?

Ans.—The strength of any beam or collar is dependent upon its maximum bending moment. The general formula for the maximum bending moment of a circular beam or collar is $M=\frac{S_t I}{c}$ where S_t is the tensile stress per square inch and $\frac{I}{c}$ is the section modulus. For a solid circular beam

$$\frac{I}{c}=\frac{\pi d^3}{32} \text{ and } M=S_t\frac{\pi d^3}{32} \qquad (1)$$

d represents the diameter of the beam.

For a collar which is uniformly loaded and supported at both ends as in the above problem

$$M=\frac{Wl}{8} \qquad (2)$$

Where W is the total weight on the collar and l is the length of the collar. Then equation (1) and equation (2) are equal; hence,

$$\frac{Wl}{8}=\frac{S_t \pi d^3}{32} \qquad (3)$$

Let

W_1 = total weight on the 8-foot collar;
l_1 = the length of the 8-foot collar;
d_1 = the diameter of the 8-foot collar.

Substituting these values in equation (3)

$$\frac{W_1 l_1}{8}=\frac{S_t \pi d_1^3}{32} \qquad (4)$$

Also let

W_2 = the total weight on the 16-foot collar;
l_2 = the length of the 16-foot collar;
d_2 = the diameter of the 16-foot collar.

Substituting these values in equation (3)

$$\frac{W_2 l_2}{8}=\frac{S_t \pi d_2^3}{32} \qquad (5)$$

But by the condition of the problem $W_2=2W_1$ and $l_2=2l_1$

Then $$\frac{W_2 l_2}{8}=\frac{2W_1 2l_1}{8}=\frac{4W_1 l_1}{8} \qquad (6)$$

But by equation (4)

$$\frac{4W_1 l_1}{8}=4\frac{S_t \pi d_1^3}{32}$$

and by equation (5)

$$\frac{W_2 l_2}{8}=\frac{S_t \pi d_2^3}{32}$$

Substituting these values in equation (6) we have $\frac{S_t \pi d_2^3}{32}=4\frac{S_t \pi d_1^3}{32}$; as $\frac{S_t \pi}{32}$ is constant to both terms of the equation the above reduces to $d_2^3=4d_1^3$. As d_1 is 10 inches $d_2^3=4\times 10^3$ or $d_2^3=4{,}000$. Hence, $d_2 \sqrt[3]{4{,}000}=15.87+$.

Ans.—Use a collar whose diameter is at least 15.87+ inches.

Note.—From equation (3) we learn that the strengths of beams or collars vary directly as the cubes of their diameters and inversely as their lengths.

Milton R. Evans,
92 Division St., Kingston, Pa.

Second prize, W. E. Hobson, 315 Maxwell St., Lexington, Ky.

Ques. 18.—*Weight of Rope.* What weight of rope will be required to hoist 7 gross tons from a shaft 400 feet deep?

Ans.—It is desired to hoist 7 gross tons or 15,680 pounds from a shaft 400 feet deep.

Doubling the load for shock gives 31,360 pounds. One-tenth of the load, or 1,568 pounds ought to be allowed for friction. If it is assumed that the rope will weigh 3 pounds per linear foot, the weight of the rope may be taken at 1,200 pounds. The sum of these loads, 17.064 net tons, represents the total maximum load on the rope. The proper working load of the plow-steel rope $1\frac{1}{2}$ inches in diameter is 19.2 tons, while that of a rope $1\frac{3}{8}$ inches in diameter is 16.4 tons. Safe practice demands the use of the larger size rope.

For a $1\frac{1}{2}$-inch rope, a drum 8 feet in diameter should be used, and to allow for three coils around the drum when the load is at the bottom of the shaft, $8 \times 3.1416 \times 3 = 75.3984$, or say 76 feet of rope must be allowed for this purpose.

Assuming that the sheave is placed 50 feet above the collar of the shaft and that the hoist engine is located at a distance of 50 feet from the center of the shaft, then the distance from sheave to drum will be $\sqrt{50^2+50^2} = 70.7$ feet, or approximately 71 feet.

The total length of rope required will be 400 feet in the shaft, 50 feet from collar to sheave, 71 feet from sheave to drum, 76 feet around the drum; a total of 597 feet.

A $1\frac{1}{2}$-inch plow-steel rope weighs 3.55 pounds per linear foot, therefore, the total weight will equal $3.55 \times 597 = 2{,}119.35$ pounds.

M. D. Cooper,
Ellsworth, Pa.

Second prize, Michael H. Galda, Box 243, Kulpmont, Pa.

Ques. 19.—*Blasting Coal.*—Explain the principle involved in the use of powder in blasting coal, stating why common black powder is better for this purpose than high explosives, such as dynamite or other nitroglycerine compounds.

Ans.—Practically every miner is familiar with the method of blasting coal. He knows that first of all a hole is bored into the material to be blasted, then into this hole is placed a quantity of powder; next, the hole is tamped, then the powder ignited, and immediately, or almost so, there follows an explosion; and when next he is enabled to go to the place of blasting, there is a portion of the coal forced away from the mass, and more or less broken up. Here, there are two things to be explained; first, why does the powder explode; then, why does it have the effect of forcing away and breaking up the coal?

First, why does the powder explode? Because it contains all of the ingredients necessary for complete and rapid combustion. Now, what are these necessary ingredients?

Well, we all know that there are certain substances, which, when once ignited, will, under ordinary circumstances, burn. These are known as combustible substances; but before they will burn the presence of air is necessary.

The reason for this is found in the nature of oxygen, which gas forms about one-fifth portion of the air in volume. It has been proved by experiments that all ordinary combustion is caused by the combination of the combustible substance with this oxygen obtained from the air.

But the air is not our only source of oxygen, and it is a fact that oxygen will support combustion, no matter from what source it be obtained, and while an ordinary combustible obtains its supply of oxygen from the air, an explosive contains oxygen within itself, usually in the form of a nitrate. Another fact is that, if we take our combustible substance and divide it into particles, then intimately mix it with its supply of oxygen; the finer the particles, and the more intimately mixed, then the more rapid will be the combustion. And in these two facts we find the reason for the explosion of the powder; since all the powder used in coal mines depends for its explosive power upon the union of combustible substances with a supply of oxygen, in such a manner that each particle of combustible substance is in contact with a source of oxygen; and also the right proportions of each; so as to cause a complete and very rapid combustion. For instance, common black powder consists of a mixture of charcoal, sulphur, and one of the nitrates, either of potassium or sodium. The charcoal and sulphur are combustible, while the nitrate contains a large proportion of oxygen, which it will readily give up to support combustion. When the powder is first ignited the nitrate commences to give up its oxygen, and the charcoal and sulphur will burn the more rapidly. This burning ignites the surrounding powder, and so causes it to burn. As the ingredients are so intimately mixed that every particle of charcoal and sulphur is in contact with a portion of the nitrate, the burning of the powder is so extremely rapid as to take the form of an explosion.

Now, we will turn to our second question: Why does the explosion of the powder have the effect of forcing away and breaking up the coal?

The explosive owes its power to the expansive action of large volumes of gases that are formed during the combustion. The burning of the charcoal and sulphur yields a large volume of gases, and there is also a large amount of heat produced.

It is well known that the effect of heat on gases is to cause them to expand, and as the heat produced is enormous, there is a correspondingly enormous expansion of the gases that have been formed; and since there is no room for the expansion, a great pressure is generated and brought to bear upon the surrounding strata.

We have already noticed that the explosive power of powder depends largely upon the fact that the different ingredients are so arranged

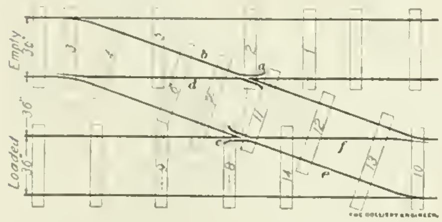

Fig. 1

that every particle of combustible matter is in contact with a source of oxygen. But there are certain explosives in which the combustible materials and the oxygen are so arranged as to be both a part of the same chemical substance. In such explosives the association of the two is, of course, much closer than in black powder and the explosive action is in consequence much more rapid. We may notice that the various nitroglycerine, and also the ammonium-nitrate compounds are of this nature.

As a result of this more rapid explosion, we get a more shattering effect in the immediate area, but this area is not so large as would be the case were a slower explosive used.

For this reason black powder is better for blasting coal than the quicker explosives. Black powder, because of its slower explosive action, spreads better, and so brings down a larger area of coal, but has not the same shattering effect as dynamite and other explosives of that class, and so we obtain a greater percentage of the larger coal.

This is the one great advantage possessed by black powder in the blasting of coal, though there may be others of very minor importance. For instance, it is possible to ignite black powder by a simple squib or fuse, whereas the quicker explosives require the use of a detonator. There can be no doubt, however, that the greater dangers attending the use of black powder in coal mines are more than enough to discount all its advantages.

Thomas C. Wakefield,
106 S. Twentieth St., Herrin, Ill.

Second prize, R. Z. Virgin, Colliers, W. Va.

Ques. 20.—*Laying a Cross-Over Switch.*—Explain each step in the laying of a cross-over switch between the loaded and empty tracks, on a mine haulage road. Show the method of locating the frog in each track, and give the proper frog angle that should be used, the frog distance, the degree of curvature of switch rails, etc.

Ans.—The following steps are to be taken when laying a cross-over switch between empty and loaded tracks:

1. Line the outside rails on both the loaded and the empty tracks, making sure that the distances of spread are equal.

2. Then the gauge of tracks and space between the two tracks must be figured out before an intelligent start can be made.

3. Assuming the track gauge to be 36 inches and the space between tracks to be 36 inches the frogs can be made to a 20-degree angle. Laying the switches can now commence from either the loaded or the empty track and this will give a switch-rail curvature of 20 degrees.

4. Having decided on the location of cross-over, commence on the empty track to break road and place ties 1 and 2, as shown in Fig. 1. Next place the frog marked *a* in position, and having gauged it to the outside rail it is to be spiked permanently. This having been done, place ties 3, 4, 5, 6, and 7 in position, and then the switch rail marked *b* is permanently spiked.

5. By the use of the track gauge from the point of frog on the empty track and the line rail on loaded track, the frog marked *c* is located and ties 8 and 9 are placed in position, after which frog *c* is permanently spiked.

6. Commence on the short arm of the frog marked *c*, and line the rail around to connect with the empty track; then by placing the switch rail marked *d* in position that end of cross-over is finished.

7. Now place ties 10, 11, 12, 13, and 14 in position and spike the switch rail marked *e* in place; then commence on the short arm of the frog marked *a* and line the rail around to connect with the loaded track, finally by placing switch rail marked *f* in position the cross-over is finished. This will give a good cross-over switch with a frog angle of 20 degrees and a switch curvative of 20 degrees.

First prize, Alexander McAllister, Box 108, Croweburg, Kans.

SECOND PRIZE ANSWER

The best type of cross-over is that having the turnouts connected by a tangent from the frog on the loaded track to the frog on the empty track. If choice is given in location of the cross-over, it should be so fixed as to cut the least possible number of rails. If *A* Fig. 2, were the end of a rail on the loaded track, measure

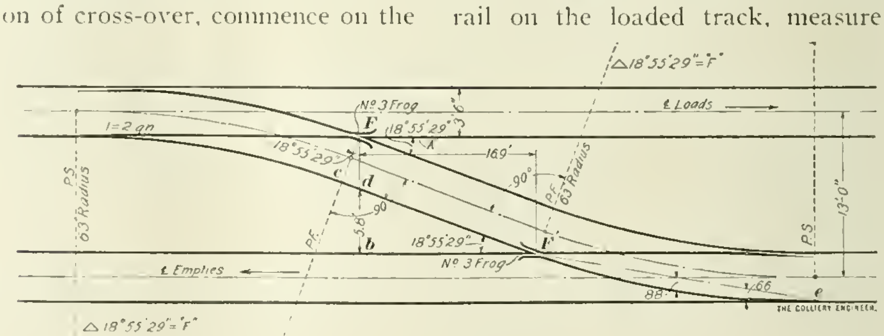

Fig. 2

from it toward the point of switch a distance equal to that between the heel and the frog point. Mark this point on the web of the rail opposite, and from this measure off the distance of the lead straight rail to the point of switch. The length of the lead equals twice the product of the frog number and the gauge, or $l = 2\,g\,n$.

The next point of the cross-over to be determined is the other frog point. $F\,d - d\,b = 9.5$ feet and $F\,d = \frac{3.5'}{\text{Cos } 18°55\frac{1}{2}'} = 3.7$ feet. Therefore, $d\,b = 9.5' - 3.7' = 5.8'$. $b\,F' = 5.8' \times \text{Cot } 18°55\frac{1}{2}' = 16.9$ feet, or the distance between frogs on the loaded track; which measure off and mark at a point on the empty track rail opposite. Having established the point of frog $P. F.$, locate the point of switch $P. S.$, in the same manner as was done on the loaded track. Lay the switch ties which are to be of the proper lengths, and tamp them. Set the frogs and connect them with the straight rails. Next stretch a string from the point of frog to the inside of the rail at point of switch, as $F'e$; divide this length into four equal parts, measure off the ordinates, and mark on the ties the distance from the string to the outside of the rail flange.

The middle ordinate equals $m = \frac{c^2}{8R}$, c being assumed as equal to the lead. The quarter ordinates are equal to three-fourths m. Spike the curve lead to these marks and then fix the other rail according to gauge. The most important point in laying a cross-over is to have the connecting rails tangent at the frogs. James R. Walthour,

Fairmont, W. Va.

Notes on Mines and Mining

Reports on Conditions and Other Matters of Interest in Various Coal Fields

By Special Correspondents

Rocky Mountain Coal Mining Institute.—The next meeting of the Rocky Mountain Coal Mining Institute will be held in Salt Lake City. A special train, consisting of a baggage coach, dining car and Pullmans, will leave Denver at 9 p. m., June 9, arriving at Rock Springs the following morning, where the day will be spent in viewing the most important properties, arriving in Salt Lake City on the morning of the 11th.

The Institute will hold a session at 10 a. m. The afternoon will be devoted to a trip to the Bingham copper properties. The morning of the 12th will be devoted to the Institute business, reading of papers, etc., and in the afternoon a visit to Salt Air will be made. The 13th will be devoted to any Institute business which may remain incomplete, to auto rides about Salt Lake City, and to a grand concert in the Tabernacle.

The party will leave Salt Lake City on the return journey, by way of the Denver & Rio Grande, sometime during the night of the 13th, and will stop over at one or more important coal properties on the return journey. It is proposed also to spend three or four hours in Glenwood Springs, to give the members an opportunity to indulge in bathing in one of the finest pools in the West. From this point will be a daylight ride through the Grand River Cañon and the Grand Cañon of the Eagle River, so that the beauties of this wonderful portion of the state may be seen by those who have not yet had the opportunity of traveling over the line in daylight.

PENNSYLVANIA

Pulverized coal, coke, and refuse is being used with success as a fuel in several metallurgical works. The coal is pulverized so fine that 98 per cent. of it will pass a 100-mesh sieve. It is introduced into the furnace through an air-blast pipe at about 1 foot from the pipe nozzle in such quantities that there will be four times as much air for combustion as theoretical conditions call for. If the method of feeding the coal is steady and regular the length of the flame is easily controlled. George E. Gay, Mining Engineer of Uniontown, Pa., has installed such a plant at Mt. Braddock, Pa., which is giving such satisfaction he considers it the acme of fuel economizers.

WEST VIRGINIA

The Workman's Compensation Law. The Workman's Compensation Law passed by the last legislature of West Virginia becomes effective October 1, 1913. It is to be administered by a commission appointed for that special purpose, of which the State Treasurer is custodian, and their salaries and expenses are to be paid from the state treasury. The law is available to any person or persons employing men for profit (except for domestic and agricultural purposes). The premiums are required to be computed on the gross pay roll for the preceding year, the assessments in no case to exceed $1 on each $100, 90 per cent. of this assessment is to be paid by the employer and 10 per cent. by the employe.

The benefits accruing from this fund are to be based on the average weekly wage of the employe. No benefits are allowed for one week after injury, except for nursing and hospital expenses, and any employe receiving benefits for a longer period than he is really entitled to them or in any way attempting to defraud the commission shall be liable to a fine of $500, or 12 months imprisonment, or both. The commission may, if deemed advisable by them, insure in any liability company doing business in the state any class or portion of the liabilities of the fund for any length of time desired and apply so much of the funds as is necessary toward the payment of premiums for such insurance. They also have the power of investigating all claims, and their decision shall be considered final, except in such cases where a claim is refused. The claimant may then apply to the Supreme Court of Appeals for a rehearing and if his plea be substantiated 30 days prior to a session of that court the case shall be placed on the docket for that term, the fees of the claimant's attorney to be fixed by the court and in no case to exceed $100. All costs of trial to be paid by the unsuccessful party to the suit.

The commission is obliged to make an annual detailed report to the Governor covering all claims paid, causes of accidents leading to the injuries meriting such awards, etc.

In compensating the employe for injury, the following regulations are made: Medical, nurse, and hospital expenses to the extent of $150 in addition to such award as the employe shall be entitled to and in case death ensues, funeral expenses not exceeding $75 are allowed.

In case of temporary disability, the employe is to receive, during such time, 50 per cent. of impairment of earning capacity, not in any case to exceed $8 per week nor to be less than $4 per week for a period of not more than 26 weeks, except in the case of loss of limb or eye, then the period shall be extended not to exceed 156 weeks.

In the event of permanent disability, compensation shall be 50 per cent. of average weekly wage, to be paid until death, but must not be more than $6 per week nor less than $3 per week.

If the injury be such that death ensues within 90 days, the following additional regulations are made: In the event of no surviving parents or dependents the disbursements shall include only medical nursing and funeral expenses. If the deceased be a minor, unmarried, and leave dependent parents, the father shall receive 50 per cent. of the average weekly wage of deceased, not to exceed $6 per week for the period between death and the time that the deceased would have been of age.

If deceased leaves a widow, her compensation shall be $20 per month until death or remarriage, and $5 per month additional for each child not old enough to be lawfully employed in any occupation, this to be paid until such child or children shall have attained such age, provided the total shall not exceed $35 per month.

If there be no widow, or dependent children surviving, partially dependent persons shall be imbursed to the extent of 50 per cent. of the average monthly support received from the deceased for the last 12 months preceding death, this to be continued so long as the commission deems necessary, not in any event to exceed 6 years in time or $20 per month in money.

All benefits before payment are exempt from any claims of creditors or attachments and any employer not availing himself of this law shall be liable to his employes, and in the event of legal proceedings shall be denied the defense of the fellow-servant rule, assumption of risk, or contributory negligence. And an employer subject to, and taking advantage of this law shall not be required to defend himself in damages at common law or statute in the event of injury or death to his employes.

Answers to Examination Questions

Questions Asked at the Examination for Mine Foreman and Assistant Foreman Held at Pottsville, Pa., March 25 and 26, 1913

Ques. 1.—(*a*) Are you a miner? (*b*) How long are you a miner? (*c*) Where did you mine coal, under what foreman did you work, and how long under each?

Ans.—To be answered according to the experience of each candidate.

Ques. 2.—What are the qualifications of a mine foreman, assistant mine foreman, and fire boss? What are the duties of these officials?

Ans.—The legal duties, qualifications, and duties are set out in the mine law. What may be called the moral and educational qualifications and duties have been discussed in this column within recent months.

Ques. 3.—In the matter of preventing accidents, are there any further responsibilities on the foreman and his assistant, after giving instructions to set a prop or take down some bad top? Explain fully.

Ans.—After issuing orders to take down bad top or to set props and having seen to it that the right kind, quality, and length of timber is on hand, there is little the foreman can do except to discharge any miner who wilfully risks his own life and that of his laborer by working in a dangerous place. General Rule 14, requires any one in charge of a place to keep it properly timbered and to permit no work in it except that necessary to make it safe. Rule 58 makes it "an offence against this act" to violate Rule 14 and all other rules. Article XVII, relating to penalties, provides that a person guilty of an "offence against this act" and in default of payment of "any penalty or cost" may be imprisoned for not less than 30 days nor more than 3 months.

Ques. 4.—There were 41.14 per cent. killed by falls of roof, slate, and coal during 1911; can you give any method by which these fatalities may be reduced?

Ans.—As to origin, accidents are commonly divided into two classes, avoidable and unavoidable. The first class are caused by carelessness or indifference, neglect of orders, etc., on the part of the victim or some one working with him, and in some comparatively few cases to ignorance. The statistics prepared by the Department of Mines, at Harrisburg, for the anthracite mines, show that carelessness, disobedience of orders, and the like were responsible for rather more than 2 out of every 3 fatalities from roof falls, for 7 out of every 10 accidents due to mine cars (Ques. 5), to 8 out of every 10 accidents due to handling explosives (Ques. 6), and for 9 out of every 10 deaths due to gas (Ques. 7). Dividing these further, about 1 in each 50 is due to ignorance and 49 in 50 to carelessness, etc. The small number of accidents due to ignorance may be diminished by personal instruction given to the men at the face, attendance at night school, the placing of the incompetent with the competent in a breast until the former have learned their duties, etc. All these methods have been tried and are being tried by the companies and with great success. But it does not seem possible to reduce the terrible number of accidents due to carelessness and disobedience of positive orders. It is impossible to have a foreman over every worker all the time to see that he does not do things that his own intelligence tells him are wrong. Just as long as men in order to save a little time or work will jump on moving trips, will go back on a hung shot, will load out one more car before fixing the top, will not bother to light their safety before going to work, etc., etc., and just so long as men lightly value their own lives and those of their fellow workers and disregard the happiness and the welfare of their families, just so long will the list of avoidable accidents be as great as now. The mine foreman can do nothing but argue, or discharge if the man is caught in the act. An arrest might be made as explained in the answer to Ques. 3, but it is highly improbable that a conviction would follow.

Of the deaths due to roof falls, some 30 per cent. are classed as unavoidable, which merely means that they are not due to carelessness on the part of the victim. In some instances they are due to the mine foreman setting men to work in places which have not been made safe, to the failure to provide suitable timber, to poor systems of timbering, but there are always some that could not have been foreseen and, hence, are really unavoidable. A uniform system of timbering will go a long way toward diminishing the number of unavoidable(?) accidents due to roof falls and will materially reduce the avoidable accidents due to the same cause. In this system of timbering, known as systematic timbering, posts are set at regular intervals apart, and are actually set at those distances, whether the roof at that particular place and time appears to need support or not. The size of these props and their distance apart should be determined by the foreman to suit local conditions. In addition to this, during times of particular danger, as during pillar drawing, the approach of a squeeze, etc., more frequent visits should be made by the foreman to the working places that he may give the miner the benefit of his greater experience.

Ques. 5.—There were 14.96 per cent. killed by mine cars in the anthracite coal region in 1911; what method would you adopt to avoid these accidents?

Ans.—In regard to diminishing the 70 per cent. due to carelessness (see answer to Ques. 4), the remaining 30 per cent., classed as unavoidable, may be largely reduced if separate traveling ways are provided and these are kept in good condition. Those gangways upon which traveling must be done should be well ditched, cleaned, and drained, should have at least 2½ feet clearance between the car and the rib, and should be provided with a series of safety holes in the rib at regular intervals, which holes should be whitewashed as often as they begin to discolor and should be kept clear of rubbish.

Ques. 6.—There were 14.31 per cent. killed in the anthracite coal region by premature blasts and reckless handling of explosives in 1911; what method would you adopt as foreman to reduce these fatalities?

Ans.—In regard to diminishing the more than 80 per cent. due to carelessness (see answer to Ques. 4), the remaining 20 per cent., or less, may be diminished by the use of first-class brands of powder only, by the use of permissible powders such as have passed the tests of the Bureau of Mines, by the introduction of proper devices for thawing frozen dynamite, by the introduction of electric shot-firing systems, and in general and as far as possible having all handling of explosives done by men skilled in their use.

Ques. 7.—There were 5.53 per cent. killed in the anthracite coal region by explosions of gas in 1911; what method would you adopt to reduce these accidents?

Ans.—In regard to reducing the more than 90 per cent. due to carelessness (see answer to Ques. 4), of the remaining 10 per cent., probably

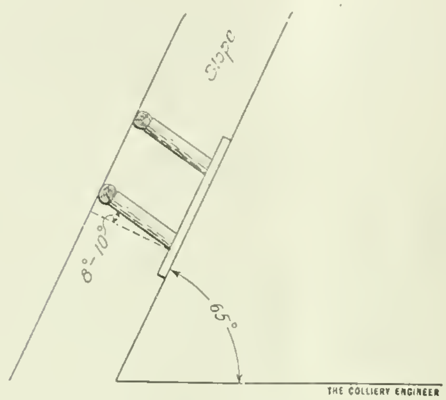

Fig. 1

a greater proportion of these are really unavoidable than in the case of accidents due to almost any other cause. Gas is invisible and concealed in the pores of the coal, and it is impossible to foretell when a pocket or blower will be encountered. Something may be done by improved ventilation in those mines where this is neglected, and in others by more carefully and thoroughly conveying the air to the face.

Ques. 8.—How would you timber a slope, dip 65 degrees, with a good top and a bad bottom, vein 10 feet thick? State at what angle you would set the timber.

Ans.—As the top is good, it may only require an occasional support. As the floor is soft this post cannot be stood upon it nor can two posts be used in the ordinary way as legs to support a collar. If the roof in the center of the slope needs support, a cross-bar must be used. This may be set in hitches in the coal, may be supported upon two short legs set in the coal, or a complete framed set may be used. The legs should have an inclination up hill of some 8 to 10 degrees from the normal, that is, should be set with a pitch of 57 to 55 degrees, in order to resist the tendency of the roof to slip down hill as shown in Fig. 1.

In regard to the bottom, or mudsills, these may extend across the slope at right angles thereto in the usual way, or they may be set parallel to the dip, one sill serving as a support to several legs. The chief trouble here is not so much from roof falls as from a possible creep. The slope should be driven as narrow as possible and very wide pillars should be left on either side between it and the first breast, so that a squeeze from the workings may not ride over and close the slope.

Ques. 9.—State where the air-current should be measured, when and by whom, and how you would proceed to measure it?

Ans.—These measurements are to be made once each week by the mine foreman or his assistant at (1) the mouth of the intake and return airways; (2) at or near the face of each gangway, and (3) at the nearest cross-heading to the face of the inside and outside breast where men are working. The quantities of air in circulation are measured by an anemometer or other approved means and the quantities found in circulation are to be entered in the colliery report book. The use of the anemometer has been described several times recently in these columns.

Ques. 10.—What are the requirements of the mine law in regard to explosives? (a) Care of explosives? (b) How should they be handled? (c) How should they be kept in mines? (d) What are the rules governing their strength? (e) How would you thaw dynamite?

Ans.—The principal question and subquestions (a), (b), and (c), are so plainly stated in the law that they need not be repeated here. (d) We are unable to find anything in the present anthracite mine law regulating the strength of explosives. (e) The mine law does not treat of the methods to be used in thawing dynamite. Small quantities may be packed in fresh manure until softened, or the stick may be placed in a dinner bucket which in turn is placed inside a larger kettleful of water, which is heated to 130° to 150° by being placed on a hot stone, a radiator, etc. The temperature may be estimated by the hand or better by a thermometer which may be of the cheapest. In event that a large amount of explosive has to be thawed, a "thaw house" is necessary. This is a small frame building, with the sides banked with earth or manure and heated by steam. Shelves are built around the house upon which several days' supply of explosive may be stored and where is should be kept 2 or 3 days at a comparatively low temperature.

Ques. 11.—What is the maximum velocity of air allowed by law and why is the speed limited?

Ans.—The speed of the air-current is limited to 450 feet per minute in all places except on the main intake and return, where gauze safety lamps are used, because at a higher velocity there is danger of the flame being blown through the meshes of the gauze and igniting any gas that may be present.

Ques. 12.—What does the mine law require when you are approaching abandoned workings likely to be filled with water? How would you drive a breast to comply with the law? Explain fully.

Ans.—The law requires that the place be not over 12 feet in width, and that there shall be constantly kept at a distance of not less than 20 feet in advance of the face at least one bore hole near the center of the working and sufficient flank bore holes on each side. Such a breast is shown in Fig. 2. One hole is driven from the center of the face and other ones from each corner. Side holes are driven at points back of the face to make sure that the narrow breast is not being driven up through the center of a pillar.

Ques. 13.—Are there any conditions where the mine law requires a working man to make a report; if so, what are the conditions and to whom is the report made?

Ans.—This is fully answered in General Rule 24.

Ques. 14.—Under what condition does the law require the workmen to be removed from the mine?

Ans.—This is fully answered in General Rule 8.

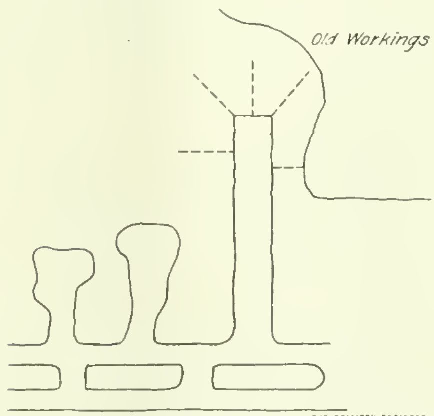

Fig. 2

Ques. 15.—What are the requirements of the mine law with regard to doors in the mine?

Ans.—This has been modified by the legislature to a slight extent. As the law now stands all doors must be so hung that they will close automatically; that is, they shall open against the current, so that they may blow shut. That all doors, except such self-acting doors as have been approved by the district mine inspector, shall have an attendant to open and close them. That all main doors must be so placed that when one is open the other is closed; that is, doors must be in pairs if on any main airway, only one of them being allowed to be open at one time. An extra main door or safety door must be provided and kept standing open in such a position as to be out of harm's way, but fixed in such a manner that it can be closed at once if either main door gets out of order or is broken. All main doors shall be set in stone or brick frames which shall be laid in mortar or cement; but the district mine inspector may permit, in writing, other methods of hanging them.

Ques. 16.—How does the mine law provide for an employe to learn its rules and provisions?

Ans.—According to General Rule 54 an abstract of them and the act of the legislature making them must be posted in one or more convenient and conspicuous places near the mine. The rules must be printed in plain type and as soon as worn so that they can no longer be easily read or are destroyed, they must be replaced by a new set. It is a misdemeanor to damage a set of rules.

Ques. 17.—Why is ventilation necessary?

Ans.—The ventilation of a mine, that is, the continuous supply of fresh air from the outside and its conveyance through the workings, is necessary to dilute and thus render harmless and to carry away all impure, poisonous, and explosive gases given off by reason of operating the mine. These gases originate from (*a*) the breathing and perspiration of men and animals, (*b*) the burning of oil in lamps, the burning of powder, gas, coal gob, or any other combustible substance, (*c*) the slow combustion or oxidation and decomposition of timber, animal matter, iron pyrites, and other minerals, and the coal itself, and (*d*) from the pores of the coal or from blowers, feeders, or bleeders. To these might be added various afterdamps due to explosions.

Ques. 18.—The anemometer makes 120 revolutions per minute in an airway that measures 8 feet 6 inches at top, 10 feet 6 inches at the bottom, and 7 feet high. What quantity of air is passing?

Ans.—The area of the airway is found by multiplying its height by its average width, thus, Area $=\frac{8.5+10.5}{2}\times 7=9.5\times 7=66.5$ square feet. The volume of air passing is equal to the area of the airway multiplied by the velocity of air in feet per minute as measured by the anemometer, in this case 120 feet, as the instrument makes 120 revolutions a minute. Hence, volume = area $\times$ velocity $=66.5\times 120=7{,}980$ cubic feet per minute.

QUES. 19.—If the current in an airway 6 feet square is maintained with a 1-inch water gauge, what pressure per square foot is required if the same quantity is passing through an airway 5 feet square, the two being of the same length?

ANS.— 1 inch of water gauge is equivalent to a pressure of 5.2 pounds per square foot. In terms of the length, perimeter, quantity, and area, the pressure in the larger airway is $P=\frac{k\,l\,O\,q^2}{A^3}$, and in the smaller airway is, $p=\frac{k\,l\,o\,q^2}{a^3}$. Since the coefficient of friction (k), length(l) and quantity (q) are the same in both airways we have for the ratio between the pressures, $P:p=\frac{O}{A^3}:\frac{o}{a^3}$, or $p=P\times\frac{o}{O}\times\left(\frac{A^3}{a^3}\right)$. The perimeter of the larger airway is $O=4\times 6=24$ feet and its area $A=6\times 6=36$ square feet. The perimeter of the smaller airway is $o=4\times 5=20$ feet and its area is $5\times 5=25$ square feet. Substituting, $p=5.2\times\frac{20}{24}\times\left(\frac{36^3}{25^3}\right)=5.2\times\frac{20}{24}\times\frac{46{,}656}{15{,}625}$ $=5.2\times 2.488=12.9376$ pounds per square feet. This is equal to a water gauge of 2.488, or, say, 2.5 inches.

QUES. 20.—If a water gauge registering 2 inches passes 15,000 cubic feet per minute what quantity will an 8-inch water gauge pass per minute?

ANS.—The quantities passed are proportional to the square root of the ratio of the water gauges. Thus, if the greater water gauge and quantity are I and Q, and the lesser water gauge and quantity are i and q, $Q=q\sqrt{\frac{I}{i}}=15{,}000\sqrt{\frac{8}{2}}=15{,}000\times 2$ $=30{,}000$ cubic feet.

QUES. 21.—Which should be the largest, the inlet airway or the outlet, and why?

ANS.—The outlet airway should be the larger, because the volume of air leaving a mine is generally greater than that entering it. This increase in volume is chiefly due to the expansion of the air brought about by the mine generally being warmer than the outside air. As the average temperature of the United States is about 50° and the average mine temperature is, say, 65°, during the fall, winter, and spring months the outside air will usually be colder than the mine and, hence, will be expanded, but in the summer it will be warmer than the mine and will be contracted in volume. On the other hand, the gases given off by the operation of mining from the causes given in the answer to Ques. 17, will of course add to the volume of the air regardless of the difference between the inside and outside temperatures.

FIG. 3

QUES. 22.—A mine has openings, one 200 feet higher than the other at the surface, the outside temperature being 80° F. and the inside temperature 45° F.; in what direction will the current flow and why?

ANS.—As the weight of a given volume of air at 45° is greater than that of the same volume of air at 80°, the flow will be by way of the higher opening through the mine and out the lower opening as shown in Fig. 3. The pressure producing the ventilation may be found from the formula

$$p=1.324\,B\,D\,\frac{T-t}{(460+t)(460+T)},$$

in which

B = the pressure of the barometer which may be taken as 30 inches;

D = the depth of the downcast = 200 feet;

t = the temperature of the downcast = 45°;

T = the temperature of the outside air = 80°.

Making the necessary substitutions, we have, $p=1.324\times 30\times 200\times\frac{80-45}{(460+45)(460+80)}=1.02$ pounds approximately.

QUES. 23.—In what proportion is the friction of air increased compared with the velocity of the current?

ANS.—The friction increases in proportion to the square of the velocity; thus, if the velocity is doubled, the friction is increased four times.

QUES. 24.—What method of ventilation reduces the danger of explosion, also the friction.

ANS.—These results may be accomplished by what is known as splitting the air-current; that is, instead of taking the air in one continuous current throughout the mine, each district of the mine is ventilated by a separate branch of the main current known as a split. In this way, with the same power applied to the fan, the quantity of air in circulation is increased in proportion to the number of splits and thus more air being supplied, there is less liability to explosion. As there is less rubbing surface there will be, of course, less friction.

QUES. 25.—What are the four principal gases found in coal mines, what are their specific gravities and where are they found?

ANS.—The principal gases met in mines are nitrogen, oxygen, methane, and carbon dioxide. Nitrogen, specific gravity .971, forms about four-fifths of the air and is, consequently, found everywhere throughout the mine. Oxygen, specific gravity, 1.106 forms about one-fifth of the air and like nitrogen is found throughout the mine. Methane, specific gravity, .559 is given off by the coal in most anthracite mines, and being much lighter than air is commonly found near the roof of flat workings and at the face of those driven to the rise. Carbon dioxide, specific gravity, 1.529, being much heavier than air is usually found near the floor of flat workings and at the face of those driven to the dip.

(To be Continued)

Use of High Explosives in Northern Mines

*F. H. Gunsolus**

It would seem that the miners in cold countries would not encounter many problems of different character from those met with elsewhere in the use of high explosives, and to a certain extent this is true. On the other hand, there are certain conditions which those who use explosives in high latitudes encounter which require certain precautions not needed where temperatures do not reach such a low point.

One of these conditions is known as the "sweating" of dynamite. When a shipment of a carload of dynamite is made from a factory to a mine in the middle of winter, it frequently takes 2 weeks or more to travel to its destination, during which time it is exposed to zero weather for several days at a time, and is not only frozen but remains very cold for a considerable time after it is moved to a warmer temperature either in the mine or in the thawing house.

Dynamite itself is a very poor conductor of heat, and by placing an open box in a room having a temperature of say 60° F. it takes quite a long time for the outer portions of the dynamite to thaw, while the explosive in the middle of the box remains frozen and cold for a very long time, just as though it were packed in sawdust, which it really is. A great many mining companies thaw their dynamite by no artificial heat, merely taking it down into the mine and storing it in underground magazines and allowing it to thaw either in the boxes or by opening the cases and spreading the dynamite out. When the dynamite is received after having been exposed to zero temperature for several days, it is, of course, very cold and the moisture from the humid mine is deposited upon it in large quantities. Sometimes so much moisture gets into the dynamite in this way as to not only lower its sensitiveness, but also to make it very much less efficient and cause misfires, blow-outs, and burned-up charges, which are dangerous, inconvenient, and disagreeable.

This may also apply to the blasting caps, which are even more susceptible to moisture than the high explosives, from the fact that they are exposed at one end and that end is the one where they are ignited. If you take a blasting cap from a temperature of zero down into a hot, humid mine and leave it several days, it will frequently absorb so much moisture that either the fuse will not explode it at all, or if it does, it will be so weakened that only a partial detonation of the dynamite will take place, or it may only set fire to the dynamite, causing a burned-out charge.

The remedy for both these conditions is simple enough. When the weather has been cold during the transportation of the dynamite, the dynamite should not be taken directly into the mine but should be kept on the surface long enough for it to warm up so that moisture will not be deposited upon it. The blasting caps themselves do not require thawing, of course, but underground storage is certainly not to be recommended for them, both on the grounds of the possible loss of efficiency and on account of the danger of carrying such caps around in the mine in any quantity over and above what is actually required at the time. So many accidents happen to women and children due to miners carrying blasting caps around loose in their pockets and being found by children in the miners' homes, that a considerable amount of care in preventing the taking of these away from the work is well worth the trouble.

In thawing the dynamite it is much better to warm it gradually, say for several days at a temperature of 70° F. or 80° F. than to attempt to thaw it quickly in a few hours at a temperature of 100° F. or over. Not only does the high temperature increase the sensitiveness of the dynamite, but it also makes the nitroglycerine less viscous and more likely to leak and run out of the cases, and leaky dynamite and leaky nitroglycerine are dangerous things to have anywhere.

The gelatin dynamites do not become affected by moisture as readily as the granular dynamites, and this is a great advantage in their use where there are low temperatures outside and high humidity and water underground.

Even the fuse requires a little attention when used in northern mines, as it becomes brittle and hard when very cold and when uncoiled in this condition the waterproofing compounds will crack underneath the outer covering, so that they cannot readily be seen but these cracks will admit moisture or water and will also cause the fuse to spit out sideways and render it liable to ignite the dynamite and cause burned-out charges again. It is frequently necessary to lead the fuse down toward the bottom of the charge in cases where there is liability of blowing off the collar of one hole from the explosion of another timed to take place before it. When the fuse travels down the bore hole alongside the powder, if the later is taken out of its wrappers or split or the paper shells slit, the liability of ignition is very much increased. In these cases it is preferable not to remove the powder from its wrappers nor to slit it but to load it in its paper covering entire. It is almost impossible to ignite dynamite from the side spit of the fuse through the paper wrapper. Fuse should not be exposed to high temperatures for any length of time, as this sometimes causes the waterproofing composition to melt and run into the powder train and make the fuse go out. The temperature of 70° F. or 80° F. should be maintained where fuse is stored in large quantities. It should not be stored in humid mines at all, as the powder will absorb enough of moisture at the ends and in the sides in a few days to make its burning through rather uncertain.

* E. I. du Pont de Nemours Powder Co.

NEW MINING MACHINERY

Langerfeld Coal and Slate Separator

*By Arthur Langerfeld**

The cleaning of the coal in the Spencer breaker, in Dunmore, was recently changed from hand picking to mechanical separation, and all the for the time during which no coal comes into the breaker and for the time during which coal does not come to the full capacity of the machines. The actual output of clean coal depends therefore on the quality of the coal fed in, and on the size and only 2 or 3 per cent. of salable bone.

The separation of valuable bony coal is an economy, because it increases the car average or quantity of salable coal obtained per mine car dumped in the breaker. This econ-

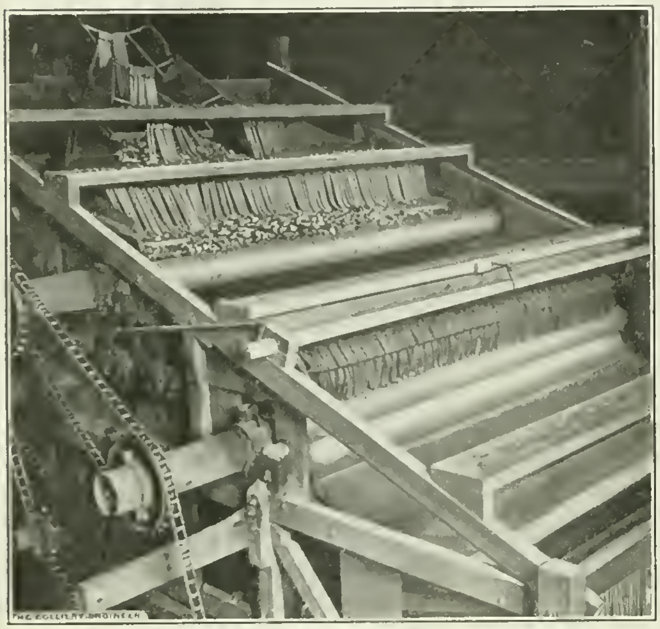

Fig. 1. Top of Langerfeld Coal Separator

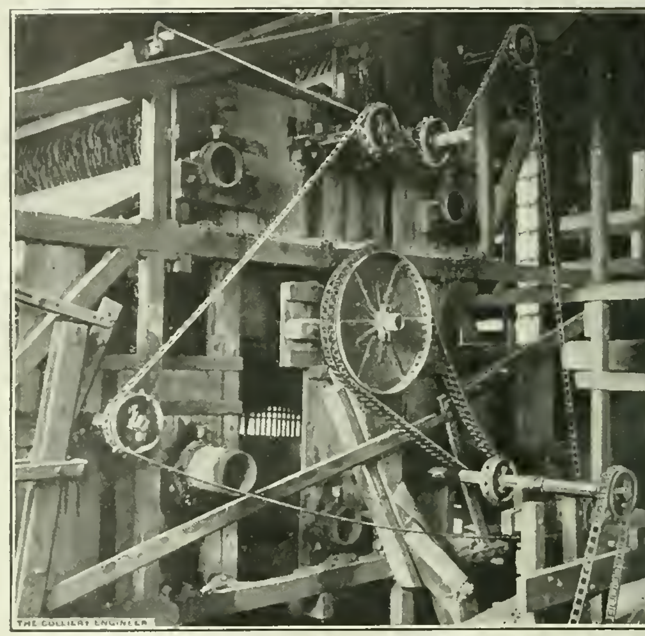

Fig. 2. Driving Gear of Langerfeld Separator

stove, chestnut, and pea coals are now cleaned entirely by Langerfeld separators. There is only a small quantity of egg coal made at this colliery and therefore no machine for this size was installed. There are two sets of these separators. Each set consists of three machines; one stove coal separator of 200 tons capacity, one chestnut separator of 200 tons capacity, and one pea coal separator of 100 tons capacity. The capacity of each set being 500 tons, the intake capacity in 9 hours of steady running while feeding to full capacity is about 1,000 tons. The output of clean coal would therefore be 1,000 tons, less the refuse deducted from the intake capacity, besides the allowance made time during which the machines are fed to full capacity. The economy that has been effected by the installation of these separators was not only the wages of the boys who were employed to pick slate by hand, but also a saving of the salable bone and coal that was formerly sent to the dump with the slate. This double saving is brought about because these machines are adjustable and they make a four-part separation; viz., coal clean enough to pass inspection; bone with little coal of the size and very little slate, suitable for reducing to one size smaller; slate or bad bone with hardly any coal of the size and with very little rock, suitable for reducing two sizes smaller; and rock with only about 1 per cent. of coal of the omy is brought about by running separated bony coal to rolls set to reduce it to the next smaller size, and then running this broken bone back in the screens together with the run of mine. This increases the quantity of material going to the separators and reduces the quantity going to the refuse dump. Ordinarily this process would make the cleaning of the coal too difficult because the quantity to be cleaned is not only increased, but it is also made dirtier, and especially high in bone. Bone is far more difficult to separate from coal than slate, and coal is condemned for too much bone as well as for too much slate. The standard specifications provide that stove coal must not contain over 3 per cent. of bone if there is 4 per

*Scranton, Pa.

cent. of slate in it, and it is customary to allow 2 per cent. more of bone for each 1 per cent. of slate there is in it less than the 4 per cent. allowed; therefore, in case there is no slate at all, there could be 11 per cent. of bone. The standard limitation for chestnut is 5 per cent. slate and 5 per cent. bone; and it is similarly customary to allow 2 per cent. bone for every 1 per cent. slate below 5 per cent., so that in chestnut containing no slate there could be 15 per cent. bone. For pea coal there is no provision for the bone allowed, and allowance of slate is 10 per cent. It is customary to also allow about 10 per cent. bone in this size so that in case there is no slate in the car of pea coal, it would be allowable to contain 30 per cent. bone. In practice there is seldom less than 5 per cent. slate in pea coal, so that 20 per cent. bone is the limit in this case.

Much of the anthracite now sold is paid for on the heat unit basis; that is, the number of British thermal units it contains.

It is said that some bone actually gives more heat than some coal. The peculiar construction of the Langerfeld separators classifies this kind of bone as coal, by reason not only of the gravity of the pieces fed in but also by the difference in frictional resistance, which has been found to be almost exactly in proportion to the percentage of carbon in the coal or bone. This classifies the pieces at their heat-giving value rather than by their appearance or gravity, and makes this kind of separation economical both for the coal company and for the public.

These separators contain seven different parts, and as each part has a definite function it can be adjusted to do its work without materially interfering with any of the other parts. The first part separates the material into two streams, one containing the largest and thickest pieces, the other containing the smallest and thinnest pieces, thus the first step in the process is not a separation by quality but by thickness. This first step or classification differentiates in quality, because most slate is thin or flat and most of the coal is thick or lump shaped; but there are some seams from which the coal splits as thin as slate, and for this reason a separation depending only on the difference in thickness is unreliable and not economical. The next two parts in the separator feed the two streams of material piece by piece, into frictional differentiators. The feeders are the most novel feature in the separator, as they feed each piece separately, spaced apart both lengthwise of the machine and crosswise, so that no collision takes place between pieces as they slide down on the differentiating slides. In all other separators or pickers the coal is fed either in dashes or in a continuous stream, so that the pieces collide and interfere with each other in their separation and spoil results to that extent.

The first separation is made in two parts of the machine. In one all the lump-shaped pieces of coal are taken out, and in the other the best pieces of flat coal. What is left in the separator after this first separation is one lot of lump-shaped rough coal, bone, and rock, and one lot of small or flat pieces of rough coal, bone, and slate. Each one of the two classes is then fed into the system of differentiators, consisting of two reverse slides and an intermediate inverter so arranged that each piece slides first on one of its sides and then on its opposite side. In this way each piece acquires a velocity in proportion to the average quality of two of its sides and therefore is separated with twice the accuracy that can be attained in any of the other ways used in pickers or separators. This makes it possible to make a good bone separation, and in this part of the machine both rough coal and most of the bone are separated. What is left is a mixture of some lump-shaped rough coal, some bone, and nearly all of the rock, in one part, and some small or flat rough coal, some bone, and nearly all of the slate in the other part. In the next two parts of the separator each one of these classes is again fed to differentiators and only the worthless rock and slate are taken out. The remainder of the materials may be classed as bone, or they can be fed back into the separator for a still better distribution. The quantity of this bony mixture is so small a part of the entire material that, if refed, it does not materially reduce the intake capacity. It has been suggested that such refeeding would cause accumulation, but in practice this is true only to a small and limited extent, because from it a piece goes through the separator a second time and the chances are that it will come out in one of the eight discharges. In this way hardly any of the salable stove coal bone is lost, but goes to the rolls to make chestnut. Nor does any considerable quantity of chestnut size bone go to the dump, because it goes to the rolls to make pea; but pea size bone may be burned at the colliery or go to the buckwheat rolls, and finally go to the pockets for a smaller size. Results have proven that these separators pay for themselves in a short time. Nor is their cost any greater than first cost of as many separators, pickers, or jigs, as would be required to handle the same quantities, and give anywhere near the same results.

Another economy was effected in this breaker by saving the expense of loading and hauling slate or refuse, there being no slate pockets. The six separators are set in line and a conveyer runs under them the full length of the breaker. All of the separated refuse drops into this conveyer and is taken out by it to an elevator. From the head of this elevator the refuse runs down a chute to the dump.

The only attention that is given to the separators is to set them for wet and dry coal and to adjust them so that the coal will be clean enough.

The cost of cleaning coal by these separators is less than 1 cent per ton for dry coal, including allowance for repairs; but in wet breakers the cost is somewhat higher, because the water adhering to wet coal contains some acid which corrodes the metal parts of the machines.

The room required for these separators is less than was heretofore required for picking chutes for boys, or for as many jigs or other pickers as are needed for the same tonnage.

Steam Hammers

Of the labor-saving machines, none is of greater convenience than a steam hammer with which to do much of the blacksmith work formerly done by men with sledges.

Fig. 1 shows a "Bell," steel-frame, "combined" steam hammer made by the Buffalo Foundry and Machine Co., which has features that especially adapt it to the various needs of a mine repair shop.

The main frame is an open-hearth steel casting. The bedplate part is of ample surface, flush on the bottom, and extending up from this heavy part is the square-shaped anvil block with dovetail slot finished in it into which is keyed the lower die. This anvil block part is set so as to bring the dies at a 45-degree angle with the main frame casting, so that long work will clear the column both ways of the die and for the full size of die face. There is a hole cored in the center of the anvil block, so that longer work may be placed in this hole when it is desired to upset it. Extending up from the bedplate at the back corner of the anvil block is the column, which is of heavy I-beam construction. Extending out from this column is the heavy section which forms the faces to which the slides or guides are bolted. This section, tapering in above the slides and the column, extends up to the projecting flange to which the cylinder is bolted. The metal throughout is carefully proportioned to resist the shock of hammering and the many shearing strains. Experience has proved that there is no breakage due to the main frame being in one piece with the anvil block, when made of steel.

The cylinder casting is in one piece with piston and throttle-valve chests, has extra heavy flanges, top and bottom, which latter is reinforced by heavy vertical ribs. The cylinder is dowel pinned and through bolted to the main frame with fitted bolts in reamed holes. The exhaust outlet being lower than the bottom of the cylinder, there is automatic drainage of water from condensation from the cylinder thus preventing damage by freezing.

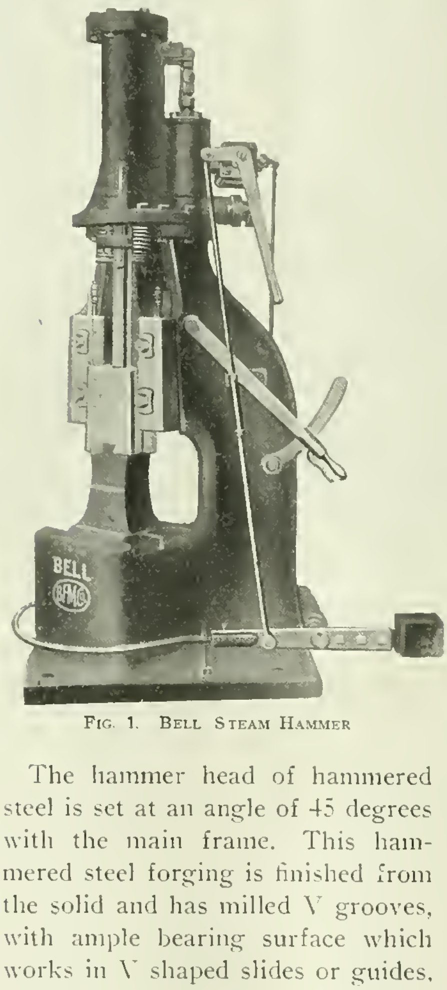

Fig. 1. Bell Steam Hammer

The hammer head of hammered steel is set at an angle of 45 degrees with the main frame. This hammered steel forging is finished from the solid and has milled V grooves, with ample bearing surface which works in V shaped slides or guides, which are bolted with through bolts and spring washers to the main frame. The guides are made adjustable by a taper gib, to take up the wear between them and the hammer head or ram. Into the taper hole bored in the hammer head is fitted the lower end of the piston rod. The jam of this taper constitutes the real holding of the rod in place. The piston rod is a solid steel forging with the piston head forged solid thereon, and into the piston part are fitted weldless forged-steel snap piston packing rings. By removing the buffer springs and piston-rod gland, which is in halves bolted together, the falling parts can be raised without disconnecting, so that the piston will project above top of cylinder to permit of the examination of the piston rings or the inserting of new ones. At the bottom of the tapering V slot in back of the hammer head is planed a taper dovetail slot into which is inserted the cam-plate or wearing strip. This plate has a corresponding taper dovetail projection to fit the slot and is securely held in the dovetail slot by the jam of the taper. The width of this plate corresponds to the width of the bearing face of the cam. This construction is a valuable improvement and does away with the necessity of making repairs in an inaccessible place, to any rivets or screws which are commonly used in other constructions. It is now a very simple matter to drive the cam-plate up out of the slot if repairs or renewals become necessary.

The valve motion is extremely simple, with few working parts, carefully fitted to give very accurate and sensitive control to the blow and not connected except by sliding contact with the hammer head. It is free from all shock or jar of the blow, takes up its own wear, is of the most durable and efficient construction, and requires no attention except for proper lubrication. The downward movement of the valve is by gravity alone. It is moved up by the thrust of a bevel slot in the hammer head against the cam.

In operation the cylinder takes steam at top and bottom of stroke, through ports arranged to give the maximum force of blow. Perfect control is maintained by the operator for doing work requiring hand operation, or continuously sustained automatic action may be obtained with close and sensitive regulation by the throttle valve through the foot-treadle connection.

These hammers are rated entirely by the actual scale weight of the falling parts, no consideration being given to the added force of blow from steam or air pressure on top of the piston.

Recently a carload of 300-pound hammers of this style was shipped to the Philadelphia & Reading Coal and Iron Co., at Pottsville, Pa., and the manufacturers state that many of them are in use in other mining regions.

Mining Machinery Exhibit

An Industrial Exposition was held at Wilkes-Barre, Pa., May 10 to 17, at which, among the many exhibits of the business interests of the city, machinery relating to mining naturally occupied a prominent place.

One of the most striking of these was that of the Howells Mining Drill Co., of Plymouth, Pa., who showed drills of various types for boring coal, salt, rock, etc., one of them in operation on a 10,000-pound lump of anthracite which was taken from the Woodward mine, of the D. L. & W. Co. Electric power was in use to operate the drill and the cuttings together with the "Great Nubian Mystery" were given away as souvenirs. The recipients surely will understand the meaning of "black art."

The Hazard Mfg. Co. had an exhibit showing the process of manufacture of insulated cables from the raw rubber to the finished cable.

The Vulcan Iron Works had a steam locomotive, such as is used about mines, mounted so that the wheels could revolve, and also a miniature one about 2 feet long; both of these attracted much attention.

The W. H. Nicholson Co. exhibited sections and models of the Wyoming steam trap and Wyoming eliminator which showed plainly the manner in which they operate. Also a number of other of their specialties were shown. The Star Electric Fuze Works showed blasting fuse and batteries.

A mining exhibit was made jointly by the Lehigh and Wilkes-Barre Coal Co., the Lehigh Valley Coal Co., the Susquehanna Coal Co., The Delaware and Hudson Coal Co. and the D. L. & W. Co. In this was a timbered heading showing the coal face and loaded car. Next to this was a Goodman electric mining machine and other machinery used in the preparation and handling of anthracite. There was also a First-Aid booth in which the use of oxygen helmets and other apparatus was demonstrated.

Goulds Triplex Mine Pumps

A Goulds electrically driven triplex mine pump was used at the Flatbush and Third Avenue, Brooklyn, part of the Catskill aqueduct, is shown in Fig. 1. This is one of eight pumps of this type used in the Holbrook, Cabot & Rollins contract, extending from Cooper Square, New York, a distance of 5 miles into Brooklyn.

This pump is situated 500 feet below the surface and has a capacity of 300 gallons per minute. The pumps are driven by two-phase, 50-cycle, General Electric induction motors, and replaces air lifts which were first tried at this station.

Two of the pumps have a capacity of 300 gallons per minute and are 8 in. × 10 in. in size; six have a capacity of 100 gallons and are 5 in. × 8 in. in size. On the Mason & Hanger contract, at Cornwall-on-the-Hudson, there is a 7 in. × 12 in. Goulds triplex pump direct-connected to a 50-horsepower motor in use, and two Goulds belt-driven triplex pumps, size 5 in. × 8 in. These pumps seem to be giving general satisfaction where used.

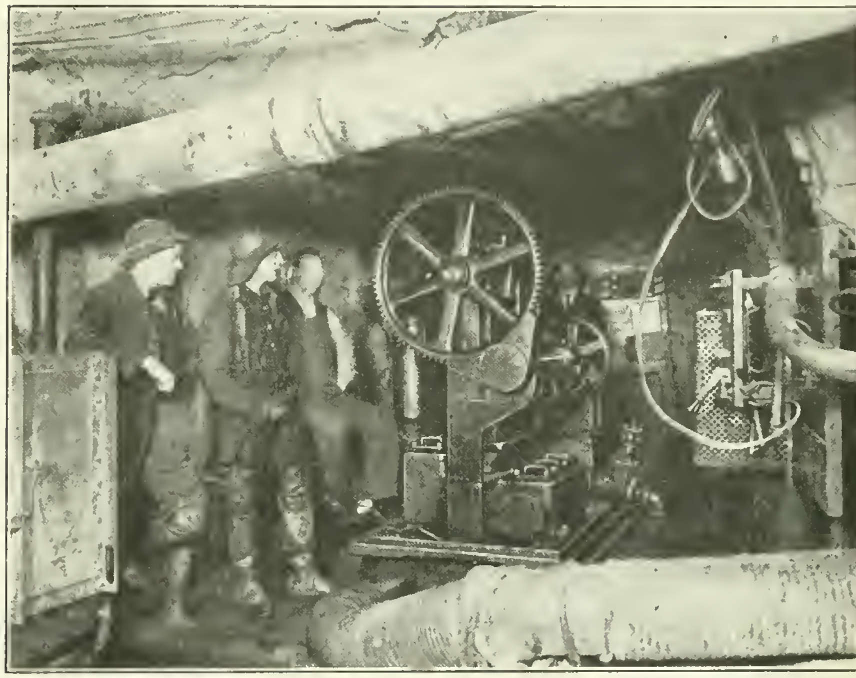

Fig. 1. Goulds' Triplex Pump Used Underground on Catskill Aqueduct

TRADE NOTICES

Matheson Joint Pipe.—National Tube Co. has issued a new edition of the Matheson Joint Pipe Booklet. This book contains 40 pages and numerous illustrations showing scenes where the Matheson Joint Pipe is being installed. The various advantages of this pipe are enumerated in the text and several new values are brought out. The duo-tone illustrations are especially good. Address National Tube Co., Pittsburg, Pa.

Removal.—The Orenstein-Arthur Koppel Co. have removed their general offices to the new office building at Koppel, Beaver County, Pa. according to plans mentioned in this department some months ago.

New Type of Jigs.—Cory & Co., who have offices in the Oliver Building, Pittsburg, Pa., and are designers and contractors for coal washing plants, are placing on the market jigs of the submerged-displacement type, which are considered a notable advancement in coal washing practice.

New Office.—The Exeter Machine Works, of Pittston, Pa., manufacturers of elevating and conveying machinery and hoists, have opened an office in Pittsburg, at 945 Oliver Building. This will be in charge of Mr. T. C. Webb.

Westfalia Rescue Apparatus.—S. F. Hayward & Co., 39 Park Place, New York City, announce that they are now the exclusive American agents for the complete line of Westfalia mine rescue apparatus and oxygen reviving apparatus, formerly sold by the Westfalia Engineering Co., of 42 Broadway, New York, and will carry a complete stock of all the different types and spare parts for the Westfalia apparatus, insuring prompt delivery of all orders for new apparatus and immediate shipment of repair parts.

Trade Press Convention.—President H. M. Swetland of the Federation of Trade Press Associations in the United States, has announced that the eighth annual convention will be held at the Hotel Astor, New York, September 18 to 20, 1913. The Federation includes the New York Trade Press Association, the New England Trade Press Association, the Chicago Trade Press Association, the St. Louis-Southwestern Trade Press Association, the Philadelphia Trade Press Association, and a number of unaffiliated publications, the total membership being 236, representing over 75 different trades, industries, and professions.

President Swetland has appointed as chairman of the committee on arrangements, William H. Ukers, who was largely responsible for the highly successful grocery-trade press convention held at the Hotel McAlpin, New York, last January. Mr. Ukers is arranging a program for the Federation Convention which will provide papers and addresses on topics of interest to manufacturers, sales managers, and advertising men, as well as to trade-paper editors and publishers.

Two sessions will be held daily. There will be editorial, circulation, advertising, and publishing symposiums, under competent leaders. Many of the leading editors, business managers, buyers, and sellers of advertising and authorities on modern merchandizing methods will take part.

On Friday afternoon, September 19, there will be a mass meeting with addresses by representative business and professional men, on subjects of timely interest to editors, publishers, and advertisers Distinguished guests and worth-while speakers will be at the annual banquet, which will be made a memorable social occasion.

Invitations are being extended to manufacturers, sales managers, advertising men, trade-paper publishers, and all others interested in the idea of business promotion through trade-press efficiency, which is to be featured at the convention.

Chicago Office.—Scottdale Foundry and Machine Co., with works and general offices at Scottdale, Pa., have opened a Chicago branch office in charge of Mr. Carl Heim, at 327 S. LaSalle Street, Chicago, Ill.

Change of Address.—The Montreal, Canada, office of the Sullivan Machinery Co., hitherto located at 403 Lagauchetiere Street, West, is now situated at Room 806, Shaughnessy Building, St. Paul and McGill Streets.

Announcement.—The Roberts & Schaefer Co., of Chicago, have now associated with their organization Mr. Willis E. Holloway and Mr. Paul W. Holstein. Mr. Holloway has had 15 years of experience in the designing and installing of coal handling equipments and conveying machinery, and has given special attention to outside mine work such as coal-tipple construction and designing of screening equipments. Mr. Holloway will have charge of the marketing of the new "Marcus" combination screen and picking conveyer which the Roberts & Schaefer Co. have recently acquired. Mr. Holstein is a contracting engineer of large experience on coal tipple and coal-washing plant construction, and will now have charge of this branch of the Roberts & Schaefer Co.'s business principally in the West Virginia field. Mr. Trevor B. Simon, mining engineer, is also now associated with Roberts & Schaefer Co.

The Goulds Mfg. Co., of Seneca Falls, New York, have issued an interesting little book on Electric Pumping.

Electric Supplies in Emergencies. The test of an organization comes in an emergency, such as arose in April in the vast territory covered by floods and storms. The first unusual demand for special service came to the Western Electric Co. for 8,000 poles, 25,000 cross-arms, 100,000 pins, 32,000 feet of telephone cables. On the date the order was placed, 20 carloads of poles, 100,000 pounds of copper wire, and all of the cables went forward. Twenty-five thousand cross-arms went to Michigan, and the poles went forward from the yards in Michigan and the balance from Chicago.

The next call was for cables for the Chicago district to the Western Union Co. This was an order for 235,000 pounds of wire, and was sent forward by express from New York. Almost every other passenger train leaving the East for Chicago carried supplies.

When the floods began in Indiana and Ohio the Western Electric Co. was obliged to call upon its distributing houses, Cleveland, Pittsburg, Indianapolis, and Cincinnati, then Boston, New York, Philadelphia, Richmond, Atlanta, Kansas City, St. Louis, Minneapolis, and Dallas, in order to replace the depleted stocks in the East. Telegraph orders were issued to send East from Washington, 50,000 cross-arms.

TABLE OF CONTENTS

"Huckleberry Miners"

OUR cover picture illustrates a familiar scene in many coal fields in the Appalachian regions. It depicts a group of wives and daughters of foreign-speaking mine workers returning from a berry-picking expedition. Last year some of the pickers near McAdoo, Pa., where the United Mine Workers are particularly strong, formed a union against cut prices, and pickers who sold below the standard were chased from the bush and their berries were confiscated.

Forest Fires

RURAL mail carriers are now ordered to report to the proper authorities all forest fires detected along their routes. Frequently careless huntsmen start fires in leaves and dried grass that end in considerable loss of property. It is the duty of every citizen to be careful in this regard and to aid in every way in extinguishing forest fires, even although on another person's property. Money lost can be regained sometimes, but trees, not in our generation.

Coal Mining and Mining Schools

OF THE large number of students recently awarded degrees as Mining Engineers or Bachelors of Science in Mining Engineering, the majority have taken metal mining and metallurgical subjects for their theses, although coal mining offers as many varying subjects on which to display erudition. This seems a pity, since the chances for young men in coal mining are more numerous, likewise the positions more stable, and advancement surer. This is not altogether the fault of the students, for the study of coal mining is not given the prominence it deserves in our mining schools.

Assessment of Coal in the Ground

ON ANOTHER page we publish an article on the assessment of coal in the ground, by William Griffith, of Scranton, Pa., whose reputation as a competent and conservative mining engineer and geologist is such as to commend it to careful consideration. Mr. Griffith treats specially of the assessment of coal in the northern anthracite field. His suggestions apply with equal force to the question of assessments in other portions of the anthracite regions of Pennsylvania. With necessary changes of ton values, his proposed method of computing the value of the coal in the ground for assessment purposes is equally rational for application in the bituminous fields. We commend this article to the careful consideration of all who are interested in sound methods of arriving at a proper assessment of the coal in the ground, so that the burden of taxation may be equitably distributed and that the taxes may not be of a nature that makes them practically confiscatory.

Rescue Work in Mine Disasters

THE number of coal mining accidents in recent years, resulting in comparatively large death lists, has impressed on mine owners, mine officials, and mine workers the necessity of an ever-ready rescue corps.

Some mining men have proposed that all men working underground be trained in rescue work. This is not advisable. A few well-selected men, including the working officials, trained to a high degree of efficiency, can do more and better work than a much larger number who have been partly trained.

We do not mean that training in rescue work should be denied the majority of mine workers. On the contrary, every mine worker should be instructed in a general way how to meet emergencies. Every underground workman cannot be, in fact, he should not be, a member of a rescue corps, but he should be taught how to take care of himself. He should be compelled to learn the local conditions surrounding his work, the various routes to the surface from his working place, the direction in which the air travels in the main entries, to be amenable to rational discipline, and above all, when something does go wrong, to proceed cautiously, remembering that the shortest way out may not be the safe one.

The keynote of rescue work is a high degree of courage without recklessness; so in organizing a rescue corps, the members should be selected carefully. Men of strong physique, of known courage and superior natural intelligence should be chosen.

Rescue corps formed indiscriminately from the crowds of mine workers willing to risk their lives in efforts to save those of their comrades are never as effective as smaller corps of trained men. Moreover, they sometimes impede proper work and often tend to increase loss of life.

In several recent disasters the effectiveness of trained men was strongly in evidence. The rescue corps moved with precision and accomplished all that could be done to rescue lives and recover bodies in a much shorter time, and with less liability of danger to themselves, than would have been the case if only partly trained volunteers had done the work. A striking example of this is noted on another page in connection with the Scott colliery accident.

When one considers that well-trained men sometimes get "rattled," as has been the case several times in individual instances when using oxygen helmets, and they in their excitement overexert themselves with disastrous results, the necessity of extreme care in the selection of men for this work is strongly emphasized.

But men not selected for rescue work can be impressed into a service equally as important; this is easily understood when we realize that all openings should be carefully guarded. An experienced man should be at the mine entrance to examine all safety lamps before they are taken into the mine, another should record all persons going into or coming out of the mine, and others should provide proper food and shelter for parties engaged in rescue work and see that all ventilating appliances are in readiness for operation when required.

Masonry versus Wooden Air Stoppings

WHILE there must be a reason for the ignition of gas and coal dust in a mine, it is extremely difficult to locate the cause when only a horse is in the mine.

Mr. James Ashworth states, on another page, that one of the most violent explosions on record occurred under just such conditions, at the Killingworth colliery, in New South Wales. The readers of this journal will remember that we have advocated that sliding doors be placed in the pillars on each side of the entry breakthroughs, so that in case of an explosion, the time now lost in building brattices, which is of the utmost importance if life is to saved, can be reduced to a minimum. Mr. Ashworth also quotes Mr. Blackett, who suggests that the violence of an explosion might be reduced and its progress to some extent arrested, if the air stoppings gave way and allowed the force to expand. To those who have seen the havoc wrought by explosions on expensive brick and stone stoppings in breakthroughs in this country, it must be an open question that Mr. Blackett propounds.

It will be remembered that at Lievin experiment station 36 feet of the gallery burst and it had a resistance to bursting pressure of 570 pounds per square inch. The only object in having strong stoppings is to prevent short circuiting of the air-current in case of an explosion, and in almost every instance they have failed to come up to the expectations by being blown down. It would seem, therefore, that air-tight stoppings that could easily be blown out, supplemented with the sliding doors mentioned offer a superior method for quick mine recovery and possibility for saving life.

A further advantage to be derived from sliding doors, if placed in entries as suggested, would be that the imprisoned men could themselves shut out the afterdamp and prevent its killing them before the rescue parties have had time to restore the ventilating current, and come to their aid.

Carbon Monoxide Is Not a Supporter of Combustion

IN ANSWERING the query of a correspondent as to whether carbon monoxide is a supporter of combustion or not, in our June issue, the editor said, "the statement in the I.C.S. Instruction Paper that carbon monoxide does not support combustion is correct." He also called attention to an incorrect statement in the last, or 1911, edition of the Coal and Metal Miners' Pocketbook, and in a kindly and impersonal manner explained the misstatements in the first edition of the book "Examination Questions and Answers" and in the Pocketbook by saying they were made by "a former employe of the publishers who, while an able mining writer, and as a rule accurate, in this instance expressed an opinion of his own, which is in direct opposition to the actual experience of chemical authorities whose works are regarded as standards all over the world."

In a recent issue of a contemporary, with which he is now connected, Mr. J. T. Beard, over his own signature, correctly assumes that we referred to him as the author of the erroneous statement.

In commenting on our answer to the correspondent, Mr. Beard first says that his statement "is not one of opinion, but of *fact*," and in the same paragraph he says: "The statement, although correct, was modified later, at my own suggestion, in the I.C.S. coal mining textbooks." If, as Mr. Beard claims, it is a fact that carbon monoxide supports combustion, why in the world would *he suggest* a modification which flatly contradicts what he claims is a fact?

The statement that carbon monoxide supports combustion, made by Mr. Beard in the first 1,000 copies of the book "Questions and Answers," was corrected in all subsequent editions by Prof. H. H. Stoek, then editor of this journal, and now head of the mining department of the University of Illinois.

The last, or tenth edition of the Coal and Metal Miners' Pocketbook, also contains Mr. Beard's statement, as did several previous editions, but the earlier editions stated correctly that carbon monoxide will not support combustion. The statement made by Mr. Beard that it will support combustion escaped the notice of the writer until very recently.

In support of his claim that carbon monoxide will support combustion, Mr. Beard says: "While carbon monoxide has no available oxygen and therefore cannot support the combustion of carbon, the gas (*CO*) will support an oxygen flame, which will burn in an atmosphere of pure carbon monoxide, although it would not burn in air."

This statement is proof of the fact that carbon monoxide is combustible, but is not proof that it supports combustion, because the so-called oxygen flame is not burning oxygen, but is the flame of the carbon monoxide burning in the presence of oxygen, or in other words carbon monoxide combustion supported by oxygen.

We suppose that "by the same token" Mr. Beard will claim that carbon dioxide supports combustion because an acetylene gas flame has been known to burn in an atmosphere so strongly charged with carbon dioxide that an ordinary flame would not burn in it.

Alaska Railroad Construction

MR. FALCON JOSLIN, of Fairbanks, Alaska, chairman of the Alaskan Committee of the American Mining Congress, president of the Tanana Valley Railroad, a pioneer connected with many Alaskan business enterprises and perhaps more familiar with Alaskan conditions from a practical standpoint than any other man, has reviewed Governmental Aid to Railroads. His statements have been incorporated in Senate Bills, Nos. 48 and 133 of the 63d Congress, inserted in the records of May 3, and printed in Part 7, May 12, 1913. If those interested in conservation and the development of natural resources will write to Senator Key Pittman, Washington, D. C., for these remarks, they will be enlightened on many subjects relative to the governmental help afforded railroads entering a new and uninhabited country. Every railroad constructed into undeveloped country must be operated at a loss until the business along its line has been developed sufficiently to make its operations profitable. The Union Pacific and the Northern Pacific railroads were not only subsidized but given land grants. The Union Pacific never paid the interest on the bonds which the Government issued in its behalf, and the Government sold the railroad upon terms anything but advantageous.

The withdrawal of the coal lands in Alaska from private entry has taken away the only possible recompense for investment and no railroad construction is possible under present conditions. Mr. Joslin simmers down the discussion "to state ownership or private ownership," each of which have certain objectionable features. Those who do not believe in government ownership of railroads and those who do, will have an opportunity to defend their theories, but in the end Alaska must have railroads. Over 99 per cent. of Alaska is public domain that cost 2 cents per acre. Its present population of 35,000 white and 30,000 Indians produces an annual trade of $60,000,000. It is estimated that Alaska has 64,000,000 acres of agricultural land that is highly productive, for at the United States experimental farms at Fairbanks, in 1912, 115 bushels of oats; 67 bushels of wheat; and 260 bushels of potatoes were produced to the acre without fertilizer and under the natural conditions of soil and climate.

In view of the strong public feeling against granting any kind of assistance or subsidy to private corporations, and the objections to public ownership of railroads, the future of Alaska offers a difficult problem, which should, however, be solved soon, since the people of Alaska import over $1,000,000 worth of coal yearly and miners dig stumps for fuel.

PERSONALS

William Nicholson, mine inspector of the Eleventh District of West Virginia, has resigned his position to become superintendent for the Jewell Ridge Coal Co., at Richlands, Va.

Arthur Swartley is to be sent out by the new State Bureau of Mines to collect information on Oregon mineral production from those who have failed to report. Within the next few weeks he will go to Portland, Astoria, Baker, and Enterprise.

J. F. Healy, general manager of the operating department of Davis Colliery Co., resigned his position on the first of June. He contemplates opening a consulting office in Charleston, W. Va.

Mr. Cunningham, consulting engineer, Huntington, W. Va., attended the meeting of the Kentucky Mining Institute at Lexington.

C. F. Fraser, mining engineer, Taylor Coal Co., Beaver Dam, Ky., wrote a paper on "Mining Laws of Kentucky," to be delivered at the Kentucky Mining Institute in Lexington on May 17. On May 10, Mr. Fraser and three other men entered an abandoned working and were smothered to death by carbon dioxide. Mr. Rash, president of the Institute, and general manager of the St. Bernard Coal Co., read an obituary at the Institute meeting, in which he dwelt on the excellence of Mr. Fraser as a man and a friend.

J. B. Atkinson, H. M., Chief Inspector of Mines for the Newcastle, England, district, resigned his post, effective May 31, in order to establish a practice in Newcastle as a consulting mining engineer. Mr. Atkinson held his first appointment as assistant inspector in the Durham district, then he was transferred to Northumberland. Later he was appointed Chief Mine Inspector in the east of Scotland, where he remained for 12 years, returning to Northumberland 11 years ago, on the death of Mr. Hedley.

Harry William Shaw, who recently received a degree of B. S. in mining engineering at the University of Missouri School of Mines, had as a thesis, "Methods of Mining and the Preparation of Coal in the Belleville, Illinois, District."

Eugene Haanel, Ph. D., Director of Mines Branch, Department of Mines, Ottawa, Canada, announces the completion of a modern laboratory for the experimental concentration and metallurgical tests of Canadian ores and minerals.

George Watkin Evans, consulting coal mining engineer of Seattle, has been selected to make an examination as to the commercial possibilities of Matanuska coal field, of Alaska, for the United States Bureau of Mines.

From advices received from John T. Davis, vice-president and general manager of the Davis Colliery Co., R. B. Isner is now assistant general manager, and J. W. Bischoff is now general superintendent of the Davis Colliery Co., with headquarters at Elkins, W. Va.

Mine Inspector P. J. Walsh, of the Ninth Bituminous District of Pennsylvania, announced that the following men passed examination for mine foreman and assistant mine foreman:

Mine foreman: Isaac L. Davis, Andrew Guidas, and W. E. Mitchell.

Assistant mine foreman: Joseph Burns, Milton Wheeler, Elmer Swink, E. J. Rowan, Thos. Fazenbaker, and John Metcalf.

H. L. Watson, formerly sales engineer with the Allis-Chalmers Mfg. Co., of Milwaukee, has accepted the position of sales manager for the DeLaval Steam Turbine Co., of Trenton, N. J.

John Gibson, Jr., superintendent of all operations of the United Coal Co., in Somerset County, has been appointed general superintendent of Pennsylvania, Maryland, and West Virginia. He is succeeded at Somerset by Mine Inspector Richard Maize, Jr.

E. F. Mullen, for many years engineer for the Jeffrey Mfg. Co., and Heyl & Patterson Co., has joined the engineering staff of the Link-Belt Co. Mr. Mullen has had extensive experience in designing and construction of tipple equipment and general coal handling machinery, particularly in the West Virginia and Pennsylvania coal fields.

Dr. M. J. Shields, M. R. C., U. S. A., the originator of first-aid instruction in the anthracite regions, is continuing the good work in charge of American Red Cross Car No. 3, and has recently been over the lines of the Texas Pacific Railway and other railroads in the Southwest, giving instruction to the employes.

Edward M. Chance, who for a number of years has been connected with the Reading Coal and Iron Co., as chemist, has opened an office and laboratory at 61 South Pennsylvania Avenue, Wilkes-Barre, Pa., where he will practice his profession of analytical and consulting chemist.

Prof. Regis Chauvenet has been appointed president of the Colorado School of Mines, Golden, Colo. Mr. Victor Alderson, former president, having resigned.

Dr. Felix Adler, of Columbia University, and head of the Society for Ethical Culture, accompanied by Messrs. H. H. Jones and A. W. Bing, of New York City, the latter also members of the society, inspected several breakers and mines in the vicinity of Scranton, on June 9, to examine at close range the labor-saving devices of the coal mining industry and to look into child labor conditions as representatives of the National Child Labor Commission.

John Hawthorne, of Hillsboro, Pa., a prominent young bituminous operator, had his right hand blown off in the Bessemer Coal Co. mines at that place, by striking a stick of explosive against a projecting hanger.

H. M. Wilson, of the United States Bureau of Mines, announces the American Mine Safety Association will hold its first convention in Pittsburg in September.

Robert H. Seip, mining engineer with the North American Smelting Co., Ltd., a Canadian corporation, has accepted a similar position with the Consolidation Coal Co., at Jenkins, Ky.

COAL MINING & PREPARATION

An Ideal Method of Mining

For Winning the Largest Percentage of Coal, the Use of Machines, and for Concentrating the Workings

By J. C. Edwards and H. M. Gibb†*

THE ideal coal mine of today would be one in which: The largest percentage of coal can be won, and at least 90 per cent. of this portion won by machine. The cutting and loading would be concentrated, thus offering the principal requirements for economical haulage. The ventilation would reach a degree of safety that would protect the miners so far as possible from accidents due to indifferent methods of ventilation. The least number of headings would be necessary for development, thus reducing the costs for heading yardage, breakthroughs, cross-overs, tracks, pipe lines, air stoppings, maintenance, etc. The mining laws and agreements with the District Union could be carried out.

The large amount of coal wasted, due to improper methods of mining, is one of the serious problems that confronts the operator, especially one who is about to open a coal property that has been purchased at the prevailing price per acre.

In those mines in the bituminous field with which the writers are familiar, about 70 per cent. of the total coal in the ground is removed. Many operators seem to be satisfied with this percentage, seemingly giving more attention to the daily tonnage output produced than to the amount of coal mined per acre. One reason for this condition of affairs seems to be due to the keen competition among coal operators, which makes the margin of profit so small that it forces an increase in the daily output in order to obtain a reasonable interest and amortization on the money invested. In the past 10 years, the miners' wages have increased from 25 to 30 per cent.; besides in addition to this, the revision of the mining laws, while adding safety to the miners' work, has increased the cost of production about 5 per cent., although the price of coal in the market in the same length of time has increased but from 3 per cent. to 5 per cent. From this it can readily be seen that the operator must increase the daily output at the mines, so as to receive a fair profit on his investment, and as a natural consequence this is accomplished at the sacrifice of the mineral wealth of the property.

The system of mining generally in use in the bituminous field is known as "room-and-pillar work." The thickness of the pillars between the rooms varies, but the room centers most in use are 33 feet, 36 feet, 39 feet, and 42 feet. With 33-foot room centers, the pillar is lost entirely. With 36-foot room centers, about 50 per cent. of the pillar is recovered, and with 39-foot to 42-foot pillars from 60 to 70 per cent. of the pillars are recovered. The small percentage of pillar coal mined is due to hurry-up methods which generally demand the use of picks to recover any portion of the pillars.

The most of our so-called miners are in reality foreign laborers or men who have little or no experience in pick mining, therefore, if a larger percentage of coal is to be saved, it must be by machines. In order to operate machines successfully on room pillars, the latter must be made wider. As the per cent. of coal recovered

83—12—3

plays a material part in the absolute cost of coal per ton mined, any method that would win 90 per cent. or more of the coal from the ground would be an exceedingly important advance in mining and of great helpfulness to all coal mining men. A method of mining which would recover 90 per cent. of the coal would not only materially reduce the cost of coal per ton mined, but would also lengthen the life of the mine, so that, in the writers' opinion, too much attention cannot be given to methods of mining.

The accompanying drawings show the writers' system of mining coal, with a cover from 300 feet to 500 feet. This method is adaptable to either a drift, slope, or shaft, opening, with locomotive, tail-rope, or endless-rope haulage. Fig. 4 shows the method used for either a slope or drift opening, dumping over the same tipple. A solid 50-foot pillar of coal separates the two sets of main entries, thus making two distinct mines. Three entries make up a set of main entries.

The inside entries are for the loaded cars; the middle entries are for the empty cars, and the outside entries are airways. The loaded and empty haulage roads are driven the regulation width, 10 feet; the airway, however, is driven 16 feet wide. Fig. 3 shows the system of timbering adopted in supporting these airways. Where the roof is good, a piece of 8″×10″ timber 10 feet long is used as a collar, with a 10″×12″ timber post supporting it in the center. Where the roof is poor, the airway is timbered in the usual way. In all instances, timbers are set on 3- or 4-foot centers. By driving this airway 16 feet wide, the expense of driving a fourth main entry 10 feet wide is saved.

The writers contend that in our present mining practice, not enough attention is given to the airways. Any attention given to the airways seems to hit a continuous sore spot, from a cost standpoint; for instance, where a roof fall occurs it becomes necessary to open the nearest stopping (which is of brick or concrete) and lay a track so that the fall can be cleaned out. This is a slow and expensive operation. The main airways should be timbered so that the roof falls will be prevented, or at least reduced to a minimum. The extra expense of removing roof falls and driving a fourth main entry would be well spent by the operator in timbering a 16-foot airway. The loaded and empty car-track system is also adopted on the cross-entries, which are driven "face on."

The panel system of mining shown in Fig. 4 is known as "the half advancing and half retreating system." The cross-entries are driven in pairs so as to serve two panels.

The panels are blocked out every 500 feet by entries driven "end on" in pairs, and from these "butt entries" rooms are turned every 60 feet and worked face on. The rooms are driven 21 feet wide and this leaves room pillars 39 feet wide.

The butt entries 2, 4, 6, etc., up to 12, which are on the side toward which the development of the panel is progressing, are termed "advance headings," and those butt entries 1, 3, 5, etc., to 11, which are on the main entry side of the panel, are the "retreat headings." Rooms turned from the advance heading are driven 255 feet long, and rooms turned from retreat heading are made 245 feet long. All breakthroughs are driven 21 feet wide and offsetted, as shown in Fig. 1, which also shows the method of extracting room pillars where draw slate is encountered.

In driving the breakthroughs between the rooms, the track is laid on the far side and the slate is gobbed on the near side, or the side toward the cross-entries. When the breakthrough *a* at the face of the room is completed, the curve and two 15-foot sections of track are removed; a cut is then taken out of the pillar, as at *b*, "working on the butt," thus leaving a 10-foot pillar *c*. This cut, made 21 feet wide, is driven the length of the pillar, 39 feet, thus leaving a pillar 10 feet wide and 39 feet long. A cut 21 feet wide is next made through this pillar *c*, which leaves a 9′×10′ block of coal, or stump pillar, at each end of the cut, to be mined with picks. This operation is repeated until the room pillars are extracted as far as the entry pillar. The tracks in all the rooms are in 15-foot sections, so that by removing two sections, previous to taking out the first cut in the pillars, the tracks are always in the proper position. The rails used on the turns are fastened together by steel ties, so they can be readily detached or assembled as desired. In cases where coal cutting is done by compressed-air machines, the pipe line is standardized in 30-foot lengths, tees with one end plugged being used for jointing. By removing one section of the pipe line to every two sections of track the machine runner always has the proper conveniences to do the cutting.

In Fig. 2 is shown the method of extracting room pillars where there is no draw slate to contend with. Instead of driving on the butt across the rib, a 21-foot cut is driven in the face, thus splitting the pillar and leaving a 9-foot pillar on each side of the cut. When these pillars are attacked a 21-foot cut is made in both the right and left pillars, which leaves 9′×10′ stump pillars, one on each end of the cuts. These are worked out as in the previous case by pick miners. The operation is repeated on each room pillar until all are extracted, to the first cross-cut or entry break.

In both systems of mining, 90 per cent. of the coal is won by machines.

In developing a panel on the butt entries by this system, a chain breast machine is used. The method is shown in Fig. 5. When room 14 is turned, room 2 is finished and in readiness for work to commence on the pillar between rooms 1 and 2. To make the pillar cut, the shortwall machine is brought into use and both machines continue in use until the last room on the retreat heading is completed. The short-wall machine is left on the heading to finish the pillars, while the breast machine is transferred to another pair of butt entries under development.

The rooms on the advance heading are 250 feet long and on the retreat heading 240 feet long—this in lieu

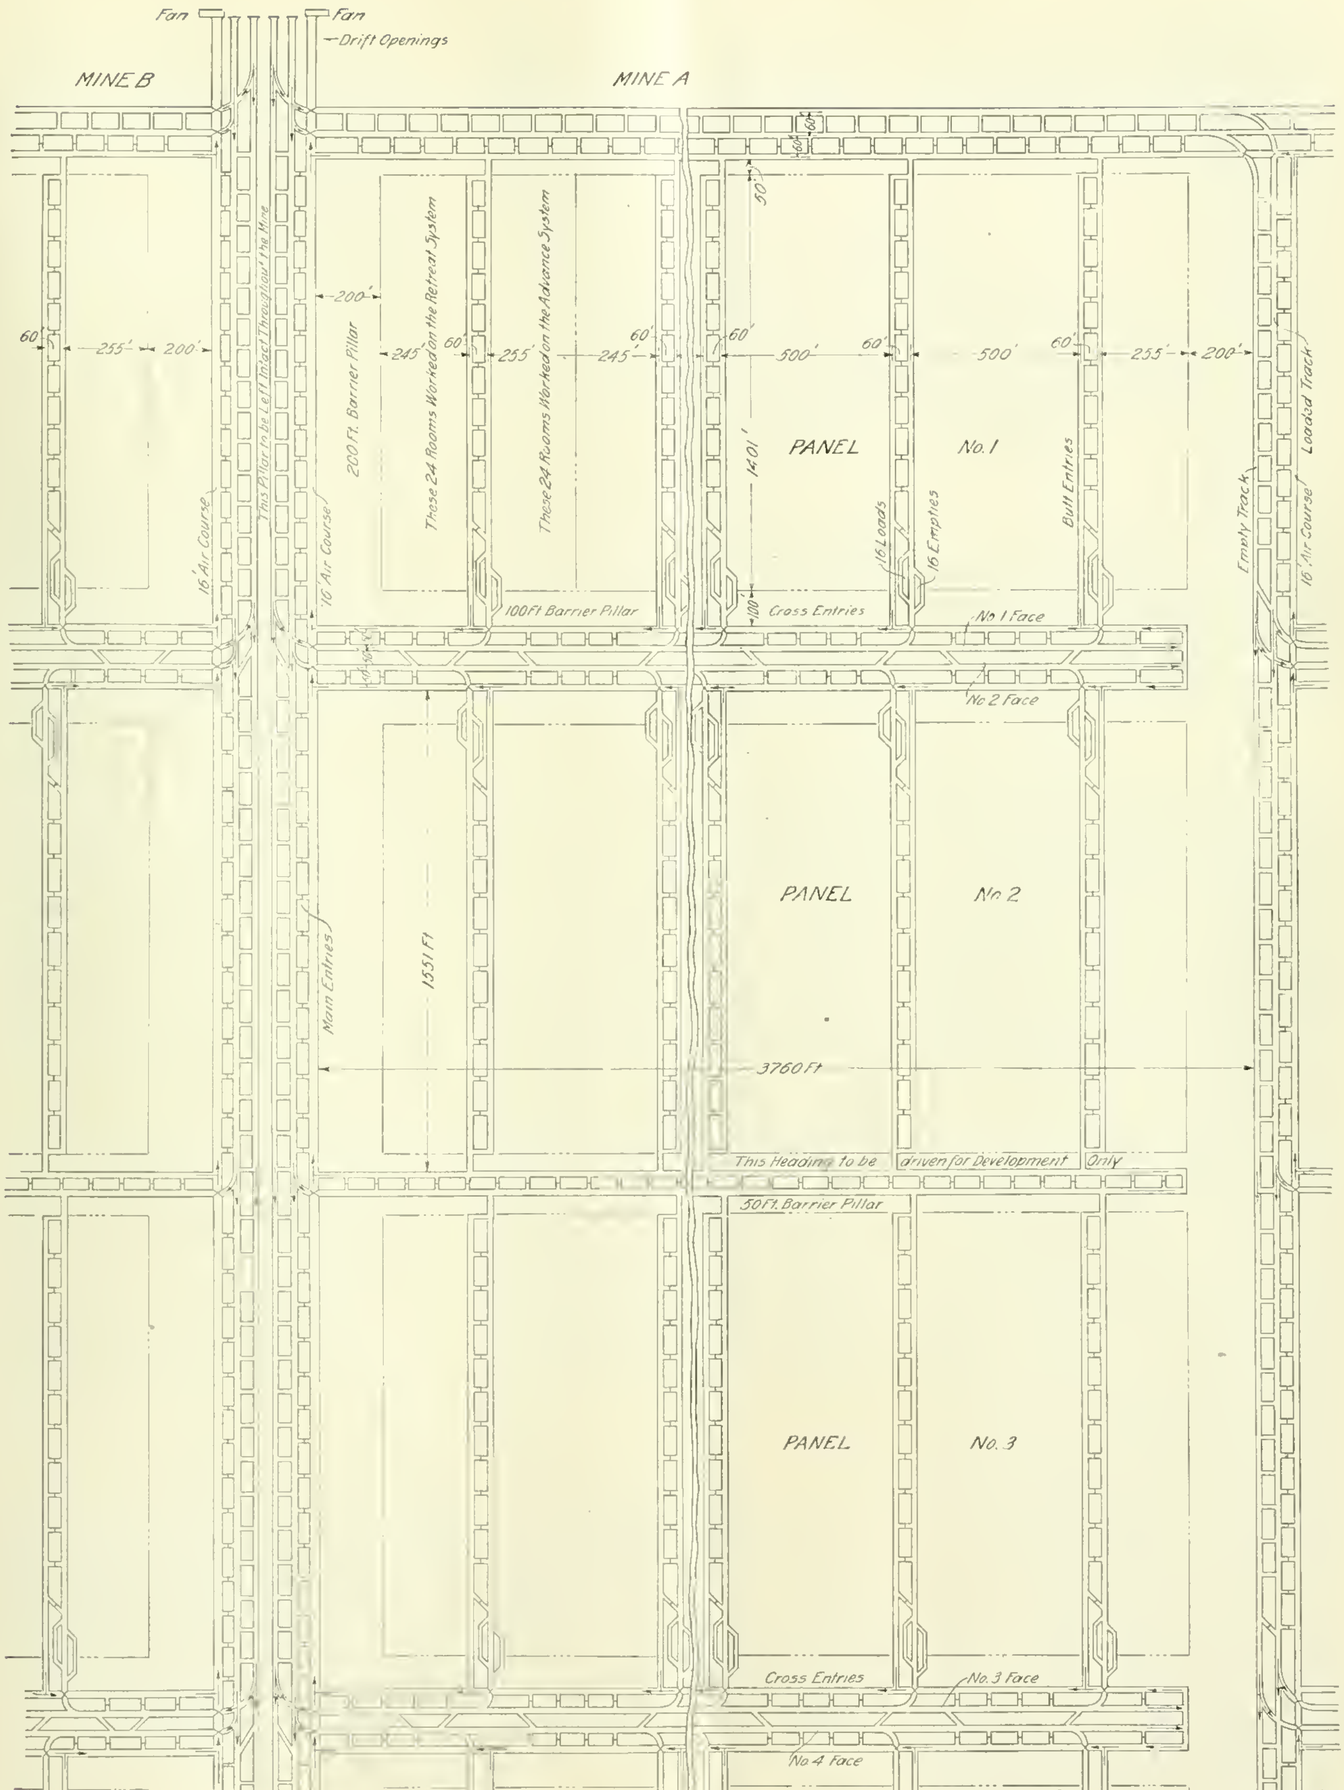

Fig. 4. Plan of Panel System of Mining

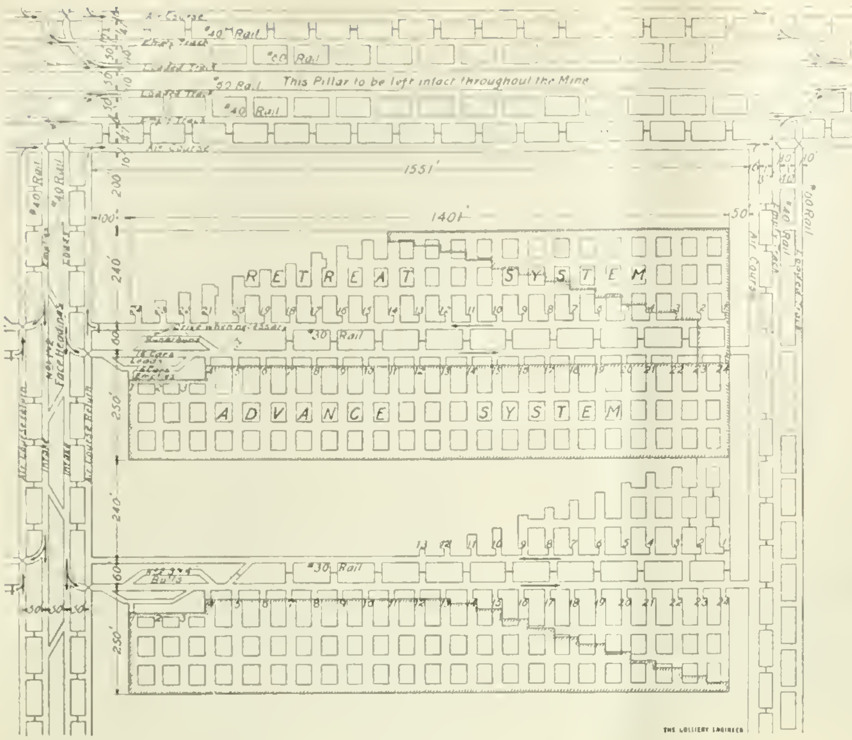

Fig. 5. Plan of Developing a Panel

of the fact that the chain pillar and entry stumps are brought back with the ribs on the retreat heading.

The most important features in economical coal mining are concentration in mining, in loading, and in haulage. The cutting and loading in this system of mining are concentrated from the time the butt entries are started until the last room is finished; however, the success of the system depends entirely upon the regularity with which the rooms are opened and the pillars drawn. In case one of the pillars is idle for any length of time a man from one of the headings works on the pillar in question temporarily, until the regular man returns to work. When the butt entries in this system are fully developed, there are from 18 to 20 working places, or practically enough to keep one locomotive busy. A feature of the haulage in this system is the individual side tracks on each pair of butt entries. Note that the arrangement consists of three tracks, one for loaded cars, one for empty cars, and one for a run-a-round for the locomotive. The side tracks are designed to allow the gathering locomotive to either pull or push the loaded and empty cars, so that the main haulage locomotive can either push or pull the loaded or empty cars from the side tracks. It will be noted that the gathering locomotive is not confined to the one pair of butt entries, or one pair of cross-entries, and further examination of this side-track plan will show that it has distinctive advantages over those now in general use; for instance, the main haulage roads are in the center with the airways on the outside. These haulage entries are connected, one with the other, by a series of cross-overs, so that individual tracks can be used for the loaded or empty cars. These cross-overs also serve the purpose of side tracks without any additional cost during the life of development of the mine. An excellent feature connected with these cross-overs, is that in case of a wreck, the locomotive can cut loose from the end of a trip and leave it for the company to clean up. While this is being done, the locomotive can continue to do its work by passing this wreck via the cross-overs, an arrangement which removes one of the most serious delays in haulage and will be most appreciated by those in direct touch with this portion of mine work.

It is unnecessary to dwell upon the importance of ventilation, as all mining men realize this. The retreat entry in this system of mining is the intake, and the advance entry, the return; thus it will be seen that the fresh air first passes over what is termed the live work and afterwards over the pillar or gob work, before it is directed to the main return airway, thus each pair of butt entries is an individual air split. This is an important feature where naked lights and electric haulage are used.

In a mine where safety lamps and compressed-air haulage are required, two or more pairs of butt entries can be used on the same split, thus saving the overcasts which would have to be built when using each pair of butt entries, as a separate split.

Shaft mines in general would be worked on the same system. In Fig. 6 is shown a shaft bottom, designed for this method of mining, the idea being that all the coal hoisted from the two shafts is to be dumped over the same tipple. Each of these shafts has two shaft bottoms, one for each section of the mine, because the shafts are sunk at or near the

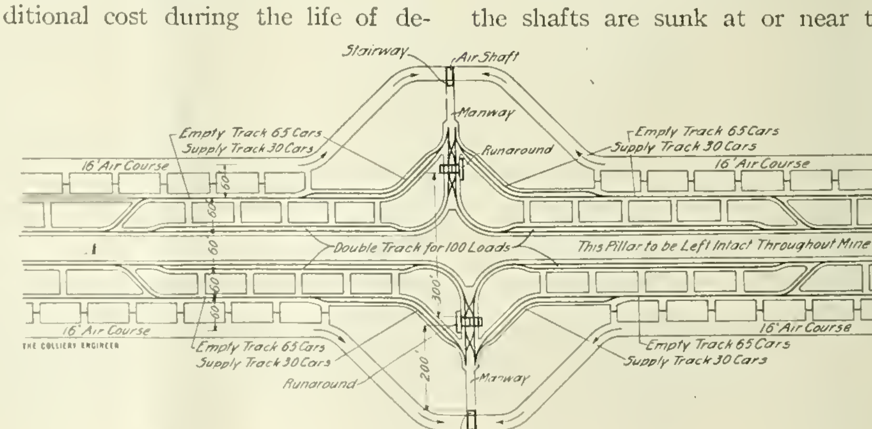

Fig. 6. Plan of Shaft Bottom

center of the coal property, and the areas to be mined for each shaft will be about equal.

The shaft bottoms are each designed for a coal capacity of 2,500 tons daily, or a total of 5,000 tons. The loaded track on each section holds 100 loaded cars; the empty track holds 65 empty cars, and the supply track 30 cars. The loaded and empty tracks at the shaft bottom proper are a continuation of the loaded and empty tracks in the main haulage entries. In landing the loaded trip at the bottom, the locomotive cuts loose from it shortly before reaching the point *A*, and is switched through the cross-over to the empty track while the cars pass on to the shaft bottom. The brakeman stops the trip and spots it properly at the shaft bottom. As all the breakthroughs are open between the loaded and empty tracks, the brakeman passes through the nearest one, to the empty track where he meets the motorman. They couple to the empty trip and leave for their destination, via the empty track. This method reduces the time lost in changing trips to a minimum. In case there are any supplies on the supply track, for the butt entries that the locomotive driver intends to pull in on the next trip, they are run on to the main entry empty track and placed as the first or second part of the trip, as the case demands. This is done by the boy who couples up the empty cars. The loaded cars are fed to the cages by chain hauls, using automatic car stops on the loaded sides. Care is taken to provide sufficient grade so that when the cage lands, the loaded car will start itself. The empty car passes from the cage to a kick-back and thence by gravity to the empty track. Care should be taken that the car is returned to the section from whence it came; which can be done by the use of cross-overs on both sides of the shaft.

The adoption of this system would mean a big saving in the amount of heading work, track work, room piping, room necks, etc., necessary for the development of the mine.

The system has been adopted by the management and chief engineers of the Pittsburg-Buffalo Co. for future work in their Marianna and Hazel mines of Pennsylvania; also the Annabelle mine of the Four State Coal Co., West Virginia.

Assessing and Taxing Coal in the Ground

*By William Griffith, E. M. and Geologist**

There would seem to be no recognized standard of value for coal content of lands at the present time among the engineers and county authorities of Lackawanna or Luzerne counties, and this lack of a recognized standard results in much confusion, litigation, and expense. The commissioners of Lackawanna County have variously estimated the value of coal at from $65 to $300 per foot-acre, and recently in Luzerne County one group of engineers employed by the land owners estimated the value of a certain tract of land at or around $700 per surface acre, while another group employed by the county authorities estimated the same land at about four times this value; thus indicating to the curious public that the judgment of experts on these questions is about as variable as the weathercock on the barn, being easily influenced one way or the other, according to the interests of the people who employ them.

Recently a representative of one of our large coal mining companies testified in the Lackawanna County courts that his company considered the coal in the ground worth to them 50 cents per ton. And I presume that at the pending tax appeals other representatives of the same company will aver that the coal is not worth 25 cents a ton.

All this indicates a sadly mixed state of affairs with reference to coal values, and it would seem that the adoption of some sane method of arriving at the standard of value would be proper at this time. In fact, the tendency, outside of the anthracite region, is in this direction. Not only have authoritative textbooks been written upon this subject, based upon sound principles of finance and engineering, but recently the Department of the Interior of the United States government, through the Geological Survey, has established rules for fixing the value of the coal lands of the public domain, based upon such standards and principles, from which to estimate the value of each particular property, according to the varying conditions which obtain. The writer has used a similar basis of valuation for many properties that he has been called upon from time to time to value, either for the purchaser or seller, or for financial interests to form the basis of value behind bond issues or other obligations, and has universally used the royalty rate as a proper standard of such valuation.

The supreme courts have declared that a perpetual lease is a sale and that the royalties are instalments on the purchase price. Therefore, the royalty represents the value of the coal in the ground, to be paid for as it is mined, and is a fair and equitable standard of value for estimating the worth of the coal; better to our mind than outright sales, because the sales of coal land in this locality are not frequent, and the deeds and records of such transactions usually cover up the actual selling price so that it cannot be ascertained. Of course, the royalties years ago were small—about 15 cents per ton. Later they increased to about 25 cents a ton for prepared coal. Still later about 35 cents was a going royalty, and at the present time it is from 50 cents to 75 cents; but the properties covered by high royalties of this kind are very few, and the tonnage contained is light, representing small comparative values.

The real question therefore would be to definitely determine a proper, fair average royalty applicable throughout the county. Having fixed such for the county, or for any particular coal property in question,

*Scranton, Pa.

the present value of the coal in the land is a matter of nearly the same degree of certainty as we find expressed in the proposition that two times two are four. Of course, each property becomes a problem in itself, but having a basic standard, deductions or allowances may be made to conform to the various conditions that are known to be peculiar to each property.

An illustration will perhaps best serve to explain the method of arriving at coal values from the royalty rate as a basis of calculation: If we have on the table before us 100 gold eagles, their value would be manifestly $10 each, or $1,000; but if a condition be attached to the possession by which the gold shall be deposited in the vault, and only one gold eagle, or $10 be used each year, then the present value is materially changed, and would be the present worth of $10 per annum, at say 6 per cent. interest for 100 years, which would be $166.17. Thus we note that the element of time affects the present value in a very material way. And the same would be the case in connection with coal. If, for example, we have a coal property which produces a royalty of $10 per year, and we know that the quantity of coal in the land is sufficient to continue this production for 100 years at the same rate, then the present worth of that coal would be $166.17. Again, Lackawanna County contains approximately 600,000,000 tons of coal, and it is being mined at the rate of 18,000,000 tons per year. At this rate it would be exhausted in approximately 33 years. If, for example, the average royalty rate for a composite ton (that is to say, a ton composed of the various percentages of different sizes ordinarily produced at the breakers) be assumed at 25 cents, the present value of one such ton per year for 33 years (that is, 33 tons), at legal interest, 6 per cent. would be $355.75, and the present value of 1 ton of coal in the ground, on the above basis would, therefore, be $355.75 divided by 33 or about 10.8 cents. At the various royalties mentioned below the values would be according to the following tabulation:

Average Royalty Rate for Composite Ton	*Present Value of One Ton of Coal in Ground*
25 cents per ton	10.8 cents per ton
30 cents per ton	12.9 cents per ton
35 cents per ton	15 cents per ton
40 cents per ton	17 cents per ton

If it is desired to express this in foot-acres, we simply multiply the above value per ton by the number of available tons in 1 foot-acre. If, for example, we assume that a fair and reasonable yield for the coal lands of this county is 1,200 tons per foot-acre, then, at the above royalty rates, the present value of the average foot-acre in this county would be as follows:

At 25 cents per ton royalty, $130; at 30 cents per ton royalty, $155; at 35 cents per ton royalty, $180; at 40 cents per ton royalty, $204. It would seem to us that a fair and reasonable royalty as between land owner and taxing authorities should be somewhat around 30 cents to 32 cents per ton for the average composite ton, because the major portion of the coal now being operated under royalty is being paid for at approximately this price.

Then, of course, the question arises as to whether it would be more equitable as between all parties to value the coal at the actual rate which is now being paid for it, or whether it should be valued at a higher rate, in view of the new leases. These are questions to be determined, but having them once settled for each county, there would then be a standard which would be a basis upon which the value of all properties could be estimated, these values of course varying according to the conditions known to exist on the several properties.

It will be noted that this method of ascertaining the taxable value of coal places the greater burden of the tax upon the coal in the going properties, which will be sooner exhausted. For example, at the royalty rate of 30 cents per ton, other things being equal, the coal in a property which will be exhausted in 10 years, would have a present value of 22 cents per ton, whereas at the same royalty rate the coal in an adjoining property which had a life of 60 years would have a present value of 8.1 cents per ton. To our mind, this is as it should be, because it is manifestly unfair to tax the unremunerative ton year after year at full rate for 60 or 100 years, whereas the remunerative ton of coal which is mined this year escapes with but the one tax. And, along the same line, virgin properties which are held for future mining, should to our mind, be considered in the same manner as we now treat unremunerative, unseated lands, by imposing simply a nominal tax until such time as they become productive. For purposes of conservation, the forestry associations have for years been endeavoring to secure the removal of the tax upon standing timber, until such time as it is cut. They are now about to realize the fruits of their long efforts through the passage of such a law by the legislature. The same legislation should be enacted to cover the anthracite coal in the ground. It should only be taxed in a nominal way until it is mined. Each ton should be taxed once and once only. Perhaps the better way to accomplish this would be to eliminate the taxation of coal as real estate, except in a nominal way, and lay a tax upon each ton of coal as it is mined, as is being advocated by the Scranton Board of Trade.

Although these latter suggestions cannot be applied through our present antiquated and unfair laws in the taxation of coal, and are somewhat aside from our subject, they are, nevertheless, important matters for immediate legislation, which should be vigorously pressed.

Mr. Otto Siedle, of the St. George Coal Co., Natal, South Africa, states that the output of coal for 1912 was 2,470,773 tons. He further states that the coal industry of Natal could be materially increased if the Government furnished sufficient rolling stock.

A Notable Scottish Colliery

First Worked Before the 13th Century, Now Equipped With Most Modern Machinery Giving Large Output.

By Special Correspondent

THE history of mining in the Newbattle coal field in Scotland is closely associated with that of Newbattle Abbey, which was founded in 1140 by the king of Scotland. The remnants of monastic coal workings are to be found on the bank of the River Usk, which indicate that the coal was even then obtained by a system of quarrying. It is impossible to say when the monks began to dig coal, but from the fact that between the years 1210-1218 they received a grant from Sehr de Quincey of a coal heugh between the rivulet of Whitrig and the boundaries of Pinkie and Inveresk, it is fair to assume that they were fully aware of its nature at an early date.

Even before they obtained this charter it is probable that they had already discovered coal in the neighborhood of the Abbey and become acquainted with its valuable properties as fuel. The coal seams in Newbattle were worked until the period of the Protestant Reformation in Europe by a long line of abbots, who may be described as the first coal operators and mining engineers in Scotland.

By 1531 the mining industry under their direction must have assumed definite commercial properties, as in that year Abbot James entered into a contract with the monks of Dunfermline by which he undertook to drive conduits through his coal field of Preston Grange in order to carry to the sea the water from the Abbot of Dunfermline's coal fields of Inveresk and Pinkie. After the Reformation the Newbattle coal field was worked by the Lothian family until 1890, when the Marquis of Lothian granted a lease to the Lothian Coal Co., which now holds about 1,300 acres of coal lands. This area is reached by pits at Whitehill, Polton, and Newbattle; the seams in the lower series exist under nearly all of this area, but those in the upper are more limited in extent. The former are worked from Newbattle collieries, the latter only from Whitehill and Polton.

The Lothian Coal Co., of Newtongrange, Midlothian, is located about 9 miles southeast of Edinburgh and comprises the Lady Victoria and Lingerwood pits and the Easthouses Incline. The sinking of the Lady Victoria pit, which, begun in 1890, occupied more than 4 years, is the last link, in this twentieth century, of the evolution of mining engineering begun in Newbattle by the monks at the end of the twelfth or beginning of the thirteenth century. It is interesting to contrast the primitive workings of the monks made to supply their own needs and those of their neighbors, with the state of progress exemplified in the Lady Victoria pit provided with machinery capable of drawing 1,500 to 2,000 tons of coal per day. Some of the books in the present colliery offices date back to 1744. From a page at that early date we learn that the output for the week June 4, to June 11, 1744, at the then Bryans pit, was 666 loads, a load being about what a woman carried on her back up the pit. The wages paid twelve men putting out the above loads at 1½d. per load, was £4 3s. 3d., the average wage per week being about 7 shillings, out of which they apparently had to pay their own bearers.

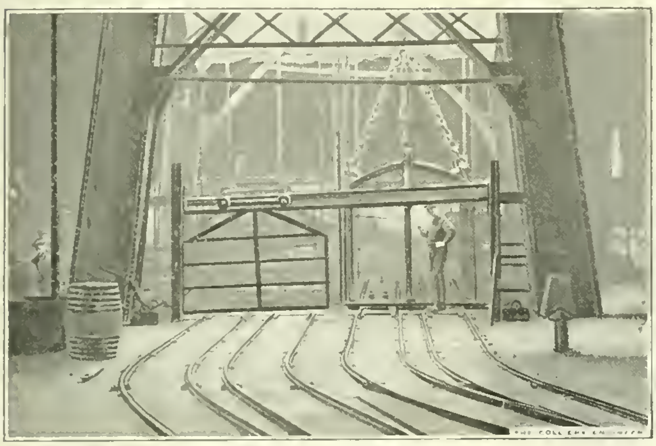

Fig. 1. Pit Mouth, Lady Victoria Mine

Fig. 2. Rotary Tipples

Before the introduction of machinery the output of coal was small, but when the introduction of the steam engine revolutionized the face of the earth, and railways and steamships, manufacturing industries, and other fuel consumers increased the demand, a great change took place in the type of operation made necessary in coal mining. For example, coal used to be conveyed to Edinburgh by a railway, the trucks of which were hauled by horses within comparatively recent times. The introduction of gas lighting into Edinburgh gave a tremendous impetus to the coal trade of Newbattle, as there is the famous seam of cannel coal which had been previously very little in demand. Here again there is a rather curious indication of the reflex action of modern progress. The cannel seam was first of comparatively little value. When the flat-flame gas burner came into existence cannel coal was eagerly sought after. Now that the introduction of the gas mantle has rendered possible a satisfactory gas from a low-priced coal of small illuminating power, the cannel seam has dropped back again into its position of comparative inferiority. Until comparatively recently, pumping was not necessary, as the workings had not gone below the level of natural drainage, and in the memory of the oldest inhabitants, the coal used to be carried in baskets on the backs of women up the pit by winding stairs. The horse gin supplanted female labor, and was in its turn supplanted by the use of steam.

At the present time the Lady Victoria pit exemplifies some of the most modern British practice. The pit has a depth of 1,650 feet, this being one of the deepest pits in Scotland. The pit head is furnished with special appliances for saving labor and expediting work. The shaft is circular in form, 20 feet in diameter, and is lined with brick from top to bottom. At the bottom of the shaft siding accommodation is provided for dealing with a large coal output. The approach to the workings consists of an arched tunnel lined throughout with brickwork. It ranges in height from 35 feet to 15 feet, and the roads to the various coal seams in the field branch off this main tunnel. Various coal-cutting machines are in operation in the workings, and the water accumulating in the various sections is forced to the bottom of the shaft by pumps, some of which are driven by electricity and others by compressed air. Electricity for driving coal-cutting machines and

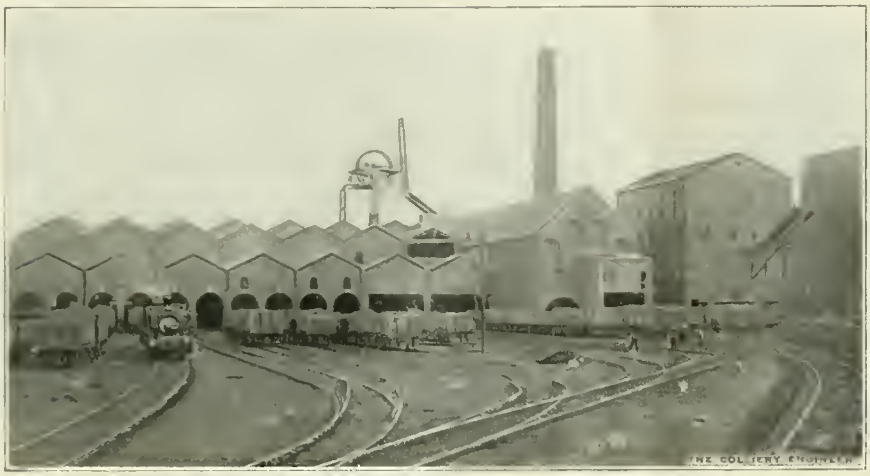

Fig. 3. Surface Arrangements, Lady Victoria Mine

pumps is taken underground by means of three double-armored insulated cables to a switchboard situated at a convenient point underground, and a distribution system conveys the current from this point to the various machines. A small proportion of the electric current is also utilized for lighting the bottom of the shaft, pumping stations, and other important points underground. Ventilation is effected, in connection with the neighboring Lingerwood mine, by means of a Guibal fan, 30 feet in diameter, and in order to avoid any possibility of breakdown in the ventilating arrangements, a duplicate fan is installed. The coal is hauled to the pit bottom by means of an endless-rope haulage, three Clifton wheels being fixed on a horizontal steel shaft in the pit bottom, and the power to drive the haulage is transmitted from a steam engine on the surface by means of a steel wire rope. In the shaft there are two double-deck cages for conveying the minerals to the surface. Each cage is capable of carrying twelve hutches of coal equal to 6 tons, or to ascend or descend with 48 men. In the shaft the cages are kept in position by rigid thick wire rope guides, and a wire cable attached to the bottom of each cage and hanging in a loop down the shaft, supplies the compensating balance to the dead weight of the winding ropes. In this way and with the weight of one cage and its hutches balancing that of the other cage and its contents, the net load which the engine has to raise to the surface is only the 6 tons of coal in the full hutches. Both at the bottom and at the top of the shaft, arrangements are made for loading and discharging the two decks of the hutches simultaneously, so that time is saved and wear and tear on the plant is reduced to a minimum. Fig. 1 shows a view of the pit mouth. Fig. 2 shows the rotary tipples, while Fig. 3 gives a general view of the surface arrangements at the Lady Victoria pit. It will be seen that the pulley frame, over which the winding gear is carried, is a massive structure of steel 85 feet high, and the winding wheels are each 19 feet in diameter. The whole of the overhead machinery and works are enclosed in substantially built brick structures and the floor is supported from the ground level by substantial brickwork, and is laid in chequered plates. The roof, consisting of galvanized iron sheet and glass, is carried on steel columns; the area covered by the works, storage ground, and railway siding is about 32 acres, the railway tracks including about 4 miles of line. The magnitude of the undertaking will be realized by the fact that in order to accommodate the workers connected with the pit it has been necessary since 1890 to build about 535 houses which form a decided contrast to the miners' houses built in bygone days.

The hoisting engine has two horizontal cylinders 40-inch diameter by 7-foot stroke, steam jacketed, over which there is a covering of non-conducting composition, the jacketing being finished with blue planished steel sheet. The valves are of the Cornish type 10-inch diameter for steam and 12-inch diameter for exhaust. After the second revolution of the engine the variable expansion gear controlled by governors comes into operation. The drum is cylindrical and is 21 feet in diameter by 8½ feet wide, built in three sets of eight arms and bosses, each set being cast in halves. The circumference is clad with steel plates ¾-inch thick in lengths of 8 feet, butt jointed, and overlaid with a cleading of oak 8 ft. × 6 in. × 5 in. thick. A brake ring is cast in each side and a double-breast brake acts on each ring. The brakes are operated by a 12-inch steam cylinder placed directly in front of the drum. The levers for controlling the steam to the cylinders, steam brake, and reversing engines, are placed at the outside of the right-hand cylinder and convenient to the engineman. An overwinding arrangement worked by bevel gear from the crank-shaft automatically shuts off the steam from the engine and applies the steam brake. In the event of inattention on the part of the engineman this arrangement comes into action when the cage is about 60 yards from the pit head.

The electric plant is also somewhat extensive. It consists of four single-cylinder engines each 15½-inch diameter by 33-inch stroke driving two dynamos of 300 horsepower and one dynamo of 100 horsepower generating direct current at 500 volts. Owing to the great distance to the workings from the pit head and the consequent drop in voltage, this plant is now only occasionally run over a week-end. A 1,000-kilowatt mixed-pressure Curtis turbine and three-phase alternator with a speed of 3,000 revolutions per minute generates current at 3,300 volts. During the day the winding and haulage engines exhaust into an accumulator which supplies the turbine with exhaust steam at pressure of 1½ to 2 pounds above atmosphere. In the event of exhaust steam not being available, an automatic controlling arrangement worked by the turbine governor admits live steam from the boilers. A condensing plant is in operation in connection with the turbine set, giving 27-inch vacuum at full load. About 3,000 gallons of water per minute are circulated through the condenser by a centrifugal pump, the temperature of the circulating water being lowered in a cooling tower.

The hauling engine was made to sink the Lady Victoria shaft, and after that had been finished it was converted into a haulage engine. The cylinders are 25-inch diameter by 5-foot stroke and the valves are of the positive type. The power is transmitted by a 3-foot diameter by 20-inch wide cast-steel pinion on the crank-shaft and 14-foot spur wheel on the second-motion shaft. An endless rope drive wheel, 12 feet in diameter, which is of cast iron with renewable cast-iron segments round the circumference, is keyed to the second-motion shaft and also bolted to the spur wheel with fitted bolts. The endless rope or band rope made of special steel 1¾ inches diameter and 1,400 yards in length, makes 4½ turns round the drive wheel, then goes down the pit to the driven wheel 10 feet in diameter at the pit bottom.

Particular attention has been given to the handling of the coal as it reaches the pit head. Fig. 2 shows the tipples. The mine cars containing the coal as they come off the cage, run by gravity to the weighing machine and then pass to the various tipples. These are belt driven and make a complete revolution, depositing the coal in a heap on a slightly inclined distributing jigger plate. The coal is slowly pushed forward to a perforated jigging screen lying at a steeper gradient, through which the dross falls into a scraper conveyer traveling at right angles to the screen. The larger coal passes over the end of the screen to an endless belt of steel plates about 35 feet long and traveling at about 60 feet per minute from which any foreign material in the coal is picked out by hand.

The dross from the various screens is carried by the scraper conveyer to a dross pit about 21 feet below surface level and alongside the washer. The dross is lifted out of the pit to a height of about 60 feet and deposited on a distributing plate from which it passes to a series of inclined screens with perforations varying from ¼-inch diameter at the top to 2½ inches at the bottom. The object of the screens is to separate the coal into the various sizes required and then wash each size separately, and for this purpose the coal is divided into five sizes. The three larger sizes are washed in plunger tanks, the two smaller being washed in feldspar jigs. As a certain amount of breakage occurs in the plunger tanks, the nuts after being washed are again passed over the screen for a final separation. The dirt washed from the coal falls into an inclined tank underneath the floor and is carried by a scraper conveyer outside the building and deposited in a wagon. The water which has washed the coal runs in a cast-iron pipe to a silt recovery tank with a capacity of about 60,000 gallons and deposits therein the fine coal which it carries. The quantity of water required to wash the coal is about 1,000 gallons per minute. An endless chain, carrying perforated steel buckets and moving at a slow speed, removes the deposit of fine coal from the tank and this coal is used for firing the boilers at the mine.

In concluding this description of what is probably one of the largest and most up-to-date collieries in the Scottish area, our thanks are due to the Lothian Coal Co., Ltd., for the information supplied, and it may be stated that the high state of mechanical perfection shown in the colliery, is indicative of the care and skill which now characterizes British coal mining.

The Pishel Coking Test

Method of Determining the Coking or Non-Coking Quality of a Coal by Its Adherence to the Mortar When Pulverized

By Max A. Pishel

In the spring of 1908, while studying the physical properties of coal, especially with reference to the color of the streak and the powder, the writer observed that some coals, while being pulverized, adhered much more strongly to the pestle and mortar than others and that the best coking coals were the ones which adhered most, whereas the non-coking coals adhered very slightly or not at all. This phenomenon gave promise of affording a simple, inexpensive, and yet rapid, method of distinguishing coking from non-coking coals, without the necessity of using an improvised rick, or the better but more expensive way of sending the coal to a coking plant for a test in a regular coke oven.

Accordingly the writer experimented systematically with all the coals in the study collection of the United States Geological survey; a collection embracing 150 different samples ranging from lignite to anthracite and including some of the best known coking coals of the country.

For years geologists, mining engineers, and coal miners had sought in vain for just such a test. In the light of these facts, the author considered it worth while to bring the test before the public and he published* it in the hope that others would make application of the test and thereby determine its value in a practical way.

Since then, other men, particularly the coal geologists of the United States Geological Survey, have applied the test to many different coals and the results obtained serve to substantiate the first conclusions that by this simple method, coking and non-coking coals can be differentiated. G. B. Richardson† who examined the Trinidad coal field of Colorado, had an exceptional opportunity to prove the value of the test as the coals in that field range from coking in the southern to non-coking coals in the northern part of the field. Mr. Richardson makes the following statement, regarding the test:

"The observations of M. A. Pishel that, when ground to a powder, coking coals show a pronounced adhesive quality, whereas non-coking coals do not, holds good for samples from nearly 40 mines in the Trinidad field that have been examined. Tests show that specimens of the high-grade coking coals from the southern part of the field adhere distinctly to the pestle when ground in the mortar. The adhesiveness decreases in samples obtained farther north and coals from the north end of the field show practically none under similar conditions."

E. Eggleston Smith,‡ while examining the coals in the state of Washington, applied the test to nearly 100 different coals and reported not a single failure. Mr. Smith carried on experiments in which he tried to powder the coals on smooth and rough surfaces and in mortars composed of different materials. Regarding these experiments, he makes the following statements: §

"Porcelain, glass, earthenware, and iron mortars were used, and the powder of coking coal adhered to all; the powder adhered to a piece of flat glass just as well as to a mortar, but it was more difficult to reduce the powder to the proper degree of fineness on the flat surface. It appears that a powder must be a certain degree of fineness in order to show the property of adhesion. Pocahontas (W. Va.) coal, powdered both on smooth and rough surfaces, was found to adhere provided the surface was not too soft or too rough to admit of the reduction of the particles to the proper size. In general, a hard, smooth surface is preferable, because the use of such a surface insures a finer and more uniform powder."

Mr. M. R Campbell, Geologist in charge of the Section of Western Mineral Fuels of the United States Geological Survey, who applied the test to perhaps more coals than any other person, has not reported a single failure.

Many others have tested coals by means of it, but only two cases reporting the failure of the test were brought to the attention of the author. James W. Hodge, of Big Stone Gap, Va., reports of having tested two samples of splint coal, one from Keokee, Va., and the other from Roda, Va. The adherence of the former was said to be poor whereas that of the latter from medium to poor. Mr. Hodge states that both coals had been successfully coked for a number of years but that they are not coked at present. He did not say whether the coke produced was good or poor, nor did he give any reasons why the coals are not coked any longer. It is possible that the coals make only an inferior grade of coke, for it does not seem likely that a mining company would discontinue the operation of 100 coke ovens if it could produce good coke. It is also possible that the beds from which the above samples were taken are made up of different grades of coal some of which make much better coke than others, and that Mr. Hodge accidently tested some of the poorer grade. At any rate the above cases are exceptional and do not even prove that the test failed in splint coal.

Conversation with coal mine operators, mining engineers, and coal miners shows that this test is very little known by practical men. In view of the above facts, the author concluded that a second publication of it was not only justifiable but also desirable. He, therefore, takes this opportunity of presenting for a second time a statement of the method used in conducting the test, and the results obtained on the samples referred to above, together with some additional data which were produced by the

* "A Practical Test for Coking Coals," Economic Geology, Vol. 3, 1908, pages 265–275.

‡ "Coals of the State of Washington," U. S. Geological Survey, Bulletin 474, 1911.

§ Smith, E. Eggleston, "Coals of the State of Washington," U. S. Geological Survey, Bulletin 474, 1911, page 31.

writer and are the results of the test on coals added to the Survey collection at a later date. The writer takes the liberty to incorporate with these, the results of the test obtained by Mr. Smith on coals of Washington, published in the report cited previously.

The method of conducting the test is as follows: Pulverize in a mortar a small quantity of the coal to be tested until it will pass through a 100-mesh sieve. Pour out the loose material and note the amount that adheres to the mortar. With some coals the mortar and the pestle will be deeply coated with coal dust which adheres so strongly that it can be removed with difficulty; with other coals, there will be only a thin film of coal dust adhering to the mortar and pestle; while with still others both mortar and pestle will be nearly as clean after the operation was completed as they were before it began.

The degree of adhesion depends on the grade of the coal with reference to its coking qualities. If it adheres strongly the coal will make a good coke; if it adheres only partly the coal will make an inferior grade of coke, and if it does not adhere the coal is to be regarded as non-coking. The illustration, Fig. 1, serves perhaps better than a written description in showing the reader the difference of the conditions of the mortar after a charge of each of a number of different coals was ground and the loose portion poured out. One-half of the gummy powder which adhered to the mortar was removed so as to make the other half more prominent.

Illustration *A* shows the adherence of the powder of a coal from the Pratt mine No. 4. This coal is reported to be one of the best coking coals in Alabama and it can be seen that it covers the mortar and pestle with a heavy coating of soot, i. e., adheres excellently.

Illustration *B* shows the adherence of the powder of a coal from the Utah Fuel Co. mine No. 2, Sunnyside, Utah. This coal makes a very good coke. It will be noted its adherence is good.

Illustration *C* shows the adherence of the powder of a coal from the Cambria Fuel Co., Cambria, Wyo. Coke from this coal has been used in the smelters in the Black Hills, but it is not first-class coke. It will be observed that the coating of soot is

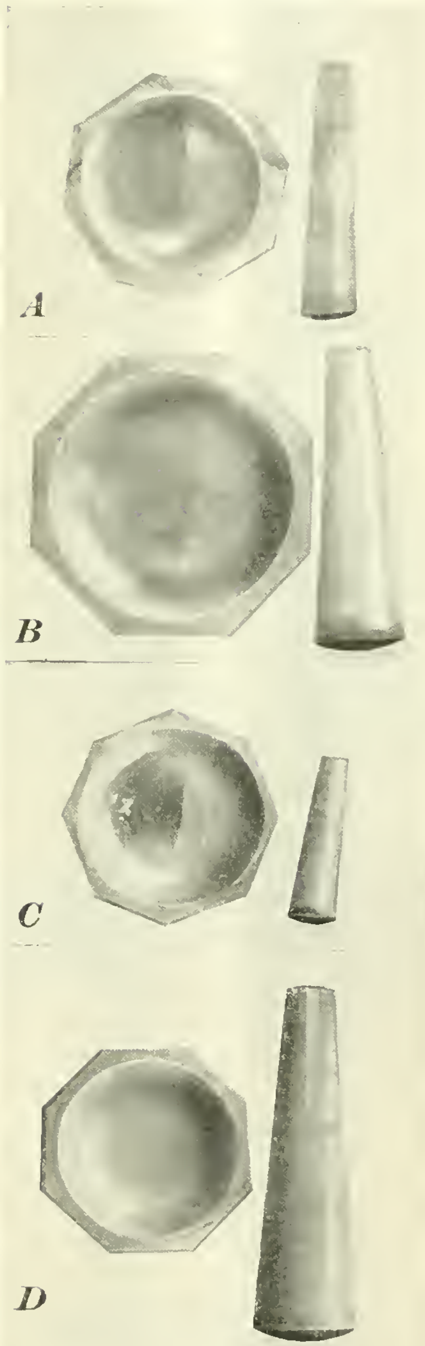

Fig 1

comparatively thin and, when compared with the behavior of the coals previously mentioned, its adherence is medium.

Illustration *D* shows the condition of the mortar and pestle after a coal from the Green Valley mine of Jasonville, Ind., had been ground. This is considered to be a good type of non-coking coal. It will be noted that the amount of adhesion is slight.

Aside from the adhesion of this gummy soot to the mortar and pestle some coals exhibit a tendency to pack together or cohere. Although it seems to be more noticeable in coking coals, this tendency to pack was observed to a lesser extent in some of the non-coking type. Hence it is thought that this behavior depends entirely on the moisture content of the coal and has nothing to do with its coking qualities; however, sufficient work has not been done to prove this point.

In the following tables are given the results obtained by the writer and Mr. Smith, in testing the various coals. The scale of adhesion used in describing the test is as follows: none, poor, medium, good, and excellent. The coking coals range from medium to excellent, whereas the non-coking coals range from medium to none. Those marked medium are doubtful and possess the coking qualities only in a small degree. If they do produce coke it is probably of such poor quality as to have very little value for commercial purposes. In the column headed "Coking Quality" is stated whether or not the coals tested are coked in actual practice. Information with reference to their coking qualities could not be obtained on some of the coals; however, those of which the coking quality is not given and ranging in adherence from poor to none, are supposed to be non-coking.

When studying the above results, the reader should bear in mind that most of the coals tested were obtained from small samples, 2 quarts or less. A large number of these samples were prepared by the mine owners or operators, who as a rule pick out the best coal, hence are not always representative of the coal bed from which they were obtained.

The condition of the coals at the time they were tested may be considered to have been the same as it

(Continued on page 678)

TABLE SHOWING RESULTS OF COKING TESTS ON 250 COALS

State and Name of Mine or Operator	Locality	Kind of Coal	Coking Quality	Adherence to Mortar When Ground	Remarks
Alabama					
Aldrich mine	Aldrich	Bituminous		Poor–medium	Montevallo bed

Madrid mine	Madrid	Anthracite		None	

[1]These coals were obtained from a bed, locally known as Coke bed from which coke has been made at a number of places.

[2]One piece of nut size taken from a two-quart sample adhered very slightly, whereas another from the same sample adhered strongly, indicating a good coking coal. It seems probable that the bed is made up of different grades of coal, some of which make very much better coke than others.

[3]This coal is the same as the Hartshorne coal of Oklahoma, which is coked a few miles west of the Arkansas state line.

[4]These coals behave alike and in appearance are very much the same. They are brittle and high in fixed carbon. When ground they behave very much like charcoal, soiling the mortar in the same way. Apparently they are on the boundary line between coking and non-coking coals. Stratigraphic position of Hartshorne bed.

[5]According to the tests these coals should coke, and it is reported that coke has been made from this bed in the vicinity of Pittsburg, Kans.

[6]The Michigan coals are generally regarded as non-coking, but from the results obtained in the mortar they would probably make a poor coke.

[7]Before the opening of the Sunnyside mine, coke was made from Castlegate coal, but this has been discontinued owing to better results having been obtained from the Sunnyside coal. Winterquarters and Clear Creek mines are on approximately the same bed as that mined at Castlegate, and it seems probable from the tests that they would produce as good coke.

[8]All the coals of Washington as given in this table were tested by Mr. Smith. As he applied this test while in the field he had an excellent opportunity to check the results of the test with the results obtained in the actual coking practice. To show the reader how favorably they compared, the column "Kind of Coke" was added.

TABLE SHOWING RESULTS OF COKING TESTS ON 250 COALS—*Continued*

State and Name of Mine or Operator	Locality	Coal Bed	Kind of Coke	Adherence to Mortar When Ground	Remarks

was when the coals were taken from the mine, because they are kept in air-tight jars.

Mr. Smith, when testing the Washington coals, was especially careful to note whether or not the high ash content in a coal had any effect on the adhesion of its powder when ground; however, he could not detect any appreciable difference between coals high or low in ash with regard to this point.

Moisture when present in large quantities interferes with this test, causing the coal to pack together and preventing its adherence to the mortar, hence the sample should be obtained in the dry part of the mine.

To make the test satisfactorily the sample should be as carefully prepared as one taken for chemical analysis, and should be taken in the same manner; i. e., by cutting a channel from top to bottom of the part of the bed to be sampled. In sampling for coking tests, each bench of the coal should be taken separately, as here and there coal beds are found which are composed of benches, some of which will coke and others that will not. In case well-developed benches do not occur, the bed might be sampled 1 foot at a time, keeping each sample separate from the others and properly labeled Each sample should be pulverized so as to pass through one-half inch mesh and then quartered down to a convenient size for handling and transporting.

About 5 years ago, when the author first published a description of the test, he expressed the hope that every geologist and mining engineer engaged in practical work would apply it with a view of proving or disproving, as the case may be, its value as a practical test for coking coals. Since then a number of geologists have applied it in the field and the laboratory on all kinds of coals, some of which are coked in actual practice, but not a single failure, except the two cases referred to above, has been reported. It is possible that it may fail in exceptional cases; therefore, the author requests men working with coals to apply this test as occasion permits and publish any case of failure observed by them, giving the exact conditions under which it was applied.

Until now, practical men have failed to avail themselves of the use of the test. But in view of what has been said in the foregoing pages and the extreme simplicity of the test, which puts it within reach of all, it should be used by all men who have any occasion to determine coking and non-coking coals.

As Applied to Family Affairs

A teacher, after long explanations on coal, impressed the class that the term *anthracite* referred to hard coal and *bituminous* to soft coal. Then she said: "Tommy, let us see if you can form a sentence containing the words anthracite and bituminous?"

Tommy thought a minute, then said: "This morning before pa went to town ma wanted $10 for groceries and things; she pleaded in bituminous words, but pa gave her an anthracite look, and when he disappeared around the corner, ma wept bituminously."

Bath House at Cameron Colliery

Written for The Colliery Engineer

The bath house for the use of miners, shown in Figs. 1 and 2, was built during 1912 by the Mineral Railroad and Mining Co., at their Cameron colliery, Shamokin, Pa.

Fig. 1. Bath House, Cameron Colliery

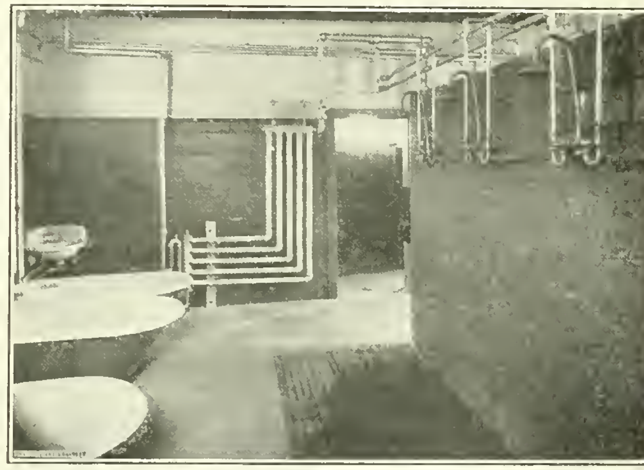

Fig. 2. Intfrior of Bath House

Similar bath houses have been erected at both Pennsylvania and Richards collieries, near Mt. Carmel, excepting that there are no bath tubs in the latter.

The walls of the building are of plain face cement blocks, and are 8 inches thick. The gable roof is of slate and supported upon three intermediate wooden trusses, the rafters and sheathing boards being exposed.

The floor is of concrete and pitches gently to properly placed drains, so that slushing out with a hose may be easily accomplished.

The building is divided transversely by a cement-block partition wall into two rooms, one called the locker or dressing room, 23 ft. 8 in. × 5 in., the other the shower or bath room, which is 23 feet 8 inches wide by 18 feet 10 inches long.

The locker or dressing room is lighted during the day by 10 single-sash windows, each having six lights. These windows are placed about 6 feet above the floor, being hung on hinges from the top, and are operated by means of a cord which serves to open the spring catch at the bottom and also to hold the window up or open.

An 18-inch Swartwout rotary ball-bearing ventilator, placed on the peak of the roof over the center of the room serves for the ventilation.

There are in all 112 metal lockers in this room, which means accommodation for 224 men, as every locker can be used by two individuals at the same time. The lockers are numbered consecutively and every man has a key to his locker only, the locks all being different. There is of course a master key for the use of the attendant. The man using the locker pays a small fee for the key, which fee, however, is refunded to him when he returns the key permanently. All lockers have a cap shelf and six two-prong hooks. The bottoms and doors are perforated, which facilitates the drying and ventilating of clothes. Coils of pipe carrying exhaust steam are run under the bottom of the lockers, thus aiding the drying and ventilating process. Two single rows of lockers are placed against the side walls under the windows, and two double rows, i. e., two single rows back to back, are placed parallel to these, leaving equal spaces between all rows for passages. The lockers are finished in dark olive green japan.

Good stout benches run the entire length of the lockers, in the center of the passages. These benches are securely held in place by having their supports imbedded in the concrete floor.

Four mirrors with aluminum combs attached to neat brass chains are conveniently placed.

The shower, or bath room, is entered by a single door from the locker room. There are six windows of the same description as those in the latter room, which furnish light during the day. Two ventilators placed on the peak of the roof, like the one in the locker room, are sufficient for the ventilation. A partition wall 7 feet high by about 14 feet long runs through the center of the room, from the back or end wall, toward the door; upon this are fastened 10 non-scalding Speakman showers, five on each side. These showers are supplied with hot or cold water as the bather may wish. There is a wooden slatted platform or grating under all the showers, even with the floor, which has a drain underneath. Ten ordinary porcelain-enameled bath tubs are arranged along the side walls, five on a side, and are supplied with hot and cold water. Two porcelain lined basins are also conveniently placed and likewise have hot and cold water. Mirrors, soap cups, towel racks, etc., are freely distributed. Over the entrance door in the shower room is placed a No. 5 Madsen automatic heater. This heater is supplied with exhaust steam and has a capacity of 750 gallons of water per hour delivered at 150 degrees. There is a regulating valve on same which may be set to any temperature desired, thus making it impossible for a man at the showers, tubs, or hand basins to get water hotter than that for which the valve is set, and thereby avoiding the chance of scalding himself. Faucets for attaching hose are supplied and by the latter's use a thorough slushing out of the entire building is easily and quickly accomplished, and as all lockers, benches, tubs, in fact everything, are off the floor, being supported by legs, the building is easily cleaned.

The only entrance into the bath house is through a vestibule, or what is virtually a storm door, built of cement blocks. This vestibule is about 4 feet deep and 7 feet 5 inches on the inside, is lighted during the day by two, one-sash windows, same as used throughout the building. The drafts prevented from entering the locker room when the outside door is opened, make this vestibule almost indispensable. It is covered with a slate roof and in all respects is in harmony with the main building.

The heating of the entire building is by radiation, the radiators being of 2-inch light-weight pipe, which were made by the colliery mechanics, and designed for the use of exhaust steam.

The bath house may be used at night as it is lighted by electricity, the current for which is supplied by the colliery generating plant.

The drips from radiators, wastes from tubs, showers, hand basins and water drained off the floor, etc., are conducted into 4-inch terra-cotta drain pipes underneath the floor.

Inside the entire building is painted white above a horizontal line, about 7 feet from the floor; below this line in the bath room the finish is in bronze green enamel, and in the locker room drab paint.

The exterior is finished all over in white with red trimmings, the pointings being accentuated in black.

Notices of the rules to be observed are conspicuously displayed and are printed in several languages.

Western Mining "Camps"

Mr. R. C. Hills, of Denver, Colo., in a letter to the Mining and Metallurgical Society of America, says that coal mine operations today, especially in the Rocky Mountains where the bulk of the government owned coal land is situated, demands the expenditure of a large amount of capital, and small operators cannot afford the equipment necessary to render a mine reasonably safe, employ qualified inspectors, provide rescue cars and apparatus with trained crews, adequate hospital accommodations with trained nurses, the maintenance of proper sanitary conditions and comfortable homes, schools and means of recreation.

He says that when we reflect that a 1,500-ton mine to have a life of 20 years must have 2,000 acres of 5-foot coal, and realize how difficult it is to obtain this acreage in one body, the reason why coal mine settlements in the West are called "camps," on account of the short life of the mines is at once apparent.

U. S. Geological Survey Fire Sale

As a result of the fire on May 18, in the Geological Survey building the Director has announced a "fire sale" of geologic folios. The entire basement, in which the folios were stored, was filled with dense smoke and many of the folios were burned, others scorched, and all more or less damaged by water. With the approval of Secretary Lane the Director announces that he will sell the entire remaining stock of some 150,000 folios, four-fifths of which are probably as near perfect as goods usually offered in a smoke or fire sale, at the nominal price of 5 cents each. The regular retail price of the standard folios is 25 cents, but a few unusually large folios have sold for 50 cents, and the regular price of the "field edition" of the later folios, a more convenient form for use in the field, is 50 cents. All these are now to be had at 5 cents each, but no wholesale rate applies. The stock includes probably 50,000 to 100,000 copies on which the real damage is practically negligible. Application should be made to The Director, U. S. Geological Survey, Washington, D. C., and remittance made by money order or in coin. Lists will be sent on application.

Specifications for Lubricating Oil

Some of the Difficulties Encountered in Drawing Specifications to Insure Satisfactory Lubrication

*By A. D. Smith**

THIS is an age of efficiency and specifications, and we attempt to purchase lubricative efficiency by carefully determined standards. I say attempt and refer to lubricating oil especially, as most of you who have bought lubricants by specification have not always bought the lubrication you expected.

In an address before the Railway Club, of Pittsburg, a few years ago, I pointed out the difficulty of securing satisfactory lubrication entirely by specification, for the reason, that lubricating oils are highly complex mixtures of still more complex compounds, varying widely in different crudes, and that it is possible in many instances, particularly in oils flashing under 520° F., to produce mixtures from one or more crude bases falling within the limits of physicial tests (as usually conducted) with an oil from another crude base, and yet the two be widely different in lubricating power.

Conversely, oils prepared from different crude bases may vary considerably in their physical constants and possess the same lubricating efficiency within a range say of 20° to 30°, while on elevation to somewhat higher temperature (possible to be reached in actual use), they rapidly differentiate, the one standing up well, the other falling off in lubricating power. In fact, an apparently superior oil, at the temperature at which the testing is made, will often prove to be inferior under the higher temperature of use. Yet again we have to contend with faultily designed bearings, too heavy thrusts for size of support, exposure to extra severe conditions, etc., where no matter what specifications for oil are drawn, it is impossible to secure efficient lubrication, and we must resort to grease, graphite, or other special lubricants.

Possibly some of you have had hitherto unexplained experiences which the preceding statements will make clear, and while it is possible to draw up specifications insuring the highest lubricative efficiency, it is also apparent from the foregoing that such specifications can only be framed from a knowledge involving the physical constants of various distillates, reduced oils, stocks, etc., refined from the different crudes; the market prices of these products; and very important, the actual conditions of use.

Quite naturally the average chemist or engineer does not possess such specific information; and if he seeks aid from treatises on lubrication, with a view to drawing up a set of specifications, he will find a table of physical constants derived from only arbitrary fractions bearing little relation to market products. Frictional values on arbitrary machines will sometimes be given, often misleading, as for example the comparison of cylinder oils on a Thurston testing machine, where no account of the action of steam, as would be encountered under actual conditions of use, is taken into consideration. Other specifications are given erring in being too broad, and sometimes where specifications are correctly framed otherwise, some minor constant is insisted upon, making special refining necessary without a corresponding increase in lubricating value.

The fact that a satisfactory oil is often obtained from loosely drawn or ill-advised specifications is merely incidental, and is more often due to the dealer or refiner trying to give satisfaction than following the letter of the specifications, and points to the fact that unless the buyer possesses in a great measure the specific knowledge referred to, he is as likely to receive the more efficient oil at the lower price by buying by brand from a reputable dealer or refiner.

The question of buying by brand or specification in these days of tests and search for efficiency is an interesting one, and it is admitted that unscrupulous dealers take advantage of a customer by substitution of an inferior product under some high sounding name at a low price, or furnish a really good oil at a price far beyond its intrinsic value; but if purchasing by specification from this type of dealer or refiner does not result in the customer being worsted in the end, I would be very much surprised. On the other hand, a definite brand to the dealer or refiner of integrity means the acme of specialization in the art of refining, and, particularly where one high-grade crude only is refined, much care and pride are taken in maintaining a constant lubricating value. Buying by brand from such a refiner is protection to the customer, for he knows what to expect from the oil in question, and considering the value of this knowledge, he could well afford to pay a slight advance over bulk price of oils of questionable history, bought on the open market.

As a matter of fact, however, many established brands can be bought for slightly less than oils of somewhat similar inspection which have to be specially refined or mixed to meet some arbitrary specification, the reason being that it is cheaper to refine for a certain number of definite products (i. e., brands), by systematic formulas sufficient to take care of all ordinary situations, than to go into special work requiring additional supervision, inspection, tankage, etc. It is, however, often difficult to convince a customer of these facts, especially one who has been taken advantage of by an unscrupulous dealer; and for the benefit of such.

*Superintendent, Canfield Oil Co., Coraopolis, Pa. From November, 1912, Proceedings of Engineers Society of Western Pennsylvania.

33—12—4

or those who wish to check deliveries, or who are otherwise interested in testing lubricants, the writer will give certain hints as to testing where liability to error exists.

Presupposing that testing will be done by chemists or other technically trained men familiar with the general methods of testing and the apparatus used, we will speak first a word about specific gravity, or as it is more familiarly called, simply gravity. Without, at this time, discussing the significance or often lack of significance of this test, attention is called to the different makes of hydrometers on the market, if it is intended to use this method in determining this constant, as it is to be noted that they often differ from each other as much as .5 degree; each claiming moreover to be correct. Without caring to enter into a discussion of the accuracy of any one make, it may be stated that the refiners as a rule use instruments of Tagliabue manufacture. In case of doubt or contention the true specific gravity should be taken preferably by bottle method, and referred back to Baumé values by tables agreeing with those adopted by the Produce Exchange of New York.

In the determination of flash test, it was customary up to a short time ago to use a thermometer scaled for total immersion without applying any correction for exposed stem. Scientifically speaking the test was inaccurate, but as no one thought of applying the correction, the error was universal with all, and the relative relation of tests of course unchanged. A few months ago a thermometer appeared on the market with its scale graduated for so-called bulb immersions; that is, a certain length and temperature for the exposed stem was assumed for average conditions and correction applied to the scale, so that a reading of this thermometer corresponds approximately to a reading of a thermometer scaled for total immersion with stem correction applied. The difference between the two at 600° F. may amount to 15°. As to the superiority of one kind over the other, I think any chemist will have some doubts, but this fact is apparent; namely, confusion and argument are likely to result unless both the refiner (or dealer) and the customer are using the same kind of instrument.

Two methods are in vogue for conducting the cold test; one is to chill gradually, and observe pour and solidification tests progressively downward, the other is to freeze solid and determine pour (and if a light filtered oil, cloud), upward. There is sometimes a difference of 15° in the cloud tests by the two methods, and it is well for a customer to know this fact.

To return to the consideration of specifications, it is manifestly impossible in a paper of this nature to attempt to give any lists of constants of different products from different crudes, even if it seemed desirable to do so; and bearing in mind how conditions of actual use should affect choice, we shall merely attempt to give an example of two sets of specifications that would insure a high-grade product without substitution. The one set is chosen as an example of how simple such specifications may be made, and the other as an idea of more specialized forms.

For the first example, we will consider a cylinder lubricant suitable for moderately high pressure steam, say at 125-pound to 150-pound pressure. The oil must suffer practically no loss from evaporation; it must not chemically decompose into products liable to attack the cylinder walls; it must be adhesive to the rings and walls of the cylinder, which means that it must not attenuate to any great extent within a range of 150° above 212° F. Such conditions are fulfilled to a great extent by Pennsylvania steam refined stocks, and for the illustration at hand, a stock of 225-230 viscosity, Saybolt, at 210° F. would be chosen. Purchased from a dealer or refiner of reputation, this would be all the specification necessary, as the flash would necessarily be above 590° F., which would be high enough for the steam pressure described. Bought on the open market, the following specifications should be added to that of viscosity; namely, minimum flash of 590° F., color dark green, or instead of color specification a minimum allowance of two-tenths per cent. insoluble tarry matter in a mixture of 17 parts 88° gasoline to one part stock. The color specification answers as well, however, as no stock of dark green color would exceed two-tenths per cent. in tarry matter. As to flash the usual figure would be 600° to 605° F. for viscosity given, but to specify it, might require special refining on some kinds of Pennsylvania crude, so that the stock would remain longer in the still and be subjected to a higher temperature than it otherwise would be, without an increase but rather a decrease, in lubricating power. All grades of Pennsylvania crude should make at least 590° flash, hence this specification. It will be noted, gravity is not mentioned, as in this case it would have no significance whatever. About the only value it possesses as a constant is an indication of origin, in this instance unnecessary, as it would be impossible to produce a stock of the inspection given from any crude oil but Pennsylvania crude. The specifications as to color or tarry matter are suggested, not for being in themselves effective as to lubrication value, but significant of this property, that is, they signify the care used in refining, whether stock was overheated, or refined from dirty crude, etc., these factors affecting the lubricating value. It will thus be seen how, for some lubricants, simple specifications can be drawn, practically guaranteeing a definite lubricating value without shouldering unnecessary meaningless standards on the refiner. Where, however, we need oils of lower flash, possible to be made from different crudes, it becomes quite a problem to write out specifications giving a reasonable latitude, and at the same time guaranteeing the lubricating efficiency desired, so that unless specially qualified, the consumer will profit but little in the end by so doing.

Take for instance, a case of a high-grade automobile oil, where a consumer, knowing something of the lasting, non-attenuating properties of a Pennsylvania neutral, desires such an oil. Consider the viscosity desired is 200, color lemon, then a gravity specification must be demanded of 31 Baumé minimum, together with a flash of at least 410° F. If a slightly cheaper oil is demanded of like viscosity, but allowable to contain a trace of carbon, say of a straw color, the gravity may be permitted as low as 30.5, flash the same; and again if this color is wanted at 225 viscosity, the gravity may be allowed as low as 30° Baumé, while if a lemon color with absolute freedom from carbon is wanted at this viscosity, 30.3 Baumé should be set as the minimum limit. Having previously stated that gravity was without significance as to lubricating power, it may seem strange that it is now emphasized, but here it identifies a crude base, and almost the slightest variation from the values given means a possible substitution. The flash test is set at 410° F. as a minimum, for the reason that on non-Pennsylvania neutrals it is extremely difficult to obtain a flash for this grade of oil as high as 410°. Again the cold test on any of the neutrals cited should not be below 20°, for while it is highly desirable to have a low cold test on automobile oils, it must be remembered that Pennsylvania neutrals are pressed from wax-containing media, and that it is hardly possible to press practically, in a large way, so that a better cold test than 20° can be obtained, hence the assumption is that an oil possessing a better test is a non-Pennsylvania product. When settled as to oil being of Pennsylvania origin, there remain special tests to indicate absence of carbon (scarcely necessary in the lemon-colored oils), and chemical tests to determine whether the neutral was acid treated or otherwise, from all of which it will be seen that if an oil of certain base is wanted at about 400-500° flash, specification writing to get just the oil desired becomes a difficult task.

Just as it is not easy to substitute other than the desired grade of lubricant in specifications of the foregoing type, it is not difficult to find an oil from almost any crude base that will comply with many of the loosely drawn standards. For example, we sometimes see a set of specifications for an engine oil reading something as follows: Gr. 27°-31° Be.; flash, not below 390°; viscosity not below 230 at 70° F. Such specifications are of course utterly valueless, and the consumer buying on them would fare just as well by asking the dealer or refiner to give him anything he happened to have that might be suitable for an engine oil. Other specifications call for admixtures of animal oils when they had better be left out, as for example, in stocks intended for cylinder lubrication where superheated steam is used. Under such conditions, the cylinder is simply a digester to the animal oil, the glycerine salt is decomposed by the high heat and pressure, the volatile glycerine escapes with the steam and the free fatty acid remains to attack the metal, cause gummy deposits, etc.

What the outcome of the present tendency to purchase by specification will be in the future is certainly an interesting question, but it is quite apparent that nothing practical will come of it unless the refiner and scientific expert, either acting for the consumer or in the pursuit of pure science, get together. One thing is self-evident, if this takes place; namely, different sets of specifications for lubricants from different crude bases will have to be prepared, which, considering the variation in absolute lubricating value and growing scarcity of some of the higher grade crudes will make the division in price wider than ever. It should also have the desirable effect of making price somewhat more of an index to quality than it is today. Conditions of actual use, new products to meet new demands, will of course continue to affect the choice of lubricants outside of their absolute value and worth, and it will not be until machinery is vastly more standardized than it is today that anything like universal purchase by specification will take place. With the idea of conservation in mind, and the gradually increasing use of superheated steam in this country, it may even take place in the not remote future that the government may prevent the exportation of Pennsylvania stocks, to provide for home industries, which course would bring the idea of specification strongly before the trade. At present, however, the situation seems to be specifications or brand, whichever you prefer, but the strong emphasis is laid on service, with testing at the end, and the main feature, as it should be, satisfactory work done.

Checking Inspectors' Work

Something new in the way of a check upon the inspectors has been introduced at Cokedale, Colo. Ordinarily the fire boss alone marks the date of his visit upon the face of each working place; thus "4-11" for his inspection made early on the morning of April 11. At Cokedale the system is as follows: Each shot firer, after all the holes have been fired, returns to the various working places to see if any traces of fire remain, if any posts have been dislodged, etc. If everything is in good shape he marks with blue chalk, say "4.10.9-05," meaning that the place was inspected at 9.05 o'clock on the night of April 10. The next inspection is made about 6 hours later by the fire boss who not only tests for gas, but examines the roof as well. His mark, in red chalk would be, say "4.11.3-25," meaning that the place was found in good condition at 25 minutes past 3 o'clock on the morning of the 11th. During the day the regular inspectors make their rounds examining particularly the roof and timber conditions and with white chalk mark the hour and date, thus, "4.11.9-30," for half past 9 o'clock on the morning of the 11th.

This method of marking, combined with a system of written reports serves to keep a complete check upon the movements of all the inspectors.

Three-Two Method of Rope Splicing

*By Alex Wilson**

Rope splicing is at times one of the most important and urgent matters required underground. To become proficient in this line of work requires practice; therefore, it is not proposed to make every reader of this article a rope splicer, but it is hoped that every reader will be able to understand from the sketches and explanations how a rope can be spliced. Of the several methods of doing this work "the overlap or rapid method" of splicing as it is called, belies its name. The "one-in-one" method is probably the best for joining a new rope, and "three-two method" is probably the best for ropes that have been in use. All three methods give the same results so far as appearance goes, that is when the ropes are joined there will be six crossings and twelve ends in view, but there is a difference in the butting in each instance: In the "one-in-one" method there is a place known as the common center; that is to say, in a 30-foot splice the ropes are unwound 15 feet on each end, and when both ends are brought together the place where they meet is termed the common center or butt. As the "overlap method" and the "one-in-one" method are known to many readers of The Colliery Engineer, particular attention is given to the "three-two" method.

*New Lexington, Ohio.

The writer uses this method on ropes that have been in use. The tools needed by the rope splicers for this work are a round marlin spike sometimes termed a "needle," a round marlin spoon, a cold cut or hardy, a hand hammer, a sledge, a pocket knife, a piece of strong cord,

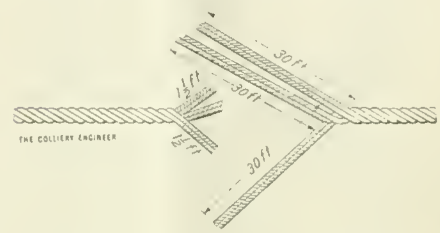

Fig. 1

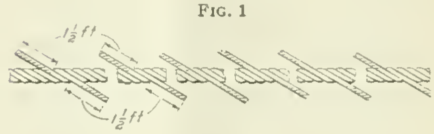

Fig. 2

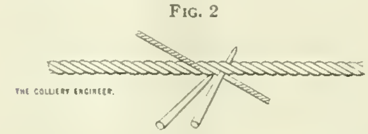

Fig. 3

a roll of friction tape, and sometimes a screw clip.

The first operation is to unlay one end of the rope that is to be spliced for about 30 feet, then unlay the other end for 1½ feet, then cut out the core of hemp. After this operation the rope will look as in Fig. 1. Next take the rope with the short ends and place each end alongside of the long ends of the other rope, crossing them over each other; then pull the two ropes close together, see that the hemp cores exactly meet, and fasten one of the short ends to the rope to which the long ends belong; this prevents any misplacing of the strands.

It will now be observed that the long ends are entirely free, and if they are in their proper position the interweaving of the strands may now be commenced. One of the double short strands is run off the rope while one of the double long strands is run in to the place from which the short strand came out. When about 7 feet 4 inches from the end of the double strand the operator stops and singles out the strands leaving two of the single ones at this point to form a crossing, the other two single strands are then worked 5 feet 8 inches further on, so that they form a crossing also; there is now 1½ feet of the long strand still in view so that the other strand, which forms the crossing, is also cut off leaving 1½ feet for hiding. The second and third double strands follow in the same way leaving 5 feet 8 inches between the crossings as shown in Fig. 2. It will now be observed that there is one crossing left exactly where the two ropes butted together, thus saving the trouble of running in two strands so that the short end to begin with is 1½ feet; therefore, there is no cutting to do on that strand. The splice should now have 6 crossings and twelve ends in view as shown in Fig. 2. To hide the ends is the next operation, and this means taking out the center core so that the ends can be put into place that the rope may have a uniform appearance. The ends are all covered with a piece of friction tape and the marlin spike driven through the center of the rope where the two strands cross each other. The rope is then pryed open so that the core can be cut and taken out sufficiently far to allow the strand to bed itself in the rope. The spike is then brought back to the crossing again and driven through the center of the rope. The spoon is then placed alongside of the spike, the strand placed between the tools and held down by a helper in the direction it is to take in the rope. Now pull the spoon toward the body at the same time push the spike away from the body. The result of this operation will allow the strand to go into the rope where the core came out. The spike is then taken out, the spoon only being needed to keep the strand in place. The spoon is whirled round with the twist of the rope until the whole of the strand is bedded from view. The spoon is then taken out and the operation proceeds in the same way with all the rest of the ends. The position of the tools when hiding an end in a rope is shown in Fig. 3.

There is no need for tying the ends of the rope where the crossings are made, as shown in some sketches. All that is required is to have the strands crossed in such a way that they will lock with each other. The writer has seen 32 ropes put together in one afternoon in a rope splicing contest and none of the teams in the competition used a string or cord where crossings were made on the rope.

Imperial No. 3 Mine Explosion

Written for The Colliery Engineer

On Saturday, May 17, at 6:30 p. m., an explosion occurred at the Imperial Mining Co.'s No. 3 mine near Belle Valley, Noble County, Ohio. This shaft mine, 187 feet deep, is situated on the Cleveland and Marietta branch of the Pennsylvania Railroad, and gives employment to about 200 men and has a capacity of from 1,200 to 1,500 tons of coal per day.

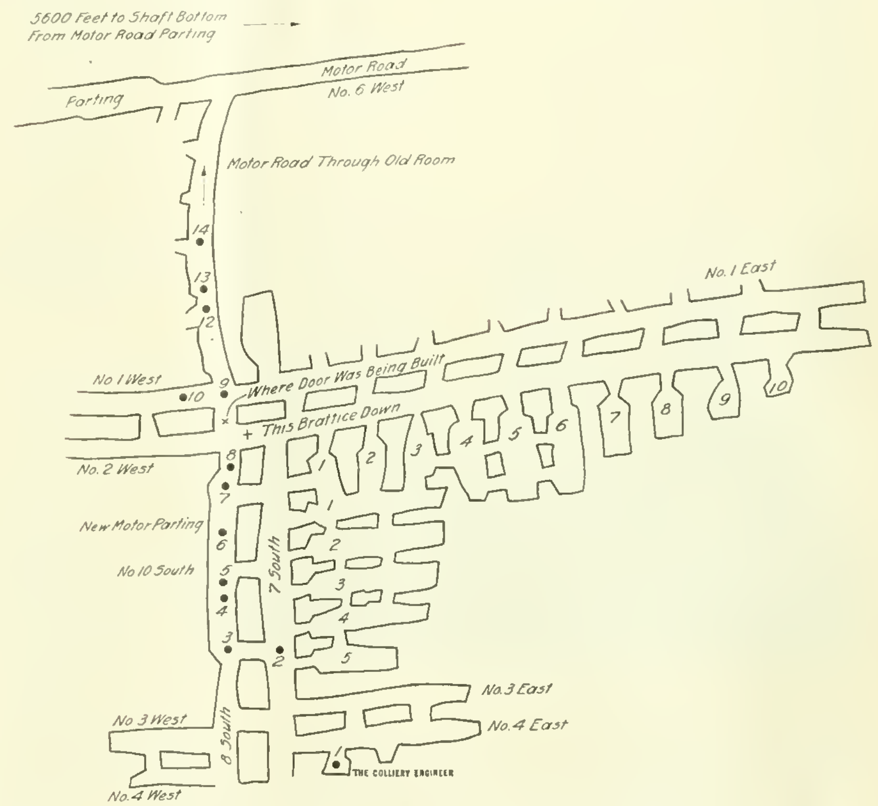
In the May issue of The Colliery Engineer the Noble County coal beds were described by Mr. W. G. Burroughs. The principal workable bed in this county is the Ohio No. 9, or Meigs Creek bed, which being from 80 to 100 feet above the Pittsburg bed, is correlated as the Sewickley bed of the upper coal measures of Pennsylvania.

According to the Ohio Geological Report, Bulletin No. 9, the Pittsburg bed in Noble County is quite thin and only worked in a small way in two places. From the same source of information, the Ohio No. 9, or Meigs Creek bed, averages about 4½ feet in thickness. It also varies in quality as the two following analyses show:

Moisture	5.35	3.12
Volatile matter	33.09	37.36
Fixed carbon	51.27	46.67
Ash	10.29	12.85

While the coal is not so valuable as the Pittsburg coal, it nevertheless, is a good domestic fuel.

Fortunately, at the time of the explosion all but 20 men were out of the mine. These, under the leadership of Harry Dudley, assistant superintendent, were engaged in repairing tracks, about 1¼ miles



Map of Part of Imperial Mine Where Explosion Occurred

from the shaft bottom. After the explosion and before the mine had been examined, the usual number of rumors were circulated as to the cause of the accident. John D. Thompson, who was in the mine at the time of the explosion, believed it was due to natural gas escaping from oil wells. Another stated that the cause of the explosion was probably due to a pocket of gas being opened and ignited from a miner's lamp, this setting off the coal dust. Samuel Soltis, fire boss of the mine, stated that he was not positive whether the last gas test was made on Friday or Saturday morning. The law requires a test to be made every day, and this mine was known to be a gaseous mine in places.

News of the explosion was brought to the surface by four men who were at work in the mine at the time; and as the fan was not stopped it was hoped that those inside could be rescued. With this object in view a rescue party was formed and entered the mine, piloted by Henry Fairhurst, who lost his life in rescuing J. Roy Yeager. J. Roy Yeager, one of the party of track layers, claims to have been thrown, by the explosion, about 300 feet, and as his thigh was broken he could not raise himself and had to lie on the floor. After a few hours of crawling he managed to get to within one-half mile of the shaft, where Fairhurst found him and placed him on a car. The fact that Yeager could not rise probably saved his life, for the cool, fresh air traveled along the floor of the entry. But Fairhurst, after putting Yeager in the car, was overcome. Others of the party seeing Fairhurst fall crawled to him, put him in the car beside Yeager, and brought them both to the surface. Fairhurst lived only a few minutes after reaching the open air.

Superintendent J. B. Morris, of the Caldwell mine, John Smalley, of the Laura mine, and others formed a rescue party and penetrated the mine to the seat of the explosion, where they encountered the bodies of several victims. The accompanying map shows the part of the mine where the explosion occurred and the numbered dots the places where the bodies were found.

Immediately following the explosion, District Mine Inspector Abel Ellwood, of the 5th District, in conjunction with the General Superintendent, Thomas Matthews, of the Imperial Mining Co., made arrangements with the Pennsylvania Railroad Co. to run a special train from Cambridge to Belle Valley carrying rescue equipment and medical aid.

Some time after Henry Fairhurst and J. R. Yeager were brought to the surface, the rescue equipment from the Cambridge Collieries Co. arrived, but it was not used to rescue the men, who it was now known could not have survived the afterdamp. The bodies of those men who met death were found about 1¼ miles from the mine mouth. They were seriously burned and were found face downwards, as if they had tried to avoid the return flame, or back lash, which usually follows a gas explosion.

The back lash is probably due to the explosion wave moving toward the shaft and creating a partial vacuum back of it, into which the mine air rushes. In case there is not sufficient oxygen to consume all the gas on its forward movement, the flame rolls back into the mine air away from the shaft. This phenomenon can be illustrated by filling a fruit jar with illuminating gas, and then setting fire to the gas. When the jar is full of gas there will be no explosion, but the flame will roll about in the jar until it is burned out. The jar now contains a kind of afterdamp, and if a little lime water is placed in it, will become white, showing that the carbon dioxide resulting from the combustion of gas has formed carbonate of lime.

Chief Inspector of Mines J. C. Davies, appointed the following inspectors as a commission to enter the mine and ascertain, if possible, the cause of the explosion: Thomas Morrison, 9th District; L. D. Devore, 10th District; Thomas F. Grogan, 11th District; Robert S. Wheatley, 12th District; and W. H. Werker, 8th District. Mr. Davies accompanied the investigating party.

Under date of May 20 this commission reported to Mr. Davies as follows:

"We have today completed an examination of the O'Gara Coal Co.'s Imperial No. 3 mine, located in Noble County, with a view of determining the cause of the explosion in that mine on the evening of May 17, 1913.

"This explosion occurred between 6 and 7 o'clock P. M., at which time 20 men were in the mine. Of this number 14 were killed and several of the others injured. The number of fatalities was latter increased to 15 by the death of Henry Fairhurst, who was overcome while attempting to rescue one of the injured men.

"As a result of our investigation it is our opinion that the explosion originated in the vicinity of No. 5 room off No. 7 south entry, and that it was produced by the ignition of a bed of firedamp in or near this room; the force of explosion seems to have radiated from this point.

"The direction of greatest force was from the vicinity of No. 5 room from No. 7 entry outward through No. 7 entry and through the breakthroughs into No. 8 entry. In No. 8 entry, opposite No. 4 and No. 5 rooms, a number of men were engaged in laying a side track and two machine men were cutting a skip from the east rib to No. 8 south entry. Ten of the victims were found along No. 8 entry, one in No. 1 east entry just west of No. 8 south; one in No. 1 room in No. 1 east entry; one in No. 7 south entry between No. 4 and No. 5 rooms; and one in No. 1 room in No. 4 east entry. None of them were mutilated to any considerable extent, and all except the one in No. 1 room in No. 4 east entry were severely burned.

"Considerable marsh gas is generated in this section of the mine and an examination of the workings in the vicinity of the scene of the explosion, on May 19 and 20, showed traces of firedamp in most of them.

"This examination showed no dates marked in the working places later than May 16, indicating that these places had not been examined by the fire boss on the day of the explosion. Evidently, the ventilation had been cut off of this section of the mine for a considerable time, thus permitting a body of firedamp to accumulate and some of the workmen, presumably the one found between No. 4 and No. 5 rooms in No. 7 entry had entered No. 5 room with a naked light."

The verdict rendered by the Coroner was as follows: "After having heard the evidence, examined the bodies, and considered facts and circumstances, I do find that the deceased came to their death by a gas explosion in the Imperial mine located in Noble Township, Noble County, Ohio, caused by the gas coming in contact with an open lamp carried by one of the men working on the new motor road, this gas being forced down upon the men by a change in placing the new motor road, the change being the taking down of a brattice in the morning between 1 and 2 E, and hanging of a door which was completed a few moments before the explosion, about 6:50 P. M., under the direction of Harry Dudley, assistant superintendent of the Imperial mine. I also find that the said Harry Dudley ordered the regular fire boss to make no inspection of the mine Saturday morning, as directed in Section 925, Laws of Ohio, requiring the mine to be inspected for gas before the miners are allowed to enter, and then allowed them to enter without the regular fire boss's inspection." Signed,

W. E. Radcliff,
Coroner of Noble County, Noble, Ohio.

Briquetting Coal

Forms of Briquets—A Description of the Shedlock System and Apparatus as Used in England

Written for The Colliery Engineer

The mechanical state of coal used for domestic and industrial purposes determines to a large extent its value to the consumer and operator.

This statement is exemplified by that coal which would otherwise be available for use being kept out of the market chiefly on account of its being too fine and small to be successfully consumed. Small pieces of anthracite known as culm, often purer coal than that which is marketed, and slack or fine bituminous coal, are wasted, because they will not burn satisfactorily on ordinary grate bars.

Some use is made of these fine coals, but not to an extent that prevents large waste from accumulating; for instance, by special arrangements at the collieries a part of the material is consumed, another part is flushed into the mine, while a very small percentage of the whole is made into briquets and burned on locomotives. Again, bituminous slack if of coking variety is partly made into coke, partly shipped to market, partly sold to railroads in some instances at prices below the cost of production, and a large quantity wasted. In recent times an an attempt has been made to briquet these fine coals, by mixing them with adhesive substances termed "binders" and then subjecting the material to pressure in what is termed a "briquet press."

The United States Geological Survey demonstrated that "lignite" could be successfully briquetted without binders; but anthracite, semianthracite, bituminous, and semibituminous slack must be treated with those materials which possess the following essentials, namely: Adhesiveness, combustibility, imperviousness to water; have practically no ash, and so far as possible smokeless. Up to the present time pitch is the favorite binder although it does not come nearly up to the requirements, as it gives disagreeable smoke and odor.*

In Europe briquets are made in large sizes for use in steamships and locomotives, and for storage in distant coal stations in hot climates. The largest forms of briquets shown in Fig. 2 are of foreign manufacture and must either be broken before firing or fired by hand. The smaller forms are suitable for domestic and boiler use in the United States, where to find favor briquets must be in sizes that can be readily shoveled.

*Mineral Resources United States, Part II, page 197. "Coal Briquetting," by E. W. Parker. Also United States Geological Survey Bulletin 316.

The problem to be solved in the production of fuel briquets of a hard nature from coal or coke, is the approximation to the calorific value of the commercial coal from which they are made and the retention of form during the progress of combustion.

A typical process for this purpose is the Shedlock, used in England. The binding material and fine coal

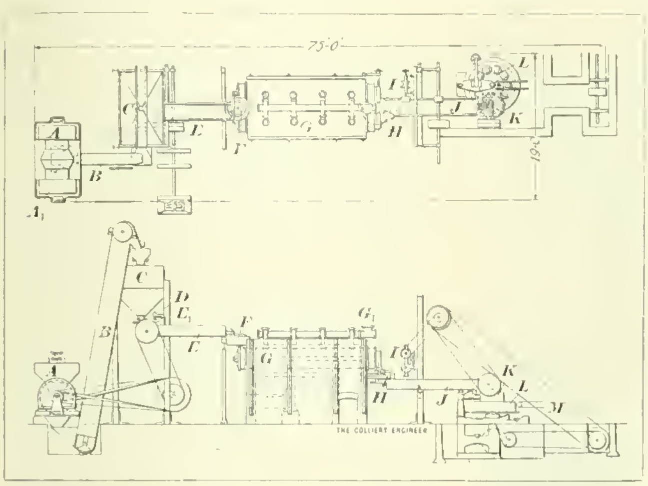


Fig. 1. Briquetting Plant

Fig. 2. Showing Forms of Briquets

after being intimately mixed, are treated in a closed gas-tight chamber, where sufficient heat is supplied to volatilize the lighter constituents and force the binding material into the pores of the finest particles. It is to be understood that it is not sufficient in such processes merely to coat the surfaces of the particles with the binder; thorough impregnation is essential. The gas produced in this chamber is used for heat or power, according to the local conditions, and the solid mixture retains the bulk of the calorific value of the original fuel. The mixture, after this treatment, is removed, and compressed into bricks that are claimed to occupy 25 per cent. less space for a given weight compared with ordinary fuel. As the bricks contain only the heavier constituents of the fuel, a minimum amount of smoke is given off in burning. The bricks are so homogeneous that they do not disintegrate when exposed, and retain their form when burning, producing a steady intense heat. They can be stored under water without excessive absorption of moisture. In some other briquetting processes pitch is used as a binder. In the Shedlock process a suitable liquid hydrocarbon is used as a binding agent and it is claimed that the cost of manufacture is nearly 20 per cent. less than for briquets made from pitch.

The process can be followed from Fig. 1, showing the general arrangement of the plant required. The coal or other fuel which must not exceed a 1-inch cube in dimensions, is fed to the disintegrator by suitable means from storage hoppers. Either a band conveyer or push plate conveyer may be used depending on the position of the storage bin with relation to the briquetting plant. The coal after passing through the disintegrator *A* is raised by means of an elevator *B* to the powdered storage bin *C* placed directly above the revolving plate feeder *D*. On the lower end of the hopper *C* there is an adjustable sleeve so that the amount of coal passing through the bottom of the hopper can be adjusted accurately. Just above the plate feeder is an adjustable scraper and as the plate revolves the mass of coal left on it after passing the adjustable sleeve is swept off in the required direction. As this stream of coal falls from the feeding plate *D* into the double-shafted mixer *E*, tar is sprayed over it by means of a spray tap E_1, and it is more or less coated by a very thin film of tar or other hydrocarbon used in the process. This mass is gradually worked by paddles throughout the length of the mixer and at the same time is formed into a homogeneous mass, which falls by gravity into a feeding pan *F*; at the other end a gas-tight seal is formed by the pan at one end of the calciners *G* into which the pan discharges through two openings connected with the two calciners. The calciners are supplied with a series of steel paddles and paddle plates which, when rotated by means of worm gearing, gradually move the mass from one end of the calciners to the other. The volatile substances produced while the mixture is being heated are drawn by exhaust pipes fixed to the upper surface of the calciners which are connected to the main outlet pipe G_1. By means of suitable exhausting apparatus these gases are withdrawn as quickly as they are formed. On account of the various grades of coal which may be treated by this process and the time taken to produce the right kind of material before briquetting, the speed at which the paddles in the calciners rotate must be adjusted over a considerable range. For this reason the regulating device *I* is installed which will give the paddles double the normal speed required.

When the material arrives at the discharge end of the calciners it passes on to a second feeding plate *H*, placed there for the purpose of maintaining a column of material. The outlet of the coal is provided with another adjustable sleeve so that the amount of calcined material deposited on the revolving plate can be regulated so as to maintain within the outlets the amount of material required to prevent the ingress of air. As the plate feeder revolves and withdraws the material through the outlet, the calcined mixture is swept off by means of a scraper into a second double-shafted mixer *J*. This not only cools the charge but allows it to be thoroughly opened up so that any included gases and vapors can detach themselves from the hot mass. On arrival at the other end of the mixer the mass is in a fairly cool state and falls into the feeding pan *K* placed directly above the rotating table of the briquetting press *L*. Within the pan are a series of fixed points and rotating paddles so arranged that further mixing of the material is given at this stage. On the lower end of the rotating spindle are placed paddles which fill pockets of the press with the mixture when rotated underneath. The briquets are then compressed and are ejected from the press on to the band conveyer *M*, which carries them either to storage trucks or to wagons for shipment.

Alternative binders, such as lime, resin, and pitch, are of course adopted for the purpose of coal briquetting in addition to the binders mentioned, in order to agglomerate the coal dust. Of these, pitch is by far the most used, and the apparatus which is usually adopted for a coal-briquet plant utilizing pitch consists of an elevating or conveying means of tranferring the materials from storage, the pitch being dealt with in a pitch cracker. The small coal and pitch are carefully mixed in the proper proportions in a mixer or measurer, from which they are passed to a disintegrator where the mixture is pulverized to small mesh. By means of chain elevators, it is then carried to a superheater and vertical heating plant, and heat is applied until the pitch becomes soft and unites with the coal. In this state the mixture is filled into molds on a briquet machine constructed on the Yeadon system, and there pressed into blocks which harden as they become cold. They are then transferred by means of endless conveyers to the storage pile or delivered to wagons. In France and Belgium briquets made in this manner have for a long time been utilized extensively, while the same development is now in progress in Germany to a large extent. Several plants have also been established in the South Wales coal area of Great Britain. The great danger in briquets made in this way, is that on burning the combustion may be attended with too much smoke and unpleasant smell; but where, as is the case with the Yeadon plant, the bricks are made of an extremely hard and durable nature by extreme pressure, it is found that not only is the life and burning quality of the fuel increased, and the briquets made of a weather-proof nature, but they are extremely durable in the fire and emit very little smoke and odor.

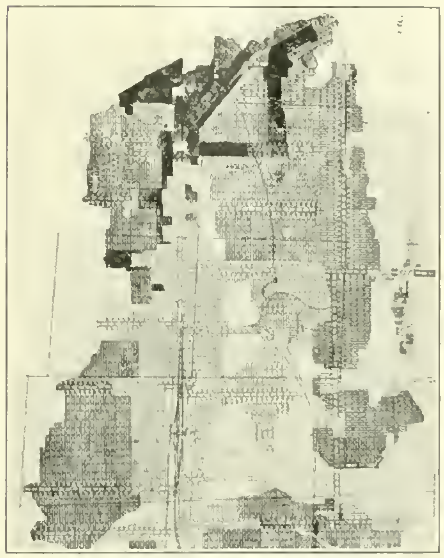
The amount of incombustible contained in briquets depends on the amount of ash in the initial coal, and if this exceeds 6 or 7 per cent. it is advisable that the small coal should be washed before being used in briquetting.

There is a fairly large range of apparatus available for the economic utilization of materials which have for a long time past been considered as waste products. The importance of the matter as regards the fuel resources of the civilized world may be judged by the small and slack coal dumped in the vicinity of collieries because there is no market for it. In addition to this, it was reported some time ago by a Royal Commission which investigated the condition of British coal fields, that about one-third of the coal of the seams remains below the surface. The production of smokeless briquets capable of withstanding the effect of climate variations such as moist air, goes a long way to solve the difficulty; and, moreover, it has been found that whereas large coal, especially that mixed with pyrites, will lose from 15 to 20 or 30 per cent. of its calorific value when exposed for 2 to 6 months to moist air, properly made briquets retain practically their original value. Within the next few years it is inevitable, owing to the economic changes which are taking place in manufacture, that this subject will come to the front even more prominently than at the present time, and it is therefore hoped that the above survey of the present conditions will provide a starting point for further investigations which would tend toward the cheapening of the cost of production.

Photographing Blueprint Maps

*By H. A. Williamson**

On several occasions the Drafting Department of the Consolidated Coal Co. has been called upon to reproduce maps on short notice. For instance, a large line print (blue lines with white background) on a scale of 800 feet to the inch was sent in. This print covered topography and geography over a certain territory and was entirely too large and bulky to embody in a report on a portion of the territory shown. It was desired to have a smaller map showing the territory covered by the print, but on a scale of 2 miles to the inch, and, also, to have a map showing a portion of the print on a scale of ½ mile to the inch, and it was necessary to have twelve of each of these maps within 24 hours.



Reduced Map of Mine

With our ordinary camera we made an 11″×14″ negative of this print. We then placed this negative in our enlarging camera and made an enlargement of it on the scale of 2 miles to 1 inch. After making these we blocked out with black paper all of the negative, except the small portion that was needed, and made our smaller map on the scale of ½ mile to 1 inch.

The apparatus and the method used in doing this was, briefly, as follows:

In making the negative the line print was placed on an easel, it first having been ironed and all wrinkles smoothed out as well as possible. The camera was placed just far enough away to get the entire print well within the limit of the 11″×14″ plate.

A trichromatic plate was used, and a process lens, with an orange filter, this combination making the blue lines strong on the negative. The exposure was 8 minutes and the plate was developed according to the method furnished by the manufacturer of the plates. Mercury vapor lamps were used to illuminate the print at the time of exposure. In making this reduction from the original print on to the plate no attention was paid to scale except that a strong black line exactly 6.6 inches long was placed on the print; the scale being 800 feet to the inch, this line would then represent 1 mile regardless of what reduction or enlargement had been made with the camera.

In making the enlargements the same lens was used, but without the orange filter. The negative was put in the enlarging camera and the mercury lamps again brought into service, this time at the back of the camera, throwing the light through the plate, then through the lens into the easel placed in the dark room. It was then a simple matter to measure the image of the black line (originally 6.6 inches long) on the easel and move the easel back and forward until this line was ½ inch long when sharply in focus, which made the scale 2 miles to the inch. When this was accomplished the light was shut off and a sheet of bromide paper (a rapid brand giving sharp lines being used) of the proper size was placed in position on the easel and the exposure made; this operation being repeated until we had 12 prints.

We then blocked out the negative as before mentioned and moved the easel until the black line was exactly 2 inches long, making the scale ½ mile to the inch, and made our prints as before.

Any one not familiar with enlarging methods can obtain, without cost, books giving complete information on the subject from any of the larger camera manufacturers. No special apparatus is necessary; any ordinary camera lens will do the work, and while we used vapor lamps sunlight can be utilized to accomplish the same result equally as well.

* Fairmont, W. Va.

Coal Mine Fires

Fires Classified According to Locations—Their Causes and Some of the Methods of Combating Them

In a bulletin recently issued on "Coal Mine Fires," Geo. S. Rice, Chief Mining Engineer of the United States Bureau of Mines, covered the causes of fires in coal mines and methods of prevention, in a very thorough manner, and J. Krzyanowski and St. Wysocki in a paper published in the Transactions of the Federated Institute of Mining Engineers, Great Britain, treat on methods of combating such fires. The two papers combined contain so much of value to coal mine officials that the most important features in each have been extracted and combined in this article.

The data extracted from Mr. Rice's bulletin are as follows:

1. Fires in entries or headings are started generally by open lights setting fire to dry timber or brattice cloth, usually at a siding where men gather to rest. Mules or horses may be fed at such places and hay may be littered around. At a ventilating door the trapper boy sometimes digs a hole in the rib at one side of the door in which to rest while waiting for trips to pass. Engineers of the Bureau have examined mines in which it has been noted that these resting places have been lined with loose hay. There have been fires that were said to have started in one or another of these ways.

To lessen the chances of such fires, safety lamps should be substituted for the open lights. English statistics indicate that there are vastly more accidents in open-light mines than in safety-lamp mines in the same districts.

2. Fires at the face may be caused by a blast setting fire to the coal or to small gas "feeders." Blasting is probably the most fruitful source of mine fires in this country, and largely because of the excessive use of black powder and dynamite in many coal fields. In certain western coal fields it is not uncommon for several fires to start in a mine every night from shooting. "Firebugs" or "fire-runners" (firemen) are employed in these mines to put out the fires. Such fires break out more often in mines that "make a little gas" than in what are termed "gaseous mines," because more precaution is taken in the latter; yet a shot overcharged with black powder or dynamite is liable to set almost any bituminous coal on fire.

Permissible explosives as used under government regulations lessen the chance of fire. Inspection of the shots as soon as possible after firing and the placing of portable fire extinguishers in boxes at convenient points are wise precautions. A still wiser precaution is to have a complete system of water pipes throughout the mine with taps at intervals of not over 100 feet and with portable hose and nozzle at regular intervals of about 200 yards. This system has been employed in a number of mines. Although its first cost is considerable, it affords efficient fire protection; moreover, in bituminous coal mines it is convenient for laying coal dust, thus lessening the danger of explosions.

3. Fires in pillar workings, that is, where pillars are being drawn, start in much the same way as those in solid workings, but pillar fires originating from explosives are less frequent because smaller charges of explosives are usually needed for pillar coal.

Fires in pillar workings are harder to put out by direct attack than those in the solid coal on account of the falling roof; if stoppings must be used, they cannot be built so readily, nor made tight in the broken coal. In consequence, large areas may have to be enclosed or sealed.

4. Gob fires are frequent in the lignite and subbituminous coal of the Rocky Mountain fields, in the bituminous coal of the Iowa and Missouri field, and parts of the Illinois field, also to less extent in many other coal districts of the United States. Generally their origin is due to spontaneous combustion. In coal mining the terms "spontaneous mine fire" and "gob fire" are almost synonymous. These fires may start in abandoned or caved workings of any mine, and in the process of pillar drawing if the work proceeds slowly. Gob fires are particularly liable to occur in mines in which the coal absorbs oxygen rapidly. Such coal has a relatively low fixed-carbon content and a high moisture content. It is a debated question how far the sulphur content of the coal (visible as iron pyrite) is responsible for spontaneous fires. Formerly it was believed to be the chief factor; now it is generally thought to be only an auxiliary factor. In either case it is safer to load the "sulphur balls" into cars and send them out of the mine. If they are abundant they may be sold to manufacturers of sulphuric acid, as is done by certain mines in Illinois, Ohio, and other states, thus partly compensating for the cost of handling.

Machine cuttings left in the goaf of longwall workings are particularly liable to give trouble by firing spontaneously; moreover, in open rooms dry coal dust, if stirred up by a blown-out shot, is a source of danger from its liability to ignition. Therefore, all cuttings and fine coal should be sent out of the mine.

In the Illinois and Iowa coal fields, among others, the author has observed that where water drips on the gob there is especial liability to heat, probably because of alternate wetting and drying, which is a well-recognized cause of spontaneous firing in storage piles on the surface.

A gob fire probably originates in the following manner: The coal and the shale from the roof or partings disintegrate as the occluded gases escape; at the same time oxygen is absorbed. At first oxidation is slow. In a goaf when the roof falls the heat is retained so that the temperature rises. With the rise in temperature more gas is liberated, and oxidation becomes more rapid. These reactions continue until the temperature reaches a dangerous point.

Fires often originate in the vicinity of timber. It has been suggested that timber acts as tinder; in other words, it probably ignites more easily than the coal itself.

The outward manifestations of a spontaneous gob fire are: first, that beads of moisture appear on the roof and upper part of the timber props, at the edge of the gob—the heat may or may not be appreciable; second, that the heat becomes perceptible and the drops of moisture disappear—thereafter the rise in temperature is very rapid. In the beginning of a gob fire the circulation of air is sufficient to carry off the heat developed in the gob, yet enough air is present to cause slow oxidation. These opposing conditions are not easily met, and gas, if present, causes difficult complications.

In pulling pillars or in longwall work, it is very difficult, and in some cases impossible, to ventilate the goaf sufficiently to keep it cool. On the other hand, the working places of the miners must be ventilated, and some of the air-current drifts into the goaf, thus providing sufficient air for the oxidation.

In some coal fields the fallen shale or slate roof fires spontaneously. In the Iowa field and in some parts of the Illinois field it is necessary to seal off rooms as soon as they have been finished or have been stopped by great falls, otherwise the material heats and fires quickly. It would be better if the pillars in such mines were extracted, so that there would be a complete closing down of the roof. Gob fires rarely occur in a tightly packed longwall goaf, and never where hydraulic filling or flushing is employed, as in Upper Silesia, Germany. This is one reason why this system has been used in the thick (20- to 40-foot) coal beds of that district, where formerly gob fires were of frequent occurrence and difficult to extinguish.

Where the customary room-and-pillar system is employed in mines liable to gob fires, if the pillars cannot be quickly drawn, it is generally best to seal off promptly before the gob heats. A concrete or brick wall, coated with cement, should be used, a pipe with a gate valve being put through it near the top, so that temperature readings and samples of the gases may be taken. There is serious objection to sealing off rooms where the mine produces methane in any quantity, because a large body of standing gas, even behind a strong stopping, is a constant menace. In such a mine the pillar-and-stall method of mining, or some form of longwall, should be employed.

Fires from electric incandescent lamps are liable to be caused by allowing such lights to rest in contact with wood, or coal dust, or even the coal itself.

A more fruitful source of fires is the short-circuiting of improperly installed lighting or power cables. The remedy is to have all electric lights and wires installed and regularly inspected by a competent electrical engineer.

Trolley wires for an underground haulage road should be installed with great care and should be inspected often. Several serious mine fires, one of which involved the loss of a large Southern Illinois mine. are said to have been caused by the short-circuiting of trolley wires, which set fire to the wooden frames of doors. To protect against such short-circuiting, doors, when necessary along the trolley road, should be set in brick or concrete frames.

Another cause of fire along entries is the grounding of power lines or trolley-road returns. Many fires have originated from this cause. In this country, power lines in mines are seldom armored or even rubber covered; a fall of roof or a movement of timber may bring the bare charged wire in contact with either wood or coal. If such lines are placed in entries not often traveled, as is frequently done, a fire may become serious before it is discovered.

The remedy is regular inspection at least twice a shift while the current is on, or the armoring of such cables. In long-lived mines it may prove economical in the end to have the power cables enclosed in conduits that lie in covered trenches.

Underground ventilating fans, especially so-called "booster" fans, to help the surface fans, are being used more and more. In Europe such fans are usually driven by compressed air, a safe but more expensive method than by electricity, which is used in this country. As it is necessary in most places to drive the fans all the time day after day, it is evident that in spite of daily inspection there is liable to be a time when an armature gets overheated and the insulating material takes fire. This is supposed to have happened in a large Ohio mine where the fire got beyond control, so that a large section of the mine had to be sealed off.

Generally such fans have been set in wood frames or there has been timbering near at hand which could be set on fire by the burning of the insulating material.

The remedy is to set such an electrically driven fan in a non-combustible frame, to line the passageway for some yards with brick or concrete, and then to inspect the fan often.

Great explosions of firedamp, and particularly of coal dust, nearly always leave fires in their trail along timbered entries or where the coal dust is thick. The using up of the oxygen and the damping effect of the carbon monoxide and dioxide produced by the explosion fortunately puts out most fires thus started. But. if the ventilation is quickly restored in order to save life, or if there are areas not reached by the explosion and able to supply air, the fires are likely to revive. In a certain breakthrough between rooms, in an Alabama mine, the burning dust from an explosion fell on a pile of fine coal, and the fire lay dormant for several days; then, when the ventilation was restored, it burst out actively.

The extract from Messrs. Krzyanowski and Wysocki's paper is as follows:

The writers consider mine fires due to the following causes:

(1) Fires due to inflammation of timber and other easily combustible materials, such as hay and lubricating oils. They cite several cases in which such fires have caused great loss of life and damage to property.* (2) Fires due to inflammation of coal; (*a*) by contact with a flame, and (*b*) by spontaneous combustion. (3) Fires caused by inflammation of coal dust. And (4) fires caused by explosions of firedamp.

The contrast between the precautions against fires which are taken in large establishments on the surface and in towns, with the general lack of such precautions in mines is surprising when one considers that in mines the risk of fire is greater than on the surface, owing to the profusion of inflammable materials and the constant use of artificial lights. The danger from the gaseous products of combustion is also much greater underground than on the surface.

The only means of defense actually available in most mines are: (1) Partial changes in the direction of the air-currents, where doors or ventilating appliances allow of such changes. (2) The modification of the whole system of ventilation, which is a complicated operation requiring much time. (3) The construction of wooden dams after the fire has broken out, in order to arrest the propagation of the products of combustion and to isolate the fire. These measures have been in use for nearly 4 centuries, and they are inadequate to meet the dangers of fires, owing to the incessant development of mines and the increased number of persons employed therein, nor are they in accord with the progress made in mining science.

It is difficult to estimate, even approximately, the speed with which a fire is propagated in timbered mines. The speed varies with the state of the ventilating current and the physical condition of the mine and the timber; the amount and direction of the inclination of the roadways are also factors. It is possible, however, to estimate with some precision the route and the velocity of the gases of combustion, which is incomparably greater than that of the fire. In a given mine, the velocity of the ventilating current may vary greatly, according to the sectional area of the passages through which it moves. Assuming the average speed of the main air-current in mines as 400 feet per minute, it follows that the rate of advance of the smoke and gases from a fire may also be estimated at 400 feet per minute, between the fire and the point of exit of the current. Smoke advances against the air-current at the same speed as the fire, but the speed in this direction is insignificant, except in cases where the passage is vertical or highly inclined.

It follows from the foregoing observations that in a mine fire the persons in greatest danger are those between the fire and the point of exit of the air-current. If the length of the main air-current is taken at from 6,000 to 12,000 feet and the speed of the air-current is taken at 400 feet per minute, it follows that the current traverses 3,000 feet of the airway in $7\frac{1}{2}$ minutes, and traverses the whole route in from 15 to 30 minutes. This is about the speed and time in which the gases and fumes traverse the main airway when the fire occurs near the entrance of the mine. A more complete idea of the greatness of the risk in such circumstances is obtained by considering that the mass of noxious gases produced by the burning of the timber in a few feet of roadway, or by the inflammation of a limited amount of firedamp and coal dust, or by the combustion of a few hundred pounds of coal, would be sufficient to fill all the mine; and that the fatal effects of these gases on men are produced, not at the end of 1 hour or one-half hour, but, according to the greater or lesser density of the poisonous mixture, at the end of some minutes.

Considering the rapidity of the progress of the smoke and gases in mines, it is evident that miners, surprised by the poisonous current, have no chance of escaping. The system of warning by word of mouth is not sufficient to reach the persons interested in all parts of the mine, or the warning only reaches them when the intake airway near their working places is saturated with poisonous gases.

The system proposed for dealing with fires in mines consists in the pre-establishment of dams capable of being instantly closed in case of fire, and situated in such places as to divide the mine into sections, which could be isolated by the closure of the dams. The dams would be fitted with doors of such size, that when open, as in ordinary times, they would not impede the ventilation. These dams are placed as near as possible to the points where currents of air divide or come together, so that access to one side of the dams may be easily maintained by ventilation. Where this is not practicable, special means for ventilation should be provided.

The dams may be made of wood or of brick, the openings being kept as large as practicable, so as not to impede the ventilation. The doors may be of wood or sheet iron, made as air-tight as possible, and there should always be a supply of mortar or moist clay at hand to make them quite air-tight.

Places which should be especially guarded, as being by their nature extra dangerous in case of a fire, are vertical shafts, timbered engine houses, stables, hay depots, and heavily timbered roads containing steam pipes.

The organization of the service for closing the doors in case of fire is to be entrusted to certain officials and special signals arranged for notifying them and those in danger.

*Pancoast mine; fire in engine room, 73 killed, February 7, 1911. Avondale shaft disaster. Cherry mine disaster, 1910; hay caught fire. 1912, Mt. Lyell, Tasmania, 42 killed; inside pump house.

The Earning Power of Chemistry

In the Coal Mining Industry—Economies Rendered Possible in Purchase of Materials and Sale of Product

*By Edmund M. Chance**

When the mine executive sees many of the great mining corporations of this country equipping costly chemical laboratories, and employing a staff of trained chemists, he must often be faced with the query "what benefit do these companies derive from this work, that can offset the considerable expense incurred?" It will therefore, be the purpose of this paper to attempt briefly to answer this question by describing a few of the many ways in which chemistry can be of service to the coal mining industries.

The role of the chemist in the production of coal is that of helpful cooperation. It is his office to supply data to the executive and operating departments of the company with which he is associated, in the light of which these departments can work more certainly and efficiently. It is for the chemist to discover and call attention to what might be termed the invisible leaks. It may be granted that the mining executives have corrected, or removed all the causes of inefficiency, friction, or waste of which they have knowledge. This does not imply by any means that none remain, as there are many that only become visible in the searching light of chemical investigation. It is in the discovery and correction of these latter that the chemist is invaluable.

The work of the chemist in the coal producing industries may be divided into three broad classes. The purchase of supplies used in mining, the production, and preparation of coal, and the merchanting of the prepared product.

As is well known, almost all coal mining supplies are purchased by brand. Now, this means that when a substance giving satisfactory service has been secured, the market narrows down to one manufacturer, and a single brand, whereas there are doubtless many similar articles upon the market, which, because of competition, are much cheaper, and yet are of equal quality. To quote a case in point; it has been found by experience that a certain lubricating oil gave excellent results under the conditions obtaining at a certain colliery. Now, this oil was sold under a brand name at 45 cents per gallon. Under the old regime. the company was practically powerless, as they had absolutely no knowledge of the nature, or composition, of this oil, and therefore were unable to duplicate it in the product of another manufacturer. On submitting this oil to their chemist, it was a simple matter to determine of what constituents it was composed, and therefore by specifying that the oil should contain these constituents the whole market was thrown open, and the same oil precisely was obtained for 28 cents per gallon. Such instances may be multiplied indefinitely. The burning oils, particularly, are purchased empirically. Not only can the same product be obtained more cheaply under specification, but it is often by no means certain that the best product for the purpose is being used. Thus, in the case of miners burning oils, it is frequently possible to purchase more cheaply oils, which, while giving far less smoke and odor, give more light.

In the use of explosives in the mines, it is possible to move the coal more cheaply when an intelligent choice of explosives is made, than when the explosives are purchased by name only. It is necessary not only to know the chemical composition of the various explosives, but also their quantitative composition. When such a course is pursued, not only is fraud on the part of the manufacturer exposed at once, but in many cases the advisability of substituting cheaper for the more costly explosives becomes at once apparent, and many of the claims advanced by the powder companies on behalf of their more expensive powders become ridiculous.

There is one problem which the coal mining official has constantly before him; that is the question of the softening of boiler waters. He must raise steam with waters ranging in purity from waters of the purity of rain water, to a moderately strong solution of sulphuric acid containing sulphates of iron and alumina. In the average case, however, the problem generally is to prevent scaling, and corrosion when a water containing a moderate quantity of incrusting solids or a trace of free sulphuric acid is to be used. Now, we must complicate this problem by the many boiler compounds now upon the market. These compounds range in nature from comparatively pure carbonate, or hydrate of soda, to mixtures containing the refuse of various manufacturing processes. They are alike in only two particulars, the fact that their price is many times their value, and that they are all put upon the market as "cure alls." It is not to be understood that all of these so-called boiler compounds are without merit. On the contrary, some are very excellent indeed, although all are unreasonably high in price. The point is this—that each boiler water requires a boiler compound especially adapted to its needs. The water must be analyzed, and the treatment then prescribed. This treatment consists ordinarily in the addition of a certain definite quantity of quick lime, soda ash, or caustic soda to the water involved. And when this is done intelligently, following the direction of a competent chemist, it is very gratifying to observe how quickly the boiler troubles will disappear. When it is

*Consulting Chemist, Wilkes-Barre, Pa.

understood that the most costly of these materials (caustic soda) can be bought for less than 2 cents per pound, it will be understood what is meant when the statement is made that boiler compounds now on the market are unreasonably costly. In fact, the indiscriminate use of boiler compounds can well be compared to the use of nostrums, or widely advertised proprietary remedies, by those afflicted with organic disease.

Though the author realizes that the examples here cited of the benefits derived from the chemical control of the purchase of supplies under specification, are inadequate, yet space will not permit further detail.

In considering the application of chemistry to the production of coal, the control of mine fires will first be discussed. By exact air analysis, it is possible to accurately follow the extinction of a sealed-in mine fire. When the attack is to be made by flushing through bore holes, the analysis of the air issuing from cracks and fissures in the surface is not only invaluable in indicating the places at which the attack can be most advantageously made, but is also useful in determining the effect of the flushed material upon the fire.

In the mining of the coal, the advice of the chemist is useful in coping with the problem of explosives and mine illumination, as before mentioned.

The tendency of the day lies unquestionably toward the purchase of materials upon their real economic value. Now, in the past, coal has been bought and sold largely in the bituminous, and almost entirely in the anthracite, fields upon its appearance and trade name. This state of affairs is being rapidly replaced by the purchase and sale of this material upon its true value as a steam raiser, source of heat, gas, or coke, or its particular usefulness in the various arts. This being the case, it is of paramount importance that the coal operator should not only know exactly the properties his coal possesses, but should prepare it so that it may best meet the conditions under which it is to be used. Now, in the anthracite field particularly, coal has been prepared to meet the arbitrary conditions laid down by a visual inspection. As unfortunately it is not possible to determine accurately the fuel value of anthracite by the eye, the preparation is more or less wasteful, as materials must be rejected because of their appearance, which, possessing a considerable fuel value, would not deleteriously affect the prepared product. When the preparation, however, is controlled by chemical analysis, only materials of low heating value are purposely rejected, and it is surprising to what extent the proportion of prepared sizes per mine car can be increased without decreasing the fuel value of the prepared coal.

When coal is sold under specification, the vendor must, for his own protection, have an absolutely accurate knowledge of the properties of his product. If an examination be made of the records of the United States Government of the purchase of coal under specification, it will become at once apparent that the vender who enters the market without this knowledge becomes liable to prohibitive penalties. In fact, one of the great sources of dissatisfaction with this method of selling coal lies in the fact that the seller is ignorant of the true quality of his coal, and therefore agrees to supply an article he does not possess.

Because of the wide variation in the intrinsic quality of the product of different collieries, it is often possible for a company by selling the product of certain collieries under specification, to reap a considerable premium, while the product of collieries preparing coal of average excellence is sold in the open market. It is often possible, also, by studying carefully the product of different collieries to secure a considerable premium for certain coals for special purposes without incurring any additional expense in preparation.

The writer appreciates fully how inadequately this paper has covered the subject set forth in its title. In extenuation, besides the lack of space, must be advanced the fact that but few general principles apply to the solution of the problems confronting the mining chemist. Each problem must be considered alone, and treated in probably a different way from all that have preceded it.

Conservation and Commercialism

*By Francis S. Peabody**

The following is abstracted from Mr. Peabody's address, delivered at the dedication of the Mining and Metallurgical Laboratory of the University of Illinois:

The coal area of Illinois is approximately 35,000 square miles, or 22,000,000 acres. It extends north and south 280 miles; and east and west 180 miles in its widest part.

Conservation and commercialism, so far as coal mining is concerned, are correlative, the same elements entering into both; namely, human life, labor, natural resources, and money or capital.

Notwithstanding the similarity in the component parts which dominate conservation and commercialism, it seems impossible at this time to reconcile the two so that a successful commercial operation will work harmoniously with conservation.

The antagonistic relationship between commercialism and conservation begins with the first element, "human life." There is no question but that safety is the first consideration, and our last legislature passed laws for the safety of miners, which, while good, the Illinois operators would like to evade because they place burdens on them in the way of expenditures which their competitors in other states are free from.

The more restrictions that are put upon the operator for the safety of his men, the more his costs increase, and, if human, he will try to evade these additional costs, notwithstanding the fact that he knows the neces-

* President Peabody Coal Co., Chicago, Ill.

sity of the law; but competition forces him to spend as little money as possible in producing his coal.

The new laws passed by the last legislature, especially in regard to the construction of shafts, tipples, top works, fire appliances, etc., have put at least 40 per cent. additional cost upon sinking a new shaft compared with the shafts sunk before the law was passed, and these new laws have added an operating cost to all mines, whether sunk under the old law or under the new law, of almost 10 per cent. on the cost of production.

Reverting now from commercialism to conservation of human life. Operators should not hesitate to spend money to protect human life. This, however, is impossible under the present keen competition.

Safety appliances, fire apparatus, rescue rooms, danger signals, steel I beams, concreting dangerous places in entries, daily inspection of mine, etc., should be most carefully done and it is believed that by proper safety methods practically all danger to life and limb could be eliminated from coal mining. But these make considerable addition to the expense and so to cost of production.

Our state is one of the most advanced in regard to legislation for the protection of life; however, added laws will increase the difficulty, from a commercial standpoint, of mining coal in our state.

If there could be an Interstate Commission of Operators and Miners from Illinois, Indiana, Ohio, and Pennsylvania, appointed by the governors of those states for the purpose of recommending similar laws in each state the result would be beneficial to those states.

Commercialism from the miner's point of view differs unnecessarily from the operators. The miner has his labor for sale and is paid on the tonnage basis. He tries to produce a large tonnage regardless of the condition in which he delivers the coal to the owner. The miner, instead of undercutting his coal, shoots off the solid, thus shattering the coal so it is almost unmarketable; in some districts since this kind of mining has been adopted by the men, screenings have increased from 20 to 40 per cent.

This is not all, as shooting off the solid knocks down timbers, causes at times windy shots that endanger the miner's life and the lives of his fellow workmen, damages the roof, and in case of an explosion, causes enormous loss to the company which employs him. It is evident that commercialism dominates the miner more than the operator who looks after life and property while the miner cares for nothing but an increased tonnage.

From the standpoint of conservation, the miner, instead of making every effort to load as much coal as possible regardless of consequences, should undermine the coal, should use only so much powder as is necessary to bring down coal when properly undermined, should use care in placing shots so as to avoid knocking down timbers or producing windy shots that are dangerous to him and his colleagues. Instead of trying to evade such laws as prohibit carelessness, the miners should live up not only to the state laws but to the rules of the operators for the protection of their men and their property.

The state should add to and increase the laws now in force for the protection of lives and the safety of men. The state should provide laws for the protection of property and should rescind the laws now in force which practically give miners now employed in the state of Illinois a monopoly of labor.

Although the state has passed laws for the protection of human life, it has not passed laws for the protection of property.

The legislature constantly caters to the laborer for political reasons and has made laws so that it is practically impossible for the operator to secure competitive conditions for the labor he hires. It, by the Mitchell bill, has restricted miners from outside coming into the state to work.

When trouble arises between the miners and the operators the officials of the state are loathe to intervene and property is destroyed. With the exception of the laws passed for the safety of men, no laws have been passed for the safety of property or for the proper recovery of the natural resources in the ground.

Under the heading of Natural Resources, commercialism and conservation are again in opposition.

Because of the competition in the coal market every operator is trying to produce coal as cheaply as possible, and that means taking out the coal nearest the shaft. Under this method of mining, less than 60 per cent. is extracted, 40 per cent. being left to support the roof, air-courses, etc. If the operator should run his entries to the boundary lines of his property, as the most economical method of mining suggests, it would take a great deal of money and a long time before any return on the investment could be realized.

I have computed that the average return from 1 ton of coal in the ground, as figured in the selling price of the coal, is less than 2 cents per ton. The waste of natural resources following the present system of mining is enormous, and makes coal mining from the standpoint of human life much more hazardous.

The railroads, the largest of all the consumers of coal, utilize, it is estimated, less than 50 per cent. of the British thermal units in the coal burned in their locomotives. This means that 50 per cent. of the 60 per cent. taken from the ground is lost, practically making 70 per cent. waste of our natural resources.

This example would possibly carry through to all small consumers of coal, although some large concerns have taken great precautions to economize in its consumption.

The last item, capital, is the one that appeals forcibly to the operator. The present method of mining means small but quick returns on the investment, although state records show that many of the largest operations in the state have become bankrupt in the last 10 years, while the coal in the ground has appreciated in many districts two-, three, four times in value; it is at the present moment practically impossible to induce capital to invest in the coal mining industry in Illinois, while millions of dollars can be secured for the purchase of the virgin coal land.

To be successful the coal operator should be prepared financially to drive the entries to the boundary of his property and work his mine so that the entire bed may be recovered.

Insurance on Mine Property

*By W. H. Charlton**

The methods of handling insurance on mine properties seem to depend a great deal on the activities and financial investment of the companies concerned. A majority of companies carry their insurance in the ordinary way, that is they place insurance on the different buildings and plant equipment and pay the premiums as they come due.

Another method is that followed by some of the larger companies who operate a number of mines and whose plant and equipment represent a considerable outlay of capital. Companies of this kind frequently carry their own insurance and maintain a separate department to supervise this feature of their work.

The general method followed in handling insurance is to open a suspense account for it. When insurance premiums are paid they are charged to this account and in the event of additional insurance being taken out during the year, or any change taking place which will effect the amount of the premium payable during the year, an adjustment of this account, which is prorated against "Operating Expense" each month, will be necessary to conform to the altered conditions.

The total amount of insurance premiums payable during the year should be anticipated and prorated, one-twelfth each month to "Operating Expense," and credited to "Insurance."

Whenever changes are made in the amount of insurance carried, an adjustment of the amount prorated against operations each month is necessary to maintain even rate of distribution for balance of the year.

* San Antonio, Tex.

Whenever a company suffers loss or damage by fire, either to buildings or equipment, the amount received from the insurance company to cover the loss is placed to the credit of the various accounts sustaining loss, according to the amounts allowed in the settlement of the insurance company.

As an example of the methods followed by a large company that carries its own insurance, a western corporation which is both an operating and holding company, is taken.

This company maintains its own insurance department, at the head of which is a manager under whom is an efficient force of inspectors to carry out the work of the department.

Examinations by the inspectors are made of the different properties of the various companies and the insurable value determined, all of which is reported in detail to the manager.

The amount of insurance and the rate thereon to be carried for each item of property and equipment is recommended by the manager in a statement to the president of the company affected, for his approval. If, in the president's opinion, adjustments in the schedule are necessary, it goes back to the manager with the modifications required pointed out, and the basis on which the changes are recommended explained.

The manager of the department requires a periodical inspection by his assistants of all property and equipment upon which insurance is carried, to ascertain if proper precautions are being taken against fire. Upon receipt of reports from the inspectors, the manager reports to the president of the company concerned any lack of what he considers efficient protection in the way of preventive measures. The advisability of carrying out the suggestions made is discretionary with the president.

In case of loss or damage by fire the mine office immediately notifies both the president and auditor, in order that proper steps may be taken to have the insurance department investigate and report on the loss or damage sustained.

The plan followed in creating the insurance fund and the methods approved for its disposition are as follows: After the amount of insurance to be carried is determined and the premium rate to be paid thereon established, each company will distribute monthly one-eighth of the amount of premiums payable during the months of April to November, inclusive, to its cost of "Operation," crediting such amount to the "Fire Insurance Fund." Quarterly each company remits to the treasurer of the holding company in cash the amount of the insurance fund so accumulated for that quarter.

The treasurer of the holding company credits each company with its contribution and invests the amount so received for the benefit of the fund, allowing each company annually or semiannually, credit for its proportion of the interest or dividends received on the fund, such interest or dividend, however, is to be reinvested by the treasurer of the holding company for the benefit of the fund.

In case of loss or damage by fire, the company sustaining the loss, will, after the matter has been adjusted with the insurance department, call upon the treasurer of the holding company for reimbursement out of the fund, the difference to be charged to the "Profit and Loss" account of the company sustaining the loss. This plan of carrying insurance is followed out on all risks of both the holding and constituent companies, and virtually makes each company its own insurer.

A variation of the above method is that followed by a coal company operating eight mines situated in widely separated districts. This company set aside each month an arbitrary sum until it had accumulated what it considered an adequate insurance fund, after which it proceeded to carry its own insurance under conditions somewhat similar to those mentioned, except that a regular insurance department is not maintained, this feature of the business being attended to by the regular officers of the company.

Notes on Mines and Mining

Reports on Conditions and Other Matters of Interest in Various Coal Fields

By Special Correspondents

ARIZONA.—A Bureau of Mines has been established at Tucson, in connection with the Mining Department of the University of Arizona, to deal with the mining, smelting, and geological problems of the state. The bureau will educate the miner and prospector. If they cannot attend the university, the bureau will bring the university to them, by series of lectures, articles in daily and weekly mining papers, publication of items of interest—all popular style and progressive. The employer as well as the miner should profit by this educational work. The bureau will offer to the miner and prospector a place for determining samples; practical advice and instruction, and education on the economic side; an office of exchange and information. The same data will be of service to those outside the state who desire information on Arizona mining. Mine operators are invited to send the bureau their engineering, smelting, concentration, and economic problems.

COLORADO

In May, the Colorado School of Mines, at Golden, gave the double-hammer degree to 68 young men and the M. S. degree to one young man. This is probably the largest number of mining engineers graduated from any one institution in this country at one time.

At the recent session of the Colorado Legislature a law was enacted providing that mines shall be assessed upon the full valuation of their real estate and improvements, and upon 50 per cent. of their gross output, together with the value of their total net output.

ILLINOIS

The University of Illinois Bulletin, No. 29, Volume X, is devoted entirely to the Department of Mining Engineering. The new mining laboratory, a brick structure 42 feet wide and 100 feet long, is divided into a chemical laboratory, a drilling and blasting laboratory, a mine-rescue chamber, and a coal washing and ore concentrating laboratory, all of which are illustrated in the bulletin. The offices and recitation rooms are in the Transportation Building adjoining. Those branches common to all engineering studies are taught in the proper departments of the University, thus leaving this department entirely devoted to mining.

Storing Coal Under Water.—The June issue of the *Western Electric News* contains an account of the manner in which the Western Electric Co. has solved the problem of storing and conserving the heating value of its fuel supply at the Hawthorne, Ill., plant.

A concrete pit has been constructed with a capacity of 10,000 tons of soft coal. This pit is divided into three sections and occupies an area of about 300 ft.×114 ft. The pit is kept flooded with water, covering the entire coal supply.

Tests show that storing coal under water prevents the oxidation which occurs when it is left in the open and results in a saving of from $10\frac{1}{2}$ to $22\frac{1}{2}$ per cent. of the heat value. The loss of heat in coal stored under water is only $1\frac{1}{2}$ per cent. Aside from this saving, there is the advantage that a much smaller size coal may be stored indefinitely without danger from spontaneously ignited fires. The large storage facilities also guard against shortage when the cold weather sets in and deliveries are uncertain.

MISSOURI

The junior class of the Missouri School of Mines spent 3 weeks in Colorado, beginning June 4. This is a required part of the curriculum. The class visited Colorado Springs, Colorado City, Pueblo, the Cripple Creek district, Leadville, Breckenridge, Valdoro, Montezuma, Waldorf, Silver Plume, Georgetown, and Idaho Springs. They were accompanied by Professors G. H. Cox, H. T. Mann, and C. R. Forbes.

The sophomore class did field work in mine surveying at Edwardsville, Ill., during the first 2 weeks in June, under the charge of Prof. C. R. Forbes and Mr. E. S. McCandliss.

OREGON

Oregon Agricultural College.—Rowley Cruit, of Wellen, a junior at the Oregon Agricultural College School of Mines, won first prize, and C. W. Anderson, of Portland, a senior, won second in a contest in the class in rock and earth excavation for working out the best graphic solutions of the problem of the cost of earth work by means of various apparatus and for varying distances. They have made diagrams by which the average cost may be ascertained instantly, whatever the wages paid, for moving earth in any quantity to various distances—something extremely valuable to all contractors who have to do with this sort of work.

It has just been announced to the O. A. C. students that they are eligible to the four fellowships in mining and metallurgy, each $675 a year, offered by the University of Utah.

PENNSYLVANIA

The Lehigh Coal and Navigation Co. will shortly begin the erection of a new steel and concrete breaker to replace the one in use for many years at their No. 11 colliery, near Tamaqua. The new breaker is to be equipped with the most modern machinery and will be one of the largest producing plants in the anthracite coal regions.

The consolidation of the Youghiogheny & Ohio and the Lorain & Ohio Coal Companies, two of the largest in the state, with big mines in the state of West Virginia, has been officially confirmed. The consolidated company will have 40,000 acres of coal in Belmont County and at present employs 3,000 men.

Announcement was made at Scranton early in June of the formal dissolution of the Temple Iron Co., by the companies controlling that corporation. This action was taken in accordance with the recent decision handed down by the United States Supreme Court. There will now be seven distinct companies to conduct the affairs of the eight collieries.

Mr. A. F. Law, who was vice-president of the Temple Iron Co., is president of each of the seven companies, and Mr. F. H. Hemelright is general superintendent in charge of all the operations.

The labor situation in the Connellsville region is causing some concern, both coke drawers and coal miners are becoming scarce. This condition seems to be spreading to the Pittsburg district in spite of the long period of idleness.

TENNESSEE

The Tennessee Foreman's Society. E. F. Buffat, foreman, of Oliver Springs, Tenn., has presented us with the constitution and mine rules of The Society of Tennessee Mine Foremen. The central body is known as the Grand Mine, the subordinate bodies are known as Mines, which accounts for "Mine Rules"; the officers of the Mines are superintendent, mine foreman, foreman of rescue corps, foreman of first-aid corps, foreman of relief corps, timekeeper, weighmaster, mining engineer, gas foreman, roadsman, timberman, master mechanic, outside foreman, greaser, and trapper. The purposes of this society are the advancement of its members in social, intellectual, first-aid training, and the promotion of greater safety in mines. The society constitution reads nicely until it reaches the heading "Disasters," where it assumes that members of this society can take the mine-rescue work out of the hands of the operator, manager, or other company officials and do as the nearest high officer of the society pleases.

WEST VIRGINIA

"*Shooting Off the Solid.*"—John Laing, Chief of the Department of Mines, makes the proud boast that "shooting off the solid" has been nearly eliminated in West Virginia. Interest is added to this statement by the fact that the United Mine Workers of America are making a determined effort to secure the repeal of a law recently enacted in Oklahoma prohibiting this highly dangerous practice.

Government statistics show that more than 48 per cent. of deaths in coal mines are due to falls of roof. One of the principal causes of these falls is "shooting off the solid." A shot in the solid seam is also more likely to blow out the tamping so that the flames may set fire to coal dust or gas, thus causing an explosion that may wipe out scores of lives. In other words, reckless or lazy miners deliberately risk their own lives and the lives of others to save themselves a little labor.

This dangerous practice has been discouraged in West Virginia by a vigilant system of inspection backed up by relentless prosecutions of offenders. The 1911 report of the Chief of the Department of Mines shows that 105 miners were fined an aggregate of $1,303 for shooting off the solid in that year. This vigorous enforcement of the law evidently had its effect in 1912.

The West Virginia Geological Survey, I. C. White, State Geologist, Morgantown, W. Va., has issued a new coal, gas, iron ore, limestone, and oil map. This new 1913 edition is the joint publication of the State Geological Survey and the State Semicentennial Commission. It contains a thorough revision of the coal, oil, and gas developments, several anticlinals being added, and others corrected from later observations. The valuable iron ore deposits of the state are also indicated on this map, and all the special features of previous editions corrected and brought up to date, showing the approximate areas of the several coal series, operating mines and their post office addresses, as well as the oil and gas pools. Scale 8 miles to the inch. Price, enclosed in strong envelope and delivered by mail, 50 cents each, but in combination with other publications see general circular of the Survey.

WASHINGTON

Joint Meeting of A. I. M. E. and C. M. I.—A number of mining men of Spokane attended the fifteenth general meeting of the western branch of the Canadian Mining Institute, in Rossland, B. C., Thursday, May 22. This was a joint meeting with the members of the Spokane local section of the American Institute of Mining Engineers. The provisional program, announced by E. Jacobs, the secretary of the Western branch of the Canadian Mining Institute, included reading and discussion of papers, visit to mines of Rossland, and a visit to the smelting works and the electric lead refinery of the Consolidated Mining and Smelting Co., at Trail.

George Watkin Evans, mining engineer, Seattle, Wash., made a preliminary trip to Alaska in May to ascertain the needs and make plans for the expedition of the United States Bureau of Mines which leaves Seattle July 5. Mr. Evans will be in charge of the expedition, which will examine into the commercial possibilities of the Matanuska coal field.

Sixteen members of the College of Mines, University of Washington, traveled to Cle-Elum, Washington, on the annual inspection trip and visited the various coal mines of the Northwestern Improvement Co., the Roslyn-Cascade Coal Co., and the Roslyn Fuel Co., in the Roslyn District. Time was divided between underground and surface work. The various systems of mining and drawing coal, transportation methods, ventilation, and pumping, as well as the surface equipment and power arrangements were thoroughly gone over. Leaving Cle-Elum, the party drove to Liberty, a former prosperous placer camp 20 miles east of Cle-Elum. Here the various methods of drift mining were studied in detail. Recent lode development in the camp came in for a share of attention in the study of the prospects and deposits opened up by tunnel and shaft.

Most of the coke used on the Pacific Coast is imported from Germany or England or brought from the Eastern States.

International Engineering Congress

In connection with the Panama-Pacific International Exposition which will be held in San Francisco in 1915, there will be an International Engineering Congress, in which engineers throughout the world will be invited to participate.

The congress is to be conducted under the auspices of the five National Engineering Societies which, acting in cooperation, have appointed a permanent Committee of Management, consisting of the Presidents and Secretaries of each of these Societies, and eighteen members resident in San Francisco. Thus constituted, the personnel of the Committee is as follows:

Representing the American Society of Civil Engineers: George F. Swain, President; Charles Warren Hunt, Secretary; Arthur L. Adams; W. A. Cattell; Charles Dereleth, Jr.; Charles D. Marx.

Representing the American Institute of Mining Engineers: Charles F. Rand, President; Bradley Stoughton, Secretary; H. F. Bain; Edward H. Benjamin; Newton Cleaveland; William S. Noyes.

Representing the American Society of Mechanical Engineers: W. F. M. Goss, President; Calvin W. Rice, Secretary; W. F. Durand; R. S. Moore; T. W. Ransom; C. R. Weymouth.

Representing the American Institute of Electrical Engineers: Ralph Davenport Mershon, President; F. L. Hutchinson, Secretary; J. G. De Remer; A. M. Hunt.

Representing the Society of Naval Architects and Marine Engineers: Robert M. Thompson, President; D. H. Cox, Secretary; George W. Dickie; W. G. Dodd; William R. Eckart; H. P. Frear.

The Committee has effected a permanent organization, with Prof. William F. Durand as Chairman, and W. A. Cattell as Secretary-Treasurer, and has established executive offices in the Foxcroft Building, 68 Post Street, San Francisco.

The ten members of the Committee, consisting of the presidents and secretaries of the five national societies will constitute a committee on participation, through whom all invitations to participate in the Congress will be issued to governments, engineering societies, and individuals. The personnel of this Committee is as follows:

Committe on Participation: Chas. F. Rand, Chairman; Charles Warren Hunt, Secretary; D. H. Cox, W. F. M. Goss, F. L. Hutchinson, Ralph Davenport Mershon, Calvin W. Rice, Bradley Stoughton, George F. Swain, Robert M. Thompson.

The actual management of the Congress and the work of the securing and publishing papers will be in charge of the members of the Committee resident in San Francisco. The work of the resident members has been assigned to different subcommittees, and Chairman Durand has made the following appointments:

Executive Committee: W. F. Durand, Chairman, Ex-officio; W. A. Cattell, Secretary, Ex-officio; E. H. Benjamin, W. G. Dodd, A. M. Hunt.

Finance Committee, W. G. Dodd, Chairman; Newton Cleaveland, R. S. Moore.

Papers Committee: A. M. Hunt, Chairman; A. L. Adams, H. F. Bain, G. W. Dickie, W. R. Eckart, C. D. Marx, C. R. Weymouth.

Publicity Committee: W. A. Cattell, Chairman; C. Derleth, Jr.; W. S. Noyes, T. W. Ransom.

Local Affairs Committee: E. H. Benjamin, Chairman; J. G. De Remer, H. P. Fear.

The papers presented at the Congress will naturally be divided into groups or sections. During the Congress each section will hold independent sessions, which will be presided over by a chairman eminent in the branches of engineering covered by this section.

The papers, which will be collected and published by the Congress, should form an invaluable engineering library, and it is intended that this publication shall be in such form and at such cost as to become available to the greatest possible number.

The various committees are now actively at work, and it is hoped that further and more definite announcements as to the membership fees, schedules of papers, etc., can be made in the very near future.

Panama-Pacific Exposition

Mr. Charles E. van Barnwald, Chief of Department of Mines and Metallurgy of the Exposition, has written an open letter to mining men in which he says:

Everybody will agree that the Panama-Pacific International Exposition is the nation's official celebration of the successful completion of the greatest task ever undertaken for the universal good. We welcome this opportunity to exhibit to the world our industrial and intellectual condition. A well-planned exposition is of incalculable value as an educator of the public mind, and no industry is in greater need of this service today than mining.

On February 15, 1911, President Taft signed the bill extending federal recognition and designating San Francisco as the official site for this great celebration. On February 2, 1912, a proclamation was issued announcing the forthcoming exposition and inviting the nations of the world to participate.

Construction work on the exhibit palaces is in full swing and all buildings will be completed by the end of June, 1914. The organization of the Division of Exhibits is completed, the last department to be organized being Mines and Metallurgy. The Department of Mines and Metallurgy deals with the natural mineral resources of the world, their exploration, exploitation, conversion into metal, their manufacture into structural forms and into raw material for various industries.

The responsibility of making a creditable exhibit in this department rests with the mining public and their suggestions will be gladly received.

THE LETTER BOX

Readers are invited to ask or answer any question pertaining to mining, or to express their views on mining subjects in this department. All communications must be accompanied by the name and address of the writer—not necessarily for publication.

The editors are not responsible for views expressed by correspondents.

Shaft Sinking in Wet Ground

Editor The Colliery Engineer:

Sir:—Will some of your readers kindly answer the following:

A shaft is to be sunk 280 feet deep, in which water will be struck at a depth of 100 feet in a formation of sandstone that extends to a depth of 175 feet from the surface.

What would be the most advisable method to eliminate the water or minimize the flow to such an extent that it will not interfere with the skip arrangement which will raise coal from the bottom bins to the top?

The water flows in such quantities as to impede the progress of sinking. How can the water be eliminated so that it will be hardly necessary to install pumps, as they are to be placed in the air shaft, 350 feet from the main shaft?

D. H. J. Stockett

The Cement Gun for Preventing Dust

Editor The Colliery Engineer:

Sir:—There have been many methods proposed for both the prevention and the laying of coal dust in mines. The idea of all these methods is to prevent, first, the origination of an explosion caused by excessive dust; secondly, to prevent an explosion originating at the workings from spreading to all parts of the mine.

Efforts in this direction have hitherto been applied to the establishment of dustless zones, but experiments have shown that an explosion usually carries sufficient dust with it to destroy entirely the dustless features of any zone unless it is a very large one. A very complete discussion of experiments along this line will be found in Bulletin 20 of the United States Bureau of Mines, "The Explosibility of Coal Dust."

Calcium chloride, stone dust, and spraying have their advocates and have been found more or less satisfactory, as the experiments at Altofts and Lievin have shown. Calcium chloride is a little expensive when used alone, and can only be applied to the floor, stone dust irritates, and experiments by the Bureau of Mines have shown that a wet zone will not certainly stop a dust explosion after it has been fairly started.

To the mind of the writer, a very obvious method of preventing dust from forming has been overlooked. This is to use the cement gun or like device for coating the walls and floor of the mine with such a coating as would keep the fine coal produced by the continuous cracking of the seam from being distributed as dust. Several compositions of this sort have been recently patented, but it seems that concrete would do very well. It is not denied that the concrete will fall in course of time, so this interval must be determined in practice. The coat should be very thin, and as soon as it cracks off, which it will probably do in the course of 3 months, it can be easily renewed. If concrete is objected to on the score of expense, mud, mixed with a little calcium chloride to keep it moist is a substitute worth trying. Five per cent. of calcium chloride by volume would be about the right proportion to mix in with mud of the right viscosity to throw with the gun. The chloride is now worth about $14 per ton. It is needless to say that the floor should be especially well treated and the coal in the mine cars kept moist. By this means, an explosion would surely be confined to the working faces, and if spraying were adopted here, there should be absolutely no excuse for such a thing as a mine explosion.

Who will be the first to try this idea on a mining scale?

Chester Tietig
Washington, D. C.

The Law Regarding Mine Inspectors

Editor The Colliery Engineer:

Sir:—I notice "Collier's" article in your May number in reference to the suggestion made by me in the March Letter Box.

I am well aware that there are two sides to the proposition.

You cannot get the best men for inspectors by examination. If so we would know in advance by their standing in schools and colleges what young men were going to be the great generals, lawyers, doctors, business men, etc., of the country.

What becomes of the first honor men of our colleges?

Take our Military Academy at West Point, how many of the first honor men ever achieved distinction as great generals?

There are two notable exceptions in the history of that Academy, Lee and Grant, one near the head and the other near the foot of his class.

On the other hand Forrest, considered the greatest military genius developed on either side, judging by results accomplished according to means at his command, had a very limited education, and no military training whatever.

While my suggestion might operate as a hardship on some inspector, he need not take the place, there would be no compulsion on him. These laws are made and large sums of money spent, not for the benefit of the mine inspector, but for the protection of the lives and health of thousands of men working in the mines.

I submit that the lives and health of these men are more important than a possible hardship to a mine inspector.

Take the record of Colorado and Oklahoma for the past 16 years, the state of Alabama for the past 9 years, and the state of Virginia for the past 5 years. Does "Collier" or any one believe that such a disastrous record would have continued, had such a law as I suggest been in force? J. de B. Hooper

Cincinnati Mine Explosion

Editor The Colliery Engineer:

Sir:—I read with much interest in the June number the account of the Cincinnati mine disaster by Mr. W. Z. Price, also the reports of the two Commissions appointed by Chief of the Department of Mines, Mr. Roderick, and I was pleased to learn that the company did so much to make the mine a safe one. The Mine Inspector's Commission testify to this in the following words: "The brick air stoppings were built up to within one breakthrough of the face of the several entries and the mine was kept in a clean, orderly condition." The Special Commission of experts reported: "There was ample ventilation and it was conducted around all of the working faces. We noticed that brick stoppings were erected, in practically every instance, to the last breakthrough, except, of course, those used for haulage purposes. The roads were moist and practically free from dust, and clean and free from obstruction." The above point to one fact, namely, that the company did its full duty toward keeping the mine in good and safe condition.

The coroner's jury was one of more than ordinary intelligence and departed widely from the path usually trod by such bodies. It made recommendations to the company, to the legislature, and the Department of Mines, blamed the now deceased mine foreman (legally) for the explosion, because he had not compelled the use of safety lamps in the district which exploded, and placed the blame (morally) on the law, or defects of the law.

To me it seems that the real cause of the explosion was entirely overlooked by the coroner's jury and was not mentioned by the double commission. The cause of the disaster was the failure of the mine foreman to obey General Rule 18. This rule has been a part of the law for 20 years. It reads as follows: "In the cutting of clay veins, spars, or faults, entries, or other narrow workings, going into the solid coal, in mines wherein explosive gas is generated in dangerous quantities, a bore hole shall be kept not less than 3 feet in advance of the face of the work, or 3 feet in advance of any shot hole drilled for a blast to be fired in."

Had this bore hole been kept in advance, the gas would have been tapped and drained off before a blast was fired in the entry. There would have been no accumulation of gas. It would have been diluted as fast as given off when it was known to be issuing from the hole. In other words the explosion could not have happened. Am I right?

The above lines are not written to criticise the conduct of any one. They are written in the interest of safety first.

A Mine Inspector

Scientific Management Applied to Coal Mining

Editor The Colliery Engineer:

Sir:—A modern epigrammarian has said: "The man who says 'It can't be done,' is pushed out of the way by the man who is already doing it." The question of "Superintendent" in your December issue, and the article by Mr. Weldin in the May number, prompt a few remarks by one who has been engaged in "doing it" and who has been too busy to stand aloof and theorize concerning certain well-known principles whose chief exponents have been suddenly heroed by their admiring followers.

Efficiency engineering, by whatever name it is called, whether "scientific management," "development of earning power," or the writer's favorite term "bug hunting," is neither mysterious nor wonderful, but combines simply the critical analyzing mind, with creative ability which assists toward mechanical improvement, and mature judgment which in an advisory capacity overcomes the serious objections mentioned by Mr. Weldin, by skilfully studying the psychology of the individual as well as the mechanics of the operation.

We differ radically, however, with the statement that there is a large amount of preliminary work to be done, and that the introduction of efficiency methods either involves revolutionary changes or protracted periods before any results can be attained. The paper of Mr. Collins, quoted by Mr. Weldin (and first called to his attention by the writer), in itself shows many opportunities for quick results, and illustrates lucidly the benefits to be derived by devoting 100 per cent. of one's time to the problem. Therein lies the secret of the success of scientific management—the whole-hearted cooperation of those in authority with the engineer thus occupying his entire time in making the studies.

It has been the writer's observation that much adverse criticism is due to the attempts of worshippers at the shrine of efficiency to introduce certain systems as installed by Taylor, Williams, Emerson, and others in certain plants, into other operations where conditions were entirely different, without first studying the elementary factors involved. Scientific management does not consider what is to be done, so much as how to do it. The prime requisites, as have been stated, are an analyzing mind, and the ability to create a flexible adaptation of existing systems and to devise new ones.

Since the article in your May issue was written the author has had opportunity to observe the exemplification of this statement in work done by staff members under his direction at one of the plants with which he is connected. The "essence of the system" lies not so much in "increased supervision" as in the improved relations existing between employer and employe, which tend toward cooperation by the employe. This great truth has been recognized by many of the largest corporations in the Pittsburg field, among them the Union Switch and Signal Co., the Pittsburg Coal Co., and the National Radiator Co.

To state that scientific management increases to any material extent the "non-producers" is simply to admit that at the plant to which he refers, the attempt to introduce it never passed the experimental stage, or was fostered by unskilled guardians. Properly applied, scientific management eliminates red tape, lost motion, unnecessary expense and "overhead," increases production, decreases cost, and automatically makes every operation and operator coactive toward maximum returns to employer and employe alike.

Nor is it obvious to those most familiar with the subject that there is so "much danger" involved in the application of what after all is plain, common-sense administration of any operation. Hundreds of industrial plants have been working under bonus systems of various kinds for months and years past, and it has been the experience of Williams, Emerson, and others engaged in their installation, that labor troubles have been erased from the list of worries which previously were a constant menace.

The writer is quite ready to agree from his own experience in mining that the Taylor system is not immediately applicable to mining, but unlike the impression to be gained from the article in question, he does not believe the Taylor system to be the *multum in parvo* of scientific management, but rather, one of its many applications, very adaptable to some operations.

The author referred to is quite correct, however, in suggesting the repair shop as the first point of attack. To the stockholder, it matters not in what department the greatest saving is effected, and to the operator, a reduction in cost of repairs means cheaper coal. An apparently insignificant saving of 1 cent a ton means much to the average operator.

There are also many operations which may be standardized, such as hanging trolley wire, laying pipe and switches, and building brattices and trap doors. Careful supervision of cables and pipe lines, definite responsibility for keeping feed-wires within reach of working places, maintenance of machines in proper repair, and proper preparation of bits and picks, all receive consideration by the efficiency engineer. Time studies of haulage will develop many delays previously unknown, which can be eliminated. Conferences between the efficiency expert and the superintendent and engineer will bring out improvements in pumping or hoisting or screening.

In many cases by charting the existing organization, certain functional changes can be made which simplify responsibilities and make for efficiency. But greater than all these, is the fact that in the proper application of scientific management, is to be found the increased margin of profit which in many instances is becoming necessary to the further operation of certain mining properties, and also that the strongest hold upon labor may be secured by a fair division of the gains so made, thus putting each man "in business for himself," so that prosperity for employer and employe becomes a function each of the other. In no better or speedier or surer way will the misunderstandings and the stubborn arguments of capital and labor be amicably and automatically adjusted. Henry M. Payne,

C.E., Ph.D., Sc.D., Chief of Staff

Correction

On page 584, May issue of The Colliery Engineer, it was stated that there were 66,889 tons of coal mined for each death in Montana. It should have read that there were 314,380 tons of coal produced for each life lost. The total number of tons of coal mined during the year 1912 was 3,143,799 instead of 6,057,186 tons.

OBITUARY

Woodward Leavenworth

Woodward Leavenworth, of Wilkes-Barre, died in that city May 26, age 59 years. At the time of his death he was president of the Red Ash Coal Co., and secretary of the Hazard Mfg. Co.

Orran W. Kennedy

Orran W. Kennedy, general manager of the Orient Coal and Coke Co., died June 8, at Pittsburg, from pneumonia. Mr. Kennedy was born in Lawrence County, in 1854, and rose from the position of clerk in the transfer department of the Pennsylvania Railroad to general superintendent of the H. C. Frick Coke Co., which position he resigned January 1, 1904, to become general manager of the Orient Coal and Coke Co. Mr. Kennedy was prominent in Masonic circles, was president of the Fayette Title and Trust Co., at Uniontown, and owned extensive coal lands in West Virginia. He was buried at Pittsburg June 10, the Masonic lodge having charge of the funeral.

Wm. H. McQuail

William H. Mc Quail, an active coal mine operator and a prominent resident of Pottsville, Pa., died in that city June 5, 1913, aged 60 years. His death was due to pneumonia.

Mr. McQuail began life at the coal mines as a slate picker and subsequently became a contract miner, in which occupation he did considerable rock work in the Schuylkill Valley and for the D., L. & W. Co., at Scranton. Later he was appointed superintendent of the collieries operated by the Alliance Coal Mining Co. In 1887 he went to the Pocahontas coal field in West Virginia, and organized the Turkey Gap Coal and Coke Co., of which he was president and general manager, a position which he held until the time of his death. In 1898 he organized the Crane Creek Coal and Coke Co. to operate in the same field, but sold out to the American Coal Co.

The Scott Colliery Disaster

The explosion at the Scott colliery, operated by the Mineral Railroad and Mining Co., and located between Shamokin and Mt. Carmel, Pa., on the morning of June 7, was not nearly so serious as first reported in the daily papers, though the result would have been much worse had it not been for the prompt action on the part of the local officials and the excellent ventilation provided in the mine. Instead of 20 to 30 lives being lost, but two men were killed, and two seriously injured.

The accident occurred in the workings of the fourth lift east gangway from an inside slope in the Buck Mountain seam. This seam ranges from 5 to 8 feet thick and has an inclination in the neighborhood of the origin of the disaster of 32 degrees. To prevent any accumulation of gas there is a strong ventilating current in the workings and locked safety lamps are used. The accompanying sketch shows the location of the source of the accident, and reference to it will make clear the cause and effect.

The gangways or entries shown on the sketch have both been stopped at the boundary pillar. Chambers were opened from the gangways with single chutes to the first cross-headings and driven up the pitch from that point 8 yards wide.

On the morning of Saturday, June 7, the miner in breast No. 42 was taking a skip off the inside pillar of his chamber just above the first heading, and prepared and fired his shot. In the meantime, his laborer, who, by the way, was his son, was down on the gangway at point marked *A*. Miner in breast No. 42 went up to dress off his shot and afterwards came back to the point *B* between breasts Nos. 42 and 43, where he had a box of dynamite which ordinarily contained 25 pounds, and the supposition is that only about one-fourth of it was used. The box of dynamite exploded from some, as yet, unknown cause, but it is the general opinion that the miner working in breast No. 42 in some manner or other was responsible for the explosion, as he was found at this heading very badly violence, it is supposed that they were knocked down by the concussion and suffocated by the fumes of the dynamite carried to the main current in the gangway through the hole from chamber 36, the stopping of which was destroyed. Ten other men, overcome by the fumes of the dynamite, were found at various points along the same gangway outside of *C C*, these fumes being carried in the air-current, which, owing

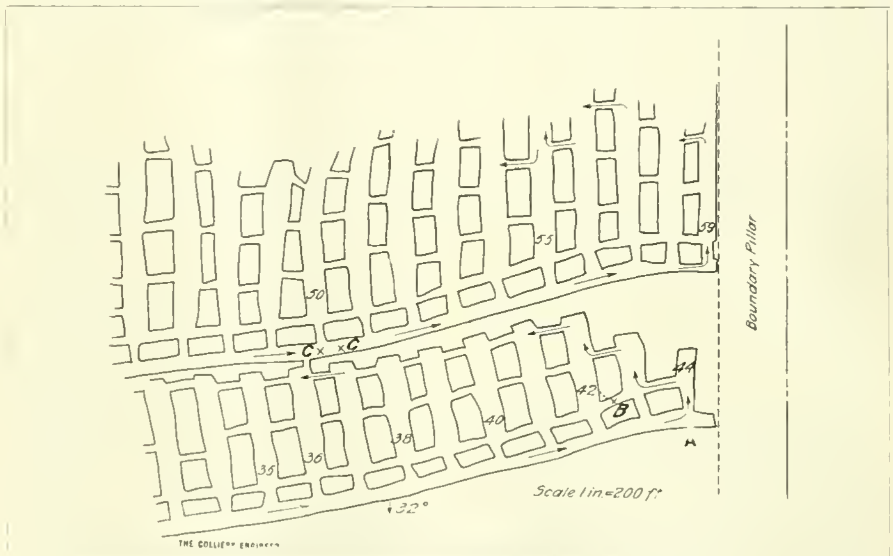


Fig. 1. Showing Place of Explosion at Scott Colliery

mutilated, necessitating the amputation of his leg. His son, the laborer, and the two miners from breast No. 44 were sitting on the gangway at point *A* on sketch when the explosion occurred and were only slightly injured by flying coal.

The theory of this being a dynamite explosion was fully justified by the fact that in the first heading, between breasts Nos. 42 and 43, all the timbers were broken out, and the corner of a pillar, as well as a hole 2 feet 6 inches deep in the rock in the bottom of this heading. There are no evidences of any damage to any other portion of the mine. There was no afterdamp or recoil, as there is usually with explosions of gas.

The arrows on the sketch show the original courses of the air-currents. At the points *C, C*, two men were found dead and another man with slight concussion of the brain. As there were not sufficient marks on their bodies to indicate death from

to the destruction of stoppings was temporarily deranged. The men were quickly taken out and resuscitated.

As soon as the accident occurred a trained rescue corps composed of the local mine officials, headed by Inside Foreman John Weir, entered the mine and their prompt work undoubtedly saved the lives of some, if not all, of the rescued men.

As soon as Division Superintendent Reinhardt, at Shamokin, received word of the accident, he started for the mine in an automobile, stopping at the Luke Fiddler colliery, 2 miles west of the Scott colliery, for oxygen helmets kept there in the company's central rescue station. On arrival at the Scott mine it was found that the helmets were unnecessary, as the excellent system of ventilation, though somewhat deranged, had cleared the workings of the deleterious fumes.

The successful work of the Scott

Colliery Rescue Corps proves the wisdom of maintaining such a corps at each colliery. The Mineral Railroad and Mining Co., operating in the Shamokin region, the Susquehanna Coal Co., operating in the Wyoming region, the Summit Branch Mining Co., operating in the extreme western end of the southern anthracite field, the Lytle Coal Co., and Wm. Penn colliery, in the southern field, are allied corporations, and they maintain at each colliery an efficient rescue corps, composed of mine officials and selected employes. These corps are regularly drilled and are always ready for service. A complete outfit of helmets, pulmotors, and other rescue apparatus is kept in first-class condition in central rescue stations when several collieries are in close proximity, and at isolated plants a complete equipment is provided for the use of each.

As quickly as possible after the accident occurred the United States Bureau of Mines Rescue Car, stationed at Wilkes-Barre, Pa., was ordered to the colliery, but as its services were not needed, the order was countermanded. Superintendent Charles Enzian, of the United States Rescue Car, was at South Bethlehem attending a meeting of the Alumni Association of Lehigh University when the accident occurred, and he hastened to the mine as quickly as possible after hearing of the accident. As the prompt and efficient action of the local officials had accomplished everything possible before he could reach the mine, he could do nothing but gather the data for his report to the Bureau, which will naturally commend the local rescue corps.

Kentucky Mining Institute

The third annual meeting of the Kentucky Mining Institute, held in Lexington, was attended by a large number of members and, owing to the attractions offered, by a large number of non-members who joined later. This institute has become a flourishing society during the 3 years of its existence and is destined to become a potent factor in the coal industry of Kentucky.

The papers read and discussed are classical and valuable additions to mining literature. Owing to lack of space they are given by title only, but later on some of them will be printed in full in The Colliery Engineer.

The first day of the meeting was given over to the state-wide first-aid contest, inaugurated and carried to completion by W. L. Moss, V. P., of the Continental Coal Co., of Pineville, Ky. Twenty-three teams took part in the competitive contests. At the regular session of the Institute, Mr. Rash, V. P., of the St. Bernard Coal Co., Earlington, Ky., and retiring president of the society, eulogized C. F. Fraser, mining engineer of the Taylor Coal Co., Beaver Dam, Ky., who was suffocated by gas just 1 week before the institute meeting, and at which he was to have read the paper on the program, entitled "Mining Laws of Kentucky." The memorial resolutions of regret and condolence were approved by the institute members and placed on the minutes.

A paper on "Calorimetric Tests Made on Kentucky Coals," by Dr. A. M. Peter, Chief of the Division of Chemistry, Kentucky Experiment Station, showed that the number of heat units in Western Kentucky coal was 14,846, against 15,066 heat units in Eastern Kentucky coal; this "may be" settles the relative value of the two coal fields, at any rate it shows neither are in the "punk" class. We would suggest that all the readers of The Colliery Engineer join this society to obtain the benefit to be derived from the papers presented. The program of papers was as follows: "Workmen's Compensation," K. U. Meguire, President Snead & Meguire Coal Co., Louisville, Ky. "Welfare of Sociological Work," W. C. Tucker, General Superintendent, Wisconsin Steel Co., Benham, Ky. "Coal and Mineral Taxation," Messrs. Hewel Davies, President, Louisville, Ky., and W. H. Cunningham, Secretary, Ashland, Ky., Mine Owners' Association of Kentucky. "Mineral Development of Western Kentucky Fluorspar District," C. S. Nunn, Manager, Kentucky Fluorspar Co., Marion, Ky. "How Best to Handle the Dry or Dusty Mine," David Victor, Chief Mine Inspector, Consolidation Coal Co., Fairmont, W. Va. "Shortwall Mining" (illustrated with stereopticon slides), Wilbert A. Miller, District Manager, Goodman Mfg. Co., Cincinnati, Ohio. Discussion of "How to Handle the Dry or Dusty Mine," Theo. Weinshank, expert on heating and ventilating, Weinshank & Fenstermaker, Indianapolis, Ind. "Mining Laws of Kentucky," Mr. C. F. Fraser, Mining Engineer, Taylor Coal Co., of Kentucky, Beaver Dam, Ky.

The officers elected for the ensuing year are: President, W. L. Moss, Pineville, Ky.; Secretary-Treasurer, T. J. Barr, College of Mines, Lexington, Ky.; Vice-Presidents, Central District, B. R. Hutchcraft, Lexington; Western District, C. W. Taylor, Greensville, and T. E. Jenkins, Sturgis; Eastern District, J. E. Butler, Stearns, and W. C. Tucker, Denton; Northeastern District, L. E. Abbot, Jenkins, and Henry La Viers, Paintsville.

A "Near-Doomed" City

In the July issue of the *Technical World Magazine*, Mr. George H. Cushing furnishes a sensational article entitled a "Near-Doomed City." The article is very inaccurate and would not ordinarily be noticed were it not that its contents discredit Scranton and distort the findings of the Scranton Mine Cave Engineers, Messrs. William Griffith and Eli Conner.

It will be read by thousands of people who, unable to distinguish between a technical article and a sensational one, will believe that Scranton is doomed to fall into the ground, when, as a matter of fact, if all the coal were removed from under Scranton proper, the greatest damage would be cracked walls.

PRIZE CONTEST

For the best answer to each of the following questions we will give any books on mining or the sciences related thereto, now in print, to the value of $3.

For the second best answer, similar books to the value of $2 will be given.

Both prizes for answers to the same questions will not be awarded to any one person.

1. The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.
2. Answers must be written in ink on one side of the paper only.
3. "Competition Contest" must be written on the envelope in which the answers are sent to us.
4. One person may compete in all the questions.
5. Our decision as to the merits of the answers shall be final.
6. Answers must be mailed to us not later than one month after publication of the question.
7. The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what books they want, and to mention the numbers of the questions when so doing.
8. In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.
9. Employes of the publishers are not eligible to enter this contest.

Questions for Prizes

29. At a certain point *A*, a bore hole is put down 350 feet to a 6-foot seam of coal; at a point *B*, 2,500 feet due north of *A*, a bore hole locates the seam at a depth of 400 feet; at *C*, which is 2,000 feet west of *A*, a bore hole reaches the coal at a depth of 800 feet. What is the direction and the amount of dip of the coal, likewise the direction of its line of strike? Assume the elevation of *A* to be 1,850 feet, of *B*, 1,650 feet, and of *C*, 1,800 feet above mean tide.

30. Assuming that a tract of 3,000 acres contains the seam of coal in Question 29, which has 2 feet of draw slate above it, that the coal pitches uniformly and its maximum elevation is 1,600 feet, how would you mine the coal, giving details of the size of pillars, etc?

31. If 25,000 cubic feet of air per minute pass through a $6' \times 10'$ airway, what volume of air will pass through a $4' \times 5'$ airway, the length of the airway and the power remaining the same? What will be the effect on the water gauge? Describe briefly what is understood by mechanical and manometrical efficiency of fans.

32. A steam engine of 300 actual horsepower is used for hoisting 600 tons of coal up a vertical shaft in 8 hours. Assuming the engine to be doing its best, making proper allowance for ordinary work such as the engine does in winding, find by calculation the depth of the shaft and state in detail all extra work taken into consideration in determining the efficiency of the engine.

Answers for Which Prizes Have Been Awarded

Ques. 13.—*Horsepower of Engine.* Calculate the horsepower of an engine that is capable of hauling a trip of 15 cars, each weighing 1,200 pounds, and having a capacity of 3,000 pounds. The haulage road has a uniform grade of 1 per cent. against the load, and is 4,000 feet long. It is desired to get out 600 cars a day. Assume the coefficient of friction at $\frac{1}{40}$.

Ans.—$(1,200 + 3,000) \times 15 = 63,000$ pounds = weight of loaded trip. $63,000 \times .01 = 630$ pounds = traction due to gravity. $63,000 \times \frac{1}{40} = 1,575$ pounds = traction due to friction. $1,575 + 630 = 2,205$ pounds = total tractive force of loaded trip.

Assuming a factor of safety for the haulage rope of 1 to 10, the breaking strain of a rope to haul the trip would be $\frac{2,205 \times 10}{2,000} = 11.025$ tons.

The strength of steel ropes varies as the squares of the diameters. A 1-inch steel rope has a breaking strain of 33 tons. The diameter of a rope whose breaking strain is 11.025 tons is

$1^2 : x^2 :: 33 : 11.025 : x = .58$ or say $\frac{5}{8}$ inch.

The empty trip on a down grade or dip of 1 per cent. would have a gravity force of $1,200 \times 15 \times .01 = 180$ pounds.

It would have a resistance due to friction of $1,200 \times 15 \times \frac{1}{40} = 450$.

As a force of 180 pounds will not overcome an opposing force of 450 pounds the trip will not run in by gravity but must be hauled in by a tail-rope.

Assuming a rope $\frac{1}{2}$-inch in diameter for the tail-rope, the weight per foot of such a rope may be found by the same formula as for strength. A 1-inch rope weighs 1.6 pounds per linear foot.

$1^2 : \frac{1}{2}^2 :: 1.6 : x$; $x = .4$ pound per foot for tail-rope.

$1^2 : \frac{5}{8}^2 :: 1.6 : x^1$; $x^1 = .625$ pound per foot for head or main rope.

$4,000 \times .4 = 1,600$ pounds = total weight of tail-rope.

$4,000 \times .625 = 2,500$ pounds = total weight of main rope.

As the weight of the descending tail-rope will tend to partly balance the weight of the ascending main rope the traction due to gravity of the main rope will 1 per cent. of the difference of their weights or $(2,500 - 1,600) \times .01 = 9$ pounds.

The traction due to the friction of the ropes will be $\frac{1}{40}$ of the sum of their weights or $(2,500 + 1,600)\ \frac{1}{40} = 102.5$ pounds. $102.5 + 9 = 111.5$ = total tractive force due to ropes.

$2,205 + 111.5 = 2,306.5$ pounds = total traction of trip and ropes.

As there are 600 cars to be hauled, and each trip consists of 15 cars, $600 \div 15 = 40$ round trips.

Allowing 10 hours for a day's work, $\frac{60 \times 10}{40} = 15$ minutes per round trip.

Each round trip must travel 4,000 $\times$ 2 = 8,000 feet.

$8,000 \div 15 = 533\frac{1}{3}$ feet per minute = velocity.

$\frac{2,316.5 \times 533\frac{1}{3}}{33,000} = 37.44+$ horsepower, Ans.

I. C. Parfett,
Jerome, Pa.

Second Prize, A. E. Smith, Merritt, B. C., Canada.

Ques. 16.—*Standing Props.*—How would you stand a prop in a seam of coal 6 feet thick, which has from one foot to two feet of slate above it, (1) when the seam is flat; (2) when the seam pitches 30 degrees; (3) when the seam pitches 70 degrees? Give details and reasons for your answer.

Ans.—Before putting in any props, the roof should be carefully examined in order to find out where they will do the most service. As the roof in this particular case is slate which often contains points and cracks, it should be examined for these, as they are often a source of great danger to the miner. These cracks may be either inclined away from the working face, vertical, or inclined toward the face, and this determines the position in which the prop is placed.

As the pressure of the roof acts vertically downwards, undoubtedly props in a horizontal seam should be placed vertically, and as they are placed to prevent sagging and falling of the roof they must also be perfectly rigid. This rigidity is obtained by means of a slightly wedged soft-wood cap, 2 to 3 inches thick, and of greater width than the thickness of the prop. A soft-wood wedge is preferable to hard wood, because, as it gradually gets the weight, it yields and crushes without snapping as a hard-wood wedge would do. In this way it forms, as it were, a hoop around the end of the prop and prevents the tendency to split.

To place the prop, it is stood vertically on one end which should be

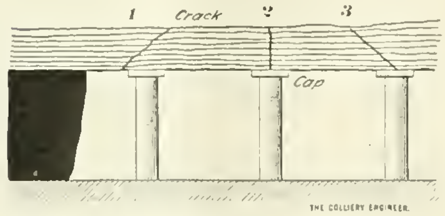

Fig. 1

cut at right angles to its length. Some miners prefer the butt end toward the floor while others reverse it. This, however, is to a large extent a matter of local practice. If the butt end is upwards the prop is more unstable yet it gives a bigger surface for the wedge to act upon, and as it is also the smaller end which is apt to split many prefer that it should crush at the floor rather than at the roof where the cap is. The prop should rest evenly on the floor which should be perfectly firm, and as the prop is slightly shorter than the distance it has to span, the wedge is placed in this space near the roof and driven with a heavy hammer until the whole is perfectly rigid.

Fig. 1 shows the positions of the props relative to the cracks in the roof. No. *1* is probably the most dangerous as the miner does not know of its existence until the coal has been undercut and the roof so

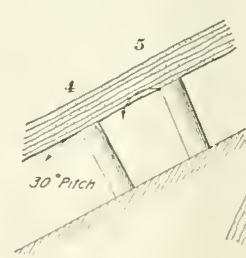

Fig. 2

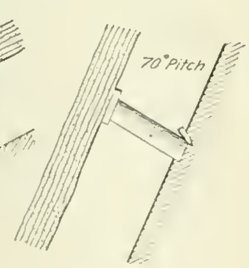

Fig. 3

weakened. When the cracks are of this nature the timbers should be close to the face. In *3* the prop is placed when the crack shows itself, but the nearness of the face will not allow it to be placed as at *1*. If necessary later, the point may be further timbered as *1*. The caps are always placed at right angles to the crack.

If the seam is inclined, the props are not fixed at right angles to the seam, but are inclined toward the rise, or "underset." The amount of underset varies from $\frac{1}{6}$ to $\frac{1}{8}$ of the angle of dip. The reason for this will be seen by reference to Fig. 2. Any movement of the roof will cause the prop to move in the direction shown by the arrow if the prop is put at right angles to the dip as at *4*. Similarly a falling stone might dislodge it. On the other hand if it is placed a little toward the vertical and the ends of the prop cut to suit the slope of the seam at *5* it would tend to move in the direction of the arc *5* and so wedge tighter.

To fix the prop, the wedge is placed with the thin end pointing in the direction of dip and firmly knocked into position. Sometimes it is more convenient to place the cap on top of the prop and secure both by beating the top of the prop toward the dip with a hammer.

When a seam has an inclination of 70 degrees a prop has a greater tendency to fall out and it is better to secure the foot by cutting a "hitch" in the foot-wall as shown in Fig. 3, about 8 to 10 inches deep, and in this place the foot of the prop, and drive it into position as in the former case. The foot of the prop should also be wedged firmly by means of soft wooden wedges. The "hitch" should be cut wedge-shaped as in the sketch with the lower face cut so that the prop rests firmly on it.

Mertola, Portugal.

Second Prize, R. Z. Virgin, Colliers, W. Va.

Ques. 21.—In a mine worked by room and pillar in the panel system, do you consider it good mining practice to work a proportion of the pillars along with the solid working? Give the reasons for your answer.

Ans.—(*a*) Yes. The following are the reasons:

(1) If pillars be left standing for even a comparatively short time after the rooms are finished, the coal, on all exposed surfaces, to a depth depending upon the structure, deteriorates, owing to oxidation and the escape of the volatile gases as a consequence of disintegration. As the value of coal depends upon its possessing, in the highest possible degree, those qualities which make it a potential industrial factor, any method of production that will maintain these qualities is, certainly, the most practical considered from a financial and economic standpoint.

By working the panel entries to their boundary before opening any rooms and then starting a series of rooms at the extreme end, keeping the last two rooms in advance so that they will be finished first, the pillar between these two rooms can be extracted as soon as the rooms are finished. As each successive room is finished the pillar can be started back. As soon as there are a sufficient number of pillars extracted the entry stumps can be taken out. By this method all the coal will be taken out in the least time with the retention of its highest commercial value.

(2) By this method of working, which for want of a better name I would designate as "room and pillar retreating," a uniform daily output can be maintained in an entry from the time the first series of rooms are opened until nearly all the coal has been taken out. This I regard as an economical condition because it permits of a concentration of work to the least possible area to produce the required daily output of the mine. That concentration results in the expenditure of a minimum proportion of powder and labor is a well-known fact.

(3) A minimum amount of timber is required to sustain the working face and a large percentage of what is used can be recovered, as it is in use for a comparatively short time. If pillars are left standing for a long time the posts in the rooms become so affected by the mine atmosphere that they are practically useless as supports. It is quite often necessary to retimber or repost a room and remove roof falls before the pillar coal can be recovered.

(4) Dangers incident to falls of roof are materially decreased. A greater continuous amount of roof area is left unsupported for a given amount of coal extracted. This roof surface will fall more readily because the contiguous strata are supported by practically solid coal, thus causing an excess of breaking strain to be thrown upon the unsupported area. When the cave occurs the line of the break is clear cut, the contiguous strata not being characterized by lines of fracture. In extracting pillars and entry stumps it is desirable to have the cave as close to the line of extraction as possible as this decreases the pressure over the supporting coal.

(5) Creeps and heaves can be avoided by this method when the conditions are such as to make the occurrence of either possible or probable. Creeps and heaves are caused by a gradual and persistent subsidence of roof strata over insufficiently supported areas.

When a sufficient amount of coal is removed to make a roof fall, the weight of the overlying strata causes the roof to bend over this area. If the supporting coal under the contiguous strata be not sufficiently strong to resist this strain and cause the strata to break, the bending is communicated to adjacent territory, the supporting coal is crushed and a creep or heave results.

(6) The airways can be maintained in proper condition and the greatest efficiency of ventilation secured. The airways with their intersecting cross-cuts and the stoppings in such are not subjected to any undue stress of roof pressure, resulting in falls of roof, crushing of ribs and breakage of stoppings and a consequent decrease of ventilation at the working face. The worked out portion is limited in its line of contact with the working faces, a line which can be swept by the ventilating current and the dangerous gases carried off in dilution without coming into contact with the workmen.

(7) Where machine mining is used a large proportion of the pillar coal can be cut and a decreased cost per ton effected. The pillars will present a comparatively solid face as they are worked before any undue stress is exercised to crush them.

Second Prize, H. J. Jakobe, Box 687, Lexington, Ky.

Ques. 22.—Working by room and pillar, what percentage of coal would you leave in the pillars at depths of 300, 500, and 700 feet, respectively?

Ans.—Various writers on coal mining have given rules in relation to the percentage of coal to leave in the pillars, which in my mind are similar to a large amount of other mining formulas, "impracticable." The amount to be left in pillars depends certainly upon the depth of bed, nature of the overlying strata, strength of the seam itself, and also on the method of working out the pillars. If the pillars have to support the roof for various lengths of time, I should then make some allowance in size, the longer they have to stand the larger I would have the pillars; then, again, if the pillars were never to be extracted, and there was no serious objection to an easy, even subsidence of the superincumbent strata, the pillars could be left very thin between rooms, if good pillars were left next to the main haulage roads and main airways. To make my answer as brief as possible, we will consider all the conditions to be normal, or in other words, average conditions, and pillars to be of such size as to hold the top steady. At a depth of 300 feet I should leave 33 per cent. in pillars; at 500 feet, 50 per cent.; at 700 feet about 60 per cent. These percentages, in my mind, would do very well if pillars were worked out in the follow-up system. If the pillars have to be worked out by the retreating method or in other words the superincumbent strata must not move in the least, the pillars should be at least 10 per cent. larger, where I have allowed less than 50 per cent.; 5 to 7 per cent. larger where I have allowed from 50 to 60 per cent.; and I should allow 65 per cent. of coal to be left (not less) where the depth was 700 feet or more and no movement of the superincumbent strata could take place. These figures, in my mind, due to practical experience with moderate strata and moderate strength of coal, would give good results.

W. H. Luxton,
Box 73, A. R. R. 3, Linton, Ind.

SECOND PRIZE ANSWER

In the Fig. 4 A represents a pillar of coal 1 foot in thickness between two adjacent rooms in a room and pillar method of working; t is the thickness of the seam in feet; and y represents the width of the pillar in feet. B represents the rectangular prism of surface strata, 1 foot in thickness that is supported by the pillar A. h = depth in feet of seam below the surface, and $d\,c$ = the width of the prism in feet, which is the same as the distance between centers of rooms.

Let x = width of prism or $d\,c$, and z = weight of 1 cubic foot of the overlying strata in pounds.

Each square foot of the surface strata will exert a pressure equal to the weight of 1 cubic foot of the strata multiplied by the depth of the seam in feet or pressure per square foot of surface = $h\,z$.

As the prism has $x \times 1$ or x square feet in its roof area, $h\,z\,x$ = total weight of prism in pounds

As the total weight of the prism is supported by the pillar, if we divide this weight by the number of square feet in the top surface of the pillar, the quotient will be the weight in pounds supported by each square foot of pillar surface.

$y \times 1 = y$ square feet in surface of pillar.

Then $h\,z\,x \div y = \dfrac{h\,z\,x}{y}$ = weight or pressure in pounds supported by each square foot of pillar surface. Assuming that $z = 160$ pounds,

$$160 \div 2{,}000 = \frac{160}{2{,}000} \text{ tons per cubic foot of surface.}$$

Substituting this value of z = the above equation we have the load in

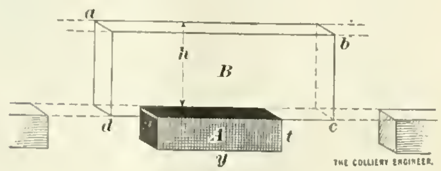

Fig. 4

tons on each square foot of pillar surface represented by the formula

$$L = \frac{160}{2{,}000} \times \frac{h\,x}{y} = \frac{160\,h\,x}{2{,}000\,y} \text{ tons.} \qquad (1)$$

It has been found by calculation based upon experiments that each square foot of pillar surface will support a pressure according to the following formula,

$$L = C\sqrt{\frac{y}{t}} \qquad (2)$$

In which L = load in tons;
y = width of pillar in feet;
t = thickness of seam in feet;
C = a constant which has been found to be between 30 and 40, or 35.

As formulas (1) and (2) equal the same thing they will equal each other.

$$C\sqrt{\frac{y}{t}} = \frac{160\,h\,x}{2{,}000\,y}$$

Assuming the distance between room centers, or x, to be 60 feet and

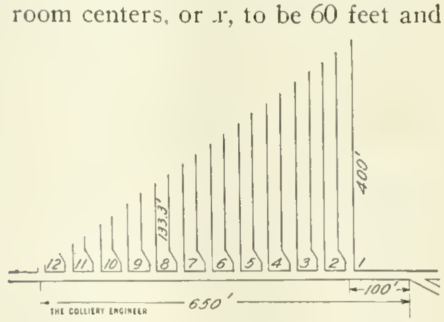

Fig. 5

the thickness of seam to be 5 feet, and substituting the other known values, our formula for a depth of 300 feet becomes

$$35\sqrt{\frac{y}{5}} = \frac{160 \times 300 \times 60}{2{,}000\,y}$$

Solving this equation y = 20.38 feet.

Then, $\dfrac{60-20.38}{60} = \dfrac{39.62}{60} = 66$ per cent. of coal to be taken out.

For the same thickness of seam and same distance between room centers, the widths of pillars for different depths are proportional to the cube roots of the squares of the depths.

$$20.38 : y' :: \sqrt[3]{(300)^2} : \sqrt[3]{(500)^2}$$

$y' = 28.4$ feet = width of pillar for 500 feet of depth.

$\dfrac{60-28.4}{60} = \dfrac{31.6}{60} = 52\tfrac{2}{3}$ per cent. of coal to be taken out.

$$20.38 : y'' :: \sqrt[3]{(300)^2} : \sqrt[3]{(700)^2}$$

$y'' = 35.86$ feet = width of pillar for 700 feet of depth.

$\dfrac{60-35.86}{60} = \dfrac{24.14}{60} = 40+$ per cent. of coal to be taken out.

I. C. Parfett, Jerome, Pa.

Ques. 23.—A mule serves a panel of 12 rooms in 6-foot coal. The parting is 100 feet from the first room, and all loaded cars, holding 2 tons each, go to it. Assuming the length of the rooms to be 400 feet when worked out, that the rooms are 20 feet wide, and the pillars 30 feet wide, what distance will the mule travel to collect 160 tons of coal in 10 hours?

Ans.—In this problem I assume that the first room is just being completed and the twelfth or last room in the panel, just being opened, as shown in Fig. 5. Also that each room has the same output and all rooms demand the same number of cars. First room gets first car, etc.

There are 160 tons of coal to be gathered from this panel in 2-ton cars, which means 80 cars per day. This number is not a multiple of 12, therefore, some of the first rooms will have more cars than the latter ones. For the first 72 cars each room gets six and the last eight cars are given to the first eight rooms.

It is 100 feet from parting to first room neck and 650 feet to the last room neck, so the distance to the average room neck is $(650+100) \div 2 = 375$ feet; average depth of room 200 feet, making average distance from room face to parting 575 feet. The mule travels double this each trip or 1,150 feet, and there are 72 such trips = 82,800 feet. The average distance from parting to face of rooms in the first 8 rooms is $(100 + 450) \div 2 + (400 + 133\frac{1}{3}) \div 2 = 542+$ and doubled = 1,084 and eight such trips = 8,672. 82,800 + 8,672 = 91,472 feet or $17\frac{1}{3}$ miles traveled per day.

W. E. Hobson,
315 E. Maxwell St., Lexington, Ky.

Second Prize, I. C. Parfett, Jerome, Pa.

Ques. 24.—On a straight track in good condition, having 1-per-cent. grade, a mine locomotive can haul 14 times its weight. The haul is 4,000 feet, and the number of loaded cars to be hauled daily is 600 in an 8-hour shift. (1) How many cars should be in a trip, the total weight of car and coal being 4,200 pounds, and having a frictional resistance of $6\frac{1}{2}$ pounds per ton of 2,000 pounds? (2) What should be the weight of the locomotive? (3) The law allows a speed of 10 miles an hour; what speed will the locomotive require?

Ans.—Assume the grade against the loads. The rated speed of most mine motors is 6 miles an hour, which is fast enough. $4{,}000 \times 2 \times 60 \div (6 \times 5{,}280) = 15\frac{5}{33}$, say 16 minutes. Allow 5 minutes for switching and bringing the trips up to speed, $16 + 5 = 21$ minutes for one round trip. $8 \times 60 \div 21 = 22\frac{6}{7}$, say 23 trips. $600 \div 23 = 26\frac{2}{23}$, say 27 cars per trip. $4{,}200 \times 6\frac{1}{2} \div 2{,}000 = 13.65$ pounds friction per car. $4{,}200 \times .01 = 42$ pounds for each car due to 1-per-cent. grade. $42 + 13.65 = 55.65$ pounds total drawbar pull for each car. $27 \times 55.65 = 1{,}503$, nearly, total drawbar pull required of motor. $27 \times 4{,}200 \div 14 = 8{,}100$ pounds, weight required for motor. A Jeffrey motor, 4 tons, 35 horsepower, 6 miles per hour, has a drawbar pull of 1,520 pounds up a 1-per-cent. grade. This is slightly under weight but will do.

The Combustion of Oxygen and Coal Dust in Mines

*By James Ashworth**

A paper on this subject has been read very recently by Mr. W. C. Blackett, the President of the North of England Institute of Mining and Mechanical Engineers, and has raised an interesting discussion. It is not the writer's purpose in these few remarks to consider this subject as a whole, but simply to select from it a few novel points. Mr. Blackett says: "It is quite possible that there are expedients which in certain circumstances would prevent ignitions, but these have not yet been tested, and would, as a matter of fact, be unnecessary, if incombustible dust were used, on the principle that the greater contains the less. It has, however, been found that the conditions to start a coal-dust explosion must be so exact that very little departure therefrom spells experimental failure. It will, he thinks, be eventually proved that without any concussion wave in the air, a large body of flame will be required to fire coal dust, while much less flame will suffice if there is also a wave."

Mr. Blackett also introduced into this paper a direct suggestion for a discussion on the topic, as to whether or not the stoppings put into the cutthroughs in a mine, should be put in so strongly that they could not be blown out by an explosion. He himself suggests that the violence of an explosion might be reduced and its progress to some extent arrested and brought to an end, if the stoppings gave way and allowed the force to expand.

In the course of the discussion Doctor Haldane suggested that a reduction of the oxygen content of mine air below the $17\frac{1}{2}$ per cent. as suggested by Doctor Harger would have a tendency to produce "mountain sickness."

The gentlemen discussing the paper did not, as also the author, favor the idea of any easy means of reversing the air-current in a mine, but there was a general agreement that dusting a mine with incombustible dust, especially flue dust, was a better protection than watering and spraying. Probably the most interesting fact brought out by the discussion, came from Mr. H. W. G. Halbaum, who is well known as an introducer of matters which involve original thought. He did not belie his reputation and probably startled some engineers by stating that he had seen coal dust fired by a jet of compressed air without any flame being present. He had hoped that he might with the assistance of others get at what was at that particular time, an unaccountable occurrence. He had been in communication with Drs. Bedson and Wheeler, but he had not heard that any success has as yet been attained in reproducing the conditions and obtaining the same results by experiment on the surface. Mr. Halbaum further said that he had dropped any further investigations owing to the unfortunate fact that some of the British Home Office staff, who had been taken into consultation on the matter, thought that the interests of safe coal mining would be better served by getting up a case for the prosecution of the management rather than to give their time to the investigation of such extraordinary phenomena and the discovery of how to prevent their reoccurrence.

This appears to be a most regrettable action on the part of the government authorities, and is on a par with an extremely serious disaster which occurred at the Auckland Park collieries, Durham, England, in the Harvey seam, in October last. No person was in the mine, but an explosion occurred which wrecked the mine, especially No. 1 district, and burned and killed 45 horses. All that is known is that there was a very heavy fall of roof in the main gangway. This was at first thought to have damaged an electric cable which was buried under the fall. On cleaning up the fall this cable was found to be perfectly sound in

*Consulting Engineer, Vancouver, B.C.

every respect, and the cause of the disaster still remains a mystery, and thus adds one more to an accumulating list of colliery disaster mysteries.

Air percussion having been generally tabooed and treated as a myth, engineers have preferably accepted theories that required falling rocks to strike fire and thus exploded mixtures of gas and air. In the Auckland Park case, however, the roof was of too soft a "post" nature to support such theory.

Another "mystery" which has not excited much interest in coal mining circles was the explosion at the Killingworth colliery, in New South Wales. A Royal Commission investigated this case, and not one single expert or government official could put forth any theory which would reasonably account for the disaster. This again was a case in which no person was underground, and only one horse was killed and unburned. The force exerted was however greater than was ever before developed by a colliery explosion, thus a weight of material consisting of loaded mine cars, ropes, and cages, was forced up a vertical shaft 620 feet deep, and rolled up in a bunch in the head-gear. The weight of this was from 10 to 11 tons. The flame of the explosion went into every district of the mine, and the effects of air percussion were in distinct evidence.

Many experiments have been made to ascertain the lowest ignition point of mixtures of firedamp and air, and of coal dust suspended in the air, but every one of these have been higher heats than have been demonstrated by actual disasters, thus at the Frick works at Brookfield, the Bristol recorder at the moment of the explosion showed that the heat did not exceed 280° F.

The writer would like to see this class of investigation taken up and discussed in a practical way. Doubtless many of the readers of The Colliery Engineer will assist such an inquiry by relating facts within their own experience.

It frequently happens after a man has seen some out of the way and extraordinary occurrence, that he is afraid to state the facts for fear of being told that he was suffering from some illusion.

Whilst referring to coal-mine mysteries the writer might draw attention to another case, which occurred at the Valley Field colliery, in Scotland, in 1911. Here two men were driving a level and in the course of doing so disclosed a fault running across the face, and a very strong blower of gas. This gas came off with such force as to bury the men in fine dust before they had a chance to escape. The body of one of the men was found to be blistered underneath his clothes. No inquiry appears to have been made into the cause of this blistering, and it will be interesting to know if there are any other similar instances known or recorded. Presumably there was sufficient heat to cause blistering of the skin, and if so the heat must have been the result of friction between the stream of escaping gas and the sides of the hole through the solid coal.

Taking this occurrence into consideration alongside the one quoted by Mr. Halbaum are we to assume that the friction of escaping gas or compressed air may under certain at present unknown conditions create a flame and thus initiate an explosion?

BOOK REVIEW

A review of the latest books on Mining and related subjects

Agricola De Re Metallica. Agricola wrote the first comprehensive book on mining and metallurgy, a task which occupied 25 years before it reached the printer's hands in 1553, and then it did not appear until a year after his death in 1555. Herbert Clark Hoover, A. B., and Lou Henry Hoover, A. B., have translated Agricola's wonderful De Re Metallica from the first Latin edition of 1556. This translation is as near a reproduction of the original as it is possible to make it, even to vellum cover, size of type, illustrations, and paper. There are 640 $13\frac{1}{4}'' \times 18\frac{1}{4}''$ pages in the book, including index. It abounds in information which shows the up-to-date reader how slowly the mining and metallurgical sciences have advanced.

Georgius Agricola, S. D., was born at Glauchau, in Saxony, March 24, 1494, when, through the aid of the printing press there was a revival of learning and an awakening from the physical to the intellectual efforts of man. Civilization increases in proportion to the ability of a people to make use of its natural resources, and from what we find in Agricola it appears that the rise of the Roman Empire was due to working its natural resources, and its fall to neglect to keep them working.

The real name of Agricola was George Bauer and it is presumed that his teachers Latinized his name as was the custom of the time.

Agricola graduated from Leipsic with the degree of B. A. in 1514. After studying philosophy, medicine, and the natural sciences in Italy and elsewhere, he became town physician at Joachimstahl. The S. D. after his name is assumed to mean "some doctor." Eckley B. Coxe owned one or two original copies of Agricola, and probably they are at Lehigh University, as he donated his library to that institution.

The book is published by *The Mining Magazine*, London, England, but can be ordered through The Colliery Engineer on receipt of the price, $6.25. The duty is $1.35.

"Calculus" is the name of a book written by Messrs. William S. Franklin, Barry MacNutt, and Rolling L. Charles, of Lehigh University, South Bethlehem. By putting correct emphasis on the fundamentals the authors have embodied a humane element (or possibly christian fortitude would be better, since most college textbook writers on higher mathematics seem to think abstruseness shows erudition) that will cause enthusiasm among students rather than physical collapse. The knotty problem of calculus is presented so plainly that a slow thinker can see that calculus is not an artificial subject devised to give students the headache. The book contains 253 pages, 123 illustrations, and is so interesting one man says he received it in the morning and read it before dinner. Now if the book will appeal to an expert mathematician in this manner it should certainly appeal to mathematical professors at large.

Digest of Compensation Laws. A digest of the various workmen's compensation laws that have been adopted in the various states has been prepared by the National Association of Manufacturers. The following appears in the Preface. "Workmen's compensation legislation has come to stay. To stand in the way of equitable laws is worse than folly. Humane as well as economic considerations demand the early adoption of workmen's compensation laws in every state of the Union. If the progressive elements among legislators, employers, wage workers, insurance experts, and the public at large do not settle this problem in an economic, efficient, and humane fashion, it will be settled for us with a vengeance by the demagogue and agitator. Thirteen states have already enacted workmen's compensation laws of one kind or another. There is little uniformity among these laws and their respective merits are problematic. Reasonable uniformity is an essential requirement to the future success of workmen's compensation legislation in the United States. There is nothing that will promote uniformity and progress more than a general knowledge of laws already enacted. This booklet, giving a complete but concise digest of details of each state law as compared with similar ones in the laws of other states, should be in the hands of every progressive legislator, writer, employer, employe, insurance expert, and every student of this important problem.

During the two years past a large number of bills, concerning compensation to injured workmen, have been presented to the State Assemblies for enactment. As many as ten different employers' liability and workmen's compensation bills were thus presented at the 1911 session of one State Assembly. There were a total of about two hundred such bills presented at the 1911 sessions of the State Assemblies. Thirteen of the states have enacted compensation laws. Commissions have been appointed in a number of the states, for the purpose of drafting workmen's compensation bills to be presented for enactment at the next sessions of the State Assemblies.

It is quite evident, after a careful study of the large number of bills presented for enactment, that the persons who drafted those bills were, for the most part, uninformed, even as to the fundamental principles necessarily involved in the subject of workmen's compensation. As to the compensation laws enacted, there is but little uniformity between them. They all differ as to their minor features, but it is possible to divide them into two classes, to wit: those laws which provide state insurance: those laws which place the burden upon the employer to compensate the injured employe. So great is the volume, and so varied the subject matter of these laws that the busy legislator, lawyer, employer, and employe cannot spare the time to read them.

The purpose of this work is to give to such persons a synopsis of the important features of each law so arranged that a comparison of the laws can be made in a very short time.

Copies of this digest can be secured at cost; for a library edition the price is 25 cents, for paper cover, 15 cents, and for paper cover in quantities, 10 cents.

Air Compression and Transmission, by H. J. Thorkelson. Published by McGraw-Hill Book Co., New York City. 200 pages, illustrated, $2 net. The book is written in clear, simple language and discusses in turn, the characteristics of air, fundamental definitions, energy equations, the various kinds of compression, classification of valves, the effect of altitude upon the power, volume, and capacity of compressors, results of compressor tests, air receivers, the measurement and compression of compressed air, closing with a chapter on the selection and care of air compressors.

The book is intensely interesting and valuable to any one connected with the design or operation of power plants or its transmission.

Industrial Arts Index.—The H. W. Wilson Co., compilers and publishers of biographies, indexes to periodicals and other reference works, Minneapolis, Minn., announces the second issue of the Industrial Arts Index.

This issue records the contents of thirty-five periodicals from January 1 to May 1, 1913, as far as they could be obtained. Thirteen new magazines which were not available for indexing in this number, have been selected and will be included in the next issue. The list of magazines to be indexed will ultimately be increased to one hundred.

Lake Superior Iron Ore Annual, 1913, contains the official figures on shipments by mines, ranges, and ports, together with complete statistics bearing on the Lake Superior ore shipments since 1844, and ore prices at the lower lake docks. This book, compiled by the *Iron Trade Review*, Cleveland, Ohio, sells for $1, cloth bound, and $2 in leather. From an examination of the cost tables it is evident that iron ore can be mined as cheaply in the East as in the Michigan and Minnesota districts, further if the magnetite ores of New York and New Jersey are compared with the Lake Superior ores the percentage of iron will be found favorable as well.

Practical Talks on Coal Mining

For men who desire information on Coal Mining and related subjects presented in a simple manner

Mine Ventilation

The Quantity of Air Required—Mine Laws and Their Requirements—What Constitutes a Dangerous Proportion of Gas

(Continued from June)

STRICTLY speaking, the proper ventilation of a mine requires that enough air be carried through it to sweep the faces of all the rooms and entries with a velocity sufficient to dislodge and carry away the gases as fast as they are given off by the freshly mined coal in order to prevent a dangerous accumulation of them in any one place. As the majority of mines do not give off methane to a dangerous extent, it is not necessary or customary to carry the air to the face of each room in American coal mining practice.

In Illinois the law requires in non-gaseous mines, 100 cubic feet of air a minute for each man and 500 cubic feet of air a minute for each draft animal, which is increased to 150 cubic feet of air a minute per man if the mine is gaseous. In Ohio, the requirements are 150 and 500 cubic feet of air per man and per mule, respectively, per minute in non-gaseous mines, and 200 cubic feet per man in gaseous mines. In the bituminous regions of Pennsylvania, the requirements per man per minute are 150 and 200 cubic feet in non-gaseous and gaseous mines, respectively; and in the anthracite districts of the same state, 200 cubic feet of air per minute must be supplied each man, whether the mine be gaseous or not. It will be noted that the Pennsylvania law makes no allowance of air for the mules, and such an allowance is really not necessary, because that made for the entire number of men in the mine is so very much more than they can possibly consume, there will always be an ample supply left over for the mules.

It will be noted that the state laws recognize the difference between the amount of air required to ventilate a non-gaseous and a gaseous mine by increasing to the extent of 50 cubic feet of air a minute the amount of air to be supplied each man in workings of the latter class. This does not mean that a man requires for breathing this much more air in a gaseous than in a non-gaseous mine, but that this much extra air is supposed to be enough to carry off the increased amount of explosive gas. Thus, 100 men and 10 mules in a non-gaseous mine in Illinois must be supplied with $(100 \times 100) + (10 \times 500) = 15{,}000$ cubic feet of fresh air per minute; if the mine is gaseous, then they legally require, $(100 \times 150) + (10 \times 500) = 20{,}000$ cubic feet per minute. The difference, or $20{,}000 - 15{,}000 = 5{,}000$ cubic feet per minute, is supposed to be enough under ordinary conditions to dilute the methane below the explosive point. Of recent years it has become recognized that it is impossible to say just how many cubic feet of air per minute per man are necessary to carry away the methane given off by the mine. It is realized that some mines will require a total, say, of 100,000 cubic feet of air a minute to carry away this gas, and in others 5,000 cubic feet will answer, so that, recently enacted laws, after fixing the minimum (the smallest) amount that may be circulated in each class of mine, have a clause attached which leaves the determination of the actual amount to be supplied to one or more of the state mine inspectors. Thus, quoting the 1911 law of Pennsylvania: "In a non-gaseous mine the mimimum quantity of air shall not be less than 150 cubic feet per minute for each person employed. In a mine wherein explosive gas is being generated in such quantities that it can be detected by an approved safety lamp, the minimum quantity of air shall not be less than 200 cubic feet per minute for each person employed therein, *and as much more in either case as one or more of the inspectors may deem requisite.*" (Note.—The italics are ours.) In some laws, the part in italics is changed to read, "*and as much more as may be necessary to dilute, render harmless, and carry off any and all noxious gases.*" Hence the Pennsylvania law means that where no gas is given off there must be supplied not less than 150 cubic feet a minute for each man. There must not be less but there may be any amount more that the state mine inspector may think necessary. Similarly, if the mine is gaseous, the law requires not less than 200 cubic feet for each underground employe, but the state inspector may increase this to any extent local conditions require.

One uncertainty in these laws is the distinction to be made between a gaseous and a non-gaseous mine. The bituminous mine law of Pennsylvania should be clear on this point as it is the most recently enacted; but it is, unfortunately, no plainer than that of other states. In Pennsylvania a mine is gaseous when "explosive gas is generated in such quantities that it can be detected by an approved safety lamp." But after this the law is silent and does not say what an "approved" safety lamp is, nor who shall use it and when and where. Now it is a well-known fact that safety lamps vary widely in the cap given by different amounts of gas. Some specially constructed lamps will give a larger cap with 1 per cent. of gas than others will with 2 per cent. As pointed out earlier in this series of articles, even 1 per cent. of gas is a dangerous amount if the mine contains a finely powdered explosive dust, and, as further shown before, this dust is present in practically all bituminous coal mines. Hence, under the laws of Pennsylvania, one lamp will show that the mine is non-gaseous and safe and another lamp, both of them "approved," will show that it is gaseous and unsafe.

Similarly, on the return airway many mines will show traces of gas when none can be detected in the workings. This does not mean that there is no gas in the working places, but so little that it cannot be detected by a lamp, and that when all the gas from all the workings is concentrated in the return, a very decided cap is visible.

Finally, men differ in the amount of gas they can detect with the ordinary approved safety lamp. It has been shown repeatedly that less than 2 per cent. cannot be detected by the average fire boss. The claim that as little as 1 per cent. may be detected is not founded upon actual tests but upon the opinion of some one. As the amount of gas in the mine air can easily be determined by a chemist, opinions and guesses should have no weight in such important matters.

Owing then, to the uncertainties of the results obtained by the use of the ordinary safety lamp in the hands of the ordinary man, and to introduce a fixed standard of safety, what may be called the modern idea of ventilation has come into existence. According to the best modern practice in Europe and the United States, a mine should be supplied with sufficient air, whether it be 25 or 250 cubic feet of air per man per minute, to sweep away the powder smoke and the gases given off by men and animals, and as much more as may be necessary to keep the amount of methane in the return air-current as determined by chemical analysis, well below 1 per cent. By the exact methods of chemistry it is possible to determine at any and all times just how much dangerous gas there is in the return and thus be entirely independent of the uncertain results afforded by the "approved" safety lamp. To sum up, modern methods of ventilation demand that enough air be supplied to keep the mine air of the same chemical composition as that of the pure outside air. As this is not always possible, enough air must be supplied to keep the composition of that in the mine such that it is not injurious to health when breathed and does not contain enough methane to lend itself to a dust explosion. And what is enough air is determined by the chemist and not by the safety lamp.

(To be continued)

Mechanics of Mining

An Explanation of the Principles Underlying Calculations Relating to Engines, Pumps, and Other Machinery

By R. T. Strohm, M. E. *(Continued from June)*

A MACHINE that is frequently used for lifting loads is the wheel and axle, a very simple form of which is shown in Fig. 22. It consists of two cylindrical parts *a* and *b* of different diameters but having their center lines in the same straight line. A rope *c* is fastened to the smaller part *a* and is

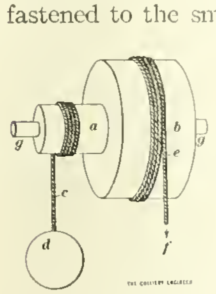

Fig. 22

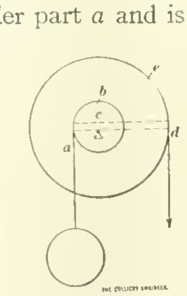

Fig. 23

wound around it several times, and the load *d* to be lifted is attached to the free end. Another rope *e* is fastened to the larger cylinder *b* and is wound around it in the opposite direction, and the lifting force is applied at the free end *f* of this rope. The force of the pull at *f* causes the wheel and axle to turn in the bearings *g* on which the machine is supported. The rope *e* then unwinds from the larger cylinder and the rope *c* winds on the smaller cylinder, raising the load in so doing.

An end view of the wheel and axle in Fig. 22 is shown in Fig. 23 in the form of a simple diagram or outline. The load, pulling downwards at *a*, tends to turn the axle *b* to the left, around the center *c*, and the force acting downwards at *d* tends to turn the wheel *e* to the right. The effect is the same, therefore, as would be produced if a lever were used, as shown by the dotted lines. The fulcrum of the lever is at the center *c*, the load hangs from the end of the short arm, and the force is applied at the end of the long arm. The force required to lift a given weight therefore depends on the relative lengths of the arms of the lever. If the force arm is three times as long as the load arm, the load lifted may be three times the force; or, if the force arm is five times as long as the load arm, the load may be five times the force.

The long arm of the lever is equal in length to the radius, or half the diameter, of the wheel, and the short arm of the lever is equal in length to the radius, or half the diameter, of the axle; consequently, if the diameter

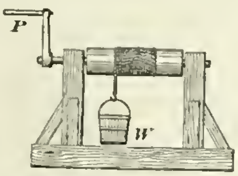

Fig. 24

of the wheel is three times that of the axle, the force required will be only one-third of the weight of the load. The advantage of the wheel and axle is that it enables a small force to overcome a much larger load.

As in the case of the lever and the pulley, however, the foregoing advantage is offset by a loss of time; that is, the load rises much slower than the force descends. Suppose that the diameter of the wheel is three times the diameter of the axle, and that these two parts, turning together, make one complete revolution. In doing so, one turn of rope is unwound from the wheel and one turn is wound on the axle. But the length of one turn of rope on the wheel is equal to the circumference of the wheel, or 3.1416 times its diameter; and the length of one turn of rope on the axle is equal to the circumference of the axle, or 3.1416 times its diameter. As the diameter of the wheel is three times that of the axle, the circumference of the wheel is three times that of the axle. Consequently, the length of rope unwound from the wheel in one turn is three times the length wound on the axle in one turn; that is, the force moves three times as far as the load moves in the same time, or the load moves at one-third the speed of the force.

The only purpose of the rope *e* wound on the wheel, Fig. 22, is to furnish a means by which the lifting force may act to turn the wheel; but it is not necessary to use a large cylinder and a rope to accomplish this. Suppose that the one end support of the axle is lengthened and that a crank, or arm, is fastened to it; also that the wheel is removed and that it is replaced by a second end support for the axle. The resulting machine is then like that shown in Fig. 24, and is known as a windlass.

In the windlass, the force *P* that causes the load to rise is applied to the handle at the end of the crank. This force follows the crank as the latter turns, and therefore acts in a circle. However, if the length of the crank is equal to the radius of the wheel in Fig. 22, and if the axle and the load *W* in Fig. 24 are of the same size as the axle and the load in Fig. 22, the same force will be required in each case. For in each case the force will act at the same distance from the center of the axle; that is, the force arm of the windlass will be equal to the force arm of the wheel and axle, and the turning effort will be the same.

The windlass is one of the simplest and most commonly used forms of hoisting machine, particularly where weights are hoisted by hand power. The ease with which a given load may be raised may be increased by lengthening the crank to which the handle is fixed or by decreasing the size of the axle on which the rope winds. The first method increases the force arm and makes the force travel farther for a given rise of the load. The second method decreases the weight arm and makes the load rise a shorter distance for a given travel of the force.

If the wheel and axle or the windlass is so arranged that the force arm is longer than the weight arm, the speed of the load in rising will be less than that of the force, but the force required will be less than the load. This is the condition of affairs shown in Figs. 22 and 24. If it is desired to have the load rise much more rapidly than the force moves, then the force arm is made shorter than the weight arm.

A simple diagram of a hoisting engine using this principle is shown in Fig. 25. The steam in the cylinder *a* causes the rod *b* to move to and fro, and by means of a connecting-rod *c* this motion is transmitted to the crank *d*, causing it to turn. The crank is fastened to the shaft *e*, to which the drum *f* also is fixed, so that the motion of the engine turns the drum in the direction of the arrow. One end of a rope *g* is fastened to the drum; and the rope is carried over a sheave *h*, the load *i* to be lifted being attached at the other end. The turning of the drum winds the rope on it and causes the load to rise.

The sheave *h* is merely a fixed pulley and alters the direction of the pull of the load but does not alter the amount of the pull. This pull, equal to the weight of the load *i* is exerted at the point *j* on the drum, and the distance from the center of the shaft *e* to the point *j* where the rope starts to wind on the drum is the load arm.

The force exerted by the engine acts on the pin *k* at the end of the crank, and the greatest length the force arm can have is the length of the crank, or the distance from the center of the pin *k* to the center of the shaft *e*. As the crank is much shorter than the load arm, the load will rise much faster than the pin *k* moves; but the force applied at the pin *k* to turn the drum will need to be much greater than the weight of the load. A hoisting engine in which the crank is fastened directly to the shaft that carries the drum, as in this illustration, is called a first-motion hoisting engine.

Another machine that uses the principle of the wheel and axle in

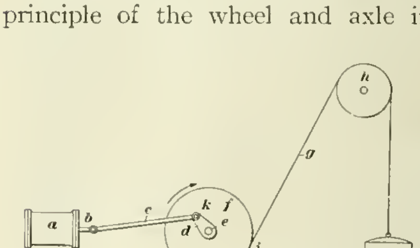

Fig. 25

connection with that of a movable pulley is the differential chain hoist shown in Fig. 26. Two iron pulleys of slightly different diameters are fastened on the same axle, so that they must turn together at the same rate, and this axle is supported by a frame attached to a stationary support. An endless chain is passed over these pulleys, as shown, forming two loops, and a single movable pulley is placed in one of the loops. The weight to be raised is hung on the hook attached to the movable pulley, and when the right-hand part of the free loop is drawn downwards, the load is slowly raised. The grooves

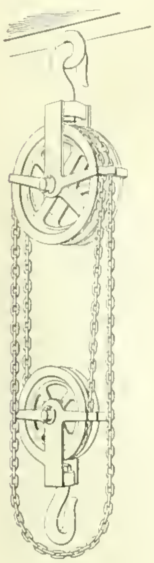

Fig. 26

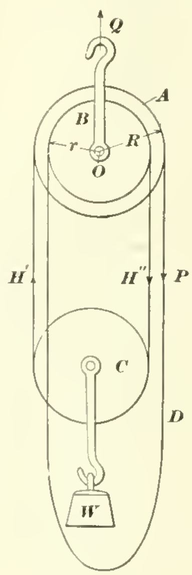

Fig. 27

of the upper pair of pulleys have notches and teeth in which the links fit, thus preventing the chain from slipping.

A diagram of the arrangement of the pulleys, chain, and load is given in Fig. 27. The load W on the pulley C is carried by the two parts H' and H'' of the chain, each of which takes half of the load. The force is applied downwards at P on the part D of the free loop, and this causes the pulleys A and B to turn with the axle O held in the stationary frame supported at Q. Now, when the chain is drawn down at P, the part at H' is drawn upwards at the same speed over the larger pulley A, which turns with the chain. But the pulley B turns with the pulley A, and unwinds the part H''. If the part H' went upwards just as fast as the part H'' went downwards off the pulley B, the pulley C and the load would not move. However, the pulley A is larger than the pulley B, for its radius R is greater than the radius r of the pulley B; therefore the chain will wind up over the large pulley A somewhat faster than it will unwind off the smaller pulley B, and as a result the load will be raised.

Suppose that the diameter of the pulley A is 12 inches and of the pulley B is 11 inches, and that the force P moves downwards a distance equal to the circumference of the pulley A, or $3.1416 \times 12 = 37.6992$ inches. The pulleys A and B then make one complete turn, and 37.6992 inches of chain go up over the pulley A while $3.1416 \times 11 = 34.5576$ inches come down off the pulley B. This means that the total shortening of chain between the upper and lower pulleys is $37.6992 - 34.5576 = 3.1416$ inches. As this is taken up by the two parts H' and H'' of the rope, each is shortened $3.1416 \div 2 = 1.5708$ inches, and the load is raised this amount. While the force moves 37.6992 inches, the load moves 1.5708 inches, and as $37.6992 = 24 \times 1.5708$, the force moves 24 times as fast as the load; therefore, the load raised can be 24 times as great as the force applied at P, if the pulleys are 12 and 11 inches in diameter. If other sizes of pulleys are used, these values will change.

(To be Continued)

Electricity in Mines

Influence of Size of Conductor on Resistance—Resistances of Different Materials—Voltaic Cells

By H. S. Webb, M. S. *(Continued from June)*

If the sectional area of a conductor be doubled, its resistance will be halved; if the sectional area be halved, the resistance will be doubled; an increase in the sectional area will cause a decrease in the resistance; a decrease in the sectional area will cause an increase in the resistance.

To calculate the resistance of a conductor after its sectional area has been changed, use the following rule:

Rule.—Multiply the original sectional area and resistance together and divide by the changed value of the sectional area.

Example.— 1,000 feet of copper trolley wire having a sectional area of 66,000 circular mils, has a resistance of .16 ohm; what will be the resistance of the same length of copper trolley wire having a sectional area of 133,000 circular mils?

Solution.—

$$\frac{66{,}000 \times .16}{133{,}000} = .0794 \text{ ohm.}$$

In most cases, both the length and sectional area of a conductor are subjected to change; in such a case, each change affects the resistance as independently as if the other change had not taken place, and their effects can be considered separately.

Example.—The resistance of 1,000 feet of rail steel of 1 square inch sectional area is .085 ohm; what will be the resistance of 1 mile of steel rail of 6 square inches cross-section?

Solution.—One mile equals 5,280 feet; hence, according to the rule, the changed resistance due to change in length is

$$5{,}280 \times \frac{.085}{1{,}000} = .449 \text{ ohm.}$$

According to the rule, the further changed value due to increase in sectional areas is

$$\frac{1 \times .449}{6} = .0748 \text{ ohm.}$$

Resistance of Different Materials. Conductors of the same dimensions and material have the same resistance, except in so far as it may be affected by impurities and temperature. Conductors of the same dimensions but of different materials have very different resistances. For example, 1,000 feet of pure copper wire having a sectional area of 8,234 circular mils has a resistance of 1.257 ohms at 20° C.; an iron wire of the same dimensions and temperature might have a resistance as high as 8.75 ohms. The conductors used in railway work are copper, aluminum, iron or steel, German silver, and carbon. Assuming all pieces to be of the same dimensions and temperature, the piece of aluminum will have a resistance of from 1.7 to 1.8 times that of the copper; iron or steel, 6.5 to 8 times; German silver, 18 to 27 times; and carbon, 2,000 to 4,000 times. For an iron conductor to carry the same current as a copper one under the same conditions, its sectional area must be $6\frac{1}{2}$ to 8 times greater; aluminum, 1.8 times greater; and so on.

Change of Resistance With Change in Temperature.—The resistance of all conductors changes with the temperature. In the case of carbon and water or other conducting liquids, an increase in temperature causes a decrease in resistance; but with all metallic conductors, an increase in temperature causes an increase in resistance. In comparing the resistances of different substances, it is essential that they be compared at equal temperatures.

Wire Gauge and Table.—Wire used in electrical work is generally designated by its gauge number; the gauge almost universally used, in America, for copper wire is known as the American, or Brown & Sharpe (B. & S.), gauge. The sizes according to this gauge vary from No. 0000, which is .46 inch in diameter, to No. 40, which is .003145 inch in diameter, the higher the gauge number the smaller being the wire.

In complete courses and handbooks tables are given which show the dimensions, weight, resistance, etc., of the various sizes of bare copper and iron and other wires according to the various gauges.

A convenient size to remember as a standard is No. 10 wire gauge, which is a little over $\frac{1}{10}$ inch in diameter. For rough estimates, its area can be taken as 10,000 circular mils and its resistance as 1 ohm per 1,000 feet. If one remembers these facts regarding No. 10 wire he will at once know that No. 7 wire, for example, has an area of about 10,000 × 2 = 20,000 circular mils and a resistance of about .5 ohm per 1,000

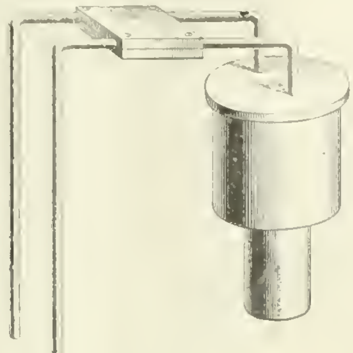

Fig. 6

feet; and that No. 13 has an area of 5,000 circular mils and a resistance of 2 ohms per 1,000 feet. These facts are easy to remember and are convenient when there is no wire table available. When exact calculations are to be made, tables should be used, as the above rules give areas and resistances that are only approximately correct.

Resistance of Conductors in Series. The resistance of two or more conductors connected in series is equal to the sum of their separate resistances. For example, if four conductors having separate resistances of 8, 12, 22, and 34 ohms, are connected in series, their total resistance will be 8 + 12 - 22 + 34 = 76 ohms.

Standard Ohm Coils.—For commercial testing, the standard column of mercury, representing the resist-

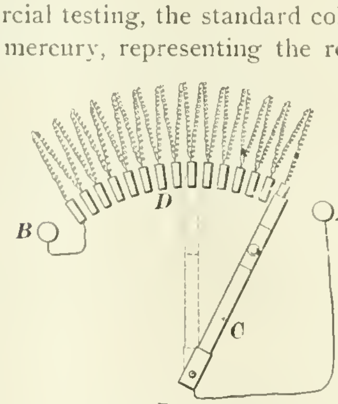

Fig. 7

ance of 1 ohm, has been replaced by a coil of wire, usually a platinum-silver alloy. The coil is carefully adjusted to offer a resistance of exactly 1 ohm at some convenient temperature, and is enclosed in a metallic case, the connections to the two ends of the coil being made by two heavy terminals of copper wire passing up through the hard-rubber cover. Such coils are known as standard ohm coils. The commercial form is shown in Fig. 6.

Rheostats.—A device called a resistance box, or rheostat, is largely used for controlling the strength of electric currents. The resistance in these rheostats is usually made adjustable by the use of a sliding contact. Fig. 7 shows diagrammatically one form of a sliding-contact rheostat. The coils of resistance wire are connected to a row of contact pieces *D*, as indicated. The current enters the rheostat through the terminal *A*, passes through the movable arm *C*, and then through all the resistance coils between the contact piece on which the arm rests and the terminal *B*. When the arm rests on the right-hand contact piece, as shown by the full lines in the diagram, all the resistance is said to be in circuit; that is, the current passes through all the coils. By moving the arm to the left, toward the terminal *B*, as shown by the dotted lines, the coils connected to the contact pieces that have been passed over by the arm are said to be cut out of circuit, and the current passes through the remaining coils only.

The flow of electricity through a circuit is due to an electromotive force developed, usually at some one point in the circuit. This electromotive force, or electrical pressure, forces electricity to flow in the circuit, in spite of the resistance to its passage offered by the wires and other devices connected in the circuit. The electromotive force may be supplied by a dynamo, storage battery, primary battery, or other source of electric power. If the resistance of a circuit remains the same, a constant electromotive force will cause a uniform, or steady, current to flow through the circuit. The unit of electromotive force will maintain a current of 1 ampere in a circuit whose resistance is 1 ohm. The unit of electromotive force is called the volt after Alessandro Volta, an Italian physicist, who lived from 1745 to 1827.

The maximum difference of potential developed by any single voltaic couple placed in any electrolyte is about 2.25 volts; in the common form of cells, the difference of potential developed averages from .5 to 1.75 volts. The electromotive force generally employed for operating ordinary surface electric cars is about 500 volts; a railway incandescent lamp requires about 110 volts pressure across its terminals to make it burn to full brightness. On some power-transmission lines, the pressure is as high as 50,000 or 60,000 volts, while the potential of a lightning flash may be several millions of volts.

Voltmeters.—Measuring instruments called voltmeters have been devised for indicating directly, in volts, the values of electromotive forces. The Weston voltmeter, Fig. 8, is based on the same principles as the Weston ammeter, and in appearance is quite similar to it. Its internal resistance, as in all voltmeters, is exceedingly high; the resistance of a Weston voltmeter for indicating up to 150 volts is about 19,000 ohms; while the resistance of a Weston ammeter, measuring strengths of currents up to 15 amperes, is only .0022 ohm. Owing to its great resistance, the current passing through a voltmeter is exceedingly small.

All voltmeters are provided with at least two terminals or binding posts p, p', Fig. 8. Connections are made by separate conductors, called voltmeter leads, from these binding posts to two points between which the difference of potential or electromotive force is to be measured.

The Weston voltmeters usually have a third binding post p'', which, when used with p', corresponds with a second graduated scale situated directly under the main scale, one division of the upper scale having the value of two or more of the lower divisions. In Fig. 8, one division of the upper scale represents ten divisions of the lower scale. The majority of voltmeters are also provided with a contact button b, which, when pressed, closes the circuit and allows the index needle to be deflected by the current. When the pressure on the button is relaxed, the circuit is opened, and the index needle returns to the zero mark.

Voltaic Cells.—A voltaic, or galvanic, cell is an apparatus for developing a continuous current of electricity. A voltaic, or galvanic, battery is a number of single cells properly connected together. A cell consists of two conducting elements immersed in a solution that acts chemically on one element only or on one more than on the other. If the two elements, or poles, of the cell are joined by a continuous metallic wire or circuit, an electric current will flow in one direction through the metallic circuit as long as the circuit remains complete or closed, provided the chemical action is sufficient to maintain the electromotive force. The ends of the two elements that project and to which wires external to the cell are connected are called the electrodes. The electrodes are generally provided with screws and nuts, called binding posts, to which wires may be readily connected. Conductors and electrical devices connected together so as to form a closed circuit from one binding post to the other, outside of the cell itself, are called the external circuit. The path through the interior of the cell is called the internal circuit.

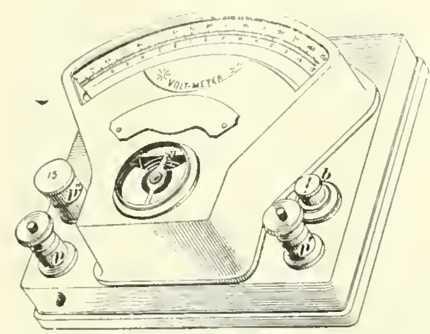

Fig. 8

One element is usually zinc and the other carbon, copper, or some other metal. The binding post attached to the zinc is the negative terminal, or negative pole, of the cell and the other binding post is the positive terminal, or positive pole, of the cell. The current always flows from the zinc element through the interior of the cell to the other element, then through the external circuit back to the zinc terminal. If this circuit is broken or open anywhere, no current will flow in any part of this circuit. The solution in the cell is called the electrolyte. In the most commonly used voltaic cells there is little or no chemical action when the external circuit is open, but as soon as the external circuit is closed so that current flows through the electrolyte, chemical action commences, the zinc is gradually consumed by forming a substance that is soluble in the solution and there is a tendency to form hydrogen gas around the carbon or copper element. It has been found that if the formation of hydrogen gas around the positive terminal can be prevented, there is developed a greater electromotive force in the cell. This is accomplished by surrounding the positive terminal with some other material, which is called a depolarizer, because it prevents the formation of an opposing electromotive force, or polarization as it is called, around the positive terminal. This depolarizer may be a solid substance or a solution of some kind.

(To be Continued)

Reinforcing Collars

Old wire ropes can be used to reinforce collars along roads where the ground is heavy and the renewal of timber is frequently necessary. This reinforcing is accomplished by fastening the wire rope to the under side of the collar by means of staples and also placing the rope around the ends of the collar and fastening it securely on top. Then when the weight comes upon the timber it will press the rope against the collar so as to hold it more firmly, and at the same time the rope is also caught between the leg and the collar. As the collar bends under the weight which it is supporting, the wire rope will be placed in tension and support the collar. It has been found possible to reduce the cost of timbering on some roads 50 per cent. by using this means.

Answers to Examination Questions

Examination for Mine Foreman and Assistant Foreman, March, 1913 and for Inspector of Mines, May, 1913, Held at Pottsville, Pa.

(Continued from June)

Ques. 26.—What are the dangers attending the use of explosives in the presence of each of these gases?

Ans.—Nitrogen, oxygen, and carbon dioxide being incombustible gases neither increase nor decrease the dangers due to handling explosives. The use of explosives when methane is present in the air is attended with danger in proportion to the amount of this gas present. As the dust of anthracite coal is not explosive, the presence of small amounts of this gas need not interfere with the use of explosives in the ordinary way. If greater amounts are present the flame of blown-out shots will begin to lengthen until, when the proper amount of methane is in the air, a gas explosion will result.

Ques. 27.—Under what circumstances may a body of gas fail to be removed after restoring the ventilation?

Ans.—By restoring ventilation, is meant the bringing of it back to the same condition in every way that it was before an explosion. Hence, if there was no standing gas before the explosion there will be none after the ventilation is restored. It is possible that bodies of afterdamp may be found in places which before were sufficiently ventilated, or it is possible that a mass of timbers may have been fired by the explosion, in which case impure gases will be given off by their burning.

Ques. 28.—Has a rising or falling barometer any influence on the ventilation of a mine?

Ans.—A falling barometer means that the pressure of the air upon the working face is less and this allows more gas to escape from the pores of the coal into the workings. As the barometer rises and the pressure increases, less gas is driven off. The change in weight of the air due to changes in pressure and temperature has a small effect upon the quantity of air delivered by the fan. Anything that increases the weight per cubic foot of the air such as

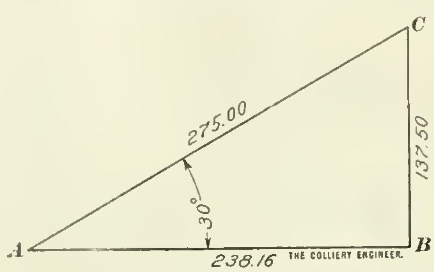

Fig. 4

rising barometer and falling temperature requires that more steam be turned on the fan engine to keep its speed the same, but if the air becomes lighter by reason of a falling barometer or rising temperature, less steam will be needed to keep the speed of the fan as before. In the first case more air will be delivered for the same speed and in the second case, less air.

Ques. 29.—A breast is driven up 275 feet on an angle of 30 degrees, how long would it be on the map, and how much higher would the face of the breast be than the gangway?

Ans.—The length of the breast is line AC shown in Fig. 4, and is equal to slope × cosine angle of rise = 275 × cos 30° = 275 × .86603 = 238.16 feet. As mine maps are commonly drawn to a scale of 100 feet to the inch, the length of this breast on the map will be 238.16 ÷ 100 = 2.38 inches. The distance of the face above the gangway is represented by the line BC, and is equal to slope × sine angle of rise = 275 × .50000 = 137.50 feet.

Ques. 30.—How much water will be discharged by a pump having a 10-inch water end and 4-foot stroke and making 48 strokes per minute?

Ans.—First find the area of the water end by multiplying the square of its diameter by .7854, then multiplying this by the length of the stroke in inches (4 × 12 = 48 inches), and multiply this by the number of strokes per minute or 48. This gives the discharge in cubic inches per minute which must be divided by 231 to give the number of gallons. Expressed as an equation,

$$\text{Discharge} = \frac{10^2 \times .7854 \times 4 \times 12 \times 48}{231}$$

= 783 gallons per minute. This is the theoretical discharge if everything works perfectly. It is customary to make an allowance of some 15 per cent. for slip, etc.; that is, the efficiency is reckoned at 85 per cent. Multiplying the above theoretical discharge by .85, we have 783 × .85 = 665 gallons (about) for the probable actual discharge.

Ques. 31.—How many cubic yards in a tunnel 8 feet by 11 feet and 300 feet long, and what would be the cost of the tunnel at $5 per cubic yard? Work out fully.

Ans.—The area of the cross-section of the tunnel is found by multiplying the height by the breadth, or 8 × 11 = 88 square feet. The number of cubic feet is found by multiplying this area by the length of the tunnel, or 88 × 300 = 26,400 cubic feet. The number of cubic feet divided by 27, which is the number of cubic feet in a cubic yard, gives the number of cubic yards in the tunnel, or 26,400 ÷ 27 = 977.778 cubic yards. The number of cubic yards multiplied by $5, the cost per cubic yard, gives the cost of the tunnel, or 977.778 × $5 = $4,888.89. Expressed as an equation, $\text{Cost} = \frac{8 \times 11 \times 300 \times 5}{27} = \$4{,}888.89$.

Ques. 32.—What instruments are required by the mine foreman and his assistants to carry out fully the duties of their position?

Ans.—The anemometer and water gauge to measure the velocity and pressure of the air are the instruments generally accounted as necessary for the mine foreman. To these should be added a tape to measure the cross-section and length of airways, and a watch to time the revolutions of the anemometer. Other useful instruments are a clinometer to measure pitches, and a thermometer, barometer, and hygrometer for measuring the temperature, pressure, and humidity of the air. These instruments and their use have been repeatedly described in these columns in recent months.

Examination for Inspector of Mines Held in Pottsville, Pa., May 5 and 6, 1913.

Ques. 1.—Have you read the Report of the Department of Mines for the year 1913, anthracite region?

Ans.—Yes.

Ques. 2.—What was (approximately) the total production of anthracite for 1911 in gross tons?

Ans.—Approximately, 81,000,000 tons. Exactly, 81,176,050 tons.

Ques. 3.—What was the number of employes, inside, outside, and total, at anthracite mines for the year 1911?

Ans.—Inside, 126,037; outside, 47,301; total, 173,338.

Ques. 4.—How many lives were lost by accidents, inside, outside, and total, at anthracite mines during the year 1911?

Ans.—Inside, 615; outside, 84; total, 699.

Ques. 5.—What were the three highest causes inside and the two highest causes outside, of fatal accidents at anthracite mines in the year 1911, and what was the number killed and the percentage of total fatalities of these causes?

Ans.—Inside: Falls of coal, slate, and roof, a total of 253, or 41.14 per cent.; cars, 92, or 14.96 per cent.; explosions of gas, 34, or 5.53 per cent. Outside: cars, 26, or 30.95 per cent.; machinery, 22, or 26.19 per cent.

Ques. 6.—How many and what percentage of total fatal accidents in the anthracite mines during 1911 were due to electricity? (*a*) inside; (*b*) outside.

Ans.—Inside, 2 fatalities, or .32 per cent. of the total; outside, 1 fatality, or 1.19 per cent.

Ques. 7.—What is the number of the anthracite inspection district in which you are now employed, the name and residence of the present inspector and what was the average number of days which the collieries in that district worked during the year 1911?

Ans.—(For illustration only. To be answered according to the residence of the candidate.) Twelfth District, P. C. Fenton, Inspector, Mahanoy City. Average number of days worked, 261.

Ques. 8.—In consideration of the increasing use of electricity in anthracite mines, a mine inspector should have some knowledge on this subject. State to what extent you have studied the subject giving the names of textbooks used.

Ans.—To be answered according to the personal experience of candidate.

Ques. 9.—Name and define the four electrical units that are in common use.

Ans.—The four electrical units in common use are the ampere, volt, ohm, and watt. The ampere is the unit of strength of the electrical current, and expresses the rate of flow of the current per second. It corresponds to the expression of the flow of water through a pipe in gallons per minute or the number of cubic feet of air passing in an airway per minute.

The volt is the unit of electromotive force, and corresponds to the head of water producing a given flow in hydraulics or the pressure procuring a given circulation of air in ventilation.

The ohm is the unit of resistance, and expresses the amount of resistance encountered by a current of 1 ampere under a pressure of 1 volt.

The watt is the unit of power, and expresses the power required to pass a current of 1 ampere under a pressure of 1 volt.

Ques. 10.—What is the practical working difference between a dynamo and an electric motor in their actual application to electric power?

Ans.—The dynamo converts mechanical power, as of a steam engine, into electrical energy; the motor converts electrical energy into mechanical power, which may be used to operate a pump, fan, haulage motor, etc.

Ques. 11.—Describe the danger that attends the use of electricity in and about mines, and state your suggestions to safeguard the workman.

Ans.—The sparking of brushes or the short-circuiting of the current will ignite bodies of gas, explosives, etc. The short-circuiting of the current will also ignite any combustible material such as hay, brattice cloth, wood, etc. Contact with a charged (live) wire, particularly if the current is alternating or of high voltage, will almost invariably result in death. The breaking of the bulb of the small portable electric lamps now in use may result in ignition of gas.

As a means of preventing accidents or of lessening the dangers due to the use of electricity, all currents should be direct and of not over 250 volts. All wires leading down shafts should be carefully insulated and placed in one corner thereof and away from the timbers. All underground structures such as stables, pump houses, shanties, etc., should be of concrete or steel. Oil, explosives, hay, wood, brattice cloth, and other inflammable substances should not be stored where there is any possibility of their coming in contact with a live wire. Feed-wires should be insulated and carried in some gangway other than that used as a traveling road. Trolley wires should be firmly fixed to the roof or timbers so as to lessen their liability to fall and should be set in an inverted wooden trough, the sides of which project at least 3 inches below the wire. At places where men are compelled to cross the haulage road, the roof should be shot so that the trolley wires may be placed at such a height that men carrying drills, etc., cannot accidentally touch them. Parts of haulage motors and other machines which are apt to spark should, in very gaseous mines, be inclosed in wire gauze as is a safety lamp. Portable electric lamps, if used in gassy places, should be of low voltage and have their light increased by using a better filament, reflectors, etc.

As the majority of accidents are caused by the carelessness of the victim or of those working with him, the men should be cautioned again and again against the probable fatal results from handling wires carrying electric currents.

Ques. 12.—What do the anthracite mine laws of Pennsylvania generally provide for, and what do they apply to?

Ans.—They provide "for the health and safety of persons employed in and about the anthracite coal mines of Pennsylvania, and for the protection and preservation of property connected therewith." They apply to "every anthracite coal mine or colliery in the Commonwealth, provided the said mine or colliery employs more than ten (10) persons.

Ques. 13.—What is required by the mine laws of Pennsylvania to make a person eligible for the office of Mine Inspector?

Ans.—He must be a citizen of the state and at least 30 years of age. "He must have a knowledge of the different systems of work in coal mines, and he must produce satisfactory evidence to the Board of Examiners of having had at least five years' practical experience in the anthracite coal mines of Pennsylvania. He must have had experience in coal mines where noxious and explosive gases are evolved." The fulfilment of the above conditions makes it possible for him to appear for examination. Before his name is allowed to be printed upon the ballots he must pass an examination nito his qualifications and secure a certificate setting forth that he has correctly answered at least 90 per cent. of the questions asked, which certificate must be filed with the county commissioners.

Ques. 14.—Give nine of the principal duties of a Mine Inspector as prescribed in the various acts and amendments thereto in the anthracite mine laws.

Ans.—He shall take an oath or affirmation that he will perform his duties with fidelity and impartiality: He shall provide himself with the most modern instruments and appliances necessary for him to perform his duties: He shall inspect such collieries as the Chief of the Bureau of Mines may direct even if not in his regular inspection district: He must reside in the district from which he is elected and must give all his time and attention to the duties of his office: He must examine all the collieries in his district at least once every 3 months, and as often in addition as the necessity of the case or the condition of the mines may require: He shall see that every necessary precaution is taken to secure the safety of the workmen; that the provisions of the law are obeyed; and shall visit each working face to see that the ventilating current is properly carried to the working faces to properly ventilate them: He shall make a report every 4 months to the Chief of the Department of Mines, designating the gangway in which the working is situated, and the number of the breast and the condition thereof; which report shall be placed in a weather and dust-proof case, with a glass front and is to be placed at some conspicuous place near each mine opening. In this report he shall certify that the employes are hoisted to the surface or given access thereto according to law: He shall attend every coroner's inquest held upon the bodies of those killed in or about the collieries in his district: He shall visit the scene of every accident for the purpose of enquiring into the particulars thereof: He shall make an annual report to the Chief of the Department of Mines of the Commonwealth enumerating the fatal and serious accidents in his district and the causes of each, the condition of the mines as regards the safety of the workmen therein and the ventilation thereof, the results to be set forth fully: He shall perform such other duties "as now are or hereafter may be required by law."

Ques. 15.—What are the principal requirements of the anthracite mine laws as to "Maps and Plans?"

Ans.—The map shall be made on a scale of 100 feet to the inch and shall show the workings of each seam and the tunnels and passages connecting them. It shall show in degrees the inclination of the strata and any material deflection therefrom as well as the elevation above tide of the bottom of each shaft, slope, tunnel, or gangway, and every other underground or surface point that the inspector thinks necessary. It shall show the number of the last survey station and the date of last survey; the boundary lines of the property and the nearness of the workings thereto; the location of any dam holding back water, with the tidal elevation, inclination of the strata and area of the working containing water. A copy of the map shall be given the district inspector (who may require each seam to be shown upon a separate sheet of tracing cloth), and one copy must be kept at the mine. Extensions of the workings must be added to the map once every six months, and his copy returned to the inspector within two months of the date of the last survey. When a mine as a whole or any particular lift therein is about to be abandoned, a survey shall be made thereof as a whole and a duplicate and practically agreeing survey must be made of such workings as have been carried to the property line or which it is intended to allow to fill with water. If the owner of the property fails or refuses to furnish the inspector with a map or extensions upon a previous map, the inspector is authorized to have a map made at the expense of the mine owner. If the inspector has reason to believe that the mine map supplied him is materially inaccurate, it is his duty to apply to the Court of Common Pleas of the county for an order to have such a map made, and if such survey shall prove that the original map was inaccurate, the property owner shall pay therefor, but if the map prove accurate then the State shall pay for it. If the owner, operator, or superintendent knowingly furnishes the inspector with a false map, he may be punished by a fine not to exceed $500 or imprisonment not to exceed 3 months. Maps in the hands of the inspector are the property of the Commonwealth and are to be transferred by him to his successor in office; and no copy of them shall be made without the consent of the owner of the property or his representative. The map in the inspector's possession shall be open to any miner or miners employed at that mine, if he or they have reason to believe that his or their working places are approaching dangerous accumulations of gas or water. The map shall be open to any interested citizen during business hours. Surveys of barrier pillars between adjacent properties must be made in duplicate, and must practically agree. All duplicate surveys, those of barrier pillars as well as of portions of the mine holding water, must be certified to and copies filed with the inspector, and in the case of barrier pillars a certified copy of the duplicate survey must be filed with the owner of the adjoining property.

Ques. 16.—What are the principal requirements of the mine law in regards to boilers and machinery?

Ans.—Boilers must be kept in good order, must be inspected by a qualified person as often as once in 6 months, and a report of their condition shall be certified in writing under oath to the inspector within 30 days thereafter. Boilers shall not be placed within 100 feet of any structure devoted to the preparation of coal provided it has been built since June 2, 1891. Each boiler shall have a safety valve properly adjusted. Every boiler house shall have a steam gauge and another shall be placed in the steam pipe in the engine house where the fireman or engineer can readily examine it. The gauges shall be kept in good order and inspected once in each 6 months and their condition reported to the inspector in the same manner as the report upon the boilers.

All machinery used in or about the mines or breakers shall be protected by a covering or railing, and sides of stairs, trestles, and plank walks shall be provided with a hand and guard rail. However, these protections may be temporarily removed for the purpose of repairs or other operations, provided proper precautions are used. The breaker engineer shall be competent and sober and not under 18 years of age. Signal apparatus shall be placed at important points in the breaker so that the engineer may be signaled to stop the machinery when necessary. No person under 15 years of age shall be employed to oil machinery and no person of any age shall oil it while in motion. No person shall play with, loiter around, or interfere with machinery.

Ques. 17.—Give the duties of a fireman in charge of boilers for generation of steam.

Ans.—He shall keep a constant watch over the boilers and shall see that the pressure does not at any time exceed the limit allowed by the outside foreman or superintendent. He shall frequently try the safety valve and shall not increase the weight upon it. He shall maintain the proper depth of water in each boiler and if this cannot be done, shall report this at once to whichever foreman is in charge and shall take such other action as may be necessary for the protection of life and property.

(To be Continued)

Safety First

*By John Dunlop**

An abstract from an address entitled "Safety First," from the standpoint of the mine inspector, delivered at the dedication of the mining laboratory of the University of Illinois.

Not in the history of mining has as much consideration been given to the miner's safety as now. The employers of labor realize that their employes must be protected from accidents, and recognize their responsibility in the matter.

Commissioners have been appointed, State Inspectors of Mines in the United States have organized a society, the Federal Bureau of Mines has been established, all for the purpose of the prevention of accidents, and yet, after all the agitation, the many bulletins issued, and the passage of laws, accidents continue. The two principal causes of accidents are falling roof and mine cars.

During the last year 58 per cent. of the fatalities were from falling coal, rock, and clod; and 20 per cent. were due to cars. The surprising causes have varied very little within the last 12 years, and are just as persistent as those given, so that for every 250,000 tons of coal mined there is a life lost.

The number of non-fatal accidents is greater in the long-wall mines in proportion to the number of men employed than in any other mines, but there are fewer fatal accidents. This is accounted for by the

*State Mine Inspector.

height of the seam. If a piece of loose coal or shale is of sufficient weight that its fall will injure a miner in a thin seam it would in all probability kill a man where the seam is 5 feet and over.

To prevent accidents the state inspectors have recommended the employment of a face boss for each 100 men in a mine. The duties of such face bosses would be to visit the working places each shift and instruct the miners in making their places safe, and further to see that the men follow instructions and that timbers are furnished as required. I am fully convinced that where suitable face bosses are employed, the number of all accidents within the mines will be decreased.

The miners object to face bosses, classing them as dictators. During the past year, a number of the large companies have put on face bosses with results that are not as favorable as might be expected.

The official of a coal company that operates two mines furnished the following information: The employment of face bosses at our mines has not been in operation sufficiently long (1 year) to determine positively just what advantage is derived, as the conditions relative to personal injuries are so different from those of last year. The men, taking advantage of the compensation act, are reporting injuries and requiring medical aid when they would not have done so in similar cases a year ago. He presented the following accident list for 1912 and 1913. In No. 1 mine in 1912 there were 3,857 accidents; in 1913, 2,364. In No. 2 mine in 1912 there were 1,378 accidents and in 1913, 1,144. Therefore it can be taken for granted that his statement is correct when he says there are no more accidents but more accidents are being reported.

At his No. 1 mine, the number of accidents reported for the last three months show a decided decrease over those of the first three months of the fiscal year, which are as follows: July, August, and September, 1912, 72; October, November, and December, 1912, 46; January, February, and March, 1913, 39.

It is commonly stated that the number of accidents in the coal mines is due to the large number of foreign miners employed; another reason is the change in the method of shooting followed; that is where more than 2 pounds of powder is used for one blast, all shots must be fired by men designated as shot firers. It is further said that the same care is not being exercised by the miners in preparing their shots as when they did their own firing, and that more powder is being used than is necessary, which is the cause of timbers being knocked down and making the roof dangerous.

It is true that fewer tons of coal are being produced per keg of powder from coal shot off the solid, but careful perusal of the reports of the State Inspector of Mines shows that 50 per cent. of the men killed from falling coal and slate are in mines where the coal is undercut by machines and less powder is used than where the coal is shot off the solid.

My own conclusions are that in mines where the coal is undercut, the proper placing of props is being neglected. Where electric mining machines are in use, the props must be placed at a distance from the face to allow clearance and, where the undercutting is 6 feet, the distance is too great, especially where there is a shale roof. Under conditions of this kind, which are general throughout the central and southern portions of the state, props should be placed before the coal is shot and, if face bosses are employed, it would be their duty to see that the place was properly timbered before allowing any shots to be fired. It must not be taken for granted that because the inspectors have recommended that face bosses be employed for each 100 men in the mine, they would be a panacea for all accidents.

The inspectors, by their close contact with mining and because they examine into the causes of all fatal accidents, have come to the conclusion that closer supervision must be maintained if the number of accidents is to decreased.

The prevention of accidents from cars was earnestly discussed by the Mine Investigation Commission, and after listening to suggestions of all kinds and considering the feasibility of having a law to prohibit drivers riding on the tail-chains, it was agreed that such a law would not be practical in all cases, so they recommended that in mines opened after the passage of this act, all mine cars should be equipped with bumpers which should project 4 inches beyond the ends of the car. This is only palliative and will not remedy the evil.

Not long ago, I investigated an accident which proved fatal to a driver. I found that he had attempted to go down a grade with a loaded trip without taking time to put in sprags. To prevent the trip running away he undertook to hold it by placing his back against the first car and bracing his feet on the ground. The trip pushed him down the grade, his feet slipped and he fell in front of the car which ran over his body. In this case, it was a matter of speed at the expense of safety.

To prevent accidents to drivers the motto must always be: "More caution and less speed."

We have mine laws which are as good and some much better than those in other states. These cover every phase of the work around the mines, and yet they do not prevent accidents. Observation has taught me that negligence engendered by familiarity with the surrounding conditions is the cause of most mine accidents

An offer has been made to the Russian Government by the collieries near Irjiustsk, Siberia, to furnish 540,000 tons of coal if a special freight of about 2 mills per ton mile is granted. The railroads are controlled by the government.

NEW MINING MACHINERY

Electric Sinking Pump

A Goulds vertical mine sinking pump, installed in a shaft at 123d Street and Seventh Avenue, New York City, in the Catskill Aqueduct, 475 feet below street level, is shown in Fig. 1.

This is one of seven pumps of this type used by the Pittsburg Contracting Co. on their contract extending from 177th Street, Bronx, a distance of 6 miles into Manhattan. The pumps are in shafts a mile apart.

In five shafts $3\frac{1}{2}'' \times 6''$ pumps are used and in the other two $4'' \times 6''$ pumps are used, delivering from 50 to 60 gallons per minute.

An interesting feature of these installations is that after the pumps were used normally in sinking the shafts, they were installed in a horizontal position, as shown in Fig. 1, and used as station pumps in the tunnel. Although built to be suspended in a vertical position for shaft sinking, they are giving excellent service in a horizontal position as station pumps.

The motors are three-phase, 60-cycle, 220-volt, 10-horsepower Westinghouse induction motors. Power is supplied by United Electric Light and Power Co., of New York City.

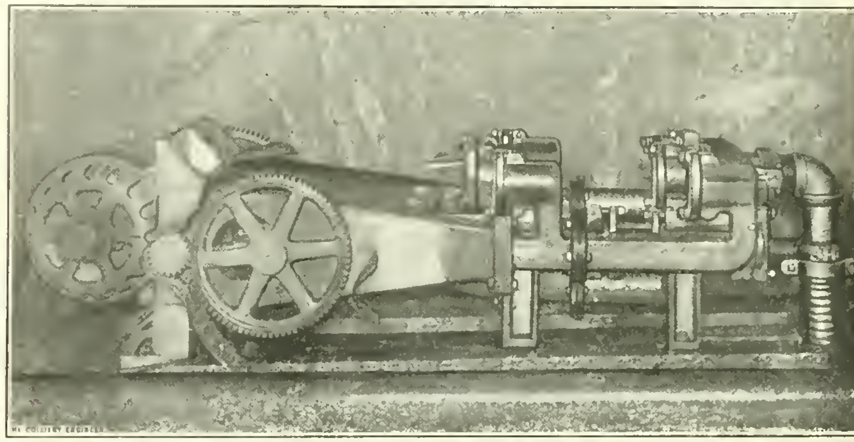

Fig. 1. Goulds Electric Sinking Pump Installed as a Station Pump

New Type of Mine Trolley

As a result of the demand for a mine trolley, differing from the standard lines, a new type, as shown in Fig. 2, has recently been placed on the market.

The design is such that there is little variation in the contact pressure where the trolley wire is suspended at different heights. When the wire is 5 feet from the top of the rail, the trolley wheel pressure is approximately 26 pounds, while at 11 feet it is about 18 pounds. This shows a variation of 8 pounds through a range of 6 feet, which is less than can be obtained by a single-pole trolley.

With the standard single-pole trolley, where the wire hangs low and extreme pressure is exerted, the pole is often damaged when the wheel leaves the wire and strikes the roof. The new trolley under these conditions, owing to the slight variation in pressure throughout the wide range in height, will be less liable to break. This slight variation makes it unnecessary to resort to the heavy pressure for low trolley wires, with the result that the wear at the wheel and harp will be less than that caused by the single-pole trolley.

In coal mines where the condition of the roof is such that narrow entries are necessary, it is often impossible to run one of the longer single pole trolleys; whereas this trolley can be turned around in passages from 4 to 6 feet in width, with the socket located approximately in the center of the locomotive.

Where high cars are used trouble is often encountered with the single-pole trolley striking the car when the trolley wire is low. The new trolley is designed to overcome this objection, as the entire operation of

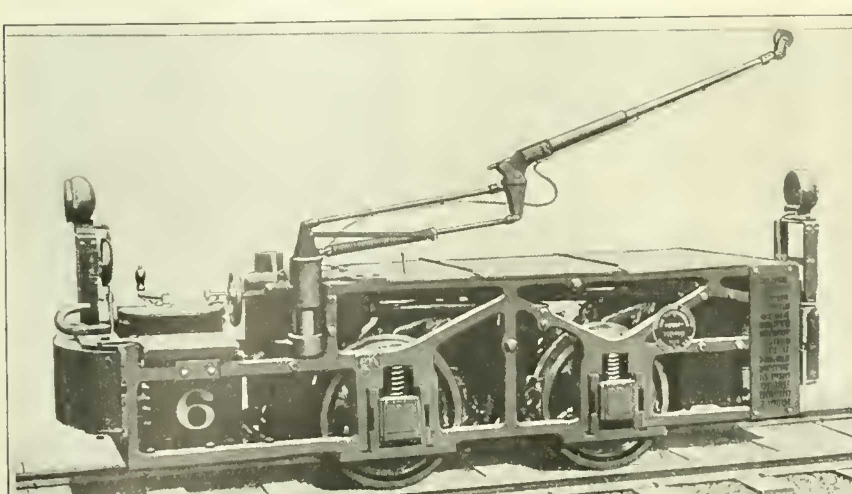

Fig. 2. Westinghouse Mine Trolley

the trolley can be kept within a radius of 4 to 6 feet from the trolley socket. If the trolley wire changes in height and position over the track during the run, the trolley wheel will follow the wire throughout a 6-foot vertical change and a wide horizontal range without stopping the locomotive.

When the locomotive is used for gathering purposes, where two single-pole trolleys are ordinarily required, the pole can be swung to operate satisfactorily on either side of the locomotive, whether the trolley wire be on the cross-cut or on the room side of the entry.

The trolley is designed to operate on a wire having a range in height of from 5 to 11 feet above the top of the rail; it being assumed that the locomotive trolley socket is about 3 feet above the rail. The trolley consists of two members which operate in sockets. By means of a latch or pin at the lower socket, the lower member of the trolley can be adjusted vertically and kept in a rigid position, and further, can be swung horizontally and fastened in any definite position required.

The trolley can be used for application to locomotives now in service, and is made by the Westinghouse Electric and Mfg. Co., East Pittsburg, Pa.

Timber Setting Derrick

The placing of timber or steel mine roof supports is an expensive item in coal mining operations and often deserves more attention than is given to it. To aid in setting timber and steel supports, the Hercules Mine Derrick shown in Fig. 4 has been invented.

The construction is such that supports of any size can be placed at desired height in a few minutes time and it can be operated by two men. Collars and legs are raised at the same time, except in places where trolley wires are in the center of the roadway. Where this is the case, the legs, of course, cannot be raised with the collar and probably 5 minutes extra time is needed for placing the collar.

By the use of this machine the liability to accidents is greatly lessened because no one is directly under the collar while it is being raised. The machine is designed for use on any pitch.

Where timbers are set from 2 feet to 8 feet apart, one man can move the machine into position to raise the next set in from 2 to 3 minutes. The construction of the machine is such that it can be knocked down and made ready to move to any part of the mine in a few minutes, and to do this will require but one timberman and his helper.

To make use of the machine it is set in the center of the entry and the approximate center of the timber is placed on the carrier. If not equally balanced the timberman can hold the stick in the desired position while it is being raised by his helper, if he sticks a pick point into and steadies it for a moment or so until the top is reached. The machine is made and patented by J. E. Jones, Centerville, Iowa.

Power-Driven Auger Drills

The accompanying picture, Fig. 3, shows the exhibit of the Howells Mining Drill Co., of Plymouth, Pa., at the recent Industrial Exposition at Wilkes-Barre, Pa., and illustrates the extent to which the auger type of drills has been developed.

Beginning many years ago with the manufacture of hand-power auger drills for boring coal, improvements were made from time to time; then power, either air or electricity, was added and the range of usefulness of the drills was extended, till now the air or electric drills are in use boring everything but the hardest rocks.

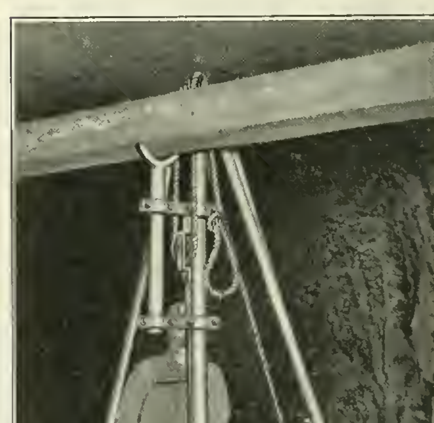

Fig. 4. Hercules Mine Derrick

In the exhibit was a 10,000-pound lump of anthracite in which a Spry, Type S, electric drill with 1½-inch bit was boring holes at a speed of 7 feet per minute. There was also an air-driven drill of a style of which the firm have shipped a number to the salt mines of Russia and which are working successfully. There was also a drill mounted on wheels for boring holes in the ground for use in the latest style of farming by dynamiting the subsoil.

The drills are made in a great variety of styles adapted for different purposes, and are the cheapest means for boring coal, slate, rock salt, gypsum, and similar material.

TRADE NOTICES

Automatic Mine Doors.—A booklet issued by the American Mine Door Co., of Canton, Ohio, describes different forms of mine doors adapted to various conditions of haulage. These doors have proved so efficient that former objections and legal restrictions to the use of automatic doors have been entirely removed and they are in use in many of the best equipped mines. The booklet will interest every man who is responsible for the placing of a door in a mine.

New Business.—Contracts for the following new plants have recently been received by the Roberts and Schaefer Co., engineers and contractors, of Chicago: From The Cleveland, Cincinnati, Chicago & St. Louis Railway, a $50,000 contract for five Holmen coaling plants to be built immediately at Paris, Ill.; Lynn, Ind.; Anderson, Ind.; Lilly, Ill.; and Dayton, Ohio. Also a $32,000 contract for two 400-ton capacity, reinforced concrete Holmen coaling plants to be built immediately at Chicago for the Indian Harbor Belt Railway Co. From the Denver & Rio Grande Railway Co., a $22,500 contract for two Holmen type locomotive coaling stations for installation at Salida and Minturn, Colo. Also a $15,500 contract from the Rock Island lines for a fireproof Holmen type coaling station, at Hulbert, Ark. The Hazard Coal Co., of Hazard, Ky., has also contracted for the designing and building of a coal mining plant at Hazard, Ky., using the new Marcus combination screen and picking conveyer equipment.

Canadian Agency.—The Orenstein-Arthur Koppel Co., of Koppel, Pa., has given the agnecy for its products in Canada to the Canadian Fairbanks-Morse Co., Ltd., having offices in Montreal, St. John, Toronto, Winnipeg, Saskatoon, Calgary, Ottawa, Vancouver, and Victoria.

New Electrical Equipment.—The Northwestern Fuel Co., St. Paul, Minn., will add to its power plant a 500-kilowatt rotary converter, 500 kv-a. transformer and switchboard. The Delaware & Hudson Co. will place in operation a new 300-kilowatt motor-generator set and switchboard in its Baltimore Tunnel mine at Wilkes-Barre, Pa.; and also a motor-generator set with switchboard of the same capacity in its Pine Ridge mine at Parsons, Pa. The Consolidation Coal Co., Fairmont, W. Va., will install at Jenkins, Ky., 33 transformers of 25, 50, 75, and 100 kv-a. capacity; 11 motors of 75 and 150 horsepower, and nine induction motor panels. The H. C. Frick Coke Co., Pittsburg, Pa., has ordered a 7-ton electric locomotive. The Lehigh Coal & Navigation Co., Philadelphia, Pa., will add to the equipment of its plant at Lansford, Pa., a 100-horsepower motor, 125-horsepower motor, three 40 kv-a. and three 50 kv-a. transformers. The Bunsen Coal Co., Chicago, Ill., has ordered a 13-ton electric locomotive. The Lehigh Valley Coal Co., Orwigsburg, Pa., has ordered a new 8-ton electric mining locomotive. The Philadelphia & Reading Coal and Iron Co., Pottsville, Pa., will place in operation in its Suffolk colliery a new 8-ton electric mining locomotive. All the above equipment has been furnished by the General Electric Co.

Steel Derricks and Drilling Rigs. The fourth edition of "Steel Derricks and Drilling Rigs," has been issued by the Carnegie Steel Co., Pittsburg, Pa. While intended as a catalog of the company's steel derricks and drill rigs it approximates a textbook on the subject.

"*Dixon Graphite Brushes*" is the title of a booklet issued by the Joseph Dixon Crucible Co., Jersey City, N. J. Dixon's brushes for dynamos and motors being composed almost entirely of high-grade graphite prevent sparking and wear of the commutator and their losses from friction on the commutator are less than with carbon brushes; moreover the commutator is always automatically lubricated, whereas with carbon brushes there are conditions under which applied lubrication is necessary. In addition to complete rules for using the brushes the booklet contains suggestions for using Dixon's lubricating rods for manufacturing arc light plungers, oilless bearings, dashpots, and for other applications where oil or grease lubrication cannot be conveniently employed. Dixon's graphite resistance rods which are furnished in a large number of combinations of size and electrical resistance are also described. The booklet will be sent on application.

New Plant.—Crawford & McCrimmon Co., of Brazil, Ind., builders of mine machinery, hoisting engines, fans, and mine pumps are starting construction of an entire new plant on a 9-acre tract. The buildings will be of the most modern steel fireproof construction. Considerable new machinery equipment is being installed and practically all contracts have been let.

Advertising.—Oliver W. Hull, formerly western advertising manager of the Hitchcock Publications of Chicago, has joined the Chamberlin Co.—Technical Publicity, Detroit. Mr. Hull's wide knowledge of manufacturing and selling problems in the field in which the Chamberlin Co. is engaged will prove a valuable acquisition to a rapidly growing force of men doing rather unusual things.

The Chamberlin Co. has always done business on a fee basis, believing that the agency should receive its compensation from the client, and not from the publisher as is the rule with general advertising agencies. The fact that the company has not lost an account since its organization is a tribute to the high character of its service.

Catalogs Received

The Improved Equipment Co., 60 Wall Street, New York, N. Y. Bulletin No. 6, Silica Retorts and Settings for Gas Benches.

Joseph Dixon Crucible Co., Jersey City, N. J. Dixon's Graphite Brushes, 16 pages.

Weinman Pump Mfg. Co., Columbus, Ohio. Circular, Pumping Outfits.

Independent Powder Co., Joplin, Mo. Circular, Brands of Dynamite.

The American Brass Co., Ansonia, Conn. Tobin Bronze, 33 pages.

Albany Lubricating Co., 708-710 Washington Street, New York. The Bearing, 18 pages.

Carnegie Steel Co., Pittsburg, Pa. Steel Derricks and Drilling Rigs, 104 pages.

Wheeler Condenser and Engineering Co., Carteret, N. J. Performance of a Wheeler Counter Current Rain Type Jet Condenser, 15 pages.

Standard Steel Works Co., Philadelphia, Pa. Rolled Steel Wheels, 56 pages.

The Watt Mining Car Wheel Co., Barnesville, Ohio. Catalog "B," Steel Ore Cars, 20 pages. Catalog "F," Steel Mine Cars, 20 pages.

Chicago Pneumatic Tool Co., Fisher Building, Chicago, Ill. Bulletin No. 128, Miscellaneous Equipment for Pneumatic Drills, 12 pages; Bulletin No. 132, Pneumatic Motors and Pneumatic Geared Hoists, 20 pages; Bulletin No. 133, Cylinder Air Hoists and Jacks, 12 pages; Bulletin No. 34-L, General Pneumatic Engineering Information, 47 pages.

The Stark Rolling Mill Co., Canton, Ohio. Toncan Metal, 70 pages.

John A. Roebling's Sons Co., Trenton, N. J. Made at Roebling's, 12 pages.

American Mine Door Co., Canton, Ohio. Coal Mine Ventilation, 48 pages.

The Gardner Governor Co., Quincy, Ill. Circular GR 2, Gardner-Rix Vertical Air Compressors, 16 pages.

Edgar Allen American Manganese Steel Co., Chicago, Ill. Gyratory and Jaw Crusher Wearing Parts, 27 pages. Stag News, 16 pages.

The Bristol Co., Waterbury, Conn. Bulletin No. 170, Bristol's Patent Electric Furnaces, 2 pages; Catalog No. 173, Bristol's Recording Differential Pressure Gauges, 4 pages; Bulletin No. 143, Bristol's Recording Differential Pressure Guages and Recording Flow-Rate Meters, 16 pages; Catalog No. 1300, Bristol's Class III Recording Thermometers, 48 pages.

Osborne Valve and Joint Co., The Rookery, Chicago, Ill. Circular, No Kut Valves and Steam Specialties.

The Ohio Brass Co., Mansfield, Ohio. Folder, Type D Trolley Frog.

Electric Service Supplies Co., 17 and Cambria St., Philadelphia, Pa. Protected Railroad Bonds and Appliances, 72 pages.

Underground Seismograph

At Nanaimo, B. C., the Western Fuel Co. takes great interest in the advancement of mining and encourages everything tending to the safety of the men in their employ. The company was the first in Canada to install a rescue station and has the distinction of having installed a seismograph 1,000 feet below the surface from which it is hoped to get information bearing on the theory of the relation of earth movements to mine explosions. During the past 10 years, the two mines had 18 accidents underground, in one mine the mortality being only three in 8 years. In 1912 their ratio was only half of one per thousand.

Hogs as Indicators

When The Colliery Engineer was Mines and Minerals and devoted to both coal and metal mining, it was customary to mention flowers, animals, birds, reptiles, and even insects whose action, habits, or characteristics were used by prospectors as indicative of mineral deposits. Recently the *Courier-Journal* interviewed Col. R. B. Hutchcraft, of Lexington, Ky., who in addition to being the Dean of Kentucky prospectors is one of the delightful old-school southern gentlemen who make it a point, even to personal inconvenience, to extend hospitality to strangers.

It seems that Colonel Hutchcraft had an opinion of his own regarding the "hawg" as an indicator, for while prospecting in what is now the Jellico field on the border of Kentucky and Tennessee in early days, he asked his host if there were any "hawg wallers" or "deer licks" in his vicinity. On receiving a reply in the affirmative he went for them with a pick and uncovered the Jellico coal bed. Colonel Hutchcraft carried a block of this coal on horseback 60 miles to Livingston where he formed a company that opened the first coal mine known as the Wooldridge, near Jellico. From this episode it will be seen that hogs are good indicators if they are incited to root for a living. Shortly after the Jellico coal bed was discovered Colonel Hutchcraft discovered the Blue Gem bed 119 feet below the Jellico bed. He was burning some of this coal one evening in the home of Colonel Wooldridge who asked what kind of coal it was. Colonel Hutchcraft seeing blue slaty looking traces on the coal which was burning remarkably well replied, "It is the 'Blue Gem' coal," and it still goes by that name.
