Mines and Minerals

Vol. XXXIII.—No. 1. SCRANTON, PA.—AUGUST, 1912—DENVER, COLO. Price, 25 Cents

PUBLISHED MONTHLY AT SCRANTON, PA.
ESTABLISHED 1881
INTERNATIONAL TEXTBOOK CO., PUBLISHERS
T. J. FOSTER, President S. P. ALLEN, Secretary E. H. LAWALL, Treasurer
RUFUS J. FOSTER, Vice-President and Manager
EUGENE B. WILSON, Editor ARTHUR J. HOSKIN, Associate Editor
WESTERN EDITORIAL OFFICE: 1221-1222 First Nat'l Bank Bldg., Denver, Colo.
CHICAGO OFFICE: 1006 Michigan Ave.
Entered at the Post Office at Scranton, Pa., as second-class matter
Address all business communications to MINES AND MINERALS, Scranton, Pa.
CABLE ADDRESS, "RETSOF, SCRANTON"
LONDON OFFICE: INTERNATIONAL BUILDINGS, KINGSWAY, LONDON, W. C.
SOUTH AFRICAN OFFICE: MANSION HOUSE CHAMBERS, ADDERLEY STREET, CAPE TOWN.
NEW ZEALAND OFFICE: 63 DIXON STREET, WELLINGTON.
AUSTRALIAN OFFICE: 83 PITT STREET, SIDNEY.

SUBSCRIPTION RATES

Single Copies........25 cents
Yearly Subscription, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines.$2.00
To Canada........2.50
To all other countries........3.00

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us.

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

AS A RULE, the operating heads of large mining plants secure most loyal support from their employes by taking a kindly interest in them, and encouraging a respectful familiarity—but, too much familiarity, and alleged humorous comments on personal appearance or traits of character, from either outsiders or employes, are distasteful to the man of ability and prominence, and tend to detract from his force and authority.

WITHIN the past 2 or 3 years a number of books have been published on subjects relating to mining, metallurgy, geology, and mineralogy. At the present time there is an over-abundance of books which add 50 cents worth of new material to old subject matter and are priced at from \$3.50 to \$4.50. It is a pity publishers are unable to grasp this point and present the manuscript to readers who have had experience and know the wants of mining men in general.

ON another page we publish an important article on the "Increased Cost of Anthracite Mining," by Wm. D. Owens, division superintendent of the Lehigh Valley Coal Co. Mr. Owens is one of the oldest and most experienced mine officials in the Anthracite region. He does not write from the standpoint of the accountant, but from the viewpoint of the man who has filled practically every position about a mine from the lowest to that of a division superintendent, and whose experience covers a period of half a century.

A HOT political campaign has a tendency to reduce the consumption of coal—for steam purposes. If all Americans would realize that no matter which party wins the country will not go to the "demnition bow wows," there would not be such a contraction in business, and the mining industry with all others would profit thereby. The tariff is the issue. Protection means high prices, tariff for revenue only means low wages. You pay your poll tax and take your choice. Meanwhile the politicians keep things hot, and the ordinary citizen is the fellow who eventually pays for the hot air.

THERE is a cause for every mine accident. As a rule American mine owners and mine managers use every possible precaution to remove the cause. Occasionally, as in other lines of business, carelessness or recklessness results in disaster.

When this is the case, the blame should rest solely on the culpable party. Sometimes accidents occur in mines at whic every possible precaution is taken. The management of such mines should not be classed with the careless or reckless management, as they frequently are by those not familiar with mining conditions. The reckless or careless mine official is not only a menace to his employes and his employer's property, but he is frequently the cause of much indirect trouble and annoyance to the careful and competent official.

The Hastings Mine Explosion

THE contention of Mr. Bert Lloyd that no fire boss should enter a gassy mine until his lamp had been inspected by a second person seems to have been verified in the Hastings, Colo., explosion. The glass in the fire boss' lamp was found so loose that an explosion inside the lamp could be communicated to the surrounding atmosphere. No man is infallible, and breaks in the gauze, dirt, oil spots, loose joints, etc., might escape one person's observation, but be discovered by a second man.

The Cause of a Mine Disaster

IN OUR July issue we criticized certain portions of the Oklahoma Mine Law. As stated there, the law is not wholly faulty, and if Section 3 of Article VII of that law had been strictly observed or enforced, the disastrous explosion at the San Bois mine on March 20, which caused the death of 73 men, would probably not have occurred.

This section reads as follows: "It shall be the duty of the mine foreman to see that the proper breakthroughs are made in all the room pillars at such distances as in the judgment of the mine inspector may be deemed necessary for proper ventilation, but not more than 30 feet apart where gas exists, and in no case more than 40 feet apart, and the ventilation shall be conducted through said breakthroughs into rooms by means of check doors made of canvas or other suitable material, placed on the entries, or in other proper places, and he shall not permit any room to be opened in advance of the ventilating current, or when the rooms already made are not connected. He shall also see that the air-current is conducted to the face of all the entries, airways, rooms, and other advance workings, so as to dilute and render harmless all noxious and poisonous gases. Should the mine inspector discover any room, entry, airway, or other working places being driven in advance of the air-current contrary to the requirements of this section, he shall order the workmen working such places to cease work at once, until the law is complied with."

We have received information that a squeeze which affected the workings off the entry in which the explosion originated so cracked the wooden stoppings that the ventilating current was, in a large measure, short-circuited, causing accumulations of gas in the rooms near the face of the entry. Besides, in some instances the cross-cuts were 75 feet apart, instead of 30 feet apart as the law stipulates. The same information states that the fire boss on occasions started cross-cuts at the required points, but his orders were countermanded by the foreman on account of the expense due to the high yardage rates prevailing in Oklahoma.

If the statements made us, are correct, and they appear to be well founded, radical reform is necessary in the Department of Mines of Oklahoma. We are informed on reliable authority that Inspector Haley of the district in which the mine is located, visited it frequently, in fact, oftener than the law required. If such conditions existed, as are stated above, it is evident that his inspections must have been of a very superficial nature. We are not prepared to say that such superficial inspections were wholly the fault of Mr. Haley. It is probable that they were due to necessary haste owing to the great territory embraced in his district. Even if the number of mines in his territory is limited, the time required to cover it with somewhat limited train service, naturally militates against the spending of the proper time in the mine, and the consequent important feature of a comprehensive knowledge of conditions existing in all parts of the workings.

Mine accidents due to violations of the mine laws, or of the rules of common sense, are a source of trouble to mine owners and mine managers who strictly observe the laws, and who use every endeavor to protect the lives of their employes. Therefore, mine officials who jeopardize the lives of their employes and the property of their employers by non-compliance with the law, are in a measure enemies of mine owners and mine managers who do obey the statutes.

Experience in Pennsylvania and other prominent coal-mining states has proved that careful inspections and rational enforcements of the mine laws have not been a burden on progressive mine owners and mine officials. In fact, in many instances the larger mining companies go farther than the law requires in their efforts to conserve the lives of their employes and the safety of their property. If the safety of the miners and the mines of Oklahoma is to be conserved, it is evident that the new state must revise its mine laws and provide more inspectors—men of proved technical knowledge, character, and good judgment—and it should require a strict compliance with both the letter and the spirit of the law.

Volume XXXIII

THIS issue of Mines and Minerals begins a new volume, No. 33. Commencing with Volume 32, the front cover was changed from an advertising medium to an artistic frontispiece, and this feature will be continued. Each frontispiece was chosen to show some phase of active mining that would be attractive to the numerous readers, and it is believed, from the extraordinary sales of particular issues, that not only the material inside, but the outside, has appealed to the mining fraternity as never before. It has been the policy of Mines and Minerals to avoid, wherever possible, publishing articles so long that they must be continued in the next issue. Beginning with this issue, a series of articles on "Practical Cyaniding," by Mr. John Randall, noted throughout the Western States as one of the foremost in this branch of metallurgy is commenced. Each article will completely cover one branch of the subject, and the entire series of articles teems with information deduced from Mr. Randall's practice in Colorado, Dakota, and elsewhwere. These articles will not be printed in book form and there is no other method of obtaining them except through a subscription to Mines and Minerals, as all rights are reserved.

The system adopted of separating the articles pertaining to coal from those pertaining to metal will be continued. In the variety of subjects treated there is sure to be something of value to every miner or metallurgist, and often a single suggestion may be worth many times the subscription price.

Next to knowing, is to know where to find what you want to know. The correspondents of Mines and Minerals are in nearly every mining field on the globe. From this vast territory authentic information is obtained on new systems of mining, new machinery for lessening the cost, and new metallurgical processes and improvements in old processes. This information is condensed and precisely worded, two features which appeal to professional men.

The Status of the Gas Producer

ROBERT H. FERNALD, in Technical Paper No. 9, United States Bureau of Mines, has recorded his investigations on producer-gas production relative to its commercial value in places where good coal is lacking or is expensive.

His tests in the gas producer have shown that many fuels of so low grade as to be practically valueless for steaming purposes, such as slack coal, bone coal, and lignite, may be economically converted into producer gas and may thus generate sufficient power to render them of high commercial value.

He estimates that on an average each coal tested in the producer-gas plant developed two and one-half times the power that it would develop in the ordinary steam-boiler plant.

He found that the low-grade lignite of North Dakota developed as much power when converted into producer gas as did the best West Virginia bituminous coals burned under the steam boiler.

It has been demonstrated that the low-grade coals, high in sulphur and ash, now left underground, can be used economically in the gas producer for the ultimate production of power, heat, and light, and should, therefore, be mined at the same time as the high-grade coal.

As a smoke preventer, the gas producer is one of the most efficient devices on the market, and furthermore, it reduces the fuel consumption, not 10 or 15 per cent. as claimed for the ordinary smoke preventing device offered for use in steam plants, but 50 to 60 per cent.

The establishment of producer-gas plants at the mines and the distribution of electric energy or gas over large areas will also tend to eliminate smoke. When a large percentage of the small, isolated, power and heating plants and all steam locomotives have been removed from the larger cities, the atmosphere of these cities will be much clearer, and heavy financial losses directly traceable to smoke will be eliminated.

July Gas Explosions

WHY gas explosions should be more numerous in the warm months than in the cold months is a mystery. Is it possible that humidity near the earth's surface causes a rarification of the upper atmosphere and so sufficient fall in barometer to permit gas to escape in abnormal quantities? In other words, does humidity have an influence which causes gas explosions, in opposition to its influence on dust explosions in coal mines? On July 15, 16, 17, and 18, dates which include the Avoca and South Wilkes-Barre gas explosions, the barometer stood at 29.07 inches without perceptible change; but on the morning of July 19 the humidity was dissipated and the mercury arose to 29.27 inches, which is about normal for those places.

During July an unusual number of gas explosions occurred in the anthracite fields of Pennsylvania and elsewhere. At about 6 A. M., July 9, a very serious explosion occurred in the Cadeby colliery, Conisboro, Yorkshire, England. The first explosion killed 31, including Douglas Chambers, the mine manager. Three other explosions are said to have followed during the day, killing a large number of rescuers, among whom were Chief Mine Inspector W. H. Pickering, and Government Mine Inspectors Hewitt and Tickle. Newspaper reports have given the total number of killed as 75, the majority of whom were rescuers.

On July 11, at 9 o'clock, there was a gas explosion at the Panama mine of the Ben Franklin Coal Co., at Moundsville, W. Va. This accident was caused by an open lamp carried by men into the mine after a shut-down of 3 days.

On July 16, six persons were reported killed and several injured at the Gayton coal mines, 15 miles from Richmond, Va. This was a gas explosion.

On the evening of July 17, there was an explosion of gas in No. 4 tunnel of No. 3 shaft at No. 5 colliery of the Lehigh & Wilkes-Barre Coal Co., South Wilkes-Barre, Pa. The explosion caused the death of three miners and injured four others. It is believed the explosion was caused by one of the miners firing a blast which ignited a pocket of gas.

On July 18, at 9:30 A. M., nine men were burned in the Langcliffe colliery of the Delaware & Hudson Co., at Avoca, Pa. This gas explosion was due to a naked light, and it is probable that three of the injured will die.

Personals

William H. Cook, former chief chemist for the El Paso Smelting Works, is now chemist for the Fresnillo Company, at Fresnillo, Zacatecas, Mexico.

M. A. Walker, M. E., has resigned from Coal Age Staff to take up construction engineering with Fairbanks, Morse & Company, Chicago.

G. A. Denny is the Mexican correspondent for the Institution of Mining and Metallurgy, London, England.

A. R. Kenner is general superintendent of the Rio Plata Mining Co., Guazaperas, Chi., Mexico.

Sim Reynolds, inside manager of the Marianna mine of the Pittsburgh-Buffalo Company, has accepted a position as Inspector for the W. J. Rainey Company, Uniontown, Pa.

Edward M. Robb, Jr., of the Pilares mine in Mexico, temporarily resigned his position as chief engineer of the Montezuma Copper Company in 1911. He was succeeded by Raymond Burnham, who has resigned and is now in Chicago.

Geo. Watkin Evans, mining engineer, of Seattle, is making a thorough examination of the Ground Hog Coal Field in Northern British Columbia.

D. C. Boag, graduate of the mining course of Pennsylvania State College, has been appointed assistant to the general manager of Solvay Collieries Company, Marytown, W. Va.

A. Van Zualenberg is superintendent of the Planta del Carmen Cyanide Works, at San Luis Potosi, Mexico. Mr. Van Zualenberg was at one time engaged in silver-lead smelting in San Luis Potosi and returned to the States.

The Western Electric Company has opened a branch house at Houston, Texas, with H. P. Hess, F. G. Caldwell, and M. A. Schon in charge.

The Governor of Kentucky has made the following appointments: State Geologist, J. B. Hoeing, Lexington, Ky.; Geological Advisory Board, Governor James B. McCreary, Hon. J. C. C. Mayo, Paintsville, Ky., Hon. R. H. Vansant, Ashland, Ky., Gen. Percy Haley, Frankfort, Ky., Hon. L. B. Herrington, Richmond, Ky.

William Poole has resigned his position as Director of the Queensland State School of Mines, Charters Towers, Queensland, to accept the position of Principal of the State School at Ballarat, Australia.

Morgan T. Townsend, formerly representative of Mines and Minerals in the western territory, but now with the Stearns-Roger Manufacturing Company, of Denver, was married on June 26 to Miss Iva M. Wright, at Breckenridge, Colo.

Ernest McCullough, C. E., of Chicago, will deliver a series of lectures on mining methods at the 6 weeks' summer school at Weir City, Kans.

H. H. Stoek, E. M., former editor of Mines and Minerals, now head of the school of mines in the University of Illinois, attended the meeting of the Society for the Advancement of Scientific Education. He has been visiting in Wilkes-Barre and Scranton with his wife and daughter, working hard to enjoy a vacation.

E. H. Coxe, E. M., of Birmingham, Ala., is inspecting the coal fields and working methods employed by the operators in West Virginia along the Norfolk & Western Railroad.

W. Ray Cox, of Colorado, has been appointed professor of mining and geology in the Pei Yang University, Tientsin, China.

D. J. Broman, chief mine inspector of Texas, is inspecting the methods of mining adopted at the coal mines near Birmingham, Alabama.

Franklin Guiterman, who has moved from Denver to New York to take charge of the technical investigations for the American Smelting and Refining Co., has resigned as trustee of the Colorado School of Mines.

Prof. J. L. Dobbins, of the Pei Yang University, China, has an interesting article on the "Coal Fields of China" in this issue of Mines and Minerals, and will shortly have another article on "Mining Enterprises in China."

A. W. Pollock has been elected vice-president and general manager of the Wyoming Coal Co., at Monarch, Wyo.

B. L. Cunningham is assistant geologist for the Southern Pacific Railroad, with headquarters in the Flood Building, San Francisco, Cal.

W. E. Tomlinson is foreman at the mines of the Utah Copper Company, Bingham, Utah.

W. G. Ramlow has recently been made superintendent of the Dolly Varden mine at Alma, Colo. This property was a famous silver producer years ago, but has been inactive for a long time.

John F. Myers is chemist and assayer for the Eagle M. & M. Company, at Belden, Colo.

P. A. Grady has resigned as mine inspector of the 12th district in West Virginia to superintend mines for the Davy-Pocahontas Coal Company at Roderfield. Mr. Grady has been engaged in coal mining since he was a boy. He acquired his education under adverse circumstances, but his determination and grit eventually landed him in the position of mine inspector. He is a graduate of the International Correspondence Schools, and being exceptionally earnest we predict his success in his new position.

Capt. W. A. May, General Manager of the Pennsylvania Coal Company, the New York, Susquehanna and Western Coal Co., and graduate of the class of 1876 of Lafayette College, was elected a trustee of his alma mater at commencement this June.

Cerrillos Anthracite Mine

This mine, formerly known as the Lucas mine, is located at the town of Madrid, Santa Fe County, N. Mex. The bed worked by the Albuquerque and Cerrillos Coal Co. is known as No. 6. This bed in one place shows badly altered semianthracite and even graphite. In another place to the south in the Cerrillos mine, there is excellent anthracite from 3½ to 3⅔ feet in thickness, and in still another place this same bed of coal is bituminous and is 5 feet 5 inches thick. The differences in the coal are chiefly due to the alterations resulting from the approach of eruptive trachyte. A slope was sunk at the No. 4 anthracite mine to a depth of 1,460 feet on an average dip of 15 degrees.

The system of mining as described by Joe E. Sheridan, United States Mine Inspector, in the mine report of New Mexico, for 1910, is as follows: The rooms are turned off the main slope alternately on either side, 50 feet apart. The room necks are driven 75 feet across manways and air-courses, parallel to the main slope, before the rooms are widened. The rooms are then made 25 feet wide and 400 feet long. Coal is shot off the solid; holes are tamped with slack and coal cuttings, and the miners fire their own shots. The fire boss inspects the mine before the men are allowed to enter, and no man on the day shift is allowed to enter this mine until 6:30 A. M., or until such time as the mine has been examined by the fire boss. At a depth of 1,460 feet, on the dip, entries have been driven about one-fourth of a mile in the virgin territory, developing a body of excellent anthracite with every indication of greater reserves beyond the present development.

The mine was operated 258 days in 1911. The total output was 32,612 tons, consisting of all sizes from slack to 7-inch lump. All of this coal was shipped to market, the average price being $3.30. The mine is equipped with a 60-horsepower hoist and exhaust fan, double, 7 feet diameter, which furnishes about 13,920 cubic feet of air per minute when making 105 revolutions. There is an escape way through the old workings to No. 3 opening, and while this is not an approved second opening it is permitted on account of the company intending to sink another slope farther to the south which will be connected with the present No. 4 slope by a cross-entry from the bottoms of the two slopes.

COAL MINING & PREPARATION

The Derringer Anthracite Stripping

Removal of Large Quantities of Coal from Pockets Near the Surface—Interesting Geological Conditions

Written for Mines and Minerals

THE Carboniferous formation in Northeastern Pennsylvania has been subjected to great pressure which folded and metamorphosed the strata, noticeably in the eastern and the western middle fields. In several places in the middle fields, the Mammoth bed was closely folded; and later, after the strata above were eroded, canoe-shaped basins of anthracite were left, some of which are of fairly good size.

To illustrate more fully the conditions that prevail a section of the Morea coal pocket is shown in Fig. 3. Morea is near the eastern end of the western middle anthracite field, while Derringer, the place to be described, is in the western part of the eastern middle field about 12 miles directly north of Morea and on another mountain range. These two mountains run diagonally, and merge near Hazleton. In no other section, so far as known, are these canoe-shaped coal pockets found, and being in different fields their sections naturally vary, which makes the coal beds between the Mammoth and the Buck Mountain difficult to correlate, particularly as in one place a bed will be thin and mixed with slate while in another place it will be excellent coal.

In the Morea section there is a cover of rock in the center of the pocket; in the Derringer, or Black Creek, district the coal is covered with soil, the erosion having been deeper than in the western middle field. The first large pocket found in the eastern middle field was at Hollywood, near Milnesville, about 10 miles directly east from Derringer; it is probable, therefore, that other pockets will be found between, and possibly each side of, these two. Derringer is 11 miles from Hazleton on the Nescopeck branch of the Pennsylvania Railroad. The coal and land, which is leased by the Lehigh Valley Coal Co., belongs to the Tench Coxe estate. For quite a number of years the Coxe and Derringer interests were in litigation over property in this vicinity; finally, however, the land was awarded to the Coxe estate.

Fig. 1. Anthracite Strippings at Derringer, Pa.

The first Derringer breaker, designed by Eckley B. Coxe, was burned in 1884; and the second one, shown in Fig. 4, constructed on the same plans, was completed in 1886. The life of wooden breakers is placed at 20 years, and this one having commenced to disintegrate, is being dismantled, although in its generation it was a model and contains features which are not altogether discarded in more modern structures. While not sure, the writer is under the impression that the exhaust fan to remove dust from inside the breaker was first installed at Derringer. The évasé chimney to the fan in the second breaker is seen near the top to the left. The fan, approximately 10 feet in diameter, is of the Guibal type.

Fig. 2. Section at Derringer

Since the Derringer breaker has been out of commission the coal from this operation is hauled on the surface to one of the company's nearby breakers for preparation, it being considered good business policy to concentrate the preparation. Until recently the coal mined at Derringer came from what engineers believe is a split of the Mammoth bed 5 feet thick; the Parlor bed, 3 feet thick, 43 feet below the Mammoth split; and the Wharton bed, 6 feet thick, separated from the Parlor bed by 1 foot of slate. Work has just commenced on the Wharton bed, while the Gamma coal, 3 feet thick, and the Buck Mountain bed, 12 feet thick, just above the Pottsville conglomerate, have not been touched. Within a comparatively short time the coal pocket, shown in section, Fig. 2, was discovered, and immediately diamond drill holes were put down to ascertain its length, width, and thickness. These holes disclosed the fact that it is a canoe-shaped basin about 1,200 feet long, with an average thickness in the center of 43 feet; a width at the top of 104 feet; and a dirt cover that will probably average 40 feet in thickness.

That portion of the coal pocket on the Lehigh Valley Coal Co.'s lease is about 700 feet long and the quantity approximates 125,000 tons. The method followed in stripping is shown in Fig. 1. The steam shovel first removes the dirt cover, which is loaded into dump cars and wasted. The coal is next attacked and loaded by steam shovel into dump cars that are hauled out of the open cut by locomotives. The grade is so heavy it requires two locomotives to pull five dump cars holding 2 cubic yards each out of the pit on the zigzag track shown. The surface water which drains into the pit, supplies the boilers of three locomotives, the steam shovel, and the pump boiler shown in the background. It is pumped to a tank on the hill where the surplus can flow to waste. Except in extremely wet weather the quantity of water which accumulates is not great.

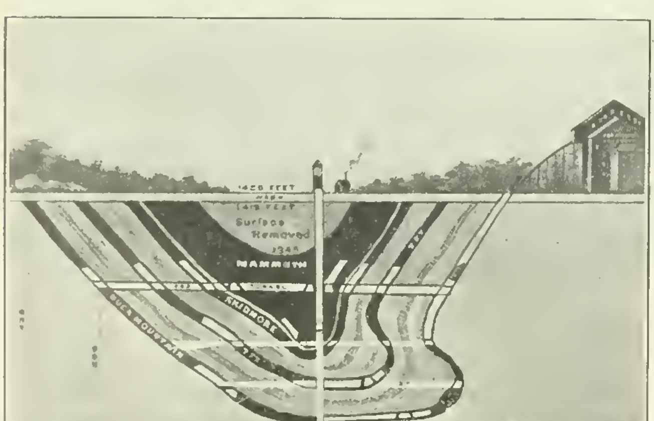

Fig. 3. Section at Morea Colliery

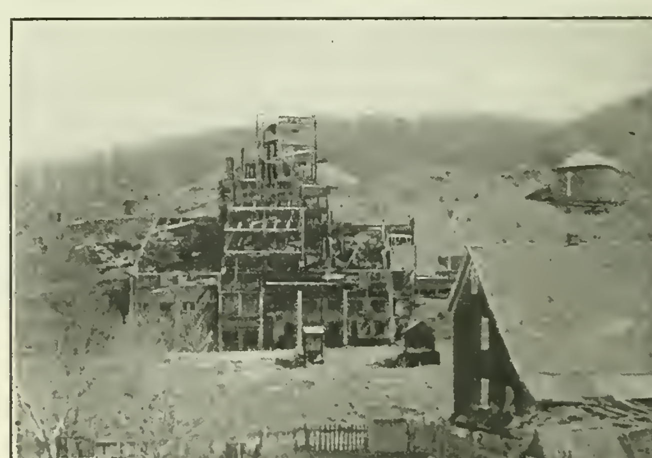

Fig. 4. Dismantled Breaker at Derringer

The Coal Mine Superintendent's Duty

Written for Mines and Minerals

The superintendent should visit all rooms in the mine and travel all the haulage roads and traveling roads and air-courses often enough to be thoroughly familiar with them. He should know the conditions in all working places, so that if, at any time, the pit boss, fire boss, or men working a place call his attention to anything regarding it, he can talk with a thorough knowledge of conditions at that point.

He should also see personally that all coal is being loaded out clean, that sufficient timber is kept convenient to the men, also that the men are using enough and in a proper manner to insure reasonable safety to themselves.

He should know that all rails, ties, and spikes are removed from places that are finished or abandoned. A few hours' work will take the track out of a room, if done as soon as the room is finished. If let go for any length of time, it may take a few days, and in some cases rails are so badly covered with falls from the roof as to make it unprofitable to try to recover them. This is carelessness and waste of property, and something a superintendent should never allow to happen. The superintendent should see that all haulage roads are kept clean. Where the roads are dry and dusty, they should be cleaned and watered, always remembering that it is much easier to water the place where the dust lay than it is to water the dust. In case of wet roads a ditch should be made to drain the water off, and no mud or dust should be allowed to accumulate on the rail. A clean rail and a well-oiled mine car will add greatly to the working capacity of a mule and help keep haulage costs to a minimum.

The superintendent should know that his fire bosses are steady, sober men, and that they get their regular rest. A fire boss who hangs around saloons until 9 or 10 o'clock at night is not a fit man to examine a mine in the morning. His intentions may be all right, but physically he is not in shape to get around, and the sooner the superintendent gets a fire boss who keeps entirely out of saloons to take his place, the better it will be for every one around the mine. He should know that the fire boss examines his own safety lamp before lighting it to go into the mine, and that he reports conditions in the book provided for that purpose immediately when he comes out, when the existing conditions are fresh in his mind. The superintendent should always look in this book before going into the mine, and if anything out of the ordinary is reported in any part of the mine, make it his business to visit that section, see if conditions were correctly reported and proper steps taken by the fire boss or pit boss to remedy the defects.

He should arrange for getting timbers and supplies into the mine without delaying the output. At most mines there is a time on each shift when 10 minutes' delay will affect the output more than 30 minutes will at some other time in the shift. The superintendent should arrange not to interfere with production by sending in timbers or other supplies at the "peak of the load." This work, if attended to regularly, can be done at a time of day when it will not delay the haulage system nor cripple the production.

The superintendent should know that all ropes used for hoisting or haulage are kept in good condition, that they are treated with the best rope compound or dressing that can be had to suit the conditions under which they are working. In case of rope haulage, there should be a close supervision kept on condition and position of sheaves and rollers. A few trips with a rope sawing on a rail over a knuckle, or on a defective sheave wheel round a curve, are harder on the rope than months of ordinary wear.

The superintendent should select the very best and most reliable men he has to take care of rollers and sheaves, and should keep a supply of the most staple kind of material on hand.

At most mines the gathering of coal and the first stage of the hauling is done by mules. Every superintendent will admit that if he gets what makes a good day's production started from the working places, he has a chance to get it out; but if the facilities for getting it started are not in good shape, no matter how efficient his organization is along the balance of the way to the tipple, he has no chance. In this case the production depends on the mules; and the condition of the mules depends in a large measure on the care they get in the stable and in the mine, by the stable boss, the driver boss, and the drivers. Every superintendent should know that his stable boss feeds his mules regularly in the morning, giving them sufficient time to eat before sending them out to work. A watchman's clock hanging in the stable with a key beside it is a great help in this direction. He should know that the stable boss uses some judgment in feeding and watering the mules, that each mule gets all it wants to eat, and no more. Oats left over in feed-boxes and a full ration dumped in on top of them are only wasted. He should know that the stable boss gives each mule a second chance to drink after its work at least 1 hour after going to the stable. A stable boss who takes care of 30 to 35 working mules and is ready to go home for the night 30 minutes after the mules go to the stable is a very poor man for the job. There is at least 2 hours' work for him cleaning collars and harness, cleaning mules, examining their feet, seeing that they are all eating, and giving them a second opportunity to drink.

The superintendent should know that his driver boss and drivers take good care of the mules in the mine, see that the collar and hames fit the mule, that side chains are of equal length and covered where they come in contact with the mule, and that under no circumstances is a sprag or a small mine prop used for whip.

The superintendent should visit the boiler room often and know that the boilers are washed as often as necessary. Also that after each boiler is washed the master mechanic or some competent person should inspect it by going inside with a hammer and trying all the braces, noticing if there is any scale on the shell or between the flues, also if there is any pitting, especially along the water line; also going into the firebox and combustion chamber and noticing the condition of the boiler there, also brickwork in these places. A record should be kept of the condition of each boiler, with the date of examination. After steam is up in the boiler, the safety valves should be made to work and steam gauge noticed to see if they are working together. The superintendent should see that all steam lines are put up so that they will drain, have traps provided where they are needed, all joints kept tight, and all steam pipes covered with a good pipe covering. By attending to this he will save a good many tons of coal in a month, besides having the satisfaction of knowing that his plant is in a safe condition and looking better.

The superintendent should have all supplies kept in a storeroom with some one person in charge of it. Where supplies are scattered, some in the blacksmith shop, some in the carpenter shop, and some in the engine room, with every one taking some article as it is needed, it is impossible to keep track of them. There should be one man in full charge of everything in the supply line whose duty it should be to keep a record of all supplies received, also supplies given out, what job they were got out for and who got them, this record being turned in to the office every night in the same manner as the time sheets, and the mine clerk should enter this list on his supply sheets daily. By doing this, when the end of the month comes everything will be accounted for and charged to the proper account, and when the annual inventory is taken the superintendent will not have to give a lot of explanations that do not explain in regard to a shortage of supplies on hand.

The superintendent should know that all scales are in good weighing order and that all coal is weighed and a correct record kept of the weight. Weigh bosses and tipple men sometimes are in a hurry and run mine cars over the scales without stopping to weigh them, depending on their ability to guess the weight. This, for various reasons, the superintendent should never permit. One reason is that it will be impossible to have his weights check at the end of the month. The paid miners' weight and the production of the mine will not tally. Another and more important reason is that the miners are not getting paid for what they actually produce. This will surely lead to trouble among the men, something the successful superintendent always tries to avoid.

The superintendent should impress upon every one whose duty it is to use oil or grease for lubrication, that it is on the bearing that oil must be put to get good results, not beside it. Oil spilled outside of bearings is money wasted. It is also a source of danger. In every building around a mine where oil and waste are used a metal can with cover should be provided for the dirty waste and this dirty waste removed regularly and burned.

The superintendent should remember that stoves are a great source of danger around mine buildings especially in a shaft house, near the mouth of the slope, or in the tipple. A few lengths of old pipe and a little spare time of the machinist can fix a radiator to take the place of the stove, and in most cases the exhaust steam can be utilized to heat it.

Smoking and matches should be positively prohibited in any building around the mouth of a coal mine.

The superintendent should know personally that all fire-protection apparatus provided is kept in A-1 condition. Fire hose, if provided, should be kept on a reel in a convenient place so that it is easy of access both day and night, and should be dried and replaced at once after being used, and should be used for no other purpose than fire protection. Fire extinguishers should be placed where they can be reached easily in case of fire, recharged regularly, and protected from freezing. Those persons around a mine whose duty it would be to fight fires should have a fire drill at least once a month so that they may be familiar with all of the fire apparatus and its position.

The superintendent should by his actions in the care of the company's interests set an example to every employe. He should keep out of saloons, and place no dependence on any man who frequents them, and above all things, he should under all conditions be loyal to the company he works for. When he cannot do that, he should quit.

Power Consumption of Coal Cutters

By G. W. Thomas

The consumption of power by coal cutters is an element of great importance when the adoption of machine mining is under consideration. Calculated consumption of power, based on the construction of the machine and assumed conditions under which the machine will work are seldom convincing to the practical mine manager. A test to determine the cutting capacity and power consumption of a Sullivan continuous cutter was conducted between December 13, 1911, and January 13, 1912, in Mine No. 2 of the Lumaghi Coal Co., at Collinsville, Ill., and the results are now available for publication. The test was made to determine the cutting capacity and power consumption of the machine, as shown by measurements, time observations, and readings from a recording wattmeter. The machine had a 30-horsepower shunt wound motor, was new, and in good order.

The No. 2 Lumaghi mine works the No. 6 seam, which is 8 feet high and practically level, although rolls or horsebacks occur in some localities. The coal varies in hardness in different parts of the mine, but is free from sulphur or other impurities. There is a good slate roof, so that close timbering is not required, and mining is done in the coal, as close as possible to the fireclay bottom. The mine was formerly worked on the double-entry plan, but the panel system is now in vogue.

Two areas were assigned for the test, in one of which the coal was rated as "hard," in the other as "soft," and a territory of 24 rooms in each was set aside. The work was done in these rooms and in cross-cuts between the rooms. The places ranged from 18 to 45 feet in width, and averaged 31 feet. The machine first cut in the "hard" territory, working 3 alternate days, single shift. The same procedure was followed in the "soft" territory, so that the test covered six shifts. Cutting in this way, over the territory described, enabled the loaders to keep enough rooms cleaned up so that a full day's cutting was ready for the machine every other day.

The readings and measurements were made by two observers, who checked each other's work and who made affidavit at the conclusion of the test as to the fairness of its conditions and the accuracy of the results contained in their reports.

The observations taken in each working place included the time, at the beginning and end of each part of the operation; the power consumed, shown on a recording wattmeter of standard make; the average voltage, shown by a voltmeter in the room; the width of the room or breakthrough, and the depth of the undercut. After each room was completed, the wattmeter was reset at zero.

No readings were taken while the machine was moving on its truck, as the test had to do only with actual mining; and, since the length of the moves varied, observations began in each room with the unloading of the machine from its truck, and ended when it was reloaded and ready to move to the next place. The following is a sample set of readings:

No. 2 East Stub Entry Off No. 9 South

Operation	Time	Watt-Hours
Unloading	2:00	0
Finished	2:06	150
Sumping	2:06	150
Finished	2:11	600
Cutting face	2:15	600
Finished	2:35	4,300
Loading	2:50	4,500

Measurements and Readings

Average voltage	225
Average depth cuts	73 inches
Width of room	24 feet
Watts per square foot	30.8

"Unloading" includes moving the machine into place against the right rib.

Table 1. Summary of Readings

Date	No. of Places	Face, Feet	Average Depth Inches	Square Feet	Actual Cutting Time	Total Watt-Hours	Weight Per Square Foot	Average Voltage
					Hours Min.			
Dec. 13, 1911	6	168′ 10″	70.0	984.3	6 17	43,475	44.1	191

Table of Totals and Averages

Days	Hours Cutting	Places Cut	Face Feet	Average Depth Inches	Total Square Feet Cut	Total Tons Mined	Total Watt-Hours	Average Voltage
6	36.45	32	1,000.75	71.7	5,976	1,770.66	263,950	191.1

Table of Rates

Face, Feet Per Hour	Face, Feet Per Day	Square Feet Per Hour	Square Feet Per Day	Tons Per Day	Watt-Hours	
					Per Square Foot	Per Ton
27.2	166.79	162.6	962.7	295.11	44	147.37

Table 1 is a summary of the six reports covering the daily performance of the machine.

The machine had 24 loaders assigned to it, and "kept up the cutting" for all these men.

To find the actual horsepower in air delivered by a ventilating fan: Multiply the number of cubic feet of air delivered per minute by the water gauge and divide the product by 6.345. If a fan is delivering 100.000 cubic feet against 2-inch water gauge, what is the actual horsepower output of the fan? Solution:

$$\frac{100{,}000 \times 2}{6{,}345} = 31.5 \text{ horsepower.}$$

The Hastings Coal Mine Disaster

A Description of the Mine and the Rescue Work—Effects of the Explosion—Probable Cause

Written for Mines and Minerals

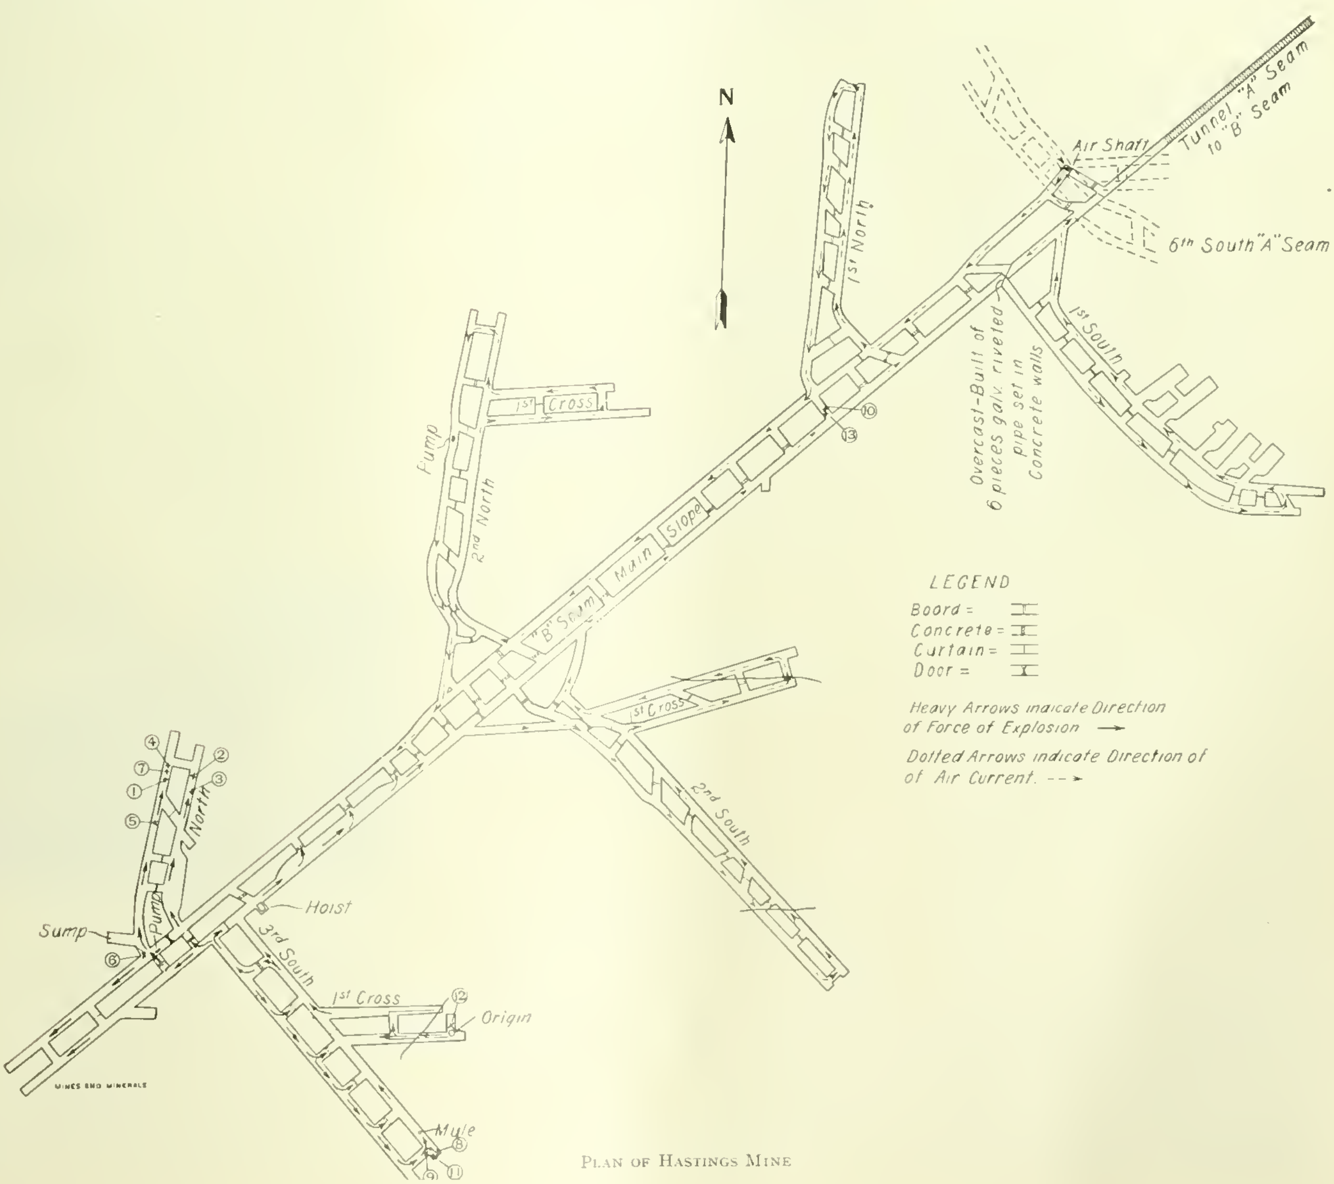
The Hastings coal mine of the Victor-American Fuel Co. is reached by the Colorado & Southeastern Railroad, and is $16\frac{1}{2}$ miles north of Trinidad Two coal beds are worked, known locally as the "A" and "B" seams. Until the year 1908, the entire daily output, approximating 1,500 tons, was mined from the upper, or "A" seam, which varies from 5 to 7 feet in thickness. In August of that year, a new slope on a $12\frac{1}{2}$-per-cent. grade was excavated through the measures to the "B" seam. On account of the large area developed in the upper workings and the fact that a portion of these workings were retreating, the coal was easily mined, and the work of development in the "B" seam was not pushed with great rapidity until the past 18 months. At the present time, the "B" operations are producing about $12\frac{1}{2}$ per cent. of the entire mine output.

Hastings mine, while not seriously troubled by water, like other operations in the Trinidad district going to the dip, is obliged to do considerable pumping. The mine is therefore comparatively wet, and sprinkling operations are not a serious burden. On account of the moisture, Hastings, from the dust standpoint, has always been one of the safest mines in the Trinidad district. The mine has always made a small amount of gas, but an ample quantity of air was always maintained by a 90″×90″ Sirocco fan, which can, at any time, be speeded up to furnish double its ordinary capacity.

The very latest and best types of safety and electric lamps are used throughout the mine, no open lights being permitted under any circumstances. All the lamps are filled, cleaned, and inspected by the regular lamp inspector before being carried into the mine. Permissible powder is used exclusively, and each miner is permitted to take but enough for his shift into the mine at one time. Shots are tamped with adobe and are discharged by the regular shot firers.

All places are inspected after the evening shots are fired, and again in the morning before the day shift goes to work. In addition, a regular inspector, whose duties are confined to this property alone, makes a careful examination daily, and at frequent and regular intervals the Chief Inspector makes his rounds.

In order to promote an interest in helmet and first-aid work, the company was preparing an elaborate contest to be given in



Plan of Hastings Mine

Walsenburg on June 22, in which rescue and first-aid teams from the several mines of the company were to compete for a silver cup. This has stimulated the rescue work to a very appreciable extent, and keen interest has been manifested in this line of work by all participating.

It so happened that on the night of June 18, the first-aid and rescue crews at

Main Slope, Hastings Mine

Hastings mine were having their practice in the emergency hospital, which is located near the pit mouth. It also happened that the regular monthly meeting of the superintendent, pit, and fire bosses was being held in the mine office about 600 feet away.

The accident happened about 9:30, while these two meetings were in progress, and it was first discovered by some of the first-aid crew, who noticed the odor of fire; and upon going to the door of the hospital, one of their number discovered smoke issuing from both the main haulage and manways of the mine. An alarm was immediately given, and the superintendent, James Cameron, accompanied by A. E. Thompson, Hastings mine inspector, and Harry Winters, lamp inspector, rushed into the mine and penetrated as far as the bottom of the air shaft in the "B" seam, Mr. Thompson, a little later, getting as far as the first south entry. In the meantime, D. H. Reese, captain of the helmet crew, had organized his men and was rushing helmets and rescue paraphernalia from the instruction car, which was standing in the yard, to the mouth of the mine. This crew, led by their captain, entered the mine shortly after 10 o'clock and worked unceasingly until 4 in the morning. The first men found, Nos. 10 and 13, were on the main slope. One of them, No. 13*, was alive and was immediately conveyed to the outside, where he was taken care of by the company surgeon. His partner, No. 10, was crushed by falling rock and timbers; both these men were slightly burned.

The helmet crew pushed forward into the lower workings of the mine, which were filled with smoke, and succeeded in exploring the main air-course, and the third north and south entries. Their examination at this time was for the purpose of rescuing any possibly living men, and to determine the presence of fire, if any existed. Seven bodies were found, but were not removed from the mine at this time.

In the meantime, the superintendent organized a force numbering 22 men, which immediately began putting up brattices with as great rapidity as possible, to replace the concrete stoppings, all of which were blown down. This was a work of considerable difficulty as, on account of the caved condition of the main slope, all material had to be conveyed into the "B" seam by way of the shaft at the outby end of the air-course, which was in very fair condition.

At 7 o'clock on Wednesday morning, Mr. Reese, with a crew of 20 men, most of them equipped with helmets, again entered the mine to more thoroughly explore the workings at the foot of the slope, and to continue the search for bodies, the first of which was taken to the temporary morgue that afternoon at 3 o'clock. While not the last body found, that of John Thomas, the fire boss, was the most difficult to remove, and it was consequently the last one taken out, at 3:50 on Thursday morning.

Cause and Effect of the Explosion.—Various theories have been formulated as to the exact cause of the accident. It was thought that a spark from the electric pump, located near the mouth of the back entry of the third north entry, might have ignited a volume of gas liberated by one of the shots fired after the day shift had retired from the mine.

A second theory was that, in some manner, possibly by a blown-out shot, a body of gas in the back entry of the third south entry was ignited, and this theory had a number of advocates, as the direction in which the stoppings separating the main and back entries were blown, the position of the bodies of the men, the mule and the car, would all seem to indicate that the explosive force had made its way through the last cross-cut, having originated somewhere in the back entry. Against this theory was the fact that no one was working in the face of the back entry, there being but two diggers in this portion of the mine and they were at work in the face of the main entry, and it appeared, upon further investigation, that they had loaded a car of coal and that the driver and the mule had come in to get it when the explosion occurred.

The fire boss, John Thomas, was working up in the face of the back entry of the first cross off the third south entry, putting up a brattice in order to improve the circulation of the air, as it was becoming somewhat sluggish, owing to the fact that the last cross-cut was not through and the face of the entry had advanced considerably beyond the one through which the air passed from the back into the main entry of the first cross.

When ventilation in this portion had been reestablished so that a more careful search could be made, it was found that a considerable quantity of rock piled along the rib in the back entry off the first cross, had been blown outward into the main entry.

When Mr. Thomas' safety lamp was examined, it was found that the asbestos gasket upon which the glass globe rests had, in some manner, become folded over, leaving a small air gap through which it is thought a volume of gas was ignited. As Mr. Thomas was one of the official inspectors or bosses, it is possible that his lamp was not given the inspection that was accorded to those of all diggers and company men, so that this condition of the gasket was due to his haste, or neglect, when making ready to go underground when he went on shift. His body was considerably burned, but was not badly broken, so that it would seem that the explosion had not gained any great violence until it was propagated in the main entry of the third south entry. The theory, with the imperfect lamp as the cause of the accident, is strengthened by the following facts: the bodies Nos. 8, 9, and 11 were hurled with terrific violence against the face of the entry and were not seriously burned. The mule was hurled outward, and was practically torn in two, though not seriously burned.

These facts, together with the location and condition of the remainder of the men, had considerable weight in deciding the direction of the lines of force, as shown in Fig. 1. No. 6, the pumper, was somewhat burned, but not badly enough to cause his death, and it appears that he, like Nos. 1, 2, 3, 4, 5, and 7, met his death by suffocation caused by afterdamp.

It was learned afterward that No. 13, of the two rock men working up the slope, had retired to the cross-cut for a drink of water and that he was standing there when

Emergency Hospital, Hastings Mine

the mine "let go." Had he been out in the entry with his partner, No. 10, the chances are that he, too, would have been killed.

A few cars were standing on the slope near the mouth of the back entry of the third south; these were apparently acted upon by equal and opposite forces, as they were turned completely around and badly shattered.

* This is the first man in a mine disaster rescued by a helmet corps in the United States.

A deposit of coke dust on the timbers was easily discernible, and its location helped to determine the direction of the travel of the explosive forces.

All the stoppings between the main slope and air-course were built of concrete, of approximately 20-inch thickness, and well backed up with rock; without exception these were blown out in the direction of the back entry. Two stoppings in the "A" seam were blown out; with this exception, no other damage was done there.

A trip of 18 cars was standing on the slope between the first and second north entries. This was well covered with fallen rock and debris, but was not derailed or otherwise disturbed. The haulage rope attached to this trip was so deeply imbedded in fallen timber and rock that it was impossible to withdraw it by means of the hoist after it was detached from the trip, and it was therefore cut in order that it might be operated for taking out the wreckage and bringing in material.

In the region where the explosion was of greatest violence, it is probable that half a dozen cars of rock would represent the amount which fell. From this point outby, very few timbers were left in the slope, and a considerable number of falls from the roofs blocked the entry.

In the rock tunnel, all timbers were blown down.

Rescue Work.—It is seldom that the work of exploration and rescue is carried on with greater promptness and efficiency than that following this disaster. The first-aid and helmet crews, with the assistance of extra men about the mine, worked untiringly, and the rapidity with which they covered the ground and brought out the bodies is highly commendable. Besides those already mentioned, among the many who risked their lives should be named: Assistant engineers J. E. Hanes, F. S. Dunlevy, Lewis Hufty, and L. M. Kuhns; superintendents and men about the mines, John Yates, N. Bivens, J. Wennberg, J. Walker, J. F. Randock, E. Hart, Archie Bell, Fred Cornish, J. Milton, W. H. Cunningham, W. Wilcox, J. Walker, Jr., J. E. Cameron, Robert McCune, Andy Young, Tom Barron, Pat Gallagher, Geo. Smith, J. P. Bares, Wm. Mates, Jas. Brown, Ed. Flynn, Gus Wennberg, Joe Gaymay, Joe Robinson, A. Washington, B. Butalino, Pete Aime, Tony Arbo, John Arbo, Ben Vigil, Joe Curo, and Frank Lottice.

The Government Rescue Car No. 2, in charge of Prof. J. C. Roberts, was in Colorado Springs when the accident was reported, and proceeded to the scene of the disaster on the first train. Professor Roberts rendered especially efficient service.

Mr. King, Deputy State Coal Mine Inspector for the Trinidad district, was upon the ground at 7 o'clock of the morning following the explosion, and he, with Chief Inspector Dalrymple and two other deputy coal mine inspectors who arrived on the evening train of the same day, gave their very best efforts to the work.

At best, an accident of this kind is a sad affair. There have been many fatalities in coal-mining operations over the country, and there is no question that all the leading operators have been improving their underground conditions, introducing new safety devices and appliances as fast as known or discovered; the operators of Hastings mine were no exception, and an honest, conscientious endeavor has been maintained to insure the safety of the miners, to the greatest possible extent. It is extremely unfortunate that, in spite of the many precautions taken, a serious accident of this kind can originate from so slight a cause.

Coal Dust and Coal Loading Machines

*Written for Mines and Minerals by C. H. Thompson, G. M.**

There has seldom, if ever, been a time in the history of the coal-mining business when the margin between the actual, honestly computed cost of a ton of coal and its actual, honestly computed selling price has been so narrow. Emphasis is laid upon these two factors because, in many cases, the computed cost per ton is not the true cost, but is nearly always less by a few cents.

There is a tendency to slight the factor of plant depreciation and it is difficult to arrive at a proper factor to cover the depreciation of the mine, caused by increased difficulties in haulage, drainage, and ventilation, all of which may rise jointly and inopportunely and demand a change of plans and an enlargement of plant. As a result, mining companies declare profits sometimes which are not real.

To minimize cost is the prime function of the mine manager. No matter what his conception of a safe and well-ordered mine may be, everything must defer to the cost sheet. Mine fatalities, sometimes attributed to lack of skill in mine management, are often the result of commercial conditions beyond the power of the mining companies to remedy. One of the largest factors of the coal cost sheet is loading. Manual loading will not stand a cut, considering the scarcity of labor and the present cost of living.

The introduction of a successful coal loader on the market will bring the best opportunity the coal operator has ever had to cheapen the cost of his coal by lowering this stubborn factor of loading. Assuming that a new device, such as an electrical shovel, with a guarantee of 150 tons or more per day, dependent on coal conditions, is produced and on the market, such a machine will present interesting features to the average coal operator. If such a shovel in a seam of coal 5 feet thick or thicker, with fair conditions as to top and bottom, with two operators, can do the work of, say, 18 average men in machine-cut coal, it will be a great boon. It is a well-known fact that the average mining machine, whether a motor, a drill, an undercut cutter, or a loader, rarely gets the chance to do maximum duty. If delays due to moving from place to place over a large territory could be eliminated, the daily performance of all of the above machines could be greatly increased.

The most natural plan in case of mechanical loading would be to apportion the territory to a loading machine so that it could be kept at work practically all the time. This would mean that the cutter, the motor, and the drill, all under the same supervision as the loader, could be likewise kept busy. Under such a plan, carefully worked out and adhered to, the cost of coal in the mine car ought to be considerably more than cut in two. The question of double shifting all these machines where the mine car equipment is sufficient is also an interesting phase of the project and lends an elasticity to it that can never be gotten on any manual basis. Such a shovel will not break the coal up as badly as hand loading, as it could be made to handle lumps that two men would not attempt to lift into a car, and there will not be the shatter to the small coal because it will be carried and not thrown into the car.

The advantages of a successful loading machine will not be confined to the loading of the coal merely, but will extend to nearly every department of the mine. The possibility of cutting and cleaning up a chamber more than once in a shift means that a much smaller development will yield a larger tonnage than with hand loading. The investment for rails and ties even is proportionately decreased. Fewer men in the mine, and these almost entirely skilled men, reduces the chances of serious accidents to a minimum. Ventilation will be simplified, the actual requirements of air being much less and the working places being more concentrated. Haulage is alike affected and the saving in this item should be material. If the cost of a machine does not exceed the cost of the houses requisite for the number of men eliminated, it is probable the depreciation will be less in the machine than in the houses. Social and sanitary conditions would be improved in camp life owing to a selective system of employing men made possible by the reign of mechanical operation of the mine in all branches.

The necessity for minimizing underground accidents can best be met by minimizing the number of men employed there; and if mechanical loading can accomplish this and in addition put a premium on skill, it will rapidly cause a new era in coal mining which will tend to greater efficiency and economy to the operator and greater safety and better living conditions to the employes.

The Muller By-Product Coke Oven

A Description of the Construction and Operation of an Improved Coke Oven Possessing a Number of Novel Features

*By Eugene B. Wilson**

Since the introduction of by-product coke ovens, it has been the aim of designers to improve on their method of firing, in order to insure a continuous, direct, and uniform heating of the retort. The object of this endeavor is to shorten the coking period; to avoid wear and tear on the retort walls; to increase the yield in by-products, including gas, which will be high in calorific value. If the by-product ovens now in use are examined critically, it will be seen that, whether the heating chambers or flues are constructed in two or more sections, only from one-half to one-quarter of the ovens are heated directly by fresh gas and air, the other parts receiving the waste heat which is about 300° C. lower in temperature than the direct heat.

In consequence of the direction of the heat current being reversed from time to time, as the regenerative stoves cool off, the oven walls are subject to fluctuating temperatures which cause them to crack and leak, and the quality of the coke to gradually deteriorate. With each reversal of the heating current one part of the coking charge has its heat lowered and the other part has its heat raised, with the result that the coke is brittle and seamed with cracks.

The gas and air inlets to the ovens are mostly constructed so that the flame jets are more or less inefficient, as the air passes through a large opening in a compact stream, generally vertical or slightly oblique to the entering current of gas, thus producing more or less large flame jets which, striking the walls, destroy or injure them, even when constructed of the best refractory materials.

One of the good features of by-product ovens is the increased yield of coke over the beehive ovens, which varies from 23 per cent. to 8 per cent. For example, the Connellsville coal should furnish 68.38 per cent. coke; in beehive ovens it yields 64 per cent., thus it takes 1.562 tons of coal to make 1 ton of coke. When the same coal is coked in retort ovens it yields 72 per cent. of coke, thus conserving 340 pounds of coal for each ton of coke made, when compared with the product from beehive ovens. Pocahontas coal cokes in beehive ovens at the expense of some of its fixed carbon, and only under exceptional circumstances yields 62 per cent. coke. In retort ovens it has yielded 85 per cent. of coke, thus saving 874 pounds of coal for every ton of coke made. In addition to this saving in coal, by-product ovens save gas, nevertheless the heat in the upper part of the oven above the charge is so great that the gases are partly dissociated, in which condition graphite results and part of the by-products are lost beyond recovery.

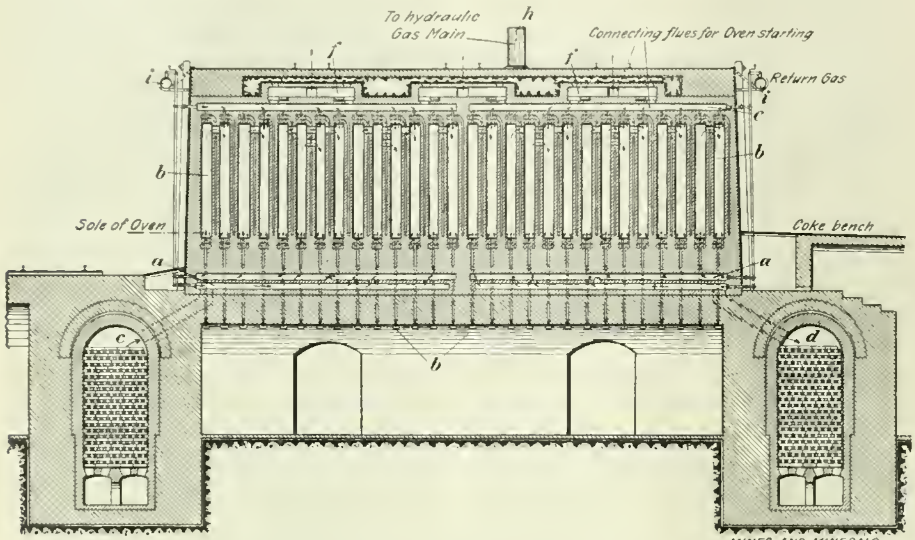

Fig. 1. Section Through the Heating Wall

This introduction is preliminary to a description of the Muller by-product oven, and is intended to draw attention to the particular features incorporated in its construction. The Muller oven has now been in successful operation for 7 months. By reference to Fig. 1, which is a section through the oven heating wall, it will be seen that the combustion or heating flues *a* are provided at their lower and upper ends with tuyères for supplying and mixing gas and hot air for combustion. The tuyères are constructed, as shown in Fig. 2, in a way that will convey the gas and air-current into the heating flues so that their movement will be parallel with and not baffle each other. In this way the flame jets are prevented from impinging at any particular place on the wall of the heating flues; also by this arrangement there is an intimate mingling of air and gas which insures a rotary movement from the tuyère nozzles into the combustion flues. In the illustration, Fig. 2, *a* is the air flue leading to the tuyères *b*, while *c* is the gas flue leading to the heating flues *d*. In the lower or sole flues, the air flue is used alternately to convey hot air to the heating flues and waste heat to the regenerators. Owing to the large openings, the tuyères admit of an adequate supply of air closely corresponding to requirements, that is, from four to five times the quantity of gas admitted. Because of the air entering the heating flues through the four nozzles, the air can be blown in by means of a fan, and thus insure a long flame suitable for the height of the oven walls. This feature has considerable bearing on the height of the oven.

For the purpose of conducting away the waste gases, every two or four heating flues are connected by small passages at their upper ends, as shown in Figs. 1 and 3. Ordinarily this is done by a horizontal flue extending along the upper part of the oven, above the flue walls, a feature which tends to weaken the oven wall. It is evidently better to conduct the waste gases within two combined heating flues than to carry them one-half the length of the oven

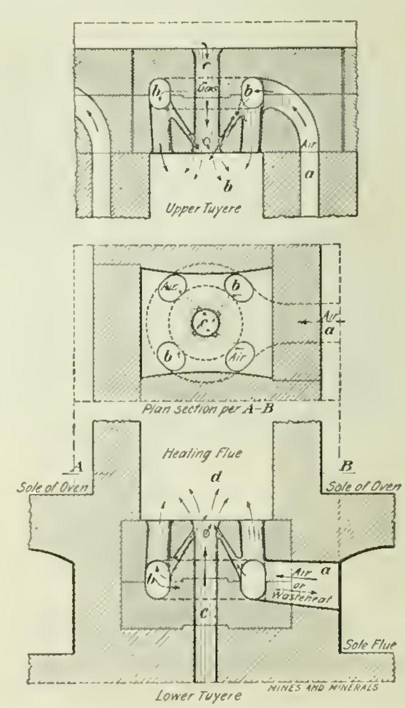

Fig. 2

*A paper presented at the Johnstown, Pa., 1912, meeting of the Coal Mining Institute of America.

through a long horizontal chamber to the 15 or 16 heating flues of the other half of the oven, as is done in some oven designs.

Underneath the combustion flues the gas supply channels *a*, Fig. 1, are arranged side by side and superposed. These are connected so that the gas supply from below is regulated from each three or four heating flues. Suitable connecting passages conduct the gas upwards through the gas nozzles of the tuyères into the heating flues. To avoid the connecting passages becoming clogged by obstructions of any kind, vertical openings *b* from the foundation arches are provided and these have removable plugs which enable all the vertical combustion flues *b* to be inspected from time to time.

The sole channels *a*, Fig. 3, alternately serve for supplying hot air for combustion from one generator *b* to the heating flues *c*, shown in dotted lines, and for conveying the waste gases from the combustion flues to the other regenerator *d*. The subdivision of this sole channel into four parts, as shown in the section of the ovens, Fig. 4, is for the purpose of regulating the incoming air and the withdrawal of the waste heat gases from the heating flues. This arrangement has been adopted to produce a uniform draft and pressure. From the sole channels, part of the hot air passes through small passages formed in the intermediate binder bricks of the walls and ascends to the upper tuyère nozzle, where it furnishes hot air from above to the downwardly flowing products of combustion. In the roof of the oven above the upper tuyères, one or two gas flues *e* are arranged, which are alternately connected with those flues having a downward draft for combustion. Separate passages and connecting flues *f*, leading from the charging holes into the upper gas supply passages and to the heating flues, are provided for use when the oven is being started, or in case the oven should be worked without recovery of the by-products as a waste-heat oven.

A further improvement is that the crude-gas collecting space *a* above the coking charge in the oven section, Fig. 4, is surrounded at the sides and top by special insulating material, which is extended down the heating flues toward the charge in order to keep the heat from the flues from radiating into this space. The gas collecting space thus cooled has a lower temperature than the charge; consequently, since the generated gases passing out of the coking charge its whole length find a cooler space, there is no possibility of the hydrocarbons in the gases decomposing.

the combustion and keep the temperature as high as that in the upward flues, which is easily attained with a small quantity of gas The waste heat or gases finally descend through the lower tuyères and passages to the sole channels, and then through one or other of the regenerators to the boiler or chimney stack.

After the reversal of a suitable three-way cock in the branches of the gas supply pipes and of the reversing valve of the two

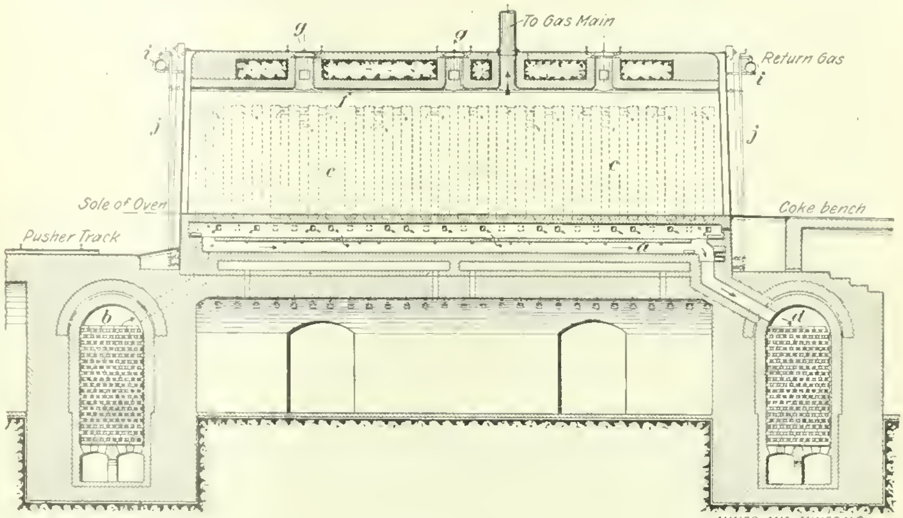

Fig. 3. Section Through the Oven Chamber

The operation of the coke oven is as follows: The retorts are charged with coal in the usual manner, either from the top through the charging hole *g*, Figs. 3 and 4, or through an end door if compressed coal is used. The gases generated are conducted from the collecting spaces above the charge, through vertical offtakes *h*, Fig. 4, and stand pipes, to the condensing or by-product plant. After the separation of tar, ammonia, and benzol, a small part of the gas to be used for heating the oven walls is conducted through pipes *i* along the sides of the battery of ovens. Small branch pipes *j* provided with valves or stop-cocks project into the upper as well as into the lower gas channels on each side of the oven walls.

Supposing now the regenerative system is employed. The gas passes from the lower channels through the tuyères alternately into half the number of tuyères in one wall, that is, into one side of one or two combined pairs of heating flues. Just below the sole of the oven hot air also enters from one regenerator, the sole channel, and lateral passages through the tuyères, and mixes with the issuing gas which, burning, flows upwards. The resulting products of combustion are now conducted through the upper passages into the next flues of one or two combined pairs. Since much of the heating power is lost on the way upwards, each of the flues having a downward combustion receives through the upper tuyères an auxiliary supply of fresh gas and hot air in order to enliven

regenerators alongside the battery, the supply of gas and air flows in the reverse direction, and likewise the flames in the combustion flues. If no regenerators are employed for heating the air, the direction of the flow of gas and air and that of the products of combustion in the supply pipes and channels always remains the same.

The method of heating the walls permits of efficiently utilizing the heating gases, and by means of the continuous upper supply of additional fresh gas and hot air to the waste gases, an extremely uniform heating of all parts of the wall is insured. The supply of gas and air to every set of three or four flues can be readily controlled and regulated at will by the pipes and stop-cocks and the dampers in the sole channels, so that a very uniform distribution of gas and air is attained. On account of the positions of the gas and air supply tuyères, an exceedingly high temperature is applied exclusively to the coking charge, consequently the oven can be run at a considerable saving of fuel.

In addition to the economy in fuel gas being realized on account of the high temperature obtainable at the sides of the coal charge, and on account of the cooled gas-collecting space, there is an increased yield of gas of a higher illuminating and calorific value, also the yield of ammonia and benzol is materially increased. Further, on account of the constant temperature over the whole retort wall, the coke produced is of superior quality to that of other ovens where only one-half of the

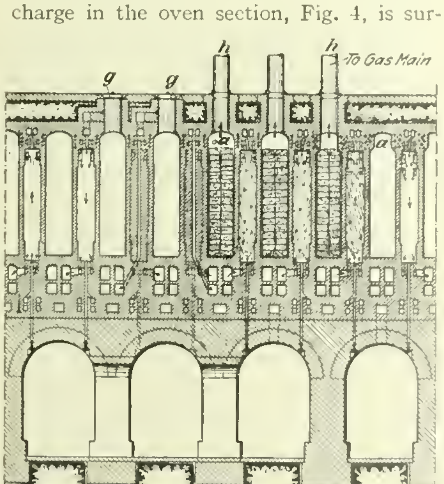

Fig. 4. Cross Section Through the Ovens

oven wall is directly heated alternately. On the other hand, the arrangement of the heating facilities and the tuyères in the combustion flues insures a short travel of the burning flames, which permits practically an unlimited height to the walls of the retort. As a combustion flame of 10 feet in length can easily be produced to suit any requirements, a capacity of 10 tons of coke and more per oven per day is obtainable.

Owing to the complete, uniform, speedy and economical coking process, the Muller coke ovens not only obtain increased by-products of distillation, but also a good sound coke can be obtained from an expanding coal, or a low-grade coal, usually regarded as non-coking. This is due to the good control and easy application of a high temperature to the charge.

The ovens are designed to work, either with regenerators, when it is desired to have surplus gas for illuminating or power purposes, or without regenerators, as waste-heat ovens, when the waste gases from the ovens are to be used for steam raising. The design and improved details of construction of the new oven are based upon careful observation and the result of more than 15 years practical experience in the construction and working of coking plants.

The claims made for the Muller ovens are as follows:

1. Easy control and regulation of the distribution of hot air and gas from outside the ovens, by means of regulating cocks at twelve different places.

2. Accessibility and inspection of each individual combustion flue, as well as of the whole oven.

3. No formation of flames which will destroy the oven walls, because of the construction and position of the tuyères.

4. The tuyères assure a very intimate mixing of gas and air. Therefore, the greatest amount of heat is obtained with a minimum amount of gas from the fact that very hot air is used to obtain combustion.

5. Absolutely uniform, continuous, and intensive heat, immediately and exclusively applied to that particular part of the oven wall beside the coking charge, where the heat is most needed for a short coking period.

7. Entire omission of longitudinal combustion, and gas-transfer channels in the walls.

8. Strongest construction of the whole oven, with special reference to unlimited height, strength, and durability of the retort walls.

9. Less cost for maintenance and labor.

10. Unsurpassed production of coke of uniform sound quality and minimum amount of breeze.

11. Production of gas of increased illuminating and calorific value.

12. Increased yield of ammonia and benzol.

13. Increase in surplus gas according to the coal used, from 45 to 60 per cent. of the total gas generated.

14. Prevention of the formation of naphthaline and graphite.

15. Use of expanding coals and of low-grade coals.

A description of the by-product plant for the recovery of sulphate of ammonia and tar from the gases belongs more to the province of the chemist than to the coke maker. The chief aim of Mr. Muller's by-product plant is the recovery of tar and ammonia from the gases in a direct manner. In order to do this it is essential first to separate the tar from the hot gases, so that during the following passage of the gases through the acid bath in the saturater the ammonical salts may not be diluted by tarry substances and rendered unsalable. To attain this end, the hot gases which come direct from the coke ovens are introduced into the tar washeries, which work on the principle of condensation by shock; that is, the gas is repeatedly split up into innumerable fine streams and caused to dash against the plane surfaces of special grids, which at the same time are constantly sprayed from above by hot gas water.

The gases in addition to being separated in the fine streams are purified by the repeated dash in a most perfect manner. When the last traces of tar have been removed the gas leaves the washer in a pure and dry hot state. The products of condensation obtained in the tar washer, namely, tar and gas water, run automatically through a siphon pipe into a settling tank where separation according to specific gravity takes place. The tar is then pumped into a high level tank and is ready for sale, and the recovered hot gas water is pumped upon the tar washer to be reused as a washing liquid. The hot gas still charged with all the ammonia constituents is now passed from the tar washer directly into the sulphuric-acid bath of the saturater in which the ammonia is recovered in the form of sulphate.

In the Muller patents, in addition to the higher percentage of ammonia recovered in the oven gas, namely, 20 per cent., an additional 6 per cent. yield of ammonia is obtained in the saturater. The sulphate of ammonia, crystallizing in the saturater by the reaction of ammonia upon sulphuric acid, is raked on to a draining table and then into a centrifugal drying machine, which leaves the salt in a salable condition. All the mother liquor which flows from the draining table and from the centrifugal drier runs into a liquor cask which automatically returns the liquor to the saturater for future treatment. The gases which are thoroughly purified for ammonia are now drawn from the saturater through a pair of common water coolers (in order to be cooled down for the benzol absorption) by means of the exhauster, which forces the gas through three benzol washers and finally into the gas holder, in which it is to be stored to be used partly for heating the ovens and the surplus for illuminating or motor power purposes.

The new method of recovering ammonia in a direct manner without the aid of steam or lime, and the construction of the new apparatus, enables the by-product recovery plant and its operation to be considerably simplified, and the recovery of the by-products is effected in an economical way. Further, the employment of the usual apparatus for scrubbing and distilling the ammonia, with its inevitable poisonous effluent liquor and mud nuisance, is entirely dispensed with.

The writer is indebted to Mr. Muller for the illustrations and the new information on by-product coke ovens incorporated in this paper.

Mining Institutes' Summer Meetings

Programs and Proceedings of Various Institute Meetings and Lists of Those in Attendance

The seventeenth annual meeting of the Lake Superior Mining Institute will be held in the Copper Country, with headquarters at Houghton, Mich., on August 28, 29, and 30, 1912. Arrangements are now under way and an interesting meeting is assured. Members are invited to prepare papers for this meeting, and forward them to the secretary as soon as possible, so that copies can be printed and mailed in advance. This will give an opportunity for more thorough discussion. The subject of "Mining Methods" on the various ranges, presented at the last meeting, should be further taken up, so that in time all the ranges in the Lake Superior district will be covered.

Attention has been called to the subject of "Uniform Mining Laws," "Workmen's Compensation Law," and "Safety Appliances," which should be taken up in special papers. Communications should be addressed to A. J. Yungbluth, secretary, Ishpeming, Mich.

WEST VIRGINIA COAL MINING INSTITUTE

The ninth semiannual meeting of the West Virginia Coal Mining Institute was held at Charleston June 6, 7, 8. The meeting was largely attended and considerable interest was taken in the proceedings. The following program was arranged and carried through without a hitch: Address of welcome, Governor William E. Glasscock; President's address, Frank Haas; 5-minute talks by the vice-presidents; "The Use of Gasoline Motors in Coal Mines," A. J. King, Mining Engineer, Charleston, W. Va.

"Quality and Quantity of Mine Air," Karl F. Schoew, Mine Inspector, Fairmont, W. Va.; "Points of Interest in Mine Ventilation," J. T. Beard, Associate Editor *Coal Age*, New York, N. Y.; "Successful Store Management in Relation to Mining Communities," Charles H. Lantz, General Manager, Buxton & Landstreet Co., Thomas, W. Va.

"The Projection and Development of a Mining School," E. N. Zern, Professor Mining Engineering, West Virginia University, Morgantown, W. Va.; "Mine Accidents and Their Prevention" (stereopticon), Ira D. Shaw, International Secretary Y. M. C. A., Pittsburg, Pa.

"Coal Mine Accidents," David Victor, Chief Mine Inspector, The Consolidated Coal Co., Fairmont, W. Va.; "Safety in Coal Mines, Especially in West Virginia," F. C. Cornet, Mining Engineer, Charleston, W. Va.; "Some Experiences in the Drainage of Mines," C. E. Tucker, Superintendent, The Consolidated Coal Co., Frostburg, Md.

Trip to the Blue Creek oil field, which is 15 miles from Charleston, on the Coal & Coke Railway. Just after leaving, an excellent new oil well commenced to flow at the rate of 200 barrels per day.

Banquet at Hotel Ruffner; toastmaster, Ex-Governor William A. McCorkle. Speakers, Hon. George E. Price, Railways and Coal; Hon. Malcolm Jackson, Laws; Hon. Henry G. Davis, Pioneer Days; Dr. J. A. Holmes, Scientific Research; Dr. I. C. White, Geology; Hon. L. E. Tierney, Practical Mining; J. C. McKinley; Hon. Z. T. Vinson; Frank Haas, Institute Work; Hon. George S. Laidley, Education; Dr. J. E. Robins, Village Sanitation; William Seymour Edwards, Oil and Gas.

Automobile ride over city of Charleston, returning to State House at 11 o'clock; A paper on "Lubrication," by L. A. Christian, Consulting Engineer, Keystone Lubricating Co., Pittsburg, Pa.

Among those in attendance were:

Wheeling: T. E. Plummer, J. C. McKinley, R. F. Hamilton.

Charleston: W. C. Alexander, W. L. C. Alston, W. H. Daffren, G. P. Crummett, T. E. Embleton, James Martin, A. J. King, F. C. Cornet, Theodore Swann, E. B. Taggart, J. T. Parks, Nason P. Pritchard, D. Q. Prenlet, G. A. Wiley, F. T. Scott, W. A. Reese, W. C. Shoemaker, J. S. Weakland, W. E. Knight, D. E. Frierson, J. N. Dewall, John M. Laing, Neil Robinson, D. C. Kennedy, J. S. Cunningham, John Dickson, C. H. Kent, J. R. Guard, James Kay, C. E. Krebs, J. E. Farquahr, P. E. Demmler, E. B. Snider, D. D. Teets, Jr., A. W. Pruitt, A. P. Rand.

Fairmont: J. C. Gaskill, Everett Drennan, K. F. Schoew, C. H. Tarleton, R. E. Rightmire, David Victor.

Huntington: J. W. Latimer, T. F. Bailey, James Clark, H. M. Ensign, J. S. Walker, Jr., D. C. Schonthal, G. W. Stevens, Jr., W. N. Oliver, Jr., J. W. Heron, H. M. Shaul, D. R. Phillipi.

Pittsburg: W. E. Fohl, J. R. Mason, E. B. Day, J. P. McIntosh, P. W. Bristol, J. R. Cameron, H. E. Marks, L. A. Christian, W. J. Johnson, Howard Curry, E. N. Zern, Winthrop Slocum, E. P. Roberts.

J. S. Healy, Elkins; L. E. Ermentrout, Borderland; J. C. Grymes, Wake Forest; F. W. Berryman, Tunnelton; D. S. Donley, W. S. Duvey, Page; C. M. Fenton, Marting; J. H. Claggett, Boomer; J. E. Cawley, Black Betsy; D. K. Graham, Eccles; R. T. Munn, Hinton; J. J. Lincoln, Elkhorn; J. R. Little, Maybeury; C. R. Jones, Morgantown; T. H. Claggett, Bluefield; C. I. Biddison, Pando; L. B. Holliday, Beckley; Daniel Howard, Clarksburg; Adam Lindley, W. Jones, Gulf; J. H. Laing, Berlin; Joseph Heylman,

Some of Those Present at the Meeting of the Kentucky Mining Institute

Coulton; Lawson Blankinsop, Bower; Dr. T. H. Elliott, Gauley Bridge; J. N. Sweitzer, Red Star; W. R. Thurmond, Oak Hill; E. P. McOliver, Mason; James H. Boyd, Newlyn; J. W. Herron, Hutchinson; P. A. Grady, Williamson; Charles Johnson, Big Chimney; William Nicholson, Bluefield; E. A. Henry, Clifton; J. H. Jackson, Montgomery; D. Evendoll, Sharon; J. W. Bischoff, Coulton; Thomas Davis, Bower; Bonner Heir, Chelyan; Josiah Keeley, Thomaston; A. C. Poole, Mt. Hope; J. H. Pierce, Mucklow; Albert Renard, Alderson; J. A. Milton, Coalburg; James Ranshard, Welch; R. S. Ord, Maybeury; Joseph Virgin, Plymouth; George Spreading, Ward; J. Page, Decota; Carl Robinson, Slump; F. L. Schoew, Chatteroy; E. E. White, Glen White; J. W. Straughn, Pratt; P. J. Stanton, Harding; Thomas Petkoski, Eccles; T. G. Wood, Sullivan; W. H. Stewart, Winnefrede; L. D. Rhoades, Fayette; L. B. Stevens, Clarksburg; Gilbert Smith, Consho; W. M. Reynolds, Fayetteville; L. D. Vaughn, Grafton; Dr. I. C. White, Morgantown; C. R. Senstreck, Black Betsey; J. S. Boyd, Newlyn; J. A. Within, Coalburg; E. H. Shonk, Miami; O. E. Tucker, R. A. Walter, J. D. Snyder, Frostburg, Md.; F. L. Garrison, Cincinnati, Ohio; J. E. Beebe, *The Black Diamond*, Chicago, Ill.; E. B. Wilson, Mines and Minerals, Scranton, Pa.; David Newton, Connellsville, Pa.; C. A. Booker, Dante, Va.; W. Jones, New York, N. Y.; William Clifford, Jeannette, Pa.; F. Darlington, Great Barrington, Mass.; P. G. Gossler, New York, N. Y.; W. G. Conley, Scranton, Pa.; J. T. Beard, *The Coal Age*, New York; Herbert Davis, Baltimore, Md.; J. T. Overstreet, Roanoke, Va.; A. D. Shonts, Plymouth, Pa.; I. D. Shaw, Ben Avon, Pa.; W. W. Hall, Ashland, Ky.

KENTUCKY MINING INSTITUTE

The Kentucky Mining Institute held its first annual meeting June 10 and 11, at Lexington, in the College of Mines and Metallurgy, State University. Henry S. Barker, president of the college, delivered the address of welcome. The response was made by J. E. Butler, superintendent of the Stearns Coal and Lumber Co. Both addresses were on subjects pertaining to mining, and Judge Barker expounded some of his ideas on Kentucky mining affairs and their expansion in an impressive manner. In the business session, F. D. Rash, manager of St. Bernard Mining Co., Earlington, Ky., was elected president. W. H. Cunningham, Ashland, Ky., vice-president First District; Dr. S. R. Collier, West Liberty, vice-president Second District; J. E. Butler, Stearns, vice-president Third District; B. R. Hutchcraft, Lexington, Ky., vice-president Fourth District; W. C. Taylor, Greenville, Ky., vice-president Fifth District; L. R. Long, Hopkinsville, Ky., vice-president Sixth District; C. S. Nunn, Marion, Ky., vice-president Seventh District. T. J. Barr was reelected secretary, and M. L. Conley, treasurer. Papers were read on "Abridged History of Coal Dust Explosions," by E. B. Wilson; on "Coal Cutting," by E. L. Thomas, Southern Manager of the Sullivan Machinery Co.; on "Mine Haulage," by C. A. Bray, of the General Electric Co.; a paper on the "Hydraulic Cartridge *vs.* Powder," by R. G. Stevens was presented, but unfortunately was read only by title, Mr. Stevens being kept from attendance; demonstration and lecture on "Mine Fire-Fighting Apparatus," by James L. Bowie, Jr.; illustrated lecture by E. B. Sutton, Bureau of Mines, Knoxville. Mr. Sutton brought the United States Mine Rescue Car for demonstrating and inspection purposes. The meeting was carried on with vigor and snap, no time being wasted during the 2 days' session. The following 51 of a total membership of about 100 were at the meeting, which speaks well for its future: R. B. Hutchcraft, vice-president, Lexington, Ky.; Prof. C. J. Norwood, Lexington, Ky.; Henry S. Barker, president State University, Lexington, Ky.; Hywel Davies, Louisville, Ky.; E. B. Wilson, editor of Mines and Minerals, Scranton, Pa.; J. E. Butler, general manager Stearns Coal Co., Stearns, Ky.; F. Julius Fohs, mining geologist, Lexington, Ky.; E. B. Day, vice-president Coal and Coke Operator, Pittsburg, Pa.; H. H. Ashmore, Keystone Lubricating Co., Knoxville, Tenn.; J. H. Danahay, special agent Henry Clay Fire Insurance Co., Lexington, Ky.; H. LaViers, manager North East Coal Co., Paintsville, Ky.; J. C. Knuckles, president and general manager, Ferndale Coal Co., Ferndale, Ky.; Hugh M. Stokes, superintendent Continental Coal Corporation, Straight Creek, Ky.; T. J. Barr, assistant inspector of mines, Lexington; R. A. Casebier, assistant foreman, Lam Coal Co., Bevier, Ky.; W. T. Underwood, president Mt. Morgan Coal Co., Williamsburg, Ky.; H. D. Jones, assistant inspector of mines, Central City, Ky.; R. R. Atkins, mining engineer, Kentucky Block Cannel Coal Co., Cannel City, Ky.; R. D. Clerc, mine foreman for Cleare Coal Co., Coalton, Ky.; Henry Neal, distributor L. H. Ramsey & Co., Lexington; White L. Carns, motorman, Ely, Ky.; R. J. Carns, foreman, Rim, Ky.; Frank D. Rash, vice-president St. Bernard Mining Co., Earlington, Ky.; John P. Barton, mine foreman for Campbell Coal Co., Coalmont, Ky.; Perry V. Cole, assistant inspector of mines, Barbourville, Ky.; C. R. Conner, of Cunningham & Conner, consulting engineers, Ashland, Ky., and Huntington, W. Va.; Wm. L. Caming, engineer, Jackson, Ky.; A. E. Morgan, superintendent Majestic Collieries Co., Majestic, Ky.; Thos. O. Long, assistant inspector of mines, Earlington, Ky.; W. L. Moss, vice-president and general manager Continental Coal Corporation, Pineville, Ky.; R. D. Quickel, fuel agent, Q. & C. Route, Lexington; W. W. Hall, president Chatfield Coal Co., vice-president Cedar Point Coal Co., Ashland, Ky.; M. D. Daniel, assistant inspector of mines, Ashland, Ky.; V. B. Abbott, chief engineer Consolidation Coal Co., Elkhorn Division, Jenkins, Ky.; W. L. Stollsworth, superintendent, Cany, Ky.; J. W. Cockill, general manager Big Branch Coal Co., Lookout, Ky.; Hiram Silvers, superintendent, Rim, Ky.; E. Dissinger, Professor State University, Lexington; John F. Pfoff, mine foreman, Mt. Morgan Coal Co., Williamsburg, Ky.; E. M. Howard, physician and surgeon, Continental Coal Corporation, Rim, Ky.; G. C. Rogers, student, Lexington; J. S. McHargue, Lexington; Henry K. Leighow, general manager KK. Fire Brick Co., Haldeman, Ky.; G. B. Rachley, Davisburg, Ky.; George Barton, Grays, Ky.; Robert Birch, Wilton, Ky.; C. M. Danir, mine foreman, Mahan Jellico Coal Co., Packard, Ky.; Forest Bice, Clay, Ky.; T. S. Mabrey, Bevier, Ky.; C. A. Bray, electrical engineer, Cincinnati, Ohio; E. L. Thomas, manager Sullivan Machinery Co., Knoxville, Tenn.

THE COAL MINING INSTITUTE OF AMERICA

The Coal Mining Institute of America held its fifty-sixth semiannual meeting at Johnstown, Pa., June 25 and 26. C. S. Price, President of the Cambria Steel Co., being indisposed, the dean of Pennsylvania mining engineers, John Fulton, gave an address of welcome. Jesse K. Johnston, vice-president of the Institute, responded with a few well-chosen words, which voiced the sentiments of the members. The business session then opened with an informal discussion on the "Weak Links in the Operating Chain of Coal Mines." In the afternoon, State Mine Inspectors Nicholas Evans and T. W. Evans presided over the question box. In the evening there was a banquet with H. S. Endsley, Esq., toastmaster; Mr. John Fulton, Mr. C. C. Geer, and Mr. Frank Gray, speakers. Mr. Fulton gave a reminiscence of the early days of mining at Broad Top and Johnstown, and brought matters up to the present day. Mr. Geer, being a lawyer, amused the diners with a Biblical, encyclopedic, and newspaper account of mining. Mr. Gray encouraged coal mining generally, also first-aid work. He is in the powder business. Mr. Endsley, as toastmaster, mixed levity and seriousness in a manner which delighted his audience. Mr. Geer tried to persuade Mr. W. R. Calverly to sing one of Harry Lauder's songs, but he balked. Wednesday morning was devoted to first-aid demonstrations.

Wednesday noon the members were lunched by the Cambria Steel Co., after which they were taken on a special train through the steel works. It is stated tbat there are over 100 miles of tracks in connection with these works, and while the Cambria Steel Co. does not receive the publicity of some other steel works, it is an exceedingly large plant. On boarding the special observation cars the visitors were taken through the Gautier works to the by-product coke ovens, where they went through the Franklin coal tipple, coal-washing plant, by-product coke oven plant, and then through the No. 7 and No. 8 blast furnace engine house. Here they boarded the train and were taken to the plate mill. On departing they were taken to the Franklin power house, then to the Franklin open-hearth department, and to the car shops where steel cars were in the process of construction; then to the forge shops, beam yard, and structural machine shops, apast the Gautier works to the Cambria plant. From there the train took them to the blooming, billet, and beam mills, then to the Bessemer steel works, No. 1 mill, 18-inch mill, and shops to the east end of the wire mill. Here they left the train and passed through the wire and rod mill drawing room, wire fence room, nail mills, to the western end of the wire plant where they entrained. From here the visitors were taken to Hinckston Run and returned by way of ore yards on No. 1 to 4 and 5 to 6 blast furnace trestles, thence to the hotel.

The entire trip took nearly 5 hours and was enjoyed by every one. The members are indebted for this enjoyable outing to Mr. C. S. Price, president of the steel company, and to Mr. M. G. Moore, who so kindly conducted them through the various departments.

MINE INSPECTORS' INSTITUTE

The fourth annual meeting of the Mine Inspectors' Institute of the United States was held in the Great Southern Hotel, Columbus, Ohio, June 17, 18, 19, 20, and 21. The sessions commenced Tuesday morning. The day was given up to organization and addresses. John Laing, President of the Institute, presided. After receiving a hearty welcome from Governor Harmon, Mayor Karb, and J. E. Todd, president, Wednesday a business session was held and papers read by Karl F. Schoew, on "Quality and Quantity of Mine Air"; by J. J. Rutledge, on "A Suggestion in Regard to Coal Mine Inspection." On Thursday Chas. H. Nesbit presented a paper on "Need of Better Discipline and Cooperation in Mining." Frank I. Pearce presented a paper on the "Coal Mining Industry in Indiana." A visit was made in the afternoon to the Jeffrey Mfg. Co.'s works, where a large delegation of Jeffrey employes welcomed the visitors and conducted them through the plant. One of the interesting sights was the construction of fans, one 36-inch fan being able to furnish 45,000 cubic feet of air per minute; another 8-foot, double-inlet, blowing fan was set in motion and furnished so great a blast none of the visitors were able to remain in front of it. Another sight was the construction of an 18-foot fan and housing. This fan has a capacity of 450,000 cubic feet under normal conditions. The members were taken through the shops, where they saw the assembling of electric coal cutters, drills, locomotives, and other mining machines. They next visited the molding shops where power molding machines are in use. It will be remembered that the introduction of these machines caused a long strike, molders being opposed to them as a usurpation of their work. Several other departments were visited where chains were being tested, the forge shop, machine shop, chain and conveyer shops, etc. The visitors could not help admiring the attractive little storage-battery locomotives which were hauling material about the works here and there. The experimental works, where working models are tested and apparatus perfected before placing on the market, and also the locomotive test machine, were shown and explained.

A banquet was held at the Great Southern Hotel for members and guests on Thursday evening and over 100 attended.

The accompanying photograph of the inspectors and guests was taken at the works of the Jeffrey Mfg. Co. The names of those shown in the photograph are as follows: First row—sitting on ground—left to right—Thomas Moses, Superintendent of Mines, Westville, Ill.; John Laing, Chief Department of Mines, Mrs. John Laing, Charleston, W. Va.; J. T. Beard, Associate Editor *Coal Age*, New York.

Second row—Miss Devore and Miss Jenkins, Bellaire, Ohio; Alexander Smith, Mine Inspector, Mrs. Alexander Smith, New Philadelphia, Ohio; Frank Parsons, District Mine Inspector, Mrs. Frank Parsons, Clarksburg, W. Va.; Miss Devore, Bellaire, Ohio; Miss Smith, New Philadelphia, Ohio; W. H. Miller, Mine Inspector, Mrs. W. H. Miller, Massilon, Ohio; Mrs. Thos. Moses, Westville, Ill.; Mrs. Jas. Martin, Charleston, W. Va.; Mr. Jas. Martin, Charleston, W. Va.; Mr. E. A. Henry, District Mine Inspector, Mrs. E. A. Henry, Clifton, W. Va.; Mrs. Isaac Hill, Zanesville, Ohio.

Third row—Robert S. Wheatley, Mine Inspector, Salineville, Ohio; Edw. Flynn, Pratt City, Ala., Inspector for T. C. I. & R. R. Co.; Thos. Graham, Department of Mines, Vistoria, B. C.; Thos. Hudson, State Inspector of Mines, Galva, Ill.; Edw. Kennedy, Mine Inspector, Carbon Hill, Ohio; John D. McDonald, Glouster, Ohio, Mine Inspector; Thos. S. Lowther, Bituminous Mine Inspector, Punxsutawney, Pa.; John Dunlop, State Mine Inspector, Peoria, Ill.; Ed. Boyle, Chief State Mine Inspector, McAlester, Okla.; J. W. Paul, Mining Engineer of Bureau of Mines,

Mine Inspectors and Guests at Columbus Meeting

Pittsburg, Pa.; Clarence Hall, Explosives Engineer, Bureau of Mines, Pittsburg, Pa.; D. J. Roderick, Anthracite Mine Inspector, Hazleton, Pa.; Mr. Roderick, visitor, Columbus, Ohio; Geo. E. Sylvester, Chief Mine Inspector, Rockwood, Tenn.; Isaac Hill, Mine Inspector, Zanesville, Ohio; L. D. Devore, Bellaire, Ohio, Mine Inspector; Mr. Thos. Morrison, District Mine Inspector, Mrs. Thos. Morrison, Sherodsville, Ohio.

Fourth row—John F. Bell, Bituminous Mine Inspector, Dravosburg, Pa.; Lot Jenkins, Mine Inspector, Bellaire, Ohio; C. P. McGregor, Bituminous Mine Inspector, Carnegie, Pa.; Oscar Cartlidge, State Inspector of Mines, Marion, Ill.; W. W. Williams, State Inspector of Mines, Marion, Ill.; Thos. Little, State Inspector of Mines, Murphysboro, Ill.; Jas. Taylor, State Inspector of Mines, Peoria, Ill.; Martin Bolt, State Inspector of Mines, Springfield, Ill.; Chas. H. Nesbitt, Chief Mine Inspector, Birmingham, Ala.; Karl F. Schoew, District Mine Inspector, Fairmont, W. Va.; R. Y. Muir, District Mine Inspector, Prince, W. Va.; M. D. Daniel, Assistant Inspector of Mines, Ashland, Ky.; W. W. Hall, Ashland, Ky.; Arthur Mitchell, District Mine Inspector, Bluefield, W. Va.; Lance B. Holliday, Beckley, W. Va., District Mine Inspector; James Hennessy, Barton, Ohio, Mine Inspector; Thomas Wangler, Columbus, Ohio; Frank Haley, Henrietta, Okla., District Mine Inspector; John Burks, Mine Inspector, Wellston, Ohio; D. T. Davis, Anthracite Mine Inspector, Wilkes-Barre, Pa.; Geo. Davis, visitor, Columbus, Ohio; J. J. Rutledge, Mining Engineer, Bureau of Mines, Pittsburg, Pa.

The following officers were elected to serve during the ensuing year: President, Thos. K. Adams, Pennsylvania; vice-president, D. J. Roderick, Pennsylvania; vice-president, Edward Flynn, Alabama; secretary, J. W. Paul, Pennsylvania; treasurer, R. T. Rhys, Iowa; assistant secretary, R. S. Wheatley, Ohio; editor, J. T. Beard, New York.

Trade Notices

New Office Building.—The Vulcan Iron Works, of Wilkes-Barre, Pa., are about to erect an office building the cost of which is estimated at $100,000. The structure, 67 x 83 feet, will be built of concrete, steel, and brick and will be directly opposite their present building. The basement will contain four office rooms, a vault, and a room for machinery exhibits. On the first floor will be ten office rooms, a vault, and a large entrance hall. On the second floor will be nine office rooms, a vault, and vestibule. A drafting room, a vault, and one office occupy the third floor. Elevators will connect the various floors.

Non-Return Boiler Stop-Valve.—It is evident that should a tube be blown out or a fitting ruptured in one of the boilers of a battery, the steam from the other boilers would rush into the header and discharge into the disabled one. To avoid the possibility of such an occurrence, The Lunkenheimer Company have designed a non-return valve to be inserted in the steam pipe between the boiler and the header; then should an accident occur to the boiler permitting the steam to escape, the valve attached to that boiler will immediately close. This will prevent the escape of steam from the other boilers connected with it in the battery, the danger to life and property will be greatly lessened, and the plant can be operated with the other boilers, without interference, thereby preventing loss of time and money. This valve will prevent steam from being turned into a boiler which has been cut out for cleaning or repairs, as it cannot be opened by hand when pressure is on the header side. It can, however, be closed when desired. Valves for this purpose have been made before, but this improved valve has special features which obviate difficulties which have been met, such as chattering and wear from sudden variations of pressure in ordinary work. It is worth while writing for a complete description, which can be had for the asking.

New Electric Equipment.—The Ophir Consolidated Mining Company, Ophir, Utah, will make additions to its electrical equipment consisting of one 50-horsepower, three 35-horsepower, and one 15-horsepower motors and three 50 kva. transformers. The Homestake Mining Company, Lead, S. D., will also add five motors to the electrical equipment in its mines. These consist of one 10-, two 15- and two 25-horsepower motors. All these will be furnished by the General Electric Company.

Coal Handling Machinery.—The Roberts and Schaefer Company have recently been awarded a contract for designing and building a large traveling coal bridge, aggregating over $100,000, for installation at the docks of the Clarkson Coal & Dock Company, Duluth, Minn. They also have closed a contract for a complete coal mining and coal washing plant for the American Fuel Company at Thompson's, Utah; and a coal tipple for the Virginia-Pocahontas Coal Company at Coalwood, W. Va. Besides these they also have received orders for Holmen locomotive coaling stations from the St. Louis and San Francisco railroad and the Michigan Central railroad.

Sullivan Machinery Compony Office in W. Va.—For convenience of users of their machines, the Sullivan Machinery Company have opened an office at 841 Court St., Huntington, W. Va., J. S. Walker, Manager. A complete stock of parts and supplies for Sullivan continuous electric undercutters, compressed air punchers, rock drills, and hammer drills will be kept on hand, and all express and rush freight shipments will be taken care of from Huntington, but in some cases large freight orders for parts for mine stock will be filled from the factory.

Current Connectors for Mine Use.—For making quick connection of circuits in mines to the trolley wire, the Ohio Brass Company, of Mansfield, Ohio, is offering two new devices. One is a current tap for lighting or other circuits carrying small current and is so designed that it may be quickly applied to the trolley wire and offers no obstruction to the trolley wheel passing under it. It consists of two sherardized malleable iron castings held together by a brass screw which, when tightened, causes the jaws to grip both wires, and it will fit any ordinary lighting circuit wire and any size of grooved or figure 8 trolley wires. The other is a cutting machine connector, designed for connecting to the trolley wire the cables from cutting machines and other apparatus requiring a comparatively heavy current for operation. It is mechanically strong, with heavy phosphor bronze contacts and springs, and is provided with a brass sleeve which fits over the insulation to prevent the breaking of the cable due to sharp bends at the point where it is soldered to the connector. It is regularly drilled for No. 2 cable and is tinned for soldering. The spring jaws will fit any round, figure 8, or grooved wire, being simply slipped over the wire either from above or below.

The Atlantic Fleet

The Atlantic Fleet of the United States comprises 102 vessels of all classes, with a displacement of 577,285 tons. Exclusive of submarines, these vessels represent 946,811 horsepower; all the battleships, cruisers, and torpedo boats, except the Iowa, have water-tube boilers. At the time of the Spanish-American war only four warships outside of the torpedo boats were equipped with water-tube boilers. Seventeen of the destroyers burn oil as fuel, and the Delaware, North Dakota, Utah, and Florida, four recently built battleships, burn oil in conjunction with coal. The fleet has a fuel-oil tank ship and eight colliers to supply it with fuel. The capacity of the colliers is 58,813 tons; the aggregate coal-bunker capacity of the fleet is 81,450 tons, or a total of 140,263 tons of coal. If the entire fleet was propelled at full power it would consume 20,000 tons of coal per day, or about 3 acres of 5-foot coal bed per day. The Government has invested $123,397,400 in this fleet, and so long as it keeps in motion and new ships are constructed, it is a good asset of the "coal and iron trade."

Mining on Loup Creek, W. Va.

Methods Employed in the Removal of Coal from the No. 2 Gas Seam in the Kanawha District

*By J. J. Marshall**

THE following article is abstracted from a paper read at the Fairmont meeting of the West Virginia Coal Mining Institute:

Unfortunately there has been, and still is, a more or less general impression that coal mining is purely a game of chance. We hear success or failure spoken of as good luck or bad luck. Likewise a "creep" or a "squeeze" is spoken of as though it were something which man could neither foresee nor prevent. However, we live and learn, and skill is now coming to be generally recognized as a controlling factor in mine management. The financial success or failure of a coal mine operation is due directly to cause and effect; and owing to the "intimate connection of its several parts," it is imperative that in judging any one phase all other interdependent factors should be kept in mind. The cause may be divided into three parts—the character of the problems presented for solution; the general plan selected as combining the solutions of these problems; and, lastly, the manner in which the general plan is interpreted and the details executed by the operating department. The effect is automatically registered on the cost sheet, which is only a true index when considered as an average for a term of years. The percentage of recovery is also due to cause and effect; for, given certain conditions and certain methods of mining, the result is inevitable.

The No. 2 Gas bed is classified as belonging to the Kanawha measures, and is the third workable bed above the Raleigh sandstone, the first being the "Eagle," or Clarion; the second, the "Powellton," which is worked locally on Armstrong Creek, Fayette County, where it is about 40 feet below the No. 2 Gas bed, but which is not worked anywhere else, to my knowledge. The No. 2 Gas bed, which was erroneously correlated with the Lower Kittanning of Pennsylvania Series, along its eastern escarpment is frequently divided into two or more benches by slate bands varying in thickness from a few inches to 50 feet, but the aggregate thickness of these benches along the eastern escarpment invariably totals about 9 feet. In many places both splits can be worked together, but as a rule they must be worked separately. This bed, in common with all the beds of this district, thins down to the westward, as it approaches the Ohio River syncline, and changes both chemically and physically. Physically this bed is marked by face and butt cleats, and this is taken advantage of in mining, as all face-cleat workings get full benefit of both grade and drainage, the face cleatage workings being in the direction of the maximum rise. In traveling westward on the Chesapeake & Ohio Railway, the No. 2 Gas coal bed makes its first appearance in the vicinity of Hawks Nest, in the Gauley and Cotton Hill mountains, at an elevation of about 900 feet above the river, and has been worked extensively at Ansted since 1873, where it is known locally as the "Ansted Seam." This bed passes under the railway grade at East Bank, 27 miles to the westward. Numerous rivers and small streams drain this region, and erosion has carved the once continuous beds of coal into irregular and fantastic shapes. The resulting long and broken outcrop lines offer many difficult problems in both outside and inside haulage, but these disadvantages are compensated by the absence of firedamp, which escapes and is rarely found in dangerous quantities under such conditions. The drainage problem is also simplified.

FIG. 1. DRUM HOUSE AND PLANES, LOUP CREEK COLLIERY CO., PAGE, W. VA.

The Loup Creek colliery is working the No. 2 Gas coal bed in the mountains, around Page, W. Va., which rise to a height of 2,700 feet above sea level, or 1,700 feet above Loup Creek. There the No. 2 Gas coal is 700 feet above the creek and dips N 22° W at the average rate of 100 feet to the mile. Thus the cover over the coal varies from only a few feet at the outcrop to a maximum of 1,000 feet in the center of the mountain, the summits being capped by the Black Flint ledge. Beginning at the lower tipple, the first 420 feet of elevation to the bench formed at the outcrop of the Eagle bed is overcome by means of a double-tracked incline, 1,000 feet long. Here is located the upper tipple and drum house,

* Mining Engineer and Assistant General Manager, Loup Creek Colliery Co.

and to it is brought the coal from both the Eagle and No. 2 Gas beds. The remaining elevation to the No. 2 Gas coal is overcome by means of a tramroad, with a minimum radius of curvature of 150 feet, a maximum grade of 2.8 per cent., and which by rising toward the dip of the coal gains slightly and reaches the coal at No. 7 drift mouth at a distance of 8,300 feet from the tipple. From No. 7 northward to No. 2, the tramroad follows the outcrop of the coal on grades varying from −1.50 to −.25 per cent., and with a minimum radius of curvature of 100 feet. In this locality the No. 2 Gas coal bed is made up of two benches which are separated by a slate of variable thickness. This dividing slate may be compared to a finely tapered wedge; beginning with a thickness of 10 inches at No. 2, it gradually thickens until 30 inches is reached near the mouth of the face entry. From this point southward the increase is rapid until a maximum of about 40 feet is finally reached. Twenty-four inches has been found to be the economical thickness beyond which it is not practicable to move this slate.

At first No. 7 was thought to be the last entry where both benches could be mined simultaneously, but later on, when it was found that the slate was thinner under the center of the mountain than at the outcrop, it was taken up in No. 8 entry left, and both benches worked. The aggregate thickness of the two benches averages about 9 feet, the upper bench ranging in thickness from 4 feet 6 inches to 5 feet 6 inches of clean coal, and the lower bench from 3 feet 6 inches to 4 feet of clean coal. Where it is impossible to mine both benches together, the upper bench only has been taken so far, and the lower bench is left intact for separate working in the future. In this paper that part of the mine where both benches are taken is termed the "high coal," and the part where only the upper bench is taken, the "upper coal."

From No. 7 entry northward to the point of the ridge, the mountain being narrow, the coal is developed by pairs of cross-entries, each of which is an independent drift opening, and has been worked as such. From No. 7 entry southward, the mountain widens to a maximum width of over 6,000 feet, and is split by a pair of face entries from which butt entries are turned right and left. In the high coal the entries are driven 10 feet wide and 110 feet center to center, rooms 400 feet long, and barrier pillar 100 feet. In the upper coal the entries are driven 10 feet wide and 70 feet center to center, rooms 350 feet long, and barrier pillar, 60 feet. All rooms are on 60-foot centers, 25-foot room, and 35-foot pillar. All breakthroughs are driven as prescribed by law, and from 10 to 14 feet wide. Except for a few "Pneumelectric" punchers, the coal is mined by pick work, the mining seam being in the middle of the upper bench.

The outside tramroad is laid with 65-pound steel rails, the entries with 35-pound, and the rooms with 16-pound steel rails of standard sections. All roads are 44-inch gauge, all turnouts and track details in general are standardized and factory made, to avoid duplications of parts, and confusion and delay when making repairs. A height of 5 feet, over the rail, is maintained in the main entry, and in the cross-entries 4½ feet over the rail is maintained. Loose slate is taken down, and except where it is impossible to avoid their use, no timbers are allowed in haulways. Permanent haulways are brought to a grade wherever necessary, and all haulways are kept in a clean, dry, safe, and serviceable condition, experience having shown that, even where trip movement is not considered, it is cheaper to maintain a haulway in this manner than to keep a dirty and unsafe haulway in passable condition. Slate and track cleanings, from narrow work, are loaded into the mine cars and sent to the slate dump. The mine cars are built by, or the materials ordered from, the Watt Mining Car Wheel Co., and are of wooden construction, height over rail 3 feet; 3 belt; flared top; 16-inch loose wheel; end brake; weight 2,600 pounds; average load, 2.6 gross tons of coal; and are equipped with patent spring bumpers. From the time the coal leaves the face, until it is dumped into the railroad car, the object has been to make gravity do the work; and only on secondary haulways is there any grade against the load, and even these exceptions are unimportant. Haulage on the outside tramroad is effected by means of 25-ton steam locomotives, of which there are on hand three—one built by the Baldwin Locomotive Works, and two by the H. K. Porter Co. One steam locomotive can, and has, returned 60 empties up the grade, which makes the capacity 156 gross tons per round trip from the main assembling point at No. 7. The time required for a round trip is about 45 minutes. To gather the cars and deliver them to the steam locomotive on the outside tramroad, there is a 500-volt, direct-current, electric haulage system, and, except in the high coal from entries No 7 to No. 3, mules have been replaced by 5-ton Westinghouse and General Electric gathering motors. Mules are in use in entries from No. 7 to No. 3, but in the territory served by the main entry, the gathering motor delivers the cars to the double partings at the mouth of the cross-entries. A 10-ton electric locomotive gathers from these double partings and delivers to the steam locomotive, which, in the meantime, has gathered from the mule hauls and is back at the main assembling point near entry No. 7. The 10-ton parting locomotive is the secondary unit of a 20-ton tandem, the primary unit of which can be added at any time. From entry No. 7 the trip is dropped down grade to the upper tipple, where the mine cars are unloaded by a Philips automatic cross-over dump (capacity three cars per minute), into the chute, which holds 75 tons. From this chute the coal is loaded into 8-ton capacity self-dumping monitors which descend and discharge into the chute at the lower tipple, the time required for this entire operation being from 1½ to 2 minutes.

Having followed the coal from the face to the railroad car, attention is directed to the electric current as it makes its circuit. Four 150-horsepower boilers furnish steam to a 50-horsepower Corliss engine which is belt connected to a line shaft that drives 160-kilowatt, 250-volt, General Electric generators, which, being connected in series, give 550 volts at the switchboard. The power line, consisting of three 4-0 copper wires, transmits the current to the mouth of the main entry and delivers 520 volts; from this point the current is transmitted to the motors and pumps by one 4-0 grooved trolley wire. The return is made through the rail, both rails being cross bonded every 500 feet. All electric wiring and bonding is kept in repair, one man and a boy being detailed to take care of the erection and maintenance.

Drainage in many instances can be made to take care of itself in the natural manner; for instance, several entries are drained by openings driven through the outcrop. Siphons are used to unwater holes which cannot be drained by ditching but are within, say, 1,500 feet of an outside opening. Where neither of the above methods is practicable electric pumps are called into service, or, if it is merely a few gallons which have accumulated at a working face, our old friend, the water box, is made to do duty. The pumping equipment consists of three rotary pumps, geared to 5-horsepower motors, with a capacity of 50 gallons per minute, and one rotary pump geared to a 10-horsepower motor, capacity 100 gallons per minute. The general direction of advance being toward the rise, the new work is not in any danger of being hampered by water from the old work.

There has been no indication of explosive gas; and the dust problem, owing to the natural conditions, offers no serious cause for apprehension; nevertheless, this is not overlooked, and by keeping the roadways clean, regulating the air-current, and, when necessary, using water in the dry places, the possibility of a dust explosion is made still more unlikely. If an explosion, or some other catastrophe, did occur, the conditions are such that, generally speaking, it would probably be local in its effect and the survivors would have numerous avenues through which it would be possible for them to escape.

The entries from No. 7 to No. 3, inclusive, are ventilated by means of the ordinary basket-grate furnace and wooden stack. The area of cross-section being large, and the distance the air travels being short, this method has proved sufficient. In June, 1909, the furnace at the mouth of the main airway was replaced by a 60-inch, double-inlet, Sirocco fan which was guaranteed to deliver 100,000 cubic feet of air per minute at a 2-inch water gauge. This guarantee called for two 35-horsepower motors, but only one was installed, and it has not been found necessary to install the second one, the fan fulfilling all present requirements and delivering with ease 80,000 cubic feet of air per minute. The fan is installed to either force or exhaust, but so far only the exhaust method has been used. The speed of the motor is varied by means of a field control rheostat, which is a valuable feature. When moisture is being precipitated on the roof of the mine, or when an excess of moisture is being carried out of the mine, the speed of the fan can be readily regulated to deliver, at the working face, only enough air to fulfill actual requirements. By applying "the rule of reason" under these conditions, to supply to the miner more air than he actually requires, is to unnecessarily increase the risk of his being killed by a slate fall or by a dust explosion. The numerous openings on the outcrop facilitate ventilation, as well as drainage and timber supply, and, by using them as intakes, the speed of the fresh air-current is kept uniformly low. The stoppings, in the main entries, are built of brick or stone, and in the butt entries of plank. Brattice cloth is used wherever it is necessary to deflect the current up into the rooms.

With the ordinary method of driving rooms and drawing pillars on the advance, the mine is now in condition to work the butt entries on the retreating system. This reversal in general method has been accomplished without lessening the output or adding materially to the cost of production.

All entries and rooms are driven on centers, the sights for which are put in with a transit, and from these the miner can check up the course of his place in a few minutes. The pillars are drawn in steps, and Fig. 2 shows the details of the method used.

The roof of the mine varies considerably in both disposition and composition, and is of blue slate, sand slate, or sandstone and slate mixed. It is usually stratified for a distance of from, say, 75 to 100 feet, when a massive sandstone ledge is reached, and this latter is very hard to break.

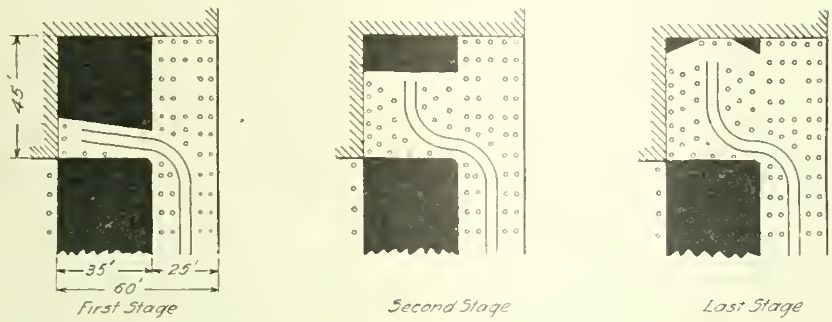

FIG. 2

In the high coal, the floor of the mine may be classed as good and is 8 inches of slate and then sandstone. In the upper coal, the floor, which is the previously mentioned dividing slate, is good in solid work and usually so in pillar work. In the latter case it has only given trouble when thin and in contact with water, in which case it may slack and creep. In the entries from No. 7 to No. 2, inclusive, the rooms were worked on the advance and were turned as soon as available. The general method of pillar mining, in this section, has been to take out the room pillar to within 100 feet of the entry on the advance, and then draw the barrier pillar, chain pillar, and room stump retreating.

The general grade of No. 6 entry is very nearly level, but there are several depressions which, due to the pillars being mined to the rise, catch a considerable volume of water during the rainy season, and due to this cause the retreat has been seriously interfered with.

The pillar drawing in No. 7 entry was advanced in strict accordance with the general method, and all indications were that the roof was breaking as soon as the coal was removed; however, a squeeze came on and it was only by hard work that the entry, from room 12 to room 20, could be kept open. This made a change in method imperative, so No. 27 room was converted into a haulway, and the coal from beyond the affected area was hauled that way to No. 8 left. An attempt was then made to start in the center of the affected area and retreat in both directions, but it was found impossible to get enough open space to insure a good fall. The men were all withdrawn and the roof allowed to settle, then by working only one place on each side, a good start was made toward getting a fall that would break the top far enough up to relieve the pressure. The only reasons to assign for this trouble are, that the previously mentioned sandstone ledge had not been broken, or that the roof was subjected to unknown strains. This occurrence is a concrete example of the advisability of working on the retreating system, and had it not been for the outlet through No. 8 left, the coal beyond the affected area would either have been lost or the profit therefrom would have been eaten up by the cost of maintaining an outlet.

Generally speaking, the methods followed have necessitated only a minimum amount of dead work, of mine timber, and of trackwork and track materials. Also the large blocks of coal, which are at present left intact, should prevent the general extension of any trouble which may be brought about by the removal of pillar coal.

On June 30, 1911, the percentage of recovery stood as follows:

COAL AREAS AND PERCENTAGES OBTAINED

	Total Area From Which the Coal Has Been Extracted Acres	Total Area in Which the Coal Has Been Lost Acres	Total Acres	Percentage of Recovery Per Cent.
High coal (both benches)	77.75	6.86	84.61	91.8
Upper coal (upper bench only)	67.00	.87	67.87	98.7
	144.75	7.73	152.48	94.9

In cost of production, the aim has been to secure a *minimum average*, rather than to let each month stand for itself alone. The cost of labor and material per gross ton of coal mined was less for the year 1910 than for the year 1906, and for the five years inclusive the difference between maximum and minimum was less than 3 cents.

Answers to Examination Questions

Answers to Questions Asked at the Examination for Mine Foremen, Held in Utah, October, 1911

(Continued from July)

OWING to an error the answer to Ques. 2, page 723, in our July number is given as 3.33 per cent. instead of 3.22 per cent.

Ques. 1.—(*a*) What in your opinion should be done with torn brattice cloth found on entries and other mine workings? (*b*) What are the dangers attending the presence of such material in the mine?

Ans.—(*a*) Torn brattice cloth, pieces of wood, as well as all other combustible material, should be gathered up and removed from the mine. (*b*) These waste materials are apt to catch fire from various agencies, but largely from burning wicking thrown upon them by a miner in changing the cotton in his lamp. One, at least, of recent dust explosions originated from a mine fire which was started by some drivers setting fire to the combustible rubbish near a brattice where they were accustomed to eat their dinners. The blaze of the burning rubbish was communicated to the nearby brattice, which in turn set fire to the coal. Dust was fed into the fire, which probably generated a certain amount of CO, until, within about an hour from the starting of the fire by the drivers, the mine exploded, resulting in the death of over 75 men.

Ques. 2.—As mine foreman, what arrangement would you make respecting miners carrying tools, such as picks, shovels, drills, etc., in the man trip?

Ans.—If practicable all supplies of this nature should be carried in a separate car from the men. If this is not possible, care should be taken to see that the end gate is closed so that nothing may drop out and derail the trip, and nothing should be allowed to project above the top of the car to come in contact with trolley wires, the roof, or timbers. In all cases where men are carried in the same car as tools, the latter should be laid upon the floor and not carried in the hand or upon the shoulder.

Ques. 3.—(*a*) If the barometer reads 23.20, what is the pressure on a square inch? (*b*) On a square foot?

Ans.—(*a*) Assuming the temperature to be 32° F., the pressure per square inch is found by multiplying the height of the barometer in inches by the weight of a column of mercury 1 inch high; that is, by the weight of 1 cubic inch of mercury, or .4911 pound. We then have, $23.20 \times .4911 = 11.39352$ pounds as the pressure per square inch. (*b*) The pressure per square foot is, of course, the pressure per square inch multiplied by 144, or $11.39352 \times 144 = 1{,}640.66$ + pounds.

Ques. 4.—Explain three ways in which an explosion can occur in a coal mine where the safety lamp gives no indication of gas?

Ans.—It is necessary to assume the presence of explosive dust; for without either gas or dust, an explosion is not possible. It must be remembered that very small quantities of marsh gas that cannot be detected by means of even the best safety lamp are a source of danger in the presence of the dry dust so prevalent in American mines. Probably the chief initial, or first, cause of explosions in dusty mines must be laid to blown-out shots, due to overcharged and misplaced holes in which black powder has been fired. By undercutting the face to at least 6 inches more than the depth of the shot hole, by properly placing the holes, and by using the right amount (and no more) of permissible, short flame, explosives, the danger from this source may be reduced to a minimum. In connection with the above, the dust from machine cuttings should be loaded out of the mine, and, where practicable, the rooms should be watered for a distance of from 60 to 90 feet back from the face.

A second, but less common, cause of explosions are mine fires. In the confined passageways of a mine, owing to lack of sufficient air to furnish enough oxygen for complete combustion, coal in burning will form more or less CO, itself a combustible gas. A sudden accession of fresh air may cause the CO to explode, or dust may be drawn into the fire and originate a dust explosion. Mine fires may be prevented by constant watchfulness on the part of those in authority that they may be extinguished before getting beyond control; by loading out all gob that contains carbon, as well as all fine coal; by keeping uncovered electric wires from coming in contact with wood, etc., and by removing from the mine all inflammable material such as old brattice cloth, chips, shavings, and the like.

A third cause of explosions is due to the use of electricity in mining operations. Numerous mine fires are known to have been started by uncovered wires coming in contact with wood and other combustible materials, but explosions from electricity are brought about by short-circuiting of the current in the presence of clouds of dust. A fall of roof may bring down the wires into contact with the rail or with the iron work of mine cars or with water or air pipes and the like. The high temperature of the arc thus produced will distil the gas from the dust, and, if the current is continued for a sufficient length of time, will generate enough gas to cause an explosion which may be communicated to the dust. The explosion at Starkville, Colo., is known to have been, and that at Monogah, W. Va., is, by the best authorities, believed to have been, caused by the short-circuiting of the electric current, in each instance the wires having been brought down by a runaway trip knocking out the supporting posts. Means of prevention are not sure. The use of storage battery locomotives, with machine wires in conduits buried alongside the track, will, of course, prevent explosions due to short-circuiting of the wires; but such means are, in many cases, not possible by reason of the cost. In any case overhead wires should be so supported as to reduce to a minimum the chance of their being knocked down by runaway trips.

Ques. 5.—If going into a working place you found the miner's lamp full of explosive gas, how would you treat it?

Ans.—The lamp should be approached cautiously so that no air-currents may be stirred up to force the flame through the gauze. It should be lowered slowly through the gas, placed under the coat and thus smothered. Before being relighted it should be most carefully examined for imperfections in the gauze.

Ques. 6.—How would you arrange electric wires on haulage roads to avoid, as far as possible, the danger of accident to workmen engaged on such roads due to live wires?

Ans.—The headings should be driven straight so that the wires may be placed a uniform distance from the rib and as far from the track as possible. By driving the headings straight the traveling way may always be placed on the side of the entry *opposite* the trolley wire. The trolley wire should be placed in an inverted wooden trough with sides 3 inches or more in depth so that a man's head may not come in contact with the wire when standing on the rail; and so that iron tools carried on the shoulder may not touch it. The road bed should be carefully drained and kept dry, as moisture tends to increase the severity of the shock. Above all, the men themselves should be instructed in the dangers connected with electricity and taught not to carry iron tools on their shoulders when traveling on a road where there are naked trolley wires.

Ques. 7.—If a slope 3,000 feet long on a

15-degree pitch was making 500 gallons of water per minute, how would you determine the horsepower of a pump to handle the water in 16 hours out of the 24 hours, allowing 20 per cent. for friction?

Ans.—Since all the pumping is done in 16 hours out of the 24, or in two thirds of the time, the required discharge is equal to $500 \times \frac{3}{2} = 750$ gallons per minute. Since an allowance of 20 per cent. is to be made for friction, the pump must be sufficiently powerful to raise 20 per cent. more than this amount of water, that is, the pump must be capable of raising $750 + (750 \times .20) = 750 + 150 = 900$ gallons per minute. The head is found from the formula, $H = L \times$ sine angle of slope $= 3{,}000 \times$ sine $15° = 3{,}000 \times .25882 = 776.46$ feet. The weight of a gallon of water may be taken as $8\frac{1}{3}$ pounds and the total weight of water to be raised in 1 minute is $900 \times 8\frac{1}{3} = 7{,}500$ pounds. From the preceding, the horsepower of the pump is

$$HP = \frac{7500 \times 776.46}{33{,}000} = 176.44$$

The result may be obtained by finding the horsepower required to raise 500 gallons a minute through the required distance; multiplying this by $\frac{3}{2}$, as the water is raised in $\frac{2}{3}$ of a day, and adding to this last result $\frac{1}{5}$ of itself as the 20 per cent. allowance for friction.

Ques. 8.—Where, and under what conditions would you consider the use of electricity safe in a dry and dusty mine in which explosive gases are generated?

Ans.—The conditions described are the most dangerous that can occur. Any answer to this question would probably be disputed by those in favor as well as by those not in favor of the use of electricity in mines. However, it will hardly be denied that under the described conditions, more than the usual precautions must be observed to render the use of electricity safe. Most persons will agree that low-voltage haulage is permissible on the main and other entries where there is an ample volume of air, no holes or pots in the roof where gas may accumulate, and where the roads are always sufficiently wet to keep down the dust. Whether electricity may be used to operate coal-cutting machines in the rooms will depend upon how well the air-current is kept up to the face. If the air is kept up to the face and the motors are encased in gas- and dust-proof casings, there appears no valid reason why electricity may not be used to operate the coal-cutting machinery, particularly if the bug dust, etc., is kept well watered down. Under the described conditions many would advocate the use of compressed air for both haulage and coal-cutting purposes. Under no circumstances could a gas or dust explosion result through the use or abuse of compressed-air haulage or coal-cutting machinery.

Ques. 9.—What is afterdamp and why is it at times so much more deadly than at other times?

Ans.—Afterdamp is the intimate mixture with the mine air of the gaseous products of combustion resulting from an explosion of marsh gas or coal dust, or of both. Or it may be defined as air in which a greater or less proportion of the oxygen has been replaced by various gaseous products of combustion. The chief constituents are usually and in the order named, nitrogen, oxygen, carbon dioxide, and watery vapor with variable amounts of carbon monoxide. The latter gas is the most dangerous constituent of afterdamp, even in most minute quantities. Should the explosion result from the detonation of large quantities of powder, etc., or of dust in a space where there was not sufficient oxygen for the complete combustion of all the carbon, the proportion of CO in the afterdamp would be much greater than if powder did not figure in the explosion or if there was enough oxygen present to completely burn all the carbon to carbon dioxide. The deadliness of the afterdamp, then, depends upon the proportion of CO contained in it, and this, in turn, depends upon the materials concerned in the explosion and the local conditions prevailing at the time of the explosion.

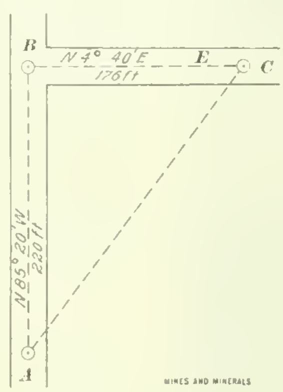

Fig. 1

Ques. 10.—It is desirous of running an entry from A to C (Fig. 1). (a) What will be its direction? (b). What is the distance between A and C?

Ans.—(a) The entry AB is in the fourth quadrant, and the entry BC is in the first quadrant, and the angle between their center lines is the sum of their bearings, or is $85° 20' + 4° 40' = 90°$; hence the problem resolves itself into the solution of a right-angled triangle with its right angle at B. The angle BAC, which determines the bearing of the entry AC, is found from the relation, $\tan A = \frac{BC}{BA} = \frac{176}{220} = .80000$. The angle whose tangent is .80000 equals 38° 40', approximately. As this entry is driven to the right from the entry AB, its bearing is less than the bearing of AB by the amount of the angle CAB and is equal to $85° 20' - 38° 40' = 46° 40'$. The bearing of the entry AC is therefore N 46° 40' W.

(b) The length of the entry AC may be found by solving the right angled triangle and finding the hypotenuse arithmetically, thus:

$$AC = \sqrt{220^2 + 176^2} = \sqrt{79{,}376} = 281.75$$

The distance may be found by trigonometry, thus:

$$AC = \frac{BC}{\sin CAB} = \frac{176}{\sin 38° 40'} = \frac{176}{.62479} = 281.694.$$

The discrepancy in the results by the use of the two methods is of interest. The first method is exact, and the difference is due to the fact that the angle CAB is not exactly 38° 40' but just a trifle more than 38° 39' 30" and is naturally taken as 38° 40'. If the sine of the true angle is used, .62468, the result is the same by either method.

Ques. 11.—How would you deal with a strong feeder of gas in the middle of a ventilating district with a view of continuing work in the remaining portion of the district?

Ans.—In determining the method of handling such a feeder, much will depend upon local conditions and the position of the feeder in the mine with respect to the intake and return; matters which are not stated. As a general rule the feeder itself or the district in which it is should be walled off by a brick or concrete stopping, in which is inserted a pipe to convey the firedamp directly to the return air-course. In some coal fields a bore hole from the surface would be sunk to the feeder to draw off the gas. It will be noted that when pillars are drawn extreme care must be taken not to allow a sudden outburst of gas into the workings because of the crushing of the stoppings put in to seal off the feeder.

Ques. 12.—How does coal dust in a mine influence an explosion?

Ans.—The dust of certain coals, particularly when dry and in a finely powdered state, will extend the effects of an explosion far beyond the initial point. The exceptions are so very few that it may be laid down as a fact that all of the explosions which have occurred in American mines since that at Pocahontas in 1884, would have resulted in a relatively insignificant loss of life had it not been for the presence of coal dust. Over 95 per cent. of explosions in American mines have taken place in those where the volatile matter in the coal was between 18 and 35 per cent., where the coal was friable and readily ground into fine dust, and where this dust would readily coke in the ordinary beehive oven. It would seem from this, that the coking or non-coking qualities of a coal have a marked influence upon whether its dust will or will not lend itself to the propagation of an explosion. It would seem that in the presence of great heat, such as that generated by an explosion of firedamp, by the arc produced by short-circuiting an electric current, by a powder explosion, etc., that the volatile matters in the dust are instantly driven off and as quickly ignited; thus producing a true explosion, which is nothing but an instantaneous combustion.

Ques. 13.—One of the entries runs into a fault. How would you determine if it was an up or down fault?

Ans.—It is not always possible to tell from an inspection of the face of the entry alone whether the throw has been up or down. In *most* mining districts it will be found that in *most* cases the *foot wall side has slipped down along the hanging wall side* as shown in Fig. 2, producing what is known as a *normal* fault. By reason of this, is given a rule found in many books; viz., when a fault is encountered, if the hanging wall is overhead the faulted portion of the seam has gone downward, but if it is under foot, the faulted portion is to be looked for at a higher level. If the reader will imagine himself in an entry driven on the levels *A* and *B*, respectively, in Fig. 2, which shows a normal fault, the reasons for this so-called rule will be apparent. Not infrequently the coal or the containing rocks are bent slightly up or down in the direction of throw, and this is a valuable guide to the position of the missing portion of the seam. In arid regions where there is little surface soil or vegetation the fault itself is often shown on the surface, a particular layer of rock being at different levels at two near-by points. Again, something may be told from the character or composition of the rock met in the fault plane in the face of the entry. In some cases it is possible to identify it with a rock found at a higher level in sinking the shaft; in which case the throw is down and its distance is determined by the distance between this rock and the coal as measured in the shaft. After developments are fairly well under way in any given mining region it is pretty well known whether faults are generally normal or reversed, and about the extent of the throw. Diamond-drill holes at the face will determine the direction and amount of the throw and, when any uncertainty exists, should be drilled.

Ques. 14.—In your experience and opinion, which is the surest way to prevent a dust explosion?

Ans.—The only sure way of preventing dust explosions is to prohibit the use underground of anything which could produce a flame. This would involve mining the coal by undercutting and breaking down with wedges or hydraulic cartridges; would require compressed-air haulage and coal-cutting machinery instead of that driven by electricity; would necessitate the use of storage-battery electric lamps in place of the customary open oil lights, and would require the prohibition of smoking in the mine. If the above precautions be adopted there can be no blown-out shots, electric arcs due to short-circuiting of the current, mine fires at doors and brattices, or firing of marsh gas, which are the chief initial causes of dust explosions.

On the other hand, the adoption of all the above appliances is not always economically possible, and the mine foreman is generally called up to "take care of" the dust either by what may be called the "wet" or the "dry" method. Whichever method is adopted, all precautions should be taken to limit the amount of dust made in mining by seeing that the coal is undercut at least 6 inches beyond the end of the deepest shot hole; that only permissible short-flame powders are used and these in well placed and properly

Fig. 2

charged holes. Bug and other dust should be loaded out with coal and hauled in as tight cars as possible. The haulage roads should be kept in good shape so that the danger of a runaway trip knocking out the posts and short-circuiting the current is reduced to a minimum. Electric lamps of the storage-battery type should be used in the workin places, no matches should be allowed in the mine, and all rubbish which might be fired in any way should be removed. Despite all precautions in the way of preventing the formation of dust, a certain amount of the finest and consequently the most dangerous dust will always be present in the workings. The question is, then, the choice of a method of taking care of this fine dust.

It will be admitted that if the workings of a mine are absolutely wet, no propagation of an explosion by means of dust is possible, and it will also be admitted that if inert rock dust is substituted for coal dust a dust explosion is equally impossible. That is, either the wet or the dry method, if carried to the limit will absolutely prevent an explosion. Which is preferable will depend upon circumstances. The wet methods of dust treatment, involving either the watering of the headings or watering in connection with preliminary moistening (with or without preheating) at the intake, have the preference in this country over the rock-dust methods of treatment. This is probably largely a matter of prejudice, and because every one knows that water puts out fire and it is fire which causes an explosion. On the other hand, the dry, or rock-dust, method of dust treatment has many points in its favor that cannot be claimed for the wet methods. It is much cheaper and is much more healthful and experiments have proved it equally as efficacious as the wet methods in preventing the spread of an explosion otherwise started. The use of any of the wet methods produces very disagreeable conditions underground, which disagreeable conditions are accentuated if the air is preheated at the intake. In the last case, the roads are apt to be deep in mud, the timbers are frequently festooned with moss and rot, in a short time producing dangerous falls, the air is foggy and is so warm and moisture laden that the least exertion brings out intense perspiration. Likewise, darkness, moisture, and heat are conditions highly favorable to the growth of tuberculosis and other germs. On the other hand, a mine treated by the rock-dust method is cool and dry and is a pleasant, healthful place in which to work, provided there is no silica in the fine rock dust.

There seems but little doubt that when further experiments have determined what proportion of rock dust to coal dust (for any particular mine) is necessary to prevent an explosion, and some way has been devised by which the dust may be cheaply sprayed into each working place, that the dry method of dust treatment by reason of its simplicity, economy, and healthfulness will supplant the present wet methods.

First Aid in Alabama Mines

*By J. F. Smith**

Not only are state mine laws being rigidly enforced, but coal companies have formulated colliery rules, which, if followed by the miners, are sure to result in a less number of accidents than heretofore. Coal operators have a personal interest in the welfare of every man in their employ, a fact demonstrated at the National First Aid meet in Pittsburg last October, where operators from every coal field in the United States assembled to witness the dexterity of first-aid teams from the collieries.

The Alabama Consolidated Coal and Iron Co. takes great pride in the efficiency of the well-trained first-aid-to-the-injured corps and mine-rescue teams at its Lewisburg mines near Birmingham, Ala.

Several months ago the First-Aid Society was organized, and from its inception rapidly became popular with the mine workers, who were quick to appreciate the advantages to be derived from a practical knowledge of the human body and the methods to be followed in the treatment of common injuries, which if neglected for a time might lead to serious if not fatal termination.

Each man who became interested was given a copy of the manual used by the New York First-Aid Society, and a life-sized manikin was obtained and practical demonstrations in first-aid work were systematically given by the writer. Dr. Thomas A. Cheatham, of Birmingham, aided in the instruction by giving a series of readily understood and practical lectures; after which Dr. G. B. Scott quizzed the students to learn the extent of their information. The general instruction given the society as a body was found to be inadequate to meet all emergencies, and four teams of five men each were selected for special training in first-aid work.

The wisdom of this step has been demonstrated at the Lewisburg mines, as it no doubt has been at other coal mines where first-aid teams have been formed and encouraged. Methods of handling injured miners have been carefully studied, and to facilitate the work two underground hospitals or emergency wards have been fixed up inside the mines by the company. One of these emergency rooms—that of the Cheatham ward is shown in Fig. 1. It will be seen that it is fitted with Johnson's first-aid cabinet, a closet for blankets, cushions, and extra Red Cross supplies, and with a stretcher in place on a hospital car. The men shown in this illustration, reading from left to right, are Dr. G. B. Scott, Dr. T. A. Cheatham, for whom the ward is named, and Mine Foreman J. F. Smith. This ward is 2 miles west from the mouth of the slope in the Mary Lee mine. No effort is made to detain a patient in these wards after first aid has been rendered, but the section of the mine stops work long enough for the hospital car to be rushed to the surface and the patient taken to the Mary Lee Hospital close at hand, where the resident surgeon has an operating room with surgical conveniences.

Fig. 1. Cheatham Ward, Underground Hospital

Fig. 2. Junior First Aid Team, in Scott Ward

There is another underground hospital in the eastern part of the mine about $1\frac{1}{2}$ miles from the tipple and at a point where all mine cars from that part of the mine must pass. This second, or Scott ward, shown in Fig. 2, is fitted up the same as the Cheatham ward. The photograph is unusually interesting, as it shows a junior first-aid team, composed of boys who work in the mine as trappers. These youngsters are even more enthusiastic and quicker to learn than their friendly rivals of more mature years. The boys are now veterans, having done creditable work, and consequently feel slighted if not given the first chance in every emergency case. The author of this article has had quite an experience in the use of helmets, and has taken a regular government course of instruction at the Bureau of Mines station in Birmingham; several of his men are also receiving instruction at present, so that Lewisburg is not very far behind the most progressive in emergency and rescue work.

Much attention has been given to sanitary conditions in Lewisburg, so that the sanitary officer seldom finds it necessary to use authority in enforcing sanitary rules. The value of sanitation is indelibly impressed, and with the citizens of Lewisburg and Mary Lee camp cleanliness is a matter of personal pride. The following rules are posted in conspicuous places that there shall be no excuse for not knowing:

1. Every person renting a house is held personally responsible for sanitation of premises; heads of various departments responsible for buildings and premises coming under their supervision.

2. Around each house, a space of 6 feet shall be cleared of weeds, trash, debris, etc., and yards kept reasonably clean.

3. Paper, cans, bottles and all other trash must be destroyed; garbage promptly disposed of; dead animals burned, buried, or removed from the camp.

4. Toilets shall be cleaned and limed twice a month; excreta burned or buried.

5. Stables shall be cleaned twice a month and manure properly disposed of.

6. Stagnant water (wash tubs, garbage pails, etc.) will not be tolerated.

7. Hogs shall be kept in reasonably clean pens at least 50 feet away from any building.

8. Contagious diseases (diphtheria, scarlet fever, measles, etc.) shall be quarantined and houses placarded; typhoid fever and whooping cough isolated; smallpox sent to the pest house.

9. Violations of sanitary rules must be reported to sanitary officer or company physician.

10. A fine of fifty cents (50c.) shall be imposed for first violation of rules, one dollar ($1.00) for second, and third offence reported to the company with recommendation from First-Aid Society. All fines shall be turned into treasury of First-Aid Society.

The Increased Cost of Mining Anthracite

A Comparison of the Present Mining Conditions with those Existing Thirty or More Years Ago

*Written for Mines and Minerals by W. D. Owens**

To explain in an intelligent manner why the present cost of mining is so much higher in the Wyoming Valley than it was some 40 years ago, when I first held an official position in the mining industry, it is necessary to consider all the operations required in mining the coal and in preparing it for market. Therefore, to be as concise in my statements as possible I have divided it into several departments as follows:

1. *Mining Thick Seams.*—The mining of anthracite 30 or 40 years ago was generally, if not all, from beds not less than 6 feet to 12 feet or more in thickness; also this mining was carried on near the surface and above the water level. What was mined below water level was in new ground, and there were no streams of water to contend with. The result of this was that the miner was able to extract the coal entirely by the use of black powder, and the yield per keg of 25 pounds was generally about 25 mine cars; and I have known of some even going much above this average. The average today for the same capacity mine cars will only run about 12 cars per keg, and in many places the product is not more than from six to eight cars, and even then much stronger powder has to be used.

2. *Mining Thin Seams.*—It is now a common thing to mine seams of coal that are so thin that a miner could not enter them, if it was not for the rock or slate lying in strata between the coal benches; and these strata of slate are often as thick in the aggregate as the coal contained in the whole seam. The fact that the seams now being mined are much less in thickness than those mined heretofore, necessitates blasting down roof rock or blasting bottom rock, as the case may be, so as to procure the proper height for mules and cars to travel. In a seam 3 to 4 feet thick, it requires from 24 inches to 36 inches of rock to be blasted out for height, and, of course, more as the seam becomes thinner.

The slate intervening between benches of coal generally has no partings and is fastened to the coal; therefore, the companies are now paying about the same price per mine car, with the wage advances added of course, as they did 30 or 40 years ago, when cleaner and thicker seams were mined; in addition, they have to pay so much per yard on the rib of a breast, varying from 50 cents to $3.70, and perhaps more in some places; also to pay for the intervening slate, laminated through the seam, which often aggregates from 15 inches to 36 inches in thickness, and, in addition to all this, pay for blasting the top or bottom rock and stowing the same away.

Many of these places again are wet; that is, some little water drips from the seam, causing all the coal mined to be wet, and the miner who has to work in such places has his clothes all wet through, from the fact that he cannot work by standing upon his feet, but has to either work in a sitting position, or in a kind of reclining position, and, if such places are worked somewhat to the dip, the water generally must be bailed out by the miner, amounting to one car per day, or one car every 2 days, as the case may be, and which, of course, has to be paid for. The quantity is generally so small that it does not pay to establish a pump and lay a line of pipes for it.

3. *Material and Labor.*—Owing to the fact that the material necessary to maintain the operation is much more when mining a thin seam than a thick one, because the advancement is much more rapid for the same tonnage produced, naturally this calls for a much higher percentage in the company hands employed necessary to keep the mine in proper condition for its operation; that is, more bratticemen, car runners and drivers, tracklayers, etc., and more mules, or other motive power, compared with what was necessary to produce the same tonnage during the period mentioned for comparison. To this must be added the increased distance for all transportation, haulage of coal and other materials, the cost of which cannot be less than three times what it was 40 years ago.

4. *Increased Depth and Ventilation.* Since nearly all the coal mined at present is derived from a much greater depth and the area of all passages for the required volume of air to travel therein are much less proportionately, and deep mining produces more firedamp, it requires larger volumes of air to circulate through the mines, which cannot, at least, be less than twice the quantity necessary during the period mentioned heretofore. To accomplish this, the machinery for transportation and ventilation must be increased in power and capacity proportionally. The operating expense in ventilation is naturally much higher, owing to numerous causes, such as the difficulty in conducting the proper quantity of air to the working faces, caused by so much rock stowed in the breasts, derived from the rock contained in the seam and from bottom or roof to make height; besides much of this rock is in the way when it is necessary to build brattice to conduct the ventilation to the working face. The bad effect caused by squeezes in old workings, which had pillars too small to carry the heavy load resting upon them, also causes leakage of air, frequently making proper ventilation very difficult.

5. *Increased Water.* The quantity of water that must be pumped from the mines at the present time, as compared with the period alluded to, is at least 10 times more, and the comparative depth to raise the water to the surface is greatly increased as well. A colliery under my charge about 30 years ago, where the mining was done entirely in a shaft about 250 feet deep, and which was shipping an average of about 25,000 tons of coal per month, had only one small Blake pump, 6 in. × 12 in. × 12 in., delivering water to the surface, and that was in operation only about 12 hours out of every 24. At two of the collieries under my charge at present, one delivers an average of 5,000 gallons and the other about 6,000 gallons per minute against heads of 400 feet and 500 feet, respectively. In other words, the one pumps to the surface about 37 tons of water for every ton of coal shipped from the colliery, and the other pumps about 26 tons of water for every ton of coal prepared at the colliery. It is evident to the reader that to contend with such quantities of water necessitates the installation of larger capacity pumps, with larger steam cylinders, so as to develop the power required. To install such pumps it is necessary to have column pipes and bore holes from the surface to the pump station, and generally such bore holes are expensive, because they have to be driven through gravel, sand, and boulders to a depth of 100 to 150 feet before solid rock is encountered, and in boring through such material, it is next to impossible to get a perpendicular hole. Into such holes again, a casing pipe has to be inserted, either iron or terra cotta, or a wooden pipe cased in with cement. It should also be remembered that there are now in the Wyoming Valley many shafts from 1,000 to 1,500 feet in depth. The reader can imagine, therefore, what has to be done under such conditions with large inflows of water.

6. *Breakers.*—Almost all breakers have been rebuilt, or otherwise remodeled, so as to be able to accomplish the proper preparation of the dirtier coal for the market.

The necessity for this was enforced upon the operators, owing to the fact that the seams of coal are so very dirty, particularly as compared with coal mined 30 years ago, which was dumped from the mine car over a few bars to separate the coal for sizing. The most of it was so pure that it could be sent direct into a railroad car with little slate picking. But now we have to resort to the operation of many rolls, shakers, screens, automatic pickers, and jigs, to separate the impurities from the coal and to automatically separate the coal from the slate, as well as expend much hand labor

*Division Superintendent, Lehigh Valley Coal Co.

in addition. The waste derived from the shakers and jigs is carried with the water back again into the mines, necessitating bore holes and long pipe lines, varying from 1,000 to 6,000 feet in length and differing in size from 3 inches to 8 inches in diameter. The life of these pipes is comparatively short, owing to the great wear on them from high velocity of the water and dirt traveling through and the action of sulphuric acid. This acid water is carried into the mine sumps and taken up by the pump, and the effect of such water on the life and durability of the pumps and their connections is very severe indeed. Again, the refuse discharged from the pipe lines from the washeries has to be taken care of by the employment of a number of men to build batteries of props and planks, or stone walls, and in many cases both kinds must be put up in the same place. The strength of such batteries must be according to the pitch of the seam in which the silt is deposited, and if the silt is very fine, the stopping must be nearly water-tight in its construction. This fine dirt and water has a bad effect upon the pillars in some localities, where there is a thin stratum of sandy clay between the roof and the seam of coal, and sometimes under the coal; the water oftentimes penetrates through the clay, leaving the roof without support and washing out the deposited silt, carrying it down into the gangways or into the main sump of the pumping station. Then great expense is entailed in cleaning out the sump and in loading the clay into mine cars to send it outside for deposit on the surface.

7. *Steam Production.*—The great increase in the boiler capacity required can be best illustrated by a comparison of two collieries; one under my charge nearly 30 years ago, which had 12 cylinder boilers, figured to develop about 200 horsepower. That mine shipped an average of 25,000 tons per month, while one of the collieries under my charge at present, shipping about the same tonnage per month, has a steam boiler plant rated at 3,000 horsepower.

The cause for such increase in steaming capacity is to be found in the many necessary slopes, planes, and shafts operated by steam machinery; electric hoisting engines and electric motors used for transportation of coal and other material; the increased machinery necessary to operate breakers and ventilating fans; and last, but not least, the high pressure and great quantity of steam required to operate mine pumps to deliver water to the surface.

The effect of all the aforesaid causes combined results in making the cost per ton of prepared coal about three and one-half times higher than it was between 30 and 40 years ago.

Of course, the much higher price paid for materials is also a great item in increasing the cost of the coal.

The danger from accidents to life and limb has increased very materially through the necessity of having to use so much more powder of various grades, to mine comparatively the same quantity of coal.

I believe that the various matters set forth in the foregoing statement will satisfactorily explain why the mining of anthracite is now so much more expensive than heretofore.

Added to this, it must be remembered that in the years from 1880-1881, the companies advanced the employes 30 per cent., which was given in three instalments; and again between 1900 and 1902 an average of about 25 per cent. was added to the earnings of the employes, and recently still further advances.

1911 Bituminous Mine Law of Pennsylvania

An Analysis of the Portion of the Law Which Will Increase Cost of Mining

(Continued from June)

Article VIII.—Signaling Apparatus, Safety Catches, Hoisting Machinery, Ropes, Boilers, and Connections

Section 1. "* * * *In all gaseous mines telephone connections shall be made from the surface to the main section of the mines.* While the convenience of mine telephones cannot be questioned, the installation and maintenance cost are naturally high, due to falls and to action of the mine atmosphere on the wires, insulation, and the telephones. "* * *, and an efficient safety device that will prevent overwinding shall be attached to every engine used for lowering and hoisting persons." This requirement for an overwinding device is new and will necessitate a considerable expenditure at shafts not equipped therewith. This section and Section 2 contain several minor requirements that are new but not important as far as expense is concerned. They pertain to cage attachments, cage testing, safety gates, and bridle chains.

Section 6. "All boilers used for generating steam in and about the mines shall be kept in good condition, and the superintendent shall have them examined and inspected by a duly qualified person once every six months, and the report of said inspection shall be posted at the mine office." This section is entirely new.

Section 8. "No boiler used for generating steam shall be placed or allowed to remain inside of any mine without the *consent of the inspector*, which shall be given in writing to the superintendent, and if the inspector allows said boiler to be placed inside the mine it shall be *enclosed in a fire-proof building within fifty feet* of the bottom of an upcast shaft, which shaft shall not be less than thirty-five square feet in area." The new law makes the allowance of an inside boiler entirely optional with the inspector and increases the minimum area of twenty-five square feet in Article VIII, Section I, in the old law, to thirty-five square feet.

Article IX.—Ventilation

Section 1. "* * * In a non-gaseous mine the minimum quantity of air shall *not be less than one hundred and fifty cubic feet per minute* for each person employed. In a mine wherein explosive gas is being generated in such quantities that it can be detected by an approved safety lamp, the minimum quantity of air shall *not be less than two hundred cubic feet per minute* for each person employed therein, and as much more in either case as one or more of the inspectors may deem requisite. The return air from each split where from *seventy to ninety* persons are employed shall be conducted by an overcast or an undercast into the return airway, which shall lead to the main outlet. In the old law (Article IV, Section 1), the minimum quantity of air for non-gaseous and gaseous mines was only *one hundred* and *one hundred and fifty* cubic feet per minute, respectively. This required increase of fifty and thirty-three per cent. will incur additional expense. It is rather surprising that the new law, like the old one, does not specify a minimum which must actually pass through the working places. The requirement to overcast the return air from each split where from seventy to ninety persons are employed puts a premium on splits with over sixty-nine men and is rather a peculiar distinction. "No permanent door shall be erected or allowed to remain in the main entry in any mine, unless its removal shall be deemed impracticable by the inspector." This is new and may lead to expensive revisions in the ventilating systems of some mines.

Section 2. "Where *five* or more persons are employed at any one time in a mine, it shall be the duty of the operator or the superintendent to provide ample ventilation in accordance with Section 1 of this article: Provided, *That it shall not be lawful to use a furnace for ventilating any mine wherein explosive gas is being generated.*" The old law (Article IV, Section 2) required ventilation only where more than *ten* persons were employed. According to Article XX, Section 1, Rule 5, of the old law, "In mines where firedamp is generated, when the furnace fire has been put out it shall not be relighted, except in his (the mine foreman's) presence, or that of his assistant under his instructions." This sanctioned the use of a furnace in a gaseous mine, whereas the new law prohibits it. "Six months after the passage of this act, not more than *seventy* persons shall be permitted to work in the same continuous air-current, unless in the judgment of the inspector of the district it is impracticable to comply with this requirement, in which case a larger number, not exceeding *ninety* persons, may be permitted to work therein." In Article IV, Section 2, of the old law, *sixty-five* were allowed, with a maximum of *one hundred* if sanctioned by the inspector. The raising of the one figure may be more than offset by the reduction of the other figure.

Section 5. "*In all mines all new stoppings in cutthroughs between the main intake and return airways shall be substantially built of masonry, concrete, or other incombustible material, and shall be of ample strength; and in mines generating explosive gas all new stoppings and the renewal of old stoppings in cross-entries shall be built of masonry, concrete, or other incombustible materials.* Stoppings in cross-entries in non-gaseous mines may be built of timber. * * * *Temporary stoppings shall be erected in cutthroughs in rooms* to conduct the ventilation to the face of each room, and such stopping may be constructed of timber or brattice cloth." In the old law (Article IV, Section 2) the only specifications for stoppings read: "And all stoppings between main intake and return airways hereinafter built or replaced shall be *substantially built with suitable material*, which shall be approved by the inspector of the district." The term "substantially built" in the old law did not necessarily mean masonry, and the above quoted specification applied to main entries only. The almost universal requirement for masonry stoppings in the new law will add considerable expense to the maintenance of ventilation in all mines, but especially those which are undergoing development. The distinction between conducting air into each room and to the face of each room has already been mentioned

Section 6. "* * * No main or principal ventilating fan shall be placed inside of any mine. No auxiliary fan, unless driven by electricity or compressed air, shall be placed in any mine. If the fan be electrically driven, the motor shall be placed in the intake airway." These provisions are new, but will not likely affect many mines.

Section 7. *In every mine all new air bridges, overcasts or undercasts shall be substantially built of masonry, concrete, or other incombustible material, of ample strength, or shall be driven through the solid strata.* In Article IV, Section 3, of the old law, these requirements applied only to gaseous mines.

Section 8. "* * * *All principal doors shall be so placed that, when one door is open, another which has the same effect upon the same current shall be closed and remain closed* to prevent any stoppage of the air-current. An attendant shall be employed at each principal door (that is, the door that controls the main air-current in the entries) through which cars are hauled. * * * Provided, that the same attendant may attend two doors if his absence from the first door does not endanger the safety of the employes. *At every door on any inclined plane or road whereon haulage is done by machinery, an attendant shall always be on duty during working hours.* * * *." The requirement for a second door to remain closed when a principal door is open is new and will be a source of considerable annoyance and delay in many mines in which hauling is done with motors, as the doors will have to be placed far enough apart to allow a motor and its entire trip to stand between them. The old law (Article IV, Section 3) permitted the same person to attend two doors if they were not over 100 feet apart, but the new law absolutely prohibits the attendant from absenting himself from a door on an inclined plane or mechanical haulage road, although it allows him to attend two doors when haulage is not done by machinery, under certain conditions.

Section 9. "No product of petroleum or alcohol, or any compound that *in the opinion of the inspector* will contaminate the air to such an extent as to be injurious to the health of the miner, shall be used as motive power in any mine." This is new and places in the hands of the inspector the right to decide whether gasoline motors may be used.

Article X.—Locked Safety Lamps and Open Lights; Defining When Either or Both Can Be Used

Section 3. "The use of open lights is strictly prohibited in the return air-current of any portion of a mine that is ventilated by the same continuous air-current that ventilates any other portion of said mine in which locked safety lamps are used. The provisions of this section shall not apply to any mine wherein explosive gas is generated only at the face of active entries." This section is new, and while the first part appears rather formidable, the latter part modifies it somewhat.

Section 4. "If at any time one portion of a mine is worked by the use of locked safety lamps while another portion is worked by the use of open lights, the return air from the gaseous portion shall be conducted directly into a return airway leading to the fan or to the outlet: Provided, That when a portion of a mine is worked by the use of locked safety lamps and other portions are worked by the use of open lights, it shall be the duty of the mine foreman to provide a suitable danger station, with an attendant on duty at all times during working hours, day and night, whose duty it shall be to see that the employes from the open light portion are not allowed to enter the locked safety lamp portion unless they are provided with locked safety lamps by said attendant." This section is entirely new, and the fact that compliance therewith as to ventilation and as to providing attendants will increase the cost of operation in mixed-lamp mines is very apparent.

Book Review

Electrical Injuries, by Chas. A. Lauffer, M. D., Medical Director of Relief Department of the Westinghouse Electric and Mfg. Co., East Pittsburg, Pa. This book is 16 mo., 77 pages. Publishers, John Wiley & Son, New York. Price 50 cents.

By prompt action at resuscitation many lives have been saved. The first 40 pages deals with electrical injuries, and factors in causation of contact burns and serious shock. This is followed by minor surgery and first aid, infections and their causes; the effects of occupation on health; and lastly by questions on the matter of the text.

The Davis Handbook of the Porcupine Gold District is issued by H. P. Davis, 25 Broad Street, New York. Mr. Davis compiled an excellent little handbook on the Cobalt district which has been of great assistance to the writer in answering questions. There are five sections in the Porcupine Handbook, with map. The first edition is 5,000, and a record of each purchaser is kept in order to supply him with revised directories. Section I contains introduction, key map, historical sketch of Porcupine, Porcupine in general, and the geology. Section II gives a directory of incorporated companies and of operating syndicates. Section III reviews the Cobalt district. Section IV reviews South Lorrain, Montreal River, and Gowganda districts. Section V furnishes general information for prospectors and mine owners. The book has 132 pages of nicely printed reading matter, illustrations, and index.

The Study of Minerals, by Austin F. Rogers, Associate Professor of Mineralogy and Petrography, Leland Stanford, Jr., University; 522 pages $7\frac{1}{4}\times5$ inches, 591 illustrations, flexible leather; price $3.50. McGraw-Hill Book Publishing Co., New York. The book is divided into eight parts, and contains a glossary, which is an added and useful feature, and is somewhat more elaborate and definite than certain other books on minerals which have recently appeared on the market. Part I, on the "Form of Minerals"; Part II, on the "Physical Properties of Minerals"; Part III, on the "Optical Properties of Minerals"; and Part IV, on the "Chemical Properties of Minerals," are arranged in an excellent manner for reference. While the book is claimed by the author to be for first-year students, we claim it is for 25- or 35-year students, for who, that is not a college professor, can do without a mineralogy after leaving the study at college?

Coal Mining in Northern China

Shallow Shafts Sunk Without Explosives and Operated Entirely by Hand—Coal and Water Carried Out on Men's Backs

*Written for Mines and Minerals by J. L. Dobbins**

Among the coal-producing regions of China, the fields of central and southern Shansi have long been considered important factors in China's source of supply. But while coal has been known to exist also in the northern part of the same province, its importance and its wide extent have only very recently been recognized to the extent of providing means for its transportation; and the development of the mines of this district has been held back to very meager proportions because of this lack of adequate transportation. So, up to the present time, the limiting bounds of these fields have remained quite undetermined, as there has been no incentive for additional touches. And at present an extension of that line is under construction, which will tap a part of this coal-bearing region which lies just west of the city of Ta Tung Fu.

Two large and distinct coal deposits have been clearly indicated by the workings already opened—deposits which are separated by several low ranges of hills, and are of apparently distinct and independent origins. These in each case have been shown to be continuous over the areas lying enclosed between extension. This is about 100 li southwest from Ta Tung Fu and about 40 li east of Tso Yun. (See accompanying map.)

The location of all these points is given in reference to their distance from Ta Tung Fu, as that is the largest city of northern Shansi, a walled city of about 200,000 population, and it is also the terminus ot the present extension of the Imperial Peking Kalgan Railway. As such, Ta Tung Fu becomes the base for all future projected transportation lines for this whole region, upon which the future of these mines so largely depends. Surveys for a further extension of the railroad westward from Ta Tung Fu to Kwei Hua Cheng have been made and its

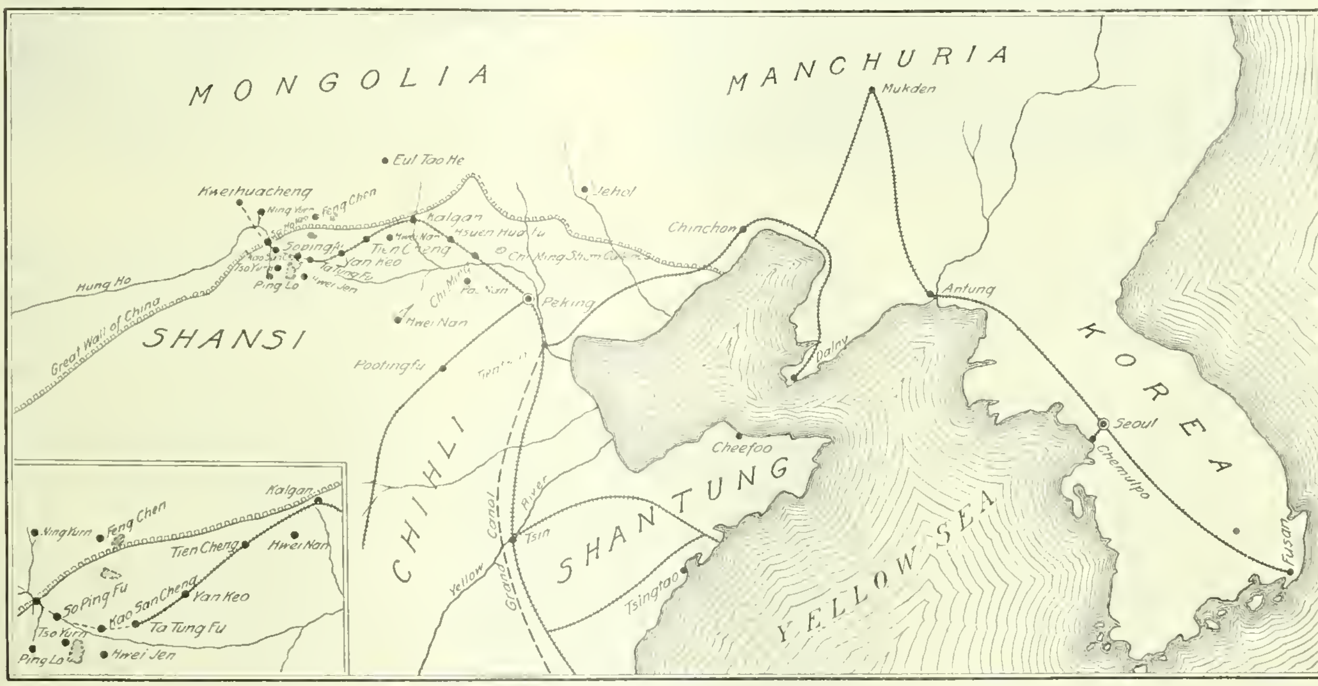

Fig. 1 Map of Part of China, Showing Coal Fields of Northen Shansi

prospecting; but the probability of the immediate advent of railroads into this field has given new impetus to the development of the mines now in it.

Mining, even by the primitive native methods, has been carried on here only during the last 35 years, and that merely to the extent of supplying the needs of local consumption within the radius of profitable haul by cart or with mule or donkey pack trains. But the large extent of the coal beds which these shallow workings have disclosed and the excellent quality of the coal produced, have led to the recognition of these northern fields as a profitable source of the future fuel supply for the Imperial Peking Kalgan Railway, and for the cities which it the present workings, but to what extent they continue beyond these is entirely unknown, as definite limits of the coal seams encountered have not been reached in any of the workings.

One of these districts lies north and west of Ta Tung Fu, its nearest mine being about 40 Chinese li† (13 miles) from that city. This deposit has been known for about 35 years and has a present proved area of about 150 square li, the axis of which extends in a northeasterly to southwesterly direction for a length of about 30 li. The second field, which is of more recent discovery, is of much larger known area, and also farther from the city and the present railroad construction decided upon, but at present Ta Tung Fu is the nearest point for rail connection.

During a recent trip by pony across northern Shansi, the writer had opportunity to visit the more distant of these coal fields; and as the conditions obtaining there, and the general methods of operating, were quite typical of all the native mines of Shansi, a description of these as found will be given.

This trip was made during the wet season; and out of a total of eight mines visited, three were flooded and could not be entered on that account. One other, known as the Pai Tso Wang Kwang, was worked through an adit which had been driven along an almost horizontal coal seam which outcropped on the side walls of a deeply eroded ravine. This was a

*Professor Railway Engineering, Imperial Pei Yang University, Tientsin, China.

† The Chinese li is the usual measure of distance. It varies in different localities, with an average value of $\frac{1}{3}$ of a mile

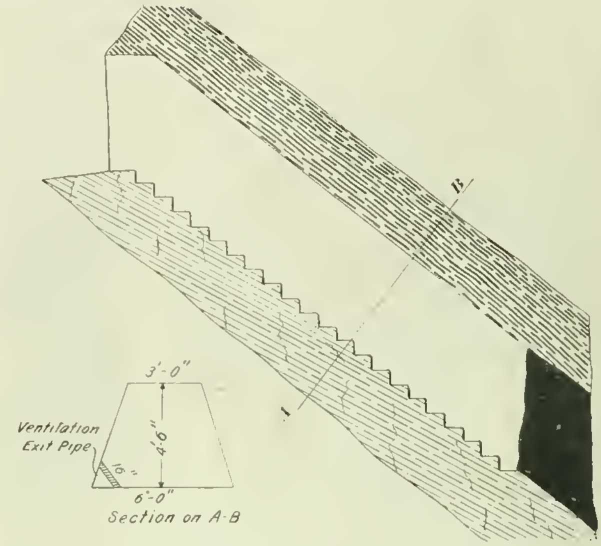
newly opened mine, having been worked for only three years, with a force of about 15 men; and this one seam, of an average thickness of 7 feet, constituted the entire known coal of the mine, for no further prospecting had been attempted or even thought necessary so long as the coal in sight seemed to be sufficient for the needs of the immediate future. The development had been confined to this one level only, and had been without dead work, as the adit right from the surface lay in good coal, and all subsequent cross-cutting had also been entirely within it. The dip of the seam was followed on approximately a minus 2-per-cent. grade, quite without regard for drainage; but fortunately in to the 480-foot depth already penetrated, the seam had proved to be very free from water. That which did accumulate in the sumps dug for the purpose was easily disposed of by two coolies employed in carrying it out, each man working a total of about 8 hours a day.

This mine was worked on a sort of cooperative basis, with an output ranging from 4 to 6 tons a day, according to the demands of the immediate market. The men who operated it regarded it as a very profitable undertaking.

Analyses of samples taken at this mine show the coal to be a bituminous coal high in volatile matter and in sulphur, and very low in its percentage of fixed carbon. The following is the analysis: Moisture, 9.47; ash, 11.18; volatile matter, 30.92; fixed carbon, 45.45; sulphur, 2.98.

These results, when compared with those from the other mines of the district, indicate also that this seam is entirely distinct from those found in the other workings, all of which showed very close agreement in the analyses of the samples taken from them.

ENTRANCE TO MINE OWNED BY MR. TU, WHO STANDS AT RIGHT OF PICTURE



SECTION ON TYPICAL INCLINED SHAFT

Of the other mines visited, all were worked with two shafts each, one an incline for entrance and for carrying out coal, and the other a nearby vertical shaft for the sole purpose of hoisting water. This arrangement of shafts, each with its particular function, seems to be typical of all the mines of this region, and is accounted for as an outgrowth of the method of bringing all the mined coal to the surface on the backs of the miners, up the incline shaft. Water was at first also handled only in this way, but in most cases where the flow increased until this was found to be insufficient for removing it all, the vertical shaft and windlass were used, but always for water only.

VENTILATING FURNACE AT INCLINED SHAFT, CHINA

At all the mines of this district, the surface formations and the strata penetrated were quite the same. The shafts first cut through the surface layer of loess, whose thickness depended upon the amount of surface erosion, and then through a single stratum of limestone which merged at depth into a fine-grained, compact shale of great transverse strength. This was bedded almost horizontally, with a dip of about 3 degrees to the west, the thickness ranging from 75 to 90 feet. Just below this and the underlying thin stratum of slate, the first coal seams were encountered. In all but one of the mines visited, no attempts had been made to explore to any greater depth, and the workings were confined to the first seam of paying thickness that was encountered.

This was due partly to the difficulties involved in sinking farther in the presence of the relatively large flow of water without adequate means for handling it, and largely also to the fact that the output from a single seam was usually more than sufficient to supply the limited demand for the coal. In the one case, in a mine owned by a Mr. Tu, in which the shaft was sunk beyond the first seam, three more seams were cut in a depth of 23 feet, of 2½, 7, and 4 feet respective thicknesses, separated by 3-foot layers of shale. In this case it was later explained to the writer that this additional depth had been sunk merely in order to provide a sump for collecting the water to be hoisted from the mine, rather than for prospecting, and this sump had been sunk only 4 feet below the foot-wall of the last coal seam encountered.

These shallow workings, located but a mile or two apart throughout this district have been sufficient to block out a very large tonnage of excellent coal, lying very near the surface, and which can be easily mined in commercial quantities when modern methods and machinery are used; and while they set the lower limits of the tonnage in sight, the full extent of these deposits can only be guessed at until diamond drills have been brought on the ground, and systematic prospecting has determined the depth and the lateral limits to which these fields extend.

Small ranges of low rolling hills of loess are the surface indications characteristic of this entire region, in which the underlying sandstone can only be seen at points of deepest erosion. And in the absence of any evidence to the contrary, the existence of a continuous coal bed is probable, extending even beyond the present proved area. This Tso Yun district is now marked out by workings that extend 50 li in a north and south direction, with width varying up to 12 li.

"Hoisting" 220 lb. of Coal from Chinese Mine

Coal Stock Pile at Mine of Mr. Tu

The coal from all the different workings here has the same luster and hardness and shows the same resistance to slaking and weathering when exposed to the open air. The coal is bituminous, and assays of samples taken from four different mines gave the following average results:

Moisture, 8.85; ash, 2.99; volatile matter, 22.60; fixed carbon, 65.20; sulphur, .36.

The very slight variations from this general average in the analyses of individual samples from the several different workings, together with the entire absence of any surface indications of faulting, and the very uniform depth at which the coal was encountered in the different mines, all point conclusively to the continuity of these seams throughout this area; while the different quality of the coal obtained from the Pai Tso Wang Kwang, and the higher elevation at which it was found there, show this seam to have been of independent, and probably later, origin than the other deposits.

The small depths to which it has been necessary to sink to reach this coal, together with the compactness and strength of the overlying strata, were all favorable to the methods used by the Chinese for mining and handling the coal. All the sinking was done entirely without the use of explosives, and the shafts were cut through the solid rock to exact dimensions by the slow method of drilling and wedging the larger pieces out, and then dressing the sides and top to size by chiseling.

The dimensions of the vertical shafts for hoisting water were usually 4 feet by 6 feet, and the inclined shafts were always of trapezoidal section, about 6 feet at the base, 3 feet at the top, and about 4 feet 6 inches high, these dimensions being for a section perpendicular to the axis of the shaft. These inclines were at angles of 38 degrees to 40 degrees with the horizontal, so the section of a vertical plane through them would be about 5 feet 10 inches high. All the shafts were entirely without timbering except at the surface; and the steps for the inclines were cut in the solid stone, in situ, across the entire width of the base. These were roughly cut out at the time of sinking and later chiseled to regular size.

View Down Incline. Note Regularity of Section, the Steps, and Mud-Plastered Ventilating Pipes at Right

The incline is the only means used for entrance and exit from most of these mines, the vertical shaft being used only for water; and all of the coal and frequently much of the water, too, when the hoist alone is insufficient to keep it down, is carried up the incline on the backs of the miners. The wear on these steps which such heavy usage would otherwise cause is much lessened by the fact that these carriers are usually barefooted; they also are generally burdened with very little other apparel of any kind except the shoulder pads and heavy leather harness with which they secure their heavy loads of coal to their backs.

Partly because of this method of hoisting the coal to the surface and partly because of the subsequent long haul over the uneven roads which is necessary to reach any market, the coal is carefully blocked out and mined in large lumps, all pieces whose greatest dimension is less than 6 inches being thrown with the waste and the dust coal, and used to back fill the stoped-out chambers. In the mines visited, the writer estimated this loss in dust and small lumps left in the stopes to be from 30 to 35 per cent., much of which would be saved were a different means of tramming and hoisting in use.

Where the seams mined were thick enough for a man to walk erect in the excavated chamber, the lumps of coal are loaded on to the carrier's back right at the face of the workings and he then proceeds out through the long, tortuous and usually low passages and up the incline without any relief from his load until he places it on the stock pile near the mouth of the incline. The loads handled in this way by one man are sometimes enormous, the writer having on one occasion seen a man bring out on his back a lump which weighed 180 catties* (240 pounds), and later noticed several lumps on the stock pile which weighed over 200 catties apiece, all of which had been brought out in the same way.

While the extreme cheapness of labor has made this method of handling the coal possible and in most cases apparently satisfactory for the small tonnages required to supply the limited demand, the lack of pumps has been a more serious difficulty when the flow of water in the mines has been large.

In some cases this inability to handle the water has been the cause of entirely stopping operations, and in many others the expense of operation is divided, with the larger portion devoted to unwatering the mine and the smaller to the actual cost of handling the coal.

At Hsien Lung Kow, the most southerly of the mines in the Tso Yun district, continuous hoisting with balanced buckets on a windlass was not sufficient to keep the water down, and an additional line of water carriers was steadily at work in the incline. Here the coal seam was 7 feet thick with a dip of almost 4 degrees to the west, so that by properly conducting the water to the sump just to the west of the foot of the incline, where both bucket hoist and carriers kept it down, the development work could go on in the eastern part of the mine. This was a new mine with only a small force of men at work, and no coal was being mined, except that taken out in development work in driving along the seam; but the following division of labor which obtained there between unwatering and mining illustrates by an extreme case the proportion which this unwatering may bear to the total expense where pumps were unknown.

Here the vertical lift at the hoist was 85 feet, and a 30-inch drum hoisting two large wooden buckets in balance was operated by four men, averaging 72 seconds a round trip and raising about 1,300 gallons per hour. Two shifts of men, 12 men a shift, were carrying water up the incline, in woven willow pails slung from poles which they balanced on their shoulders, leaving one hand free to help them climb. They carried about 10 gallons a trip and were paid by the trip. Each shift consisted of 350 trips for which the carrier was paid 350 copper cash, equivalent to about 19 cents United States gold. The men at the hoist received the same pay as the miners, 240 copper cash a day, for shifts of about 10 hours. There were thus required for this unwatering 36 men a day, including two bosses and two tally men, to handle 110,000 gallons, while only 16 men, in two shifts, were engaged in actual mining.

*A catty is exactly equivalent to 1⅓ pounds.

The Tiao La Sü mine, in about the center of the Tso Yun district, is less troubled by water than the above rather extreme case, and affords an excellent example of successful operation of one of these mines on such a scale as these methods permit. This mine was opened in 1903, and has since then maintained an average daily output of 30 tons a day of lump coal, all of which has come from a single 7-foot seam, 100 feet below the surface. Here one shift of six men, working 8 hours a day, was sufficient to hoist all the water, which was allowed to collect in the sump during the rest of the day. The entire force of men at work numbered 42.

The sump and the vertical shaft were located some distance to the west of the incline at the lowest point of the workings, as the seam also dipped slightly to the west. Below the incline and around the sump, pillars of coal were left in place to support the overburden, and the stopes were run out radially from a point near the foot of the incline, giving the stoped-out chambers a fan-shaped appearance as the supporting walls diverged from each other. An extreme case of this was evident in one chamber, the working face of which had a clear width, as paced, of 210 feet and an unobstructed length, radially, of over 100 feet to the nearest supporting pillars. The seam here was of very uniform thickness, and being almost horizontal, the excavated chamber had the appearance of a 100′×200′ room with a low horizontal roof, entirely unsupported and held up only by its own beam action. The older workings of the mine showed some signs of bad caving, but the limestone roofs in the newer stopes had stood without any signs of failure, despite their unusually great unsupported spans. The coal here was mined in large lumps with very little waste, as the uniform thickness of the seam made the undercutting and breaking out of large blocks easy. The piles of waste used for backfilling were therefore rather widely separated.

Ventilation was very simply secured in this mine by keeping a coal fire burning near the sump at the foot of the vertical shaft. This was sufficient to create the necessary updraft there; and the two drifts connecting this shaft to the rest of the workings were both fitted with doors, so that either could be closed when the other needed the ventilation. The down draft was always down the incline.

In the other mines ventilation was obtained by means of a suction stove placed at the mouth of the incline, the air pipe for which was merely a triangular wooden trough leading from the workings below. This was placed in the lower corner of the incline and sealed with mud plaster. These stoves were usually conical, built up of brick and mud, from 5 to 7 feet in diameter and 20 to 25 feet high. The down draft entered through both shafts. As no explosives were used and the coal itself was rather free from noxious gases, this simple means of ventilating gave very satisfactory results.

Because of the cheapness of labor, and the ability of the Chinese miners to do hard work, coal is produced at these small mines at such low cost that it can be sold at a profit for ½ cash per catty for lump coal at the mouth of the mine, which price is equivalent to about $.37 in gold a ton. The individual outputs of these several workings are small, averaging under rather than over 15 tons a day scattered throughout *all* the different coal fields of the province and their total output is even now very considerable. And they are the forerunners of a later extensive development that will come with the advent of adequate transportation facilities and the subsequent installation of modern machinery and modern methods. And by blocking out immense tonnages of coal, they have prepared the way for the advent of the railways, and have assured them of a large traffic whenever they are prepared to handle it.

ORE MINING & METALLURGY

Ore Loading on the Island of Elba

Methods Employed for Transporting Iron Ore and Loading It Into Ships Under Difficult Conditions

Written for Mines and Minerals

THE Elba Mining Co. possesses on the island of Elba rich and extensive deposits of iron ore which is smelted and fabricated in its blast furnaces and steel works at Portoferraio and Follonica. The Savona company, which works Elba iron ores in its plants at Bagnoli near Naples, likewise takes some part of the production. The ores are also smelted at the Piombino iron works.

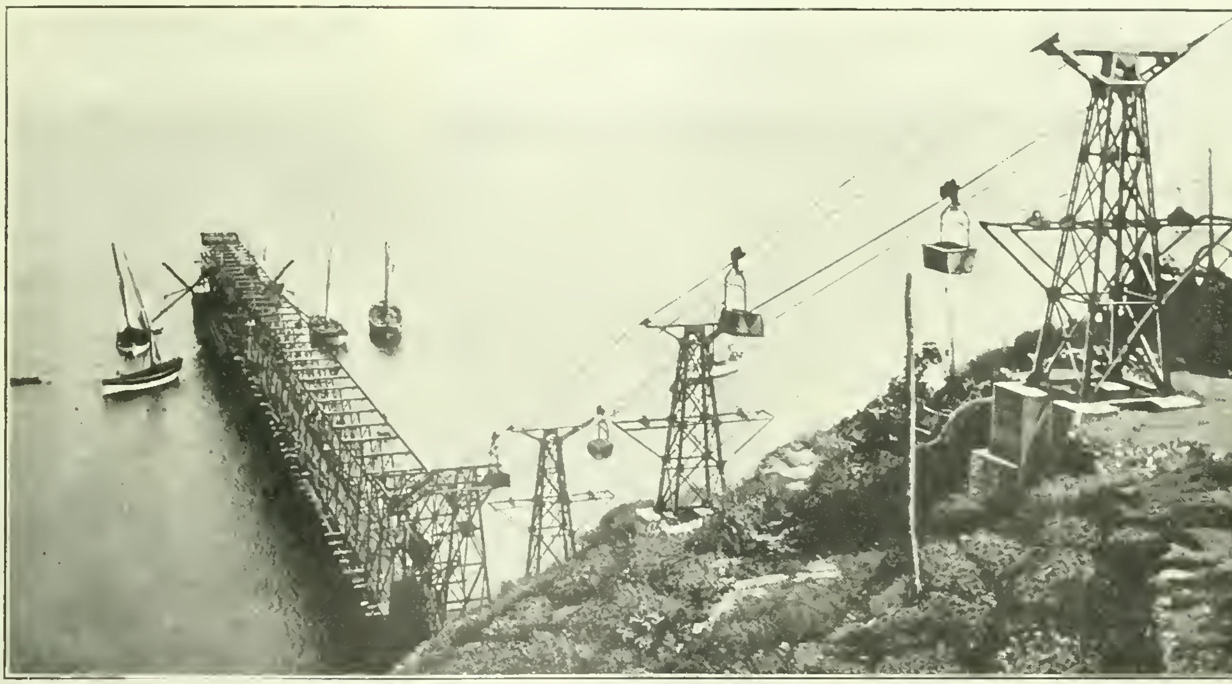

FIG. 1. LOADING PIER IN THE SEA, RIO ALBANO MINE, ISLAND OF ELBA

The main deposits are situated on the precipitous east coast in the mountains north of Rio Marina where the promontory of Pero rises nearly vertically from the sea with the peak of Callendozio on the summit in which are found the important Rio Albano ore deposits. To the north of Callendozio is the Giogo, another ore producing hill, which is popularly called Giove (Jupiter), it being supposed that some ruins there found are those of a Jupiter temple. This deposit is worked in the two mines of Zuccoleto and Rosseto. The most extensive deposits, however, are near Rio, on the same coast. It is estimated that these contain some 11,000,000 tons, and they are worked in a number of mines. Other important deposits are found at Calanita.

The ore is a hard spathic brown ironstone of compact, or crystalline, structure with traces of ocher veins. It is mined by open cut, especially at Giove Portello, where the best class of ore is found. Fig. 5 shows a mine working in the Rio Albano deposits. In the whole mining district about 2,000 men are employed. The inhabitants of this district formerly were fishermen or else peasants who cultivated figs; in view, however, of the progress made in the Italian mining industry, the fishing boats have been abandoned and the fields left untilled, the work in the mines being so much more lucrative.

The ore is hauled over narrow-gauge railways, by horses or locomotives. Difficulties were experienced in transporting the ore to the coast and in loading the richer ores into steamers of 3,000 to 4,000 tons capacity for shipment to Naples and Piombino, the lower grade ores going by the shorter route to Portoferraio in sailing vessels of 150 to 600 tons capacity. These difficulties are due not only to the transference of the ores from the shore to barges and their conveyance to vessels in the open sea, but to the fact that the sea on this exposed coast is only sufficiently smooth for about 150 days in the year for the ores to be loaded in deep water. This is why the ores had to be loaded in as large quantities as possible in a minimum time, for which, as a rule, empty ships in sufficient numbers were available. In fact, serious difficulties in the service were not anticipated before the Bagnoli blast furnaces, near Naples, approached their completion, the first two being started in 1910.

The mining company therefore was compelled in 1909 to consider the question of loading the ships by mechanical means. The most important condition to be accounted for in this connection was the necessity for an output of about 200 tons per hour, thus allowing the few days with favorable weather to be taken full advantage of. As the vessels cannot approach nearer to the shallow coast than from 100 to 200 yards, it was further necessary to carry the loading plant to a considerable distance into the open sea.

The first solution suggested was the construction of a masonry mole on which the mine cars could run. This would, however, have acted as a breakwater on such an exposed coast and a construction of unusual strength would have been necessary. It is also questionable whether a structure of this kind could have been completed in the course of a year. Such a mole would, moreover, have acted as a sand catcher, gradually extending the shallows to the extremity of the mole. A pier resting on piles would doubtless have been a more satisfactory arrangement as the thin driven piles would not act as sand catchers and would afford the additional advantage of offering a comparatively small resisting surface to the action of the waves. Another alternative for loading the ships was the construction of a wire-rope tramway. In spite of the high capacity of 200 tons per hour there was in fact, the possibility of connecting Rio Albano and Giove Portello with a ship-loading station out at sea, in a single span of 350 to 650 feet. An isolated ship-loading station in the sea would, however, have necessitated a foundation on caissons which would have involved a very considerable additional outlay, whereas a pier built of railway rails—in accordance with the local practice—would have been far less expensive. These considerations led to the adoption of a loading pier.

Relative to handling the ore on the pier, there were two possibilities, according to whether a surface railway or an aerial line was chosen. The former would have necessitated various intermediate appliances such as gravity planes, and the automatic return of the empty cars which would have caused difficulties, and the construction of the pier would have been comparatively heavy and expensive. This is why a Bleichert aerial tramway was finally adopted.

The plan as adopted and completed, provided for two smaller aerial tramway lines, one for Rio Albano and another for Giove Portello, and both have proved a simple and economical solution of the loading problem. The ore arriving in mine cars is dumped at the mine into the hopper bins shown in Fig. 2 from which the ropeway buckets are loaded. These hopper ore bins are of masonry, with inclined floors for the pockets, 12 being installed at Rio Albano with a length of 167 feet, and 24 at Giove Portello with a total length of 265 feet, from six of which the ropeway buckets are simultaneously loaded by means of gates. The buckets, which are designed for a load of 20 hundredweight of ore, are weighed after loading and automatically registered by three self-acting scales fitted for this purpose on three parallel branches in the suspension railway sections of each loading station, after which they are pushed from the station on to the open track, where they are coupled automatically to the traction rope which is in continuous motion.

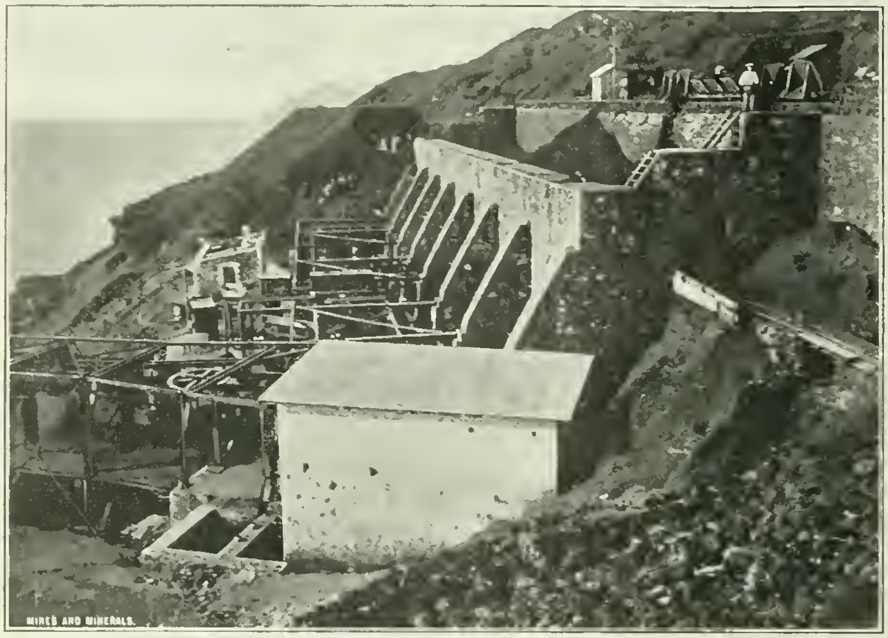

Fig. 2. Ore Hopper and Loading Station for Tramway

The open track consists of steel wire ropes on which the carriages of the buckets run. These ropes are anchored in the loading station, and as will be seen in Fig. 1, the carrying ropes are supported by iron towers. The line has heavy gradients on which the Bleichert coupling apparatus grips the traction rope with absolute safety. On the shore are erected several supports between which the deflection of the carrying ropes is compensated by means of heavy tension weights. In this manner it is quite impossible to overload the ropes. The tension appliance is shown in Fig. 1, near the shore, also the construction of the pier of railway rails. Fig. 1 also shows the whole plant in the sea for the Rio Albano line. The supports carrying the fixed suspension rails which form the continuation of the carrying ropes over the sea are arranged on the pier. The traction rope is also guided along this section, and is deflected at the end of the pier construction by a deflection sheave. The height of the suspension line is $42\frac{1}{2}$ feet above sea level, so that vessels can be conveniently loaded from above at any stage of the tide. The loading pier for the ships is 10 feet in width, expanding 100 feet from the end to a platform 30 feet wide. Here the ships are loaded by hoppers and chutes into which the tramway buckets are tipped automatically.

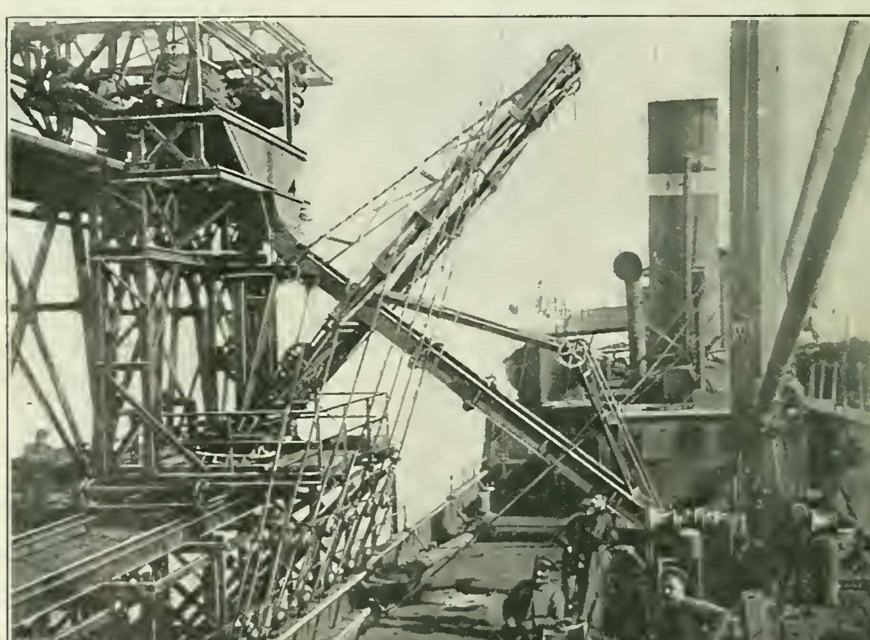

Fig. 3. Movable Loading Chutes at End of Pier

The hoppers for the transference of the ore are portable as shown in Fig. 3, the chutes being raised by a rotary crane and moved to one side, so that they can be easily pushed past the vessels lying at the pier. Only one chute is fitted on each side of the pier. The buckets discharge their contents into one or other of the chutes, in accordance with the position of the hopper, so that the traffic can proceed without interruption. The passage of the buckets around the return sheave at the extremity of the pier is automatically effected without detaching them from the traction rope, therefore no men are required on the pier to attend to the line except those shifting the hopper and chute from time to time.

The Rio Albano line is 1,000 feet in length, with a fall of about 160 feet. Some 200 buckets are handled per hour, which follow one another at intervals of 18 seconds, so that with a speed of the traction rope of 4 feet per second the distance between the buckets is about 70 feet. There are therefore always 28 buckets on the rope and six in the loading station for loading and weighing. The staff required for attendance on the line, including the hands engaged at the hoppers and the weigh scales, consists of 25 men; three men on the loading pier assist in towing the ships. As the line has a fall in favor of the traffic, an excess of 30 horsepower is produced, which is utilized to drive a pump for the ore washery, the uniformity in the speed of the line being maintained by an automatic brake regulator.

The Giove Portello plant, shown in Fig. 4, is designed exactly like the Rio Albano plant, and shows that the ships being loaded do not touch the pier, hence their movements cannot interfere in any way with the process of loading.

The line has a length of about 2,460 feet with a fall of 395 feet, producing a surplus power of 70 horsepower which is neutralized by a wind-sail brake.

Fig. 4. Giove Portello Loading Pier

The capacity of the two lines is 200 tons per hour. When the distance between the buckets is relatively small, the time intervals between them (18 seconds) are not the smallest attainable. On an ore loading line at Vivero, Spain, where 250 tons per hour are handled, the buckets follow one another at intervals of 14.4 seconds; but a further reduction in this direction will hardly be possible. Other measures, such as the use of double carriages or the installation of double ropeways, will therefore have to be taken, in order to further increase the capacity of aerial railways.

Fig. 5. Rio Albano Mine

[The method of loading iron ore into ships at Elba differs materially from the practice followed in Cuba by the Spanish-American Iron Ore Company, where shore conditions are somewhat similar. Without in the least detracting from the merits of the wire rope tramway, for it has no equal in some situations, it is probable that American engineers would have arranged the ore bins nearer the shore and then used an endless conveyor belt for carrying the ore to the point where it is loaded into the ships. While the capacity of 200 tons per hour is excellent for two wire tramways, it would require 25 hours to load a 5,000 ton vessel, where the traveling belt will load such a boat in 10 hours and at a cost of one cent per ton.—Editor.]

Gold and Tin Production of Seward Peninsula

The gold produced in Seward Peninsula, Alaska, for 1911, had a value of $3,100,000, which was a decrease of about $400,000 compared with the figures for 1910. This falling off, according to P. S. Smith, of the United States Geological Survey, is attributable to three main causes—first, a decrease in the amount of winter mining; second, a general decrease in the number of mining operations, except dredging; and, third, the handling of low-grade material. All these causes may be referred more or less directly to the exhaustion of the known rich bonanzas before enterprises have been established capable of handling cheaply the large amounts of low-grade material which are known to exist on the peninsula. From this statement it may be inferred that at some future time the gold production of the Seward Peninsula will increase.

Although practically all the mineral production has been derived from gold placers, interest has been renewed in the tin deposits, and a production of nearly 100 tons of concentrate, worth about $50,000, is reported from the tin placers on Buck Creek.

Not only has dredging for placer tin been carried on, but certain lode tin mines near York have been reopened under the superintendence of a competent mining engineer. It is understood that the company intends to ship the tin concentrate to Seattle, where it will be smelted.

Mining by Timbering and Filling

Timbering Methods and the Filling System as Employed by the Homestake Mining Co., Lead, S. Dak.

*Written for Mines and Minerals by Albert L. Toenges, E. M.**

Before describing the mining methods at the Homestake mine, it will be well to explain the geology which has, to a large extent, been responsible for the abandonment of the older methods of working and has necessitated the evolution of the present system.

The Homestake mine is situated at Lead, S. Dak., in the northern part of the Black Hills. The Black Hills consist of rocks from the Archean period to the Tertiary period. The rocks are Algonkian schists, slates, and quartzites; Cambrian quartzite; Ordovician schist; Carboniferous limestone; Jurassic and Triassic sedimentaries; and Cretaceous limestones. At the end of the Cretaceous period, the Black Hills region was slowly uplifted into a quaquaversal fold—or great dome-like, anticlinal mound—the strata of which dip away in all directions toward the surrounding plain. Tertiary rocks were then deposited, but erosion has removed practically all of these. The older schists and those sediments deposited upon them were intruded by volcanic rocks.

The most important deposits of gold are in the crystalline schists as impregnations that appear to have taken place along two converging zones of crushing, one striking N 10° W, and the other N 30° W. There are evidences of several periods of mineralization, all along the same channels. The deposition of pyrite and gold was at the period of, or subsequent to, the intrusion of Tertiary flows of rhyolite-porphyry. The ore-bearing zone is approximately one-half mile wide and several miles long, with a general course of N 35° W.

The ore occurs in lenses of great extent. Some of these ore bodies attain a width of 500 feet. They dip to the east at steep angles, and pitch to the south. The large lenses are along the west side of the mineralized zone; while, on the east, there is a series of smaller, parallel lenses, some of which join the larger in depth. Near the surface, the ore bodies follow the rhyolite intrusions, but at depth, diverge from them and become associated with phonolites. The ore is quartzose, chlorite, and amphibole schist, carrying pyrite, pyrrhotite, arsenopyrite, and occasionally chalcopyrite. The accessory minerals are dolomite, calcite, garnet, tremolite, and asbestos. The distribution of the gold seems to be independent of the accessory minerals. In the upper levels, the gold seems to be associated with arsenopyrite, while below it is associated with pyrite. On the 100-foot level ore was found that was chiefly pyrite running comparatively high in gold. Over 60 per cent. of the gold is free milling, the remainder, associated with pyrite and arsenopyrite, must be treated in the cyanide mills. The Homestake Mining Co. has, at the present time, 1,000 stamps in its mill.

The lowest workings in the mine are on the 1,700-foot level. The Ellison shaft is, however, sunk to 2,000 feet.

The ore body was first mined by means of an open pit. The gold taken from this oxidized zone was about 72 per cent. free milling. Later on, the Star shaft was sunk in the lode and the Homestake company thereafter incurred heavy shaft maintenance expenses because of the movement of the ore body. When underground methods were first adopted, the stopes were worked by the use of stulls, for the ore bodies were not then of extensive widths.

However, as depth was gained, it was found that these ore bodies became wider and, in fact, joined together, and they became too wide to be mined by using stulls. It became necessary, therefore, to adopt the Deidesheimer system of square-set timbering, or the style of timbering originally used in the large ore bodies of the Comstock Lode, in Nevada. This system of timbering was revised somewhat from time to time. Ordinary square-set timbering was used until the ore bodies became of such great width that is was found impracticable. The old style of filling system, called the Homestake system, was next adopted. It was found, however, that less timber could be used, so still another system was devised and, at the present time, it is being used on all the lower levels of the Homestake mines.

Until recent years, as explained, the system of mining was that of stoping and timbering entirely with square sets. At the present time, the use of square sets is limited. Originally, the timbers for the square sets were all dressed, but now only rough timbers are used in stopes, and the only framing done is the making of the tenons. All shaft frames, however, are of dressed 12″×12″ timbers.

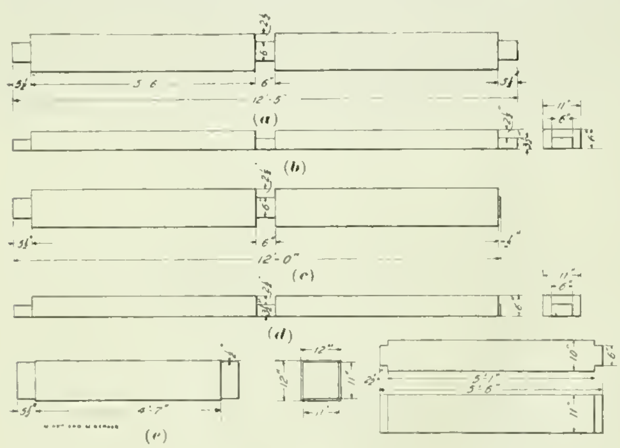

Fig. 1

Fig. 2

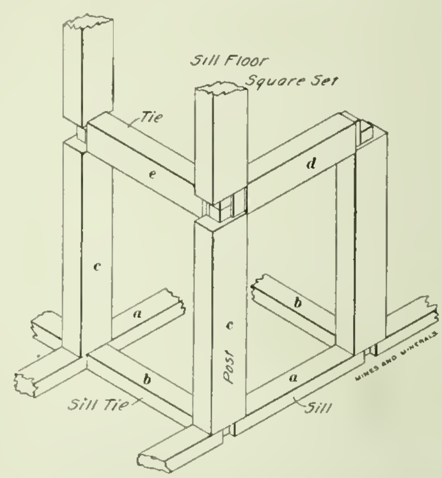

Fig. 3

The timber-framing shop is near the Highland shaft. The timbers are usually left round and cut into the various lengths, as follows: Sills, 12 feet; ties, 5 feet 6 inches; caps, 5 feet 6 inches; sill-floor posts, 8 feet $9\frac{1}{2}$ inches; second-floor posts, 8 feet 5 inches; lagging 5 feet 10 inches.

The sills are cut as shown in Fig. 1 (*a*) and (*b*). They are framed on two sides to about 6 inches high. Sill-floor ties, Fig. 1 (*c*) and (*d*), are also framed to 6 inches high. The machine for framing the ends of the timbers was designed by a Mr. Balentine. The framing of the cap timbers (*e*) and the tie-timbers (*f*) is also shown in Fig. 1, while Fig. 2 (*a*) shows the sill-floor post and Fig. 2 (*b*) the posts above the sill floor. The framing of a post, cap, and tie costs 60 cents. Cut-

*Trinidad, Colo.

ting and sawing lagging costs 5 cents per running foot.

In the erection of a nine-post set, a gang consisting of a timberman and his helper is required. A nine-post set requires three

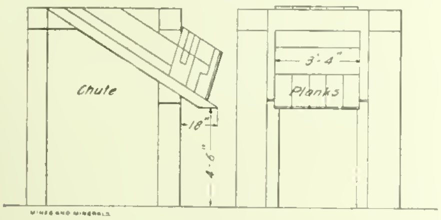

Fig. 4

sills, nine posts, six caps, six ties, six sill ties, and about 38 pieces of lagging.

The sill floor of the stope is first leveled. The sills *a* are then laid flat on lines set by surveyors, as shown in Fig. 3. These sills are leveled up and blocks placed under the end and middle of each. This gives each sill a smooth, bearing surface. The sill ties *b* are next placed in position and the sills and ties centered. The posts *c* are next stood, and after these, the caps *d* and ties *e* are joined with the upper ends of the posts.

After all timbers are in place, the entire set is trued by a plumb-line, and braces are placed from the set to the walls of the stope. The set is made rigid by means of wedges driven in between the walls of the stope and the braces. The number of braces required depends upon the condition of the walls of the stope, whether they are cracked or solid, and the ease with which the set can be braced to form a rigid structure. Each wedge used is 4 in.$\times 12\frac{1}{2}$ in. $\times$2 in., tapering down to an edge.

After all the braces are in place, and before the lagging is put in, pieces of wood $2\frac{1}{2}$ in.$\times 2\frac{1}{2}$ in.$\times$4 ft. 6 in. are placed along the caps. These planks are known as "lagging strips." Lagging is now put into place, and held there by the lagging strips. All weight is borne by the caps.

Stoping.—The stope is now ready for further development. Drill runners will set up their machines upon the lagging and drill. They will then blast down the back on to the lagging. An 8-hour shift in a stope consists in setting up a piston rock-drilling machine, drilling two 6-foot holes, tearing down the machine, loading the holes, and blasting. Ingersoll-Rand rock drills are used. The rock is thrown through a set of lagging if no chute has been constructed. When enough rock has been taken out for another set of timbers (four posts, two caps, and two ties), a windlass is placed over the first set, and the timbers hoisted and erected. When enough rock is excavated, the set is ready for two more posts, two caps, and one tie. This will complete the second floor of the nine-post set.

By this time—or probably before this—it will be necessary to build a chute. The details of an average chute are shown in Fig. 4. Chutes are usually 3 feet 4 inches wide, and are built of either 3-inch or 4-inch plank. Some chutes are lined throughout with sheet iron, one-eighth inch thick. The usual practice is, however, to place sheet iron on the bottom only of the chute. This makes the ore run considerably better than if the chute be not lined. It is the usual practice to put in a chute before starting a second floor to the stope. In regular stoping, there is usually employed a machine man, one helper, one "block holer," and two shovelers. There may be but one shoveler and no block holer, if the broken rock is not large. A "block holer" is a miner using a small "Jap" air machine to drill holes in large rocks and breaking them by means of powder.

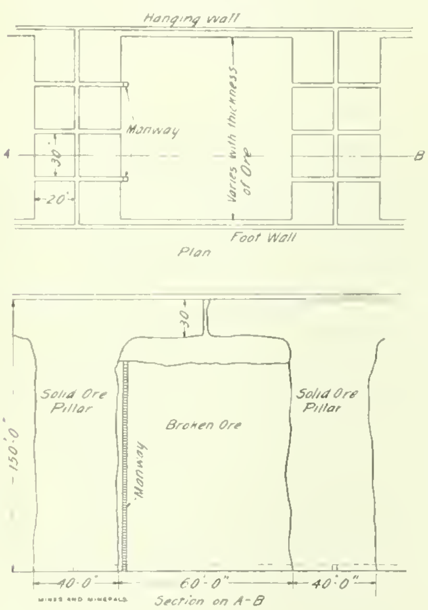

Fig. 5

Two gangs of timbermen (four men) can set up nine posts, six caps, and six ties, brace them and lag over the whole set in 8 hours. From this, the cost of one floor of square set can be figured as follows: Labor: Two timbermen, at \$3.50, \$7; two helpers, at \$3, \$6; Timber: Nine posts, at \$1.27, \$11.43; six caps, at 88 cents, \$5.28; six ties, at 92 cents, \$5.52; 38 lagging, at 25 cents, \$9.50; six lagging strips, at 4 cents, 24 cents; 30 wedges, at 1 cent, 30 cents; a total of \$45.27.

The prices on the timber may vary somewhat, but the above is a fair estimate of the cost of erecting one floor of a nine-post set. The prices given for the timbers include the labor in sawing and framing.

When a raise has reached several floors, it is desirable to build in a bin. The purpose of this bin is to keep the broken rock nearer the chute. A bin is made by lacing up three adjacent sets of timber, using 2-inch planks for the purpose. Before the lacing is put in, the caps and ties are protected by what are known as grizzlies. A grizzly is a piece of timber 6 feet 10 inches long and usually about 12 inches in diameter and two of these are placed across the caps, parallel to the ties. A lagging is cut to fit between these two grizzlies and to act as a sprag. There are two laggings placed, one on each cap. The caps and ties of the middle set of timber only are thus prepared, and this set acts as the chute or opening through which the material will be thrown to the floor below.

A tunnel set consists of two 6' 10" timbers for posts, and a 6' 8" timber for a tie The only tunnel sets used are in the cross-cuts through old stopes, and they are placed in the sill and between the sill-floor posts. They are placed close together, for the purpose of supporting the waste rock in filled stopes.

The writer had no experience in shaft timbering, but obtained the information contained in the accompanying figures from persons familiar with this work. One and one-eighth-inch rods are used as hanger rods in the construction of shaft sets.

The Homestake Stoping System.—The ore is low grade, averaging about \$3.86 a ton in gold. To make this material payable a large tonnage with low mining and treatment costs is necessary, and to meet these conditions the "Homestake system of stoping" was devised. This system will be explained by following its use in the development of territory tributary to the Golden Star shaft, which is sunk in country rock rather than in the lode formation.

First, a cross-cut is driven from the shaft into and through the ledge of ore. A drift is then excavated in the foot-wall north and south from the cross-cut. All stopes will be numbered from this cross-cut and "Stope No. 2, South" should thus be the second stope south of the cross-cut.

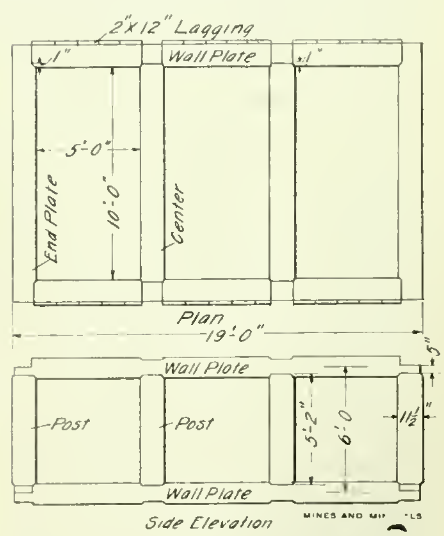

Fig. 6. Ellison Shaft Timbering

From the drift in the foot-wall, rooms or stopes are opened 60 feet wide and are spaced to leave intervening pillars of ore also 60 feet wide.

The rooms are driven from the foot-wall

to the hanging wall, irrespective of the distance, and about 10 feet high and all the ore thus broken is removed. A complete sill floor as for a timbered stope is put in and lagged over, and three lines of sets parallel to the strike of the lode are lined over doubly. One line of these sets is in the foot-wall, another line of sets is in the center, and the third line is in the hanging wall. A track is laid in each of these passageways. There are cross-connections between these trackways, placed as may seem convenient.

Ore is broken down as soon as the timber is in position. The lagging over all the sets—except the track sets—is used as temporary staging and is removed when the sets are filled with broken ore. The track sets are laced and kept intact, but the ore as broken from the roof is allowed to fill all the other sets. Some of the lacing is then removed from the sides of the trackways and ore is shoveled out. Enough ore is regularly withdrawn in this manner to make room for the miners to work on top of the broken material.

The timbers of the sill floor are the only timbers lost. The miner is not restricted as to the amount of rock he brings down at a single blast and the up-keep of the trackways may thus be a considerable amount.

Several sets of timber are carried up along the side of the stope, or room, as the work proceeds overhead. These sets are laced to be used for manways or ladderways. The stope is worked up to within 30 feet of the next level above, and the back is barred for the purpose of breaking down loose rocks. Raises are now driven along the center line of the stope to the upper level.

The ore body is of such nature that it is self-supporting, that is, the walls and back of the stope will stand during the process of withdrawal of broken ore from the bottom. When one end of the stope has been cleaned by shoveling into cars along the trackways, as explained, the sill-floor set is laced and waste rock is dropped into the stope from the level above through the raises. In this way the walls of one end of the stope are supported by the waste, while the walls of the other end are supported by broken ore. Before the waste is thrown in, a quantity of old timber is laid over the entire floor of the stope, and this timber mat is known as the "mud-sill."

The waste for filling is obtained from and through raises, which are kept filled from the surface. These are known as continuous raises. A raise is driven from one level to another. The next raise above is placed about 10 to 15 feet to one side of the lower and the two raises are then connected by an inclined by-pass. A gate is placed in the by-pass to regulate the amount of ore or waste coming from the upper raise. Each raise is also connected to a cross-cut by a small inclined raise. At the place where the small inclined raise cuts the floor of the cross-cut there is placed a grizzly, made of 12"×12" timbers placed about 10 inches apart. A rock over 9 inches thick cannot therefore pass through these grizzlies into the raise. Either waste or ore can be handled by these continuous raises; but in this present case, waste is drawn from the raises and thrown into the stope. The raises are really storage bins for either waste or ore.

The Present System.—The present system of stoping does away with all the sill floor timbers. Drifts are excavated in the hanging wall and in the foot-wall a short distance from the ledge. The ore body is then divided into stopes 60 feet wide and pillars 40 feet wide as shown in Fig. 5. A 6-foot cross-cut is driven through the center of each pillar from the hanging wall to the foot-wall. Along the cross-cuts, headings are driven about every 30 feet. These extend from the cross-cut in both directions to the stoping ground. The stope is then opened by taking out ore through the headings on either side of the stope.

On one side only of the stope timbered manways are carried upwards as the stope progresses. These manways are not in the pillar, but in the broken ore, a few feet from the pillar. As the ore is drawn out into the cross-cuts, the miners are at work on top of the broken mass. Shovelers keep the ore drawn off just sufficiently to give the miners enough room for their work. With this system, the stope can be worked about 120 feet high. When this amount of ore has been taken down, raises are driven to the level as in the Homestake system. Then the ore is drawn out completely, a mud-sill is laid down, and the waste thrown in as before. The stope is next filled with waste, nearly to the arch of ore between it and the level above. When the filling is completed, square-set timbers are put in on top of the filling and the remaining arch of ore is taken out, using the square sets for supports. As the stope approaches the upper level, great care is taken to prevent cave-ins. The arch is removed in small sections—a set at a time—while the mud-sill above the floor of the stope above prevents the running in of the waste. A stope on one level is directly below one on the upper level. As the arch is removed, waste rock is filled into the timbered part of the stope. These few square sets are the only timbers lost in this method.

After all the stopes are worked out and filled, the pillars of ore that have been left are worked by means of ordinary square-set timbering, the waste rock being prevented from running into the stope by lacing the outside sets of timber.

The features of this method that have reduced the cost of mining to a minimum are the following:

Levels may be placed at a comparatively long vertical interval. Below the 1,100-foot level, all levels are spaced 150 feet apart. The present deepest level is the 1,700-foot.

A minimum amount of timber is used.

Ore is broken at a small cost.

Stopes are easily and cheaply filled.

Nearly all of the ore can be extracted by this method.

The output is large and regular.

There are always large ore reserves, broken and in the pillars. At the present time there are about 1,000,000 tons of ore in reserve.

As a conclusion, it will be well to compare the costs of stoping with timber, by the so-called Homestake method and by the present system. The wage items will, of course, remain the same in all schemes and are as follows:

Miners and timbermen, $3.50; helpers and shovelers, $3.

To insure a fair comparison, take the figures resulting from the actual development of complete stopes by the three methods.

Timbered Stope	
Cost of labor	$ 2,057.08
Cost of timber	11,174.47
Incidentals (placing timber and chutes and breakage)	5,538.97
Total	$18,770.52

Homestake Method	
Cost of labor	$ 500.34
Cost of timber	3,108.15
Labor, placing sill-floor timbers	758.16
Total	$4,366.65

Present Method	
Cost of labor	$ 500.34
Cost of timber (manways)	1,255.44
Incidentals	758.16
Total	$2,513.94

To compare these costs on a tonnage basis, assume (as is fair) that 73,000 tons are mined from each of the three stopes. Then,

$\frac{\$18,770.52}{73,000} = \$.257$ cost per ton of ore by timbering method

$\frac{\$4,366.65}{73,000} = \$.06$ cost per ton by Homestake method, or a saving of nearly 20 cents per ton

$\frac{\$2,513.94}{73,000} = \$.034$ per ton by present system, or a saving over the old method of 22 cents per ton, and over the Homestake method of nearly 3 cents per ton.

Altitude and Air Compression

The effect of altitude on the efficiency of air compressors is considerable. The calculation of the volume of compressed air delivered at sea level and at a higher altitude may be shown by the following example: If 300 cubic feet of air at an atmospheric pressure of 14.7 pounds is compressed to a gauge pressure of 80 pounds the volume will be $300 \times 14.7 \div (80 + 14.7) = 46.5$ cubic feet. If the air is at an atmospheric pressure of 10.1 then the volume would be $300 \times 10.1 \div (80 + 10.1) = 33.5$ cubic feet. The volumetric efficiency of a compressor at 10,000 feet above sea level is therefore only 72 per cent. of what it would be for the same machine at sea level.

Creep in the Panama Canal

Conditions Caused by, and the Method of Dealing With, the Large Masses of Moving Earth and Rock

*By Frank G. Carpenter**

MIGHTY masses of earth and rock are sliding down into the Culebra cut of the Panama Canal. There are two places where more than 1,000,000 cubic yards of earth and rock are now moving. The material in action is equal to a solid block 300 feet square and 300 feet high. This enormous quantity of rock is advancing at the rate of almost 2 feet per day, and since the beginning of digging thirteen or fourteen times as much as that mass has been excavated, or a total of over 13,000,000 cubic yards. If there had been no slides the excavation for the canal would have been done long ago. As it is there are 11,000,000 cubic yards yet to dig and of this something like 4,000,000 are the direct result of the slides.

The Culebra cut is altogether 9 miles in length, and about 300 feet deep. In some places the cutting back that has been made on account of the slides is almost 2,000 feet wide at the top, and the sloping goes down in steps to the bottom of the canal, where the width is 300 feet.

It is impossible to conceive the vast amount of earth that has been taken out of the canal, since the figures convey no idea of the concrete dimensions. In 1 month enough stuff was removed to fill a ditch 3 feet wide and 3 feet deep from Boston to Chicago, and most of that was of such nature that it had to be blasted.

As one looks down into the cut he can see the mighty work everywhere going on. Trains of earth are moving this way and that. Scores of steam shovels are puffing and groaning as they drop the earth and rock on the cars, and everywhere are gangs of negroes who are drilling the ledges as shown in Fig. 3, and putting in dynamite to break up the earth for the shovels.

*Copyright, 1912.

The pipe line which carries the air for the drills is 10 inches in diameter, and extends from one end of the cut to the other. It is fed by three air compressors that can compress 17,000 cubic feet of air every minute. The air feeds the drills and keeps them chugging away day and night, boring the holes 6 inches in diameter and from 15 feet to 30 feet deep for the blasting. Colonel Gaillard, division engineer in charge of Culebra cut, said that last year the holes put down, if joined end to end would have reached 900 miles. They would have equalled a pipe running all the way from Philadelphia to Chicago, or if sunk straight through the earth would have reached almost one-fourth of the way to the center. The consumption of dynamite for 12 months was over 5,000,000 pounds. Every hole requires 20 pounds. The dynamite is wrapped in pink paper to keep track of it and prevent the workmen stealing it to dynamite the waters for fishing. The loss from this source was considerable, but this pink paper can be seen a great distance, and now whenever a man is caught with dynamite so wrapped he is arrested.

Going down into the cut, cracks are seen everywhere. In some places they are so wide that one could put his foot in them, and others would hold only a finger. There are cracks all over the hills, and some of them mark out bodies of earth which will have to be moved, as they are already sliding down into the cut.

There is one great crack at Culebra which incloses 4 acres, comprising a million or more cubic yards, which are already moving, although so slowly as to be imperceptible. The crack is about a foot wide and it steadily grows. Another movement of the same kind is apparent at Empire, where Colonel Gaillard has his headquarters, and the workmen in pointing to it facetiously say that Mother Earth is about to take her revenge on Engineer Gaillard for the scars he is making upon her old body at Culebra.

These cracks mark the beginning of slides, and later on in the cut the earth comes down. There are several kinds of slides. The first consist of the material lying above the bed rock. These are composed of clay and other earth, and they may have a great deal of rock mixed in them. Such a slide is caused by the digging away of the material which holds it in place and also by the increased weight made by the water of the heavy rainfalls. This aids in carrying the earth down into the canal.

Fig. 1. 1st Photo of Moving Canal Bed

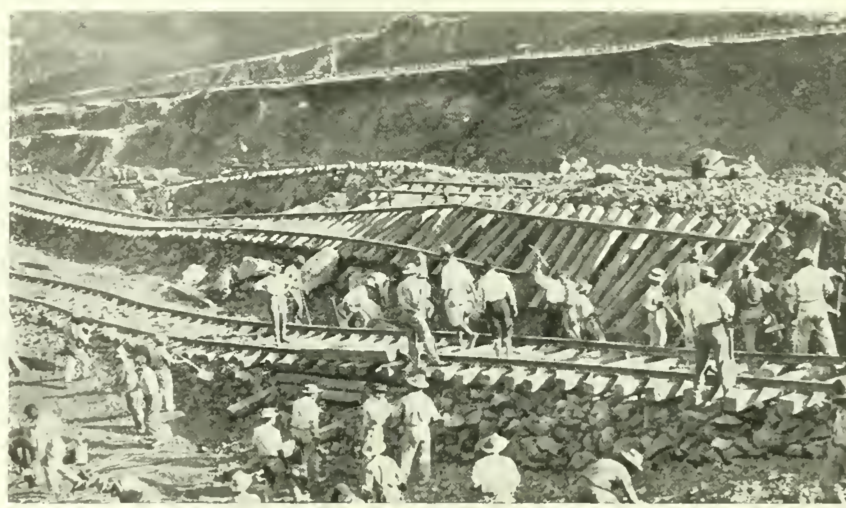

Fig. 2. Photograph of Canal Bed Taken Two Minutes After Fig. 1

Most of such slides occur in the rainy season, although there are some also in the dry season. One such mass seen moving comprised about a million cubic yards, equal to a block 300 feet square and 300 feet high, and was going forward at the rate of 18 inches per day. From the bed of the canal the place where the clay joined the rock could be plainly seen. It was a sort of a hollow in the hills where the rock of the cut had been blasted off sheer so that one could follow with the eye the line where the clay ended and the bed rock began. There was a 95-ton steam shovel at the foot of the rock, and it was catching the earth as it fell and loading the cars. It was working just fast enough to keep the stuff from the slide out of the way. The earth fell slowly and in great masses, continuously dropping down into the cut.

Take the Cucuracha on the east side of the canal. The word Cucuracha means "cockroach," and this cockroach is the biggest of its kind upon earth. It covers an area of 47 acres and forms a great mass of earth which has broken off 1,820 feet from the center line of the canal.

It began when the French were working, and it has caused trouble ever since digging was begun. The United States have already moved out of it a mass of earth amounting to 2,000,000 cubic yards, and it is still active. At one time it came onward at the rate of 14 feet every day. Nevertheless the steam shovels ate it up as it came, and there is no doubt but that the shovels and dredges will be able to care for it and all the other slides of the future. The ordinary slide can be handled by one shovel, and this is so even when the slide is a long one. At Las Cascades a shovel moved up and down a slide one hundred times, going back and forth and removing its toes as they were pushed into the cut.

There is a big slide on the west side of the cut near Culebra which covers 28 acres and another on the east side north of Gold Hill where about 17 acres have broken off, beginning 1,200 feet back from the center line of the canal. So far an area something like 157 acres of slides has been taken out, and there are many acres still in motion. Colonel Gaillard, who has seen the glaciers of Alaska, says that these slides move just like them. The earth flows down the sloping surface of the bed rock, the lateral support of the masses having been removed by the digging. It is just as though the earth were made of molasses and held back by dams at the sides. These dams were taken away by the digging of the canal.

In addition to these surface slides or flows there is another class of earth motion which is carrying great masses of rock into the canal. These masses do not come from the top, but from the strata of which the canal banks are made. Sometimes they come from below the canal bed and force themselves up in humps through it, overturning steam shovels and heaving the railroad tracks.

This morning, at a point just opposite Gold Hill, I saw a hump, or great hill, which had risen up in the bed of the canal during the night, moving the four railroad tracks which ran parallel across it. The rails were twisted and torn, and the ties were pulled out of the earth. Colonel Gaillard and myself stopped to watch the men who were getting ready to repair the tracks and were bringing up shovels to take out the hump, when lo, right under our eyes, we saw the earth rise and throw the railroad, ties and all, to one side. I had my camera ready and made photographs of the ground while it was moving. As the last picture was finished one of the tracks turned over and rolled down the side of the hill. This hump was right in the bed of the cut and almost on the bottom of what will be the permanent bed of the canal.

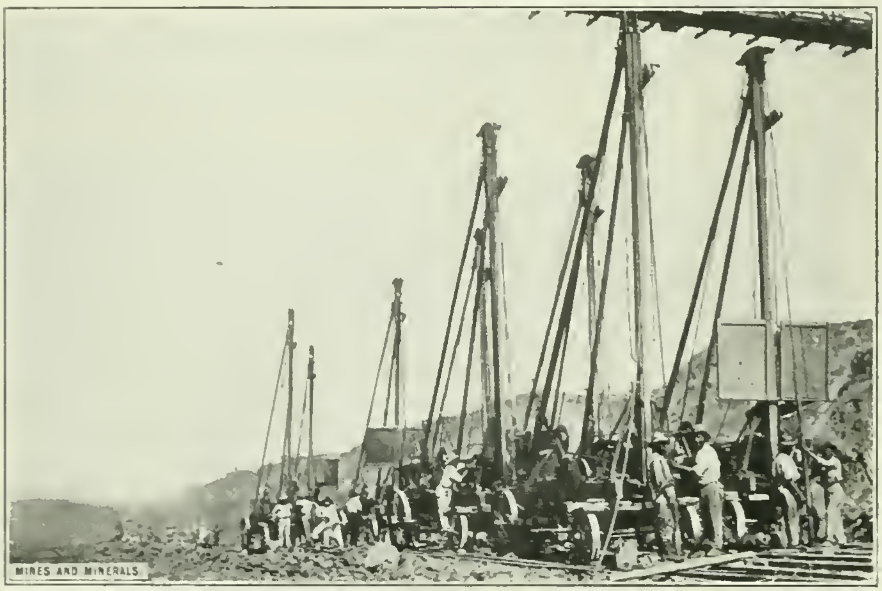

Fig. 3. Churn Drills on Panama Canal

In another place the walls of the cut contained many different layers of rock of varying degrees of density, lying one upon the other. Here was a stratum of shale, there one of lava, and above it one of limestone or a layer of volcanic dust hardened to stone.

Before excavating began these strata lay one upon the other, and the weight of the mass was equally distributed, bed upon bed, so that it was not possible for any of the strata to move, no matter what lay above them. Then the great ditch was cut and the weight and pressure on that side were taken away. This allowed the great weight above to exert its force on the weaker strata beneath, and it has squeezed some of them out into the canal. The weaker strata are like the jelly in a layer cake. The layers above pressing on the jelly cause it to ooze. The soft strata give way to the weight above and are forced out into the canal bed, or if the stratum is under the bed of the canal it is squeezed out so that it humps up and throws the railroad as described.

Slides of strata such as described are common, but the engineers know how to control them. They have occurred so often that they are now taken as a matter of course. The hump or creep of this morning will be out of the way before night. Four hundred men are working at it and sending it down to Balboa.

Colonel Gaillard says that there has not been 1 week during the past 3 years when the bottom of the canal has not been heaving and rising, but he adds that the heaving grows less and less as the weight from the sides of the cut is removed and the upper banks properly sloped. At present the only place where the earth is creeping is right under Gold Hill. The trouble occurs within a length of perhaps 200 feet, whereas it formerly extended over 2,000 feet. The creep makes it necessary to rebuild a great deal of track, and on this account altogether more than 100 miles of track have already been shifted.

The rains here are often exceedingly heavy, retarding the work. During the wet season the clay flows down like a river and it takes time to clear the railroad of mud. As an instance of the rainfall, there are some places on the isthmus where it has spurts as heavy as anywhere in the world.

In the cut are heated areas where the chemical condition of the earth is such that it oxidizes upon exposure to the air and generates heat. In some places the cut steams, and in others the ground is so warm that you cannot put your hand in it.

These hot spots are found at various depths, and they are often of such a temperature that the dynamite would explode if put down into a hole, drilled through them. For this reason a long iron pipe is dropped down into every drill hole before it is charged. It is left there for 10 minutes and then taken out. Then, by running the hand along the pipe one can find whether there is a hot place in the hole, as this heats the pipe at that place. Some premature explosions have occurred owing to the lack of this test, and some of the material now being handled would fire dynamite if brought near it.

In one place in the cut steam was pouring forth like a geyser. The smell of sulphur was strong, and one had to get to windward to prevent being overcome by it. At this place the ground was yellow with sulphur and the steam was oozing out over an area of several square yards. A manilla envelope held over one of the cracks was destroyed by the heat which even charred a piece of white pine lumber, although it did not bring it to a blaze.

In looking at the earth near the steam vents it seems cool, and, to the touch of the hand on the surface, there is no sign of heat, but when the crust is scraped away a bit the hand would almost be burned by the contact.

In loading this stuff the mass is sometimes so hot that the brakemen cannot ride on the loads, and they hang outside, holding on by the irons, as the trains move on toward the dump.

There is, however, no danger from these heated areas. The geologists of the commission have examined them, and they say they are due to the oxidation of pyrites and other materials which generate heat on exposure to air.

Characteristics of the Mexican Miner

Written for Mines and Minerals by Harold Lakes

The first 3 months an American mine manager operates in Mexico is "hell"; the next 3 months, he begins to enjoy life in his new surroundings; and thereafter it is hard to drive him out of the country. If he does leave, he will always possess an attraction for Mexico.

Mexican peons are, as a class, most ignorant. Very few of them can write their names. They are inveterate thieves, and they will stand and look a man squarely in the eye while they calmly lie out of any predicament. If it happens that a storekeeper puts in a new clerk for a day or two, every native within reach will attempt to purchase things from the clerk cheaper than usual, upon the bluff that such articles have always been sold at lower prices heretofore. If bosses are changed in a mine, the men will invariably endeavor to bluff their new taskmasters as to what may be reasonably expected of them in the matter of a day's work.

In the ignorance and shiftlessness of these people, lack of consideration for the morrow's existence plays a prominent part. They live for today, only, and have no compunctions concerning the throwing up of a job even if they have not a nickel in sight, and will calmly take chances on finding something else to do when money is needed. This mental attitude is encouraged by their ability to always partake of the food and shelter of other natives.

If it chances that a peon is invited to take a meal with an American, the Mexican will probably take his seat, fail to remove his hat, and will observe none of the rules of table etiquette. Perhaps the saddest part of his meal lies in his wrestling with a knife and fork, implements scarcely ever used by him among his own people. If a peon is requested to ascertain the time of day, he will go to a house containing a clock; but, having no idea what the clock says, he will take special notice of the sun's position and will, upon his return, report the time.

It is strange how strong some of these men are, physically, for one of them will eat about as little in two days as would make an ordinary meal for a single American. They do not possess great strength in their backs, but can carry great loads upon their shoulders if such loads are placed thereon by others.

In our country much sweet and greasy food is considered heating to one's system and hence unfit for summer diet; but in Mexico, a family of five or six members will consume a kilo (2.2 pounds) of lard per day as well as one or two kilos of sugar. This latter staple is bought in cubes, and from seven to ten of these cubes are used per cup of coffee. The Mexicans prepare their native beans in a manner that is highly aceptable to Americans, and "gringoes" always ask for frijoles when arriving in a native camp.

A peon house will have one room which may, perhaps be 12 feet by 14 feet, and this will provide shelter for two or three families, comprising 12 to 15 persons. Beds consist of blankets or sacks spread on the floor. Instead of removing a stone which may be found in the way of comfort, a person will adjust his body to miss it. Pigs help to make up a family. A dog will be kicked around, but a pig never, for frequently a pig comes in for more consideration than a person. Chickens also live in the house and roost at night over the occupants of the beds. It is commonly remarked that peon women will use more water and will look dirtier than their hogs; so that women are a nuisance in those camps where water is scarce.

Mexican peons will often starve themselves to save up a few dollars, only to gamble and drink the money away in a single night. In the state of Sonora, men who refuse to work and who are drunk much of the time, are considered public nuisances. They are put into the army for 5 years and are paid 26 cents per day from which they must board themselves. A soldier of this class is a picture of forlorn humanity. He wears sandals on his feet as the only protection from the cactus and other thorns of the country. His uniform is wrongly named for it is nondescript. He lives with the feeling that he is serving time—not his country—and his fighting value is correspondingly measured. Of course, not all Mexican soldiers are of this class.

The average mine manager from the States generally selects and takes his corps of miners with him to Mexico; for it is the case that, until the recent political disturbances in Mexico, there have always been many American miners who sought experience in this other republic. The boss will begin by putting Mexicans and Americans at work together, and there soon results the inevitable trouble, due to a difference in the customary wages paid the two classes. The native at $2.50 per day, is expected to do the same kind and amount of work as the American who receives $3.50 per day. The Mexican, of course, objects. Then the American soon begins to complain of the heat, the poor water, the Mexican "grub," and the difficulty of conversation with the natives. Finally, the manager realizes the incompatability of the two classes of laborers, and he solves his problem by discharging all of his Americans except just enough to do the mine timbering and to fill a very few of the important positions. Affairs progress all right in this manner until, within a week, the manager finds his miners are driving drifts in directions directly opposite to the correct ones, and it becomes necessary for him to devote a great share of his time to personally pointing all the drill holes, telling the men just how much powder to use in each hole, which holes to shoot first and which last, and restricting the number of candles used by each man per day to a certain number.

In most parts of Mexico, miners are paid according to the inches of drilling, for in this way the men may be held up to a fair amount of work. A Mexican will undertake contracts for driving at so much per foot, but he will never agree to carry on his contract for any specified length of time, nor for any given number of feet. As long as his progress pays satisfactorily, he stays with his contract, but upon entering harder rock, he quits. The only advantage in giving such contracts lies in getting longer days from the men and thus in finishing the work quicker than it could be finished under day's pay. There is a saying that "when a Mexican is working his best, cut his wages and tell him to dig in," for if he is promoted or complimented, he believes that his services are indispensable, and he becomes useless.

An American who does not understand Spanish finds plenty of trouble; for after explaining points to his men in detail and inquiring if he has been understood, he is invariably told "yes," whereas the truth is the men are perfectly blank as to what has been told them. That same night, perhaps, the manager, finding things quite the reverse of his orders, will "fire" a poor man, replacing him with a poorer one, and the whole trouble has been due to the American's own deficiencies.

Practical Cyaniding—Part 1

History—Chemical Reactions—Solubility of Minerals—The Mill Solution and Its Constituents—Laboratory Work

*Written for Mines and Minerals by John Randall**

THAT cyanogen combined as a cyanide is a solvent for gold and silver has long been known, but it was not until MacArthur and the Forrests made improvements in the method of precipitating gold from the solution by means of zinc, using zinc shavings, freshly cut, that the cyanide process for gold extraction assumed commercial importance. In the same year that the MacArthur-Forrest patents were granted in England (1888), Ernest Siemens, of Berlin, applied in the principal mining countries of the world for patents upon a method of depositing gold from cyanide solutions upon cathodes of sheet lead by means of an electric current. Owing to a meager knowledge of the chemistry of the process during its early history, zinc precipitation was somewhat imperfect and uncertain, and therefore in some fields, notably in South Africa, the Siemens method was for a while a keen rival of zinc precipitation.

The scope of the cyanide process has been so much enlarged within recent years that any gold or silver ore of moderate richness not known to contain too great quantities of substances destructive to the cyanides, should be tested with a view to cyanidation. In cases where a good recovery can be made by the simpler process of amalgamation, a profit can generally be realized by cyaniding the tailing. The fact that the field for the process is such a wide one makes many modifications necessary in its successful application to different kinds of ores.

When gold is treated with a cyanide solution, oxygen or some other element that acts as an oxidizing agent must be present. The reaction, presuming oxygen to be present, is expressed by the following equation, known as Elsner's equation, as Elsner advanced the theory in 1844:

$$2Au+4KCN+O+H_2O=2AuK(CN)_2+2KOH$$

The probable reaction is that the gold unites with the cyanogen, liberating potassium. Part of the potassium immediately unites with the gold cyanide, forming the double salt, auropotassic cyanide; the remainder, uniting with the water, liberates hydrogen and forms caustic potash or potassium hydrate. When such a solution is evaporated, it yields octahedral crystals, which show on analysis to be auropotassic cyanide, $AuK(CN)_2$.

The order of solubility of the more common minerals in a .1 per cent. cyanide solution, according to Julian and Smart, is shown in Table 1.

In arriving at the values named in this table each substance was taken alone, but when more than one of these substances are acted upon in the same solution at the same time the case is somewhat different. If the substances are in contact or near enough together to be electrically connected, they form galvanic couples, accelerating the dissolution of the more soluble substance and retarding the dissolution of the other. Sometimes this action is a hindrance to the process, as a couple formed between copper pyrites and marcasite would accelerate the dissolution of the copper. Other couples formed, as between gold and the sulphides, would be a distinct advantage. This action undoubtedly occurs to a greater or less extent during the treatment of all ores containing base metals or their compounds.

Table 1. Solubility of Minerals

Minerals	Degree of Solubility
Marcasite, white iron pyrite, FeS_2	1.0
Mispickel, arsenopyrite, $FeAsS$	4.8
Iron rust	7.0
Galena, lead sulphide, PbS	11.5
Iron pyrite, FeS_2	18.0
Charcoal iron	22.0
Copper pyrite	36.0
Lead	43.0
Silver	45.5
Gold	82.5
Zinc	100.0

An accumulation of hydrogen at the cathode of a galvanic couple causes a condition called polarization, in which action is greatly diminished or ceases altogether, unless this hydrogen is removed as fast as formed. In the case of an ore acted upon by a cyanide solution the oxygen dissolved in the solution plays the important part of keeping down the accumulation of hydrogen. It is almost needless to remark in this connection that a solution while moving, as in percolating, is much more efficient in this regard than while at rest. Comparatively strong solutions tend to the evolution of hydrogen faster than it can be removed, thus inducing polarization, which is a reason why such solutions are much less efficient per unit of strength. Also when the dissolution of gold is impeded or stopped from this cause, other galvanic couples are formed and base-metal compounds are brought into solution with considerable rapidity. This has given rise to the idea that weak solutions exercise some kind of selective action in their preference for dissolving gold.

Another effect of even partial polarization should receive attention. The deposit of hydrogen, tending to reverse the polarity of the couple, is extremely liable in a complex solution like a working mill solution to deposit some insoluble or difficultly soluble substance upon the gold. This affords an explanation of the fact observed by many mill men, that if abnormally low extraction occurs upon a vat of ore from some cause known not to be attributable to the ore itself, it is usually impossible to obtain a normal rate of extraction by subsequent treatment.

From the foregoing remarks it is easy to see why, in many early attempts at cyanidation with comparatively strong solutions, and with considerable intervals of rest between the periods of leaching, many ores were not regarded as amenable to cyanide treatment that are now considered quite docile.

Iron sulphide is but little acted upon by cyanide solutions provided they are properly applied and kept in working order, but with ores containing partly oxidized iron sulphides the case is quite different. Ferrous sulphate, $FeSO_4$, soluble in water, reacts with the potassium cyanide solution forming potassium ferrocyanide as follows:

$$FeSO_4+6KCN=K_4Fe(CN)_6+K_2SO_4$$

Soluble sulphates can be removed by a preliminary water wash with an alkali added near the end of the operation to neutralize acidity, but unless the ore is well oxidized complex reactions are likely to occur resulting in a loss of cyanide.

Copper compounds in some quantity, are generally found in gold ores. Whether a small quantity of copper sulphide is objectionable might depend on the presence of other elements, and could best be determined by experiment. Copper oxides and carbonates are readily attacked by cyanide solutions and their presence generally renders the cyanide process inapplicable.

Antimony, as stibnite Sb_2S_3, is not objectionable unless occurring in considerable amount. The sulphur combines with the alkalies in the solution forming alkaline sulphides which must be kept from accumulating.

Blende ZnS, is but very little affected by cyanide solution.

Tellurium. Ores containing compounds of tellurium are generally difficult and often impossible to treat with cyanide solutions until oxidized, the tellurium seems to coat the gold with a more or less insoluble film.

Coarse gold, owing to the time required to dissolve it, should be removed before treatment with cyanide. This is generally done by amalgamation or concentration.

Silver chloride is readily soluble in cyanide solutions, but other silver compounds are much more slowly dissolved, metallic silver being less soluble than gold. The dissolution of silver sulphide Ag_2S, is generally accounted for according to the following equation:

$$Ag_2S+4KCN=2KAg(CN)_2+K_2S$$

*Boulder, Colo.

If very much potassium sulphide K_2S is formed in the solution the action is liable to be reversed and dissolved silver is precipitated as Ag_2S. Cyanide is also destroyed by the formation of thiocyanate $KCNS$.

It has been customary to add acetate of lead to silver ores to form lead sulphide with any free sulphate or soluble sulphide, thus rendering the sulphur harmless. Sodium cyanide $NaCN$, in solution, seems to have the preference over potassium cyanide in cyaniding silver sulphide ores. By grinding silver ore very fine and then agitating, an excellent recovery may be effected with cyanide solutions.

The addition of a lead compound should only be made when the silver exists as argentite Ag_2S, and then it is more economical to use litharge than lead acetate. However, air perseveringly and judiciously applied costs much less than chemicals and can generally be made to answer every requirement as an oxidizer.

Slime.—While clayey, or talcose, ores produce the most slime, any ore will form some slime when ground with water. A substance having something of the characteristic of gelatine is developed when pure feldspar is ground in water. This substance, termed a "colloid," absorbs water which greatly increases its bulk. When a solid is dissolved in water, a force called cohesion exists between the molecules of water and the soluble substance that tends to keep it in solution. But in this case the molecules of the solid are so separated that there is no cohesion between them, so that they are free to move among themselves and through the dissolving medium. This force of adhesion is stronger than the original cohesion of the molecules of the solid among themselves, else the solid would not dissolve. The strength of this adhesive force is illustrated in a strong solution of common salt that will not freeze, as the adhesion of the salt molecules prevents the water from separating from them to form ice crystals. This only partly explains the action of colloids in water or watery solutions, for the reason that colloids do not form true solutions with water, but owing, probably, to the shape of their molecules, exhibit a considerable amount of cohesion, forming with water a jelly or semisolid. The point to be particularly considered is that neither the colloid particles nor the entrained water is entirely free to move by diffusion as in the case of true solutions. Thus diffusion, so necessary to the dissolution of solids, is greatly retarded or entirely stopped by the presence of slime. This gelatinous matter coats the granular particles of ore in much the same manner as the gelatinous perisperm of some seeds surrounds them when moistened, this preventing diffusion between the solution in contact with the ore granule and the solution outside. But if a solution of a considerably different density is brought in contact with this coating of slime, the tendency toward diffusion will overcome the adhesion of the slime for its entrained solution, osmosis taking place through the colloid, as illustrated in the pressure developed by the tendency of salts in solution to diffuse through membranes. After partial diffusion takes place the osmotic pressure becomes too low to break down the adhesion of the colloid for its entrained liquid, and diffusion and consequent dissolution cease until another considerable change of density occurs in the surrounding solution. Thus it is found that in treating slime by the cyanide process agitation is imperatively necessary, while a number of changes in the strength of the solution can be made with a beneficial effect on the extraction.

Flocculation.—Ore slime can generally be flocculated, or caused to shrink somewhat and break into flakes, by the addition of a small amount of caustic lime. This is of great service in thickening slime, but does not prevent the slime retarding diffusion.

THE MILL SOLUTION AND ITS PRINCIPAL CONSTITUENTS

Water, the great natural solvent makes up the entire bulk of the working solution in a cyanide plant. The solid constituents of many mill solutions comprise only about one-thousandth of their entire weight and do not appreciably increase their volume. A general knowledge of the properties of this solvent is necessary to the cyanide operator.

Natural surface waters, found in springs, rivers, and lakes, contain air in a state of solution. 1,000 cubic centimeters of pure water, at sea-level pressure and temperature of greatest density, contain when saturated 17.95 cubic centimeters of air of the following composition: Oxygen, 34.91, and nitrogen, 65.09 per cent. by volume. Atmospheric air contains considerably less oxygen.

Stagnant waters from swamps and ponds and from old mine workings usually contain organic matter undergoing decomposition. These impurities act as reducers, i. e., deprive other bodies of oxygen. These waters also usually contain organic and mineral acids. They can generally be rendered fit for use in mill solutions by aeration and by treatment with an alkali.

The affinity of water for carbon dioxide CO_2 is considerable, one volume of water being capable of dissolving several volumes of this gas. The capacity of water to absorb carbon dioxide is partly accounted for from the fact that the two form a definite compound, carbonic acid H_2CO_3. Water containing H_2CO_3 is capable of dissolving large quantities of calcium carbonate, which is practically insoluble in pure water.

Waters containing carbonates in solution should not be used in making up a fresh quantity of mill solution until these impurities are removed. What is called "liming," treating with freshly slaked lime $Ca(OH)_2$ is the most efficient method of purifying such water. The calcium hydrate removes the carbonic acid according to the following equation:

$$H_2CO_3 + Ca(OH)_2 = CaCO_3 + 2H_2O$$

The calcium carbonate formed, as well as that in solution, is precipitated. Should the water contain carbonates of the alkalies, they are decomposed by the lime, the alkalies becoming free and the CO_2 being locked up with the lime and removed from the solution.

Waters containing chlorides are not particularly objectionable, sea water having been successfully used in cyanide solutions. Such waters, however, have a lower absorption coefficient for oxygen.

The cyanides, potassium cyanide KCN, sodium cyanide $NaCN$, and calcium cyanide $Ca(CN)_2$, are the principal cyanides found in mill solutions. Cyanogen CN composed of carbon and nitrogen is classed as a compound radicle for the reason that it exhibits many of the characteristics of a single element. It is sometimes denoted by the symbol Cy, particularly in foreign countries. Combined with alkaline bases it forms cyanides. When freed from this combination it takes one atom of hydrogen, forming hydrocyanic acid HCN, a gas having a smell not unlike that of peach kernels, and one of the most deadly poisons known.

The strength of cyanides is computed according to the amount of contained cyanogen; a cyanide having the amount of cyanogen contained in pure KCN being called 100 per cent.

The alkalies, caustic soda $NaOH$, and caustic potash KOH, if not introduced directly into a mill solution find their way there by the decomposition of their cyanides. They are useful in making up the amount of free alkali required in the solution.

Protective alkali. Free alkali in a cyanide solution is termed "protective" because it protects the cyanide from decomposition. Acidity in the ore, that would otherwise cause cyanide loss, is neutralized and rendered innocuous by this protective alkali.

Lime, not classed as an alkali but as an alkaline earth, is a much more energetic base than either potash or soda. Its properties and the points of difference between it and other alkaline elements merit the special study of the cyanide operator. Calcium is bivalent, therefore a molecule of calcium oxide CaO having the molecular weight 55.87 is equivalent to two molecules of sodium hydrate $NaOH$, the molecular weight of $2NaOH$ being 79.92. Bearing in mind that the caustic soda of commerce usually contains only 70 per cent. $NaOH$, an interesting comparison can be made as to the comparative efficiency of the two substances, taking into consideration the difference in cost.

The sparing solubility of calcium hydrate $Ca(OH)_2$, one in 530 parts of water, makes it practicable to mix lime CaO directly with the ores as it comes to the mill, thus getting the benefit to some extent of a preliminary alkaline treatment, without complications which might occur from a too strong alkaline solution if a more soluble alkali were thus used. In many cases the lime combines with enough moisture from the ore in slacking to make the ore work materially better in the feeders and the conveyers.

Lime combines with CO_2 with great avidity. In the presence of potassium or sodium carbonate it robs these elements of their CO_2, the calcium carbonate thus formed being insoluble. The lime, at first sparingly soluble as $Ca(OH)_2$, then goes out of solution entirely. The small amount of CO_2 always present in the air has a marked effect in removing lime from a cyanide solution. Some free calcium hydrate should always be formed in a working cyanide solution.

Lime with arsenic forms an insoluble compound and will decompose alkaline arsenites, forming insoluble calcium arsenite, thus removing arsenic from a solution.

Reducing Agents.—Alkaline sulphides, principally as potassium sulphide K_2S and sodium sulphide Na_2S, are formed in working solutions and seriously impair their efficiency. Various chemicals have been used to oxidize these sulphides but nothing has been found to be as economical and efficient, generally speaking, as atmospheric air properly and persistently applied. Skey, in 1888, proved by experiment that K_2S and hydrogen sulphide H_2S cause the deposit of an exceedingly thin film of sulphur upon particles of gold, that interferes with cyanidation as well as amalgamation, and that a small quantity of H_2S is usually formed during the wet crushing of pyritous ores, but metallurgists generally seem to have been rather slow to appreciate the full significance of his discoveries.

Oxygen.—By reference to the Elsner equation it will be seen that the presence of oxygen in a working mill solution is a necessity.

In any dilute solution of a solid in a liquid the molecules of the solid tend to separate until they are equally diffused through every portion of the liquid. This property of solutions in general plays an important part in the cyanide process. For example, a particle of porous ore one-fourth inch in diameter becomes saturated with cyanide solution. The minute particles of gold within these pores form with the solution a soluble gold compound $KAu(CN)_2$, at the surface of the gold particles, but if no diffusion occurred to carry away the dissolved gold as well as to bring fresh cyanide in contact with the gold, dissolution would cease. Further, diffusion must occur between the solution contained in the pores of this ore particle and the solution outside, or the dissolved gold could not be recovered from the particle of ore. As might be expected, this distribution of the molecules takes place more slowly as the liquid more nearly approaches complete balance or diffusion. If the first solution should be removed from around the ore particle in question and a solution substituted having an appreciably different strength, diffusion would be materially accelerated.

LABORATORY WORK IN CONNECTION WITH CYANIDE SOLUTIONS

There is some diversity in practice among chemists in the use of standard solutions, some adhering in part at least to the normal system. The following test solutions shown in Table 2 do not require any computations, and are recommended as being convenient for determining volumetrically the different important components of a working cyanide solution.

Silver Nitrate Test Solution.—Weigh out 6.6 grams of chemically pure silver nitrate and dissolve in sufficient pure water to make one liter. Keep the solution protected from the light.

Table 2. Test Solutions

Name of Solution	Grams of Reagent in One Liter		Standard	Used in Determining
	Theoretical	Practical		
Silver nitrate $AgNO_3$	6.5201	6.6*	1 cc. .005 gm. KCN	Total cyanides as KCN
Sulphuric acid H_2SO_4	8.7558		1 cc. .005 gm. CaO	Free alkalies as CaO
Potassium permanganate $KMnO$	3.9516	4.0	1 cc. .001 gm. available oxygen	Reducing Agents

*Note.—It may seem that this excess of silver nitrate, amounting to nearly 2 per cent. is unnecessarily large, but it is believed to be within the requirements of usual mill practice. With a test solution containing exactly the theoretical amount the end point would be at the point of saturation and before any permanent turbidity. In mill practice titrations are often required by artificial light, sometimes of poor quality, and sometimes upon slightly turbid solutions, which makes it necessary to carry the titration somewhat beyond the end point in order to get an unmistakable indication. The test solution is made stronger in order to balance this source of error. For instance, a 2-pound solution requires 2 cubic centimeters or 32 drops of a theoretically correct $AgNO_3$ test solution. One-half to one drop additional in order to make the end point discernible would introduce an error amounting to 1½ to 3 per cent. The figures "six point six" (6.6) have also the advantage of being easily remembered.

Sulphuric Acid Test Solutions.—Weigh into a beaker 9 grams of chemically pure sulphuric acid, place 1 liter of water in a bottle, add the sulphuric acid and mix. This solution is too strong and must be standardized in the following manner: Prepare a standard solution of oxalic acid by dissolving 1.126 grams of chemically pure oxalic acid free from moisture in enough pure water to make 100 cubic centimeters. Fill a burette with the oxalic acid $C_2H_2O_4$ in solution and fill another burette with the sulphuric-acid solution to be standardized. Next prepare an alkaline solution of any convenient strength but the strength need not be known. Lime water made clear by filtering will do. Put 20 cubic centimeters of this alkaline solution in a beaker, add two or three drops of phenolphthalein solution and titrate with the oxalic-acid solution. Next titrate a like portion of the alkaline solution with the sulphuric-acid solution to be standardized. It is required that the sulphuric-acid solution remaining in the bottle shall be so diluted that on further trial the amount to be run in to the alkaline solution from each burette will exactly correspond.

Example.—Suppose that 6.3 cubic centimeters of the oxalic-acid solution and but 5.8 cubic centimeters of the sulphuric-acid solution were required at the first trial. Then every 5.8 cubic centimeters of the stronger solution must be diluted with water until it attains a volume of 6.3 cubic centimeters. Suppose further that 982 cubic centimeters of the sulphuric-acid solution still remains in the bottle. The problem can then be stated by proportion, thus:

$$5.8 : 6.3 :: 982 : (x)$$

Whence $x = 1{,}066$, the required volume, and $1{,}066 - 982 = 88$, the number of cubic centimeters of water to be added. After the water has been added, the titration should be repeated and a further adjustment made if found necessary. Standardizing this solution is quite necessary on account of the fact that the concentrated acid cannot be depended upon to be of uniform strength on account of the avidity with which it absorbs moisture from the air.

Potassium Permanganate Test Solution. Dissolve 4 grams of potassium permanganate $KMnO_4$, in 1 liter of water recently boiled and filtered and keep in an amber-colored glass-stoppered bottle. For use in testing mill solutions it is not necessary that this solution should be standardized.

Phenolphthalein Test Solution.—Dissolve 2 grams of phenolphthalein ($C_{20}H_{14}O_4$), in 100 cubic centimeters of grain alcohol. Then carefully add from the end of a glass stirring rod a dilute solution of any fixed alkali until the test solution acquires a pale pink color, but is not yet reddened by the alkali. This solution is used as an indicator.

Potassium Iodide Test Solution.—Dissolve 10 grams of potassium iodide in 100 cubic centimeters of water. This solution is used as an indicator. After the iodide is dissolved, place a drop of the solution on the spot plate, test with phenolphthalein test solution and, if alkaline, carefully add sulphuric-acid test solution to the iodide solution in the bottle until by further test it is found to be neutral.

Apparatus.—A burette stand should be

provided, capable of holding at least three burettes and it is best to have the burette always occupy the same position on the stand, for instance, beginning at the left, $AgNO_3$, H_2SO_4, and lastly $KMnO_4$. After being filled, the burettes should be covered by loosely fitting caps. This is imperatively necessary if used in a mill or where exposed to lime dust. The usual precaution of always rinsing a presumably clean burette with a little of its test solution just before filling should never be neglected. Muddy solutions sometimes require filtering. Filter papers and funnels should be provided, care being exercised to see that these are not contaminated by acid fumes which might render the determinations utterly valueless. A small portion of each indicator is conveniently kept near the burette stand in bottles of about 25-cubic-centimeter capacity, provided with a perforated stopper in which is placed a piece of glass tubing so drawn as to make a small nozzle. Solution samples are conveniently brought into the laboratory in tin cups holding abount one-half liter. It is presumed that the operator is somewhat acquainted with volumetric methods and will provide himself with such other apparatus as he may deem convenient. He will also be habitually careful in his work when he recollects that he is dealing with very dilute solutions, mill solutions sometimes carrying as little as one part of solids to five thousand parts of water, and negligence in some seemingly unimportant particular is liable to produce grave results.

Determination of Cyanide.—By means of a pipette, transfer 10 cubic centimeters of the solution to be tested to a small flask or beaker. If the solution contains more than 5 pounds of cyanide per ton it is best to dilute it with an equal volume of water before proceeding with the titration. Add two or three drops of the potassium iodide solution and begin running in the $AgNO_3$ solution from the burette, shaking the flask or beaker to redissolve the precipitate formed. In case a mill solution is under examination a white, flocculent precipitate may form which cannot be redissolved by shaking. This should be disregarded, as it is not silver, but probably zinc, the silver iodide being distinguishable by its yellowish color. Proceed with the titration until after shaking a yellowish opalescence remains, due to undissolved silver iodide. This is most readily observed by transmitted light, that is, by holding the liquid between the eye and the light. This end point should be so sufficiently pronounced as to be distinguished with certainty from a slight original turbidity of the solution. Each cubic centimeter of the silver-nitrate solution run in from the burette indicates the presence of 1 pound of KCN or its equivalent in other available cyanides in a ton of solution.

The use of the iodide indicator causes the estimation of the cyanogen in the double zinc cyanide as if it existed in free cyanide, but not the corresponding salt of copper. As the zinc compound is known to be a solvent for gold, no material error is thereby introduced. Without the iodide indicator, a part of the cyanogen of the copper double cyanides is indicated. As the copper salt is entirely useless, the iodide indicator should be used to eliminate error due to possible presence of copper, if for no other reason.

In testing weak solutions or when greater accuracy is required, from 20 to 50 cubic centimeters of the solution may be taken for titration and the reading divided by the required number.

Determination of Free or Protective Alkali. To the same portion of solution that has already been tested for cyanides, add one or two drops of the phenolphthalein indicator. If free alkali is present the liquid will assume a deep red color. Titrate with the sulphuric acid solution until the red color is discharged. Each cubic centimeter of the acid test solution used indicates the presence of 1 pound of lime CaO, or its equivalent in alkalies, in a ton of solution.

Determination of Reducing Agents.—To the same portion of solution that has already been tested add $1\frac{1}{2}$ to 2 cubic centimeters of a 10-per-cent. sulphuric-acid solution. This acid solution is made by mixing one part by volume of sulphuric acid with nine parts of water. Titrate the acidified solution with the permanganate solution until the reddish color of the permanganate remains permanent for about 10 seconds. This is generally sufficiently accurate for mill work. When greater accuracy is required, the permanganate solution should be accurately standardized, a larger quantity of the solution to be tested should be taken, and at least an hour of time allowed for the color of the permanganate to be discharged. It is not necessary that the cyanide solution be first tested for cyanide and alkali. When 10 cubic centimeters of the solution to be tested are taken, each cubic centimeter of the permanganate solution used indicates that approximately one-tenth of a gram per liter (two-tenths of a pound per ton) of oxygen must be combined in the solution to oxidize alkaline sulphides or other reducing agents. Ferrocyanides, generally present in mill solutions, discharge the color of permanganate, but their quantity is generally so small as not to materially affect results when the rapid method above outlined is used.

Determination of Gold and Silver.—A fairly good method, and one in common use, is to evaporate 10 assay tons of the solution on litharge, and making up the litharge into a half-assay-ton crucible charge with silica and fluxes, put it through the regular routine of a fire assay. The solutions are measured into shallow tin or graniteware plates and the litharge added by means of a small measure. The solution may boil quite rapidly until nearly dry when the heat should be moderated. When dry the litharge is scraped out upon a mixing cloth, the silica put into the pan and by means of it the remaining litharge scoured off, which together with the flux is transferred to the cloth and rolled. The mixture is next put into a crucible, inquartrated with silver if necessary, a cover of salt added and it is ready for the furnace. If this method is used it is best to estimate 30 cubic centimeters for an assay ton.

An accurate method of assay requiring less labor than the last is as follows: Procure some tall-form beakers that will conveniently hold 10 assay tons. Have a 10 per cent. solution of lead acetate prepared in a large bottle. Have on hand a quantity of commercial hydrochloric acid as its action is generally more rapid. Fine zinc shavings, or zinc dust, will also be required. Measure into a beaker 10 assay tons of the solution to be assayed. Add 1 to $1\frac{1}{2}$ grams of zinc dust by means of a measure of the required size, mixing the zinc dust by means of a stirring rod. Then add 15 cubic centimeters of the lead-acetate solution and set on the hot plate. When the temperature is about half way to the boiling point add 15 cubic centimeters of the crude hydrochloric acid, adding the acid in two separate portions if the action is too violent. The assays are then left on the hot plate until the zinc is dissolved, which usually occurs in about 15 minutes, but they may be left a much longer time if it is not convenient to give them immediate attention. The solution will be clear and contain a quantity of spongy lead, mostly in the bottom of the beaker. The gold and silver is in the lead. Decant off the solution, collecting the lead if necessary by means of a glass rod. Add about 100 cubic centimeters of water and again decant. Place the spongy lead upon a small square of lead foil, fold, squeezing in the fingers, dry for a minute on the hot plate and the assays are ready for cupellation. If inquartration is necessary this is best done by adding silver nitrate solution from a burette as soon as the solution is measured into the beaker. Some use a $1\frac{1}{2}$-inch square of aluminum foil instead of the zinc. If the foil is one-sixteenth inch in thickness it will last a long time, as but little of it is dissolved. The spongy lead is easily separated from the foil.

Solution Tests Without Reagents.—The presence of caustic lime can be detected by breathing upon the solution. If the amount of lime is considerable, say, 2 pounds per ton, the solution will be at once covered with a pellicle of $CaCO_3$. If only a trace of lime is present the pellicle will form slowly and only in small patches. Absence of protective alkali is evidenced by the evolution of HCN, plainly discerned by its smell. This state of affairs anywhere about a mill calls for prompt action.

(*To be continued*)

The Ocher Deposits of Georgia

Where the Ocher Is Found, Its Method of Occurrence, and the Manner in Which It Is Prepared

*Written for Mines and Minerals by S. W. McCallie**

THE ocher mines of Georgia are in the vicinity of Cartersville, Bartow County, about 50 miles northwest of Atlanta. The deposits are confined to a narrow belt some 8 miles long and less than 2 miles in width. The associated rocks are chiefly quartzites of Cambrian age, which have been closely folded and also faulted.

Drying Shed, Riverside Ocher Co., Bartow County, Ga.

Ocher mining had its beginning in the Cartersville district in 1877. A year later a small plant for drying ocher was erected and put in operation within the corporate limits of Cartersville. In 1890 the Peruvian Ocher Co. began operations on a large scale, and during the following year made its first shipment of ocher to European markets. Subsequent to the last-named date three other large ocher plants were put in operation, all of which have been operated more or less continually. The four plants have a total maximum output of about 800 tons of washed ocher per year. The most extensive workings are those of the Georgia-Peruvian Ocher Co., on the left bank of the Etowah River, 2½ miles east of Cartersville.

The Georgia ocher is a pulverulent, yellowish earthy material consisting largely of iron oxide intermixed with more or less clay and sand. In addition to the minerals here named some of the deposits carry a small amount of manganese, which gives to the refined ocher a greenish tint. Barytes is also often met with in the form of beautiful crystals, and, strange to say, these crystals are frequently almost perfectly transparent and free from iron stain. Barytes crystals are especially abundant at the mine of the Georgia-Peruvian Ocher Co., which has become a well-known locality to mineral collectors.

The ocher occurs in greatest abundance along the shattered zones of what is known as the Weisner quartzite and in the residual clays derived from the quartzite. So far as mining developments have progressed at present, there seems to be nearly an equal occurrence in the broken quartzite and in the residual clays. In the quartzite the ocher forms irregular branching and intersecting veins, which often expand and enlarge into bodies of ocher 10 feet or more across. When the ocher is taken from these irregular veins and pockets, the quartzite is left completely honeycombed with irregular passages and rooms, not unlike the labyrinthine passages often met with in limestone caverns. In the residual clays, the ocher is likewise irregular in occurrence, both in its vertical and longitudinal extent, but at the same time its occurrence is not so variable as in quartzite. Here, as in the quartzite, the contact of the ocher and the clay is never distinct, there being a gradual blending of the one with the other.

Mining is carried on largely by tunnels, drifts, and slopes, similar to coal mining. None of the ocher is marketed in the crude state. To obtain the merchantable product, the only preparation necessary is the separation of the ocher from its mechanically admixed impurities, and otherwise preparing it for market by washing, drying, pulverizing, and packing.

After the ocher has been mined it is carried on a tramway to the washer and dumped into a long trough or box filled with running water. A central shaft armed with iron blades arranged in the shape of a broken helix, revolves lengthwise in the box and violently agitates the ore. The very finely divided particles of ocher remain in suspension in the water and are floated off through an opening near the top of the box into a race or flume which empties into a series of vats some distance away, where the ocher is allowed to settle. The water is in large part siphoned from the vats by means of rubber hose, and the ocher is allowed to partly dry. It is then removed from the vats in the form of a stiff mud to the drying racks under a shed, where the drying process is completed. Artificial drying is in vats or tanks arranged in series, and in which iron pipes are run at close intervals along the sides and bottoms for steam heating. Drying by this method requires usually not longer than 1 or 2 days, when the ocher is ready to be removed to the racks and the drying continued for the usual time, 8 to 12 days, before the ocher is dry enough to pulverize. After being thoroughly dried on the racks, the ocher is removed to a room where it is pulverized and packed under steam

Plant of Georgia-Peruvian Ocher Co.

*State Geologist.

pressure. Packing is in barrels and bags of uniform size. Capacity of the barrels is from 350 to 400 pounds, and that of the bags 210 to 250 pounds.

The principal use made of the yellow ocher mined in Bartow County, up to the present time, is in the manufacture of linoleums and oilcloths. For this consumption the markets are in England and Scotland, to which the bulk of the Cartersville product is exported. Some of the ocher is used for a similar purpose in the plants manufacturing linoleums and oilcloths in the United States. It is used also to a limited extent in the manufacture of paints.

Until recently, the American ochers have been considered inferior to the imported ochers from other countries for the manufacture of paints. Gradually, however, the excellent qualities of the Georgia ochers for paint purposes are beginning to be recognized, and it may be confidently predicted that in the future an increasing demand will be made for this product in paint manufacture. By reason of its high grade, containing proportionately a smaller amount of impurities and a larger amount of iron oxide than most of the yellow ochers produced in the United States, the Georgia ocher yields on calcining a rather desirable red pigment, which must eventually make its way into the markets. The Georgia ocher is further used in a variety of minor ways, the demand for which, however, is very limited.

The principal markets at present for the Georgia product are foreign, and they include points in England, Scotland, Ireland, and to some extent, Germany. It is also shipped for use to many of the larger towns both in the North and in the South.

"Curie," the Standard for Radium

A conference of all civilized nations requested Mrs. Curie, the well-known radium scientist, to establish a standard for the measurement of radium and radioactivity. Mrs. Curie took up this work with great zeal and brought it to a successful finish. She established a standard by which the radioactivity will be uniformly measured throughout the world, and through which in future all radioactivity may be determined. In honor of the famous scientist the standard measurement is called "curie." It is very interesting to get acquainted with the full particulars of this "curie."

The "curie" consists of pure radium which has been produced by Mrs. Curie herself in her own laboratory. It has the form of a tube, is 30 millimeters long, 3 millimeters thick, and weighs .2 gram. But in medical use there are only quantities of .001 gram since larger quantities are not supplied. The quantity of the emanation from .001 gram of radium is called one "millicurie." This measurement probably will be, before long, the standard for radium measurements. The governments of Germany, England, and Italy have already taken steps to secure for their respective countries standard measurements for radioactivity. The "normalcurie," created by Mrs. Curie, will be preserved at Breteuil near Paris and deposited there at the "Bureau International," in which is also a standard meter measurement that can be affected neither by heat nor cold. The weights and measures preserved in this "Bureau International" will therefore be enriched by the most modern of all measurements, the "normalcurie." It took Mrs. Curie more than 2 years to finish her work.

Asphalt Minerals

There are several asphalt minerals. Albertite differs from ordinary asphaltum in being only partly soluble in oil of turpentine and its very imperfect fusion when heated. It emits a bituminous odor and when rubbed becomes electric. It is brittle with a conchoidal fracture. Its luster is brilliant and pitchlike, its color jet black, and its streak black to brownish black. It softens a little in boiling water and intumesces in the flame of the spirit lamp, emitting gas, but it does not melt like asphalt. In the closed tube, however, it can be melted with some intumescence. It is soluble to the extent of 4 per cent. in ether, 30 per cent. in oil of turpentine, but is practically insoluble in alcohol.

Grahamite resembles albertite in its pitch black lustrous appearance, but is distinguished from it by its action with various solvents. It is brittle and has a subconchoidal fracture. Its streak and powder are a dark chocolate brown, it has the hardness of 2 and a specific gravity of 1.145. Heated to 400° F. it softens so that it can be melted and drawn out into threads, but it melts only imperfectly and with a decomposition of the surface. On heating it decrepitates and behaves very much like caking coal. It is dissolved rapidly by chloroform and carbon bisulphide; it is slowly but mostly dissolved by oil of turpentine and coal tar benzole, and partly by ether, naphtha, benzine, and gasoline. It is insoluble in alcohol and is unacted upon by caustic alkalies and nitric or chlorhydric acid. Strong sulphuric acid is colored brown by it. It consists essentially of 79 per cent. carbon, 6.5 per cent. hydrogen, 14 per cent. oxygen. It is one of the indicators of petroleum. Gilsonite is considered to be a variety of grahamite. It has a brilliant and lustrous black color, gives a rich brown streak with a shade of red. It is very brittle, showing a conchoidal fracture and is easily crushed to powder. It has a hardness varying from 2 to 2.5 and specific gravity of 1. It is a non-conductor of electricity and is electrically excited by friction. It fuses easily in the candle flame and burns brilliantly, much like sealing wax, and like sealing wax it will take a clean sharp impression from a seal, but unless the melted mineral is very hot it does not adhere to cold paper. It has considerable plasticity when warm and is not sticky, but retains after melting its lustrous black and smooth surface, and can be melted and cooled rapidly without any apparent change in composition, although it doubtless loses some of its volatile matter. Upon distillation a very small quantity of clear white dense oil is driven off and a little gas or vapor. It dissolves readily in melted wax, ozokerite, spermaceti, and stearine; it also dissolves readily in crude petroleum and heavy lubricating oil, but the white distillates from petroleum have little or no effect upon it at ordinary temperature. It dissolves freely in oil of turpentine when warm, but does not dissolve readily in cold spirits of turpentine. It is soluble in ordinary alcohol. Ether does not attack fragments, but slowly dissolves the powder. Its composition is about 80.5 per cent. C, 10 per cent. H, 3.3 per cent. N, and 6 per cent. O.

Ozokerite is a mineral of the simple hydrocarbon group which consists chiefly of members of the paraffin series. In appearance and consistency it resembles wax or spermaceti. When pure it is colorless to white, often leek green, yellowish, brownish yellow, and brown, translucent, and greasy to the touch. Fusing point about 56° C. Specific gravity .85. It is soluble in ether, carbon bisulphide, oil of turpentine, benzine, and naphtha. Slightly soluble in boiling alcohol.

Wurtzilite is a solid black mineral with brilliant conchoidal fracture and a general resemblance to jet or some of the cannel coals. It is sectile and the shavings are somewhat elastic, and if bent too suddenly when cooled they snap like glass, but when slowly pressed and warmed, a flake may be bent nearly double. The mineral in very thin plates is of a deep red color and by reflected light is jet black. Its hardness varies from 2 to 3 and its specific gravity is .03. It does not melt in boiling water but becomes softer, tougher, and more plastic. In the flame of a candle it melts, takes fire, and burns with a bright luminous flame with very little smoke, giving off a strong bituminous odor. Fused in a glass tube, it emits a dense cloud of white and yellow smoke and a distillate of a thick brown tarry oil with a strong odor, leaving a small residue of fixed carbon. Fragments warmed in the hand emit a strong odor, rather offensive, like that of some of the crude petroleums.

There are two classes of bitumen rocks, known as bituminous limestone and bituminous shale. The color of these rocks is usually greenish. The shale will take fire and burn, giving off the peculiar odor of bitumen somewhat similar to that of burning rubber. The limestone will not burn as readily.

Refining With Boiling Water.—Asphalt, such as is found in asphaltic sandstone, is extracted by boiling the asphalt-bearing rock in water, the cooled rock is crushed and deposited in iron kettles which previously have been about half filled with water. As soon as the temperature of the water and rock reach the melting point of the asphalt, the latter separates from the rock and floats to the surface from whence it is collected. The mineral tar thus obtained contains water and earthy substances which must be removed, and to accomplish this the pure bitumen is again heated in proper vessels until the water is evaporated and the larger part of the impurities separated and settled, and the bitumen is placed in barrels. The residum of the second operation is utilized in the manufacture of mastic blocks. The heavier asphaltum cannot be refined by the boiling process, on account of its high specific gravity and because of the nature and occurrence of the impurities, which are mixed through the asphaltum in a state of so fine division that they cannot be separated without effecting a solution of the asphaltum. This is accomplished in a crude way by melting the asphaltum and keeping it at a temperature sufficiently high to evaporate the water and light hydrocarbons, while at the same time part of the heavier impurities settle out. Rock asphalt and more especially asphaltic limestone, is beyond doubt the most suitable for paving purposes.

For the recovery of the bitumen of very asphaltic rock, the oldest process consists in subjecting the rock to a temperature above the melting point of the bitumen and collecting whatever drains from the heated rock. This process is carried out in reverberatory furnaces and yields from 25 to 75 per cent. of the asphalt, according to the density of the rock. It is very difficult by this means to obtain a uniform product, and it is, therefore, considered better to extract the asphalt by means of a solvent such as benzine, petroleum, naphtha, and carbon bisulphide. In selecting a solvent, however, to extract asphalt, it is to be borne in mind that the solubility of both petrolene and asphaltene is unlimited in carbon bisulphide, while petroleum naphtha will only dissolve a fixed amount of asphaltene at a given temperature, though it dissolves petrolene in all proportions. This property of petroleum naphtha offers excellent means to control the constituents of asphaltum, and, in the process of extraction, to adjust the desired proportions of asphaltene and petroleum to a nicety. The process is to crush the rock and put it in a large iron cylinder which has a steam jacket surrounding it, then to admit naphtha; the distillate which arises is carried off in a tube and deposited by condensers. The carbon bisulphide process differs somewhat from this and there is a complete extraction, which is more rapid than that of naphtha. The use of carbon bisulphide as a solvent requires the same amount of labor and about 10 per cent. less steam. For the extraction of asphalt from rock with carbon bisulphide the same apparatus may be used as for naphtha.

Great Alaskan Earthquake

The United States Geological Survey has just published an account of one of the 10 greatest earthquakes of historic times—that in the Yakutat Bay region of Alaska. Although there is no especial relation between earthquakes and volcanic eruptions, the recently reported earthquake at Fairbanks as well as the activity among Alaskan volcanoes gives perhaps added interest to this account of a natural phenomenon of another class.

The Yakutat Bay earthquake occurred on September 3, 1899, and was followed during the next 3 weeks by many less violent shocks. The area of greatest intensity lay along the flanks of the St. Elias Range, in a region of high mountains and suberb glaciers, and the movement was accompanied by enormous avalanches and rock slides. This is a vivid demonstration that the growth of mountains is still in progress. At some places in the region the land subsided and forests were submerged. At most places, however, the land rose, and many points which before had lain below sea level were elevated above it. Barnacles which had lived in sea water were found 47 feet above sea level. The study of the effects of this earth movement was undertaken by the late Ralph S. Tarr, of Cornell University, and Lawrence Martin, of the University of Wisconsin, and their report of the work has been published as Professional Paper 69 of the United States Geological Survey, with a preface by G. K. Gilbert.

In addition to making an exhaustive study of the movements of the land which took place in the Yakutat Bay region and of the effects of the earthquake upon the many glaciers of the region, the writers amassed a great fund of information in regard to the intensity of the quake throughout the whole area within which it was sensible and recorded the testimony of many witnesses. The shock was felt at distances of 670 and 1,200 miles in opposite directions from Yakutat Bay, and the area of the region over which the tremblings were felt is more than 1,500,000 square miles. This gives the Yakutat Bay earthquake a place among the very greatest earthquakes of historic times. The other great shocks, without exception, resulted in heavy loss of life, the number of persons killed reaching in one of them the enormous total of over 60,000. The Yakutat Bay shock was fortunately free from fatalities, not because it was less severe than the others, but on account of the sparsely settled character of the region in which it occurred.

This report—"The earthquakes at Yakutat Bay, Alaska, in September, 1899"—is illustrated with half-tone views showing the effects of the earthquake, maps, and seismograms of the shock as recorded at places as far distant as Batavia, Java; Cape Town, South Africa; and Catania, Italy. A copy of the report may be obtained free on application to the Director of the Geological Survey, Washington, D. C.

Once More the "Dowser"

The "bob stick" is not American exclusively, nor is it an article that has passed from interest, for we are told in a recent issue of the *Mining Journal* (London, England), that it has recently been so seriously held in the Cornwall mining region as to have been the subject for a public lecture. The inventor of this new "dowsing rod" has combined just enough mysticism with an appearance of scientific investigation to have influenced the credulity of the correspondent, and we abstract from his write-up as follows:

"The instrument employed by Mr. Fosdick bears no resemblance to the hazel-fork branch, its form being that of a truncated octagonal cone of Jarrah wood, about $1\frac{1}{2}$ inches in diameter at the top end, $\frac{3}{4}$ of an inch in diameter at the bottom, and $3\frac{1}{2}$ inches long. There is a groove in each of the eight facets into which to slide various slips of metal. This cone is attached by a supple piece of twine about 18 inches long to the middle of a bar of the same kind of wood about 5 inches long, $\frac{3}{4}$ of an inch wide, and $\frac{3}{8}$ of an inch thick. The operator takes the bar of wood in the right hand, letting it rest on the thumb and little finger, the other three fingers being above and not touching the bar, the cone being allowed free play and hanging from the bar by the twine. When hanging vertically over any metal-bearing substance, the Jarrah wood cone oscillates with a good swing in the direction of the greatest length of the substance. In this tracing of lodes, the direction of the swing denotes the strike; whereas, if there is no metal-bearing substance underneath, the cone remains stationary. As with the hazel twig, not everybody can operate it. In some hands, the cone remains stationary whatever there may be underneath. With an adept, a certain qualitative analysis of an ore can be discovered, for if there is a tin lode underneath, the cone will vibrate freely, but if strips of tin are inserted into the grooves of the cone, the instrument will not vibrate. The same obtains with the other metals, so that the insertion of any metal strip causing the cone to cease vibrating, points to the fact that the stone contains that metal."

Power Consumption of Hoisting Plants

Relative Economies of Steam, Air, and Electric Hoists—Tests of Electric Hoists Under Varying Conditions

Written for Mines and Minerals by S. W. Sykes

Reference has often been made to the development of the electric hoist abroad; and with the increasing use of this kind of hoist for hoisting from mines, it may be of interest to discuss the question of economy of the various types of electric hoists compared with steam and compressed-air hoists. It is useless to give specific figures of the cost, as these will depend upon local conditions; but it is believed that some test results may be of interest as indicating the basis on which to estimate the cost of operation.

The economy of electric hoists is affected so much by operating conditions that to properly appreciate the subject a very close examination of local requirements is necessary. The great flexibility of electric-power transmission and distribution renders it possible to locate electrically driven hoists in situations where steam would be impossible, and where it would be necessary to use compressed air.

The ease of control of the electric hoist, and also the possibility of making it more or less automatic, is, for a great many locations, of the utmost importance. The ease with which distribution lines can be insulated, eliminates any question of loss except that due to voltage drop.

In case of steam hoists, it is necessary to have steam pipes connecting the engine to the boiler house, which generally are a source of considerable loss. Even comparatively short lengths of piping cause considerable, condensation, and seriously affect the over-all efficiency of the equipment.

The steam hoist, because of the conditions under which it operates cannot compare with the electric hoist for underground service, owing to the heat from steam pipes and the troubles arising from the exhaust. The steam plant also has the disadvantage of requiring generation of the steam close to the hoist, and this eliminates the possibility of purchasing power from any central generating equipment. In the case of small hoists, the burden of a boiler plant, with its attendant labor and up-keep, adds considerably to the cost of hoisting.

When electric power can be purchased, it is economical to pay even as much as the full cost of the fuel for a steam hoist, on account of the saving of labor and and maintenance. The economy of the small steam hoist is, however, generally very low, and the fuel cost is, as a rule, considerably more than cost of current; and it can generally be stated that the difference in favor of the electric hoist increases as the size of the plant decreases.

The only other competitor of the electric hoist is the air hoist, which has been used to a limited extent in certain localities. The air hoist suffers from the disadvantage of the steam plant, as far as the trouble of handling pipe is concerned, but it is possible to transmit air over considerable distance with very little loss, if the lines are in perfect condition. This is seldom the case, and one of the causes for the low efficiency of air hoists, is the leakage that invariably takes place. By reheating the air, the loss of efficiency due to the air cooling during transmission can be considerably improved, but this requires either a steam supply or a furnace close to the hoist.

The air hoist has the same limitations as the steam hoist, as far as control is concerned, and does not lend itself readily to the use of automatic devices. The limitations of the steam and air hoists are more evident the larger the equipment; and owing to the difficulty of operation only the highest class of labor can be used.

Electric Hoists.—In the case of small electric hoists, the power consumption is generally of minor importance, although such hoists are as a rule naturally efficient. The advantage the small hoist has over any other system for mining, is so great that the cost of current is a secondary matter. In case of large hoists, however, where the power consumption may be considerable, more attention must be given to the question of economy, although this may not be by any means the controlling feature. Where power is purchased and the rate is based upon load factor, or where the generating capacity available for supplying the hoist is limited, the peak load may be of greater importance than the power consumption, and it will pay to use some system of equalization, although the kilowatt hours required to perform a certain amount of work may be increased. In such cases it is necessary to carefully consider the local conditions existing, as it is not always obvious which is the best system to adopt. For instance, some power companies charge for power on a certain percentage of the instantaneous peak load or upon the 5-minute average load, at their option. Under certain conditions it may happen that the rate of charging is determined, not by the peak load, but by the average input to the hoist. In such a case there would be no advantage in equalizing the load although at first sight it would appear that this would reduce the cost. The system of charging is of primary importance in determining the kind of hoisting equipment when power is purchased and should always be given the first consideration.

In comparing different hoists designed for different duties, it is difficult to find a proper basis, on account of the various features entering into the design of such equipments. From a standpoint of power consumption, however, we are concerned only with the input to the hoist required to perform a certain amount of useful work. Useful work performed is that necessary to hoist the net load the required distance, and this is the same whether the hoist is working balanced or unbalanced, as with 100 per cent. efficiency the amount of power required to lift the unbalanced weight of cage and rope would be returned when lowering. In general, the over-all efficiency is expressed in terms of input to shaft horsepower or

$$\frac{\text{Net load in pounds} \times \text{vertical height in feet}}{550} = \text{shaft H. P. seconds}$$

The economy of electric hoisting depends partly upon the system used, but to a certain extent cannot be controlled by any system of driving, as there are certain losses which are independent of the motor or engine. The principal of these are:

The shaft friction which is generated by the movement of the cage on the guides, and the resistance of the air to the cage movement. In vertical hoists, the air friction is considerably more than the friction of guides, especially for high-speed hoists. With two-tracked incline hoists, the friction of the car on the rails or guides is generally more than the air friction.

Sheave friction is as a rule very small except in certain cases where a number are used for guiding and supporting a rope when the shaft is not vertical. In case of vertical shafts, it is practically negligible.

Friction of hoist and gear: This item is generally the greatest loss that is independent of a system of driving, although with modern equipment, using direct-connected motors or engines, the loss may be very small. Where gearing is used, the loss is greatly increased, unless considerable care is taken in the manufacture of the gear and in the alinement of the equipment.

Rope friction. There is some loss involved in bending ropes due to the internal friction of the strands, and this may be considerable where the rope is wrapped around several sheaves, such as in the Whiting system of hoisting. As a rule, however, this loss is very small and can be neglected.

The losses due to the electric drive depend upon the system of control. Where a simple rheostatic control is used either for a direct-current or alternating-current motor, the losses will be:

1. The motor loss consisting of copper, iron, windage, and bearing losses.
2. Loss in rheostat.

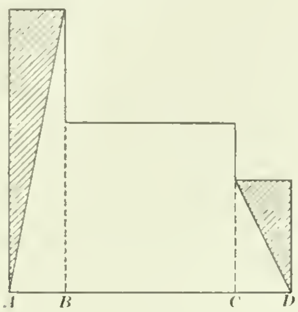

Fig. 1

When the voltage control system is used and a special generator supplied, the field of the generator being varied so as to vary the voltage applied at the motor terminals, the losses are as follows:

1. Motor losses consisting of copper, iron, windage, and bearing losses.
2. Losses in motor-generator set, due to the individual losses in the machine. The loss in the motor-generator set may be divided into two parts: (a) the constant loss, due to the set running light, and (b) the variable loss which is caused by the operation of the hoist. The variable losses are made up of the iron and copper losses of the generator and copper loss of the motor. The constant loss is the windage and bearing friction, as well as the iron loss of the motor. When a flywheel is used with a motor-generator set for equalizing the input, the losses are the same as the voltage-control system except that the constant losses are increased by the amount necessary to drive the flywheel and these losses may be considerable, under unfavorable conditions. There is also the loss due to the slip regulator, if the hoist is operating on an alternating-current system, which may be from 5 per cent. to 10 per cent. under normal conditions.

Rheostatic Control.—In order to understand properly the losses due to rheostatic control, it is necessary to refer to a characteristic load diagram.

In Fig. 1 is shown a load diagram for a balanced hoist with a tail-rope. *AB* represents the acceleration, *BC* the period of running at full speed, and *CD* the period of retardation.

The energy absorbed in the resistance is made up of two parts, one being equivalent to the amount of energy stored in the moving parts and the other being equal to the power required to move the static load through the distance traveled during the period of acceleration.

It will be seen that this is equal to half the energy put into the hoist during the period of acceleration and retardation, which will be readily understood when it is considered that the average speed during these periods is half the full speed if the rate of acceleration and retardation is constant. It is obvious that the time of acceleration and retardation influence considerably the rheostatic loss, as the energy absorbed during the acceleration of the moving parts remains the same, independent of the time; but if it is increased, the period during which the motor must overcome the static load at a reduced speed, is greater, and the difference in output, when working at the reduced speed compared with the full speed, must be absorbed in the rheostat. Considered solely from the standpoint of minimum power consumption, the acceleration should be as short as possible and the retardation so arranged that when the current is cut off, the hoist comes to rest at the landing stage without any braking. This is not always practical and it is sometimes necessary to sacrifice economy to meet operating conditions. This diagram illustrates a simple case where the static load is that due to the material to be hoisted and it is constant during the whole of the hoisting period,

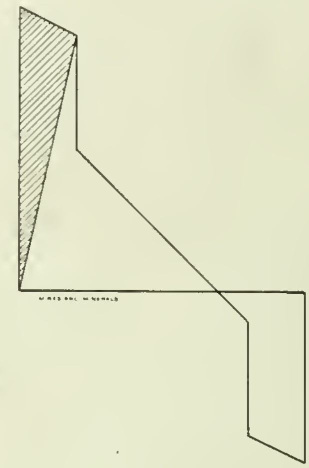

Fig. 2

as the other moving parts are balanced. With the ordinary cylindrical drum without a tail-rope, but with the cages balanced, the static load during starting may be very much greater than that due to the net load alone, on account of the fact that the rope is not balanced. The static load in such a case is made up of that due to the net load, rope, and friction. At the end of the trip there is no unbalanced rope on the loaded side, but on the empty side there is the full weight of the rope suspended, and if the rope weighs more than the load, the diagram will show the load driving the drum.

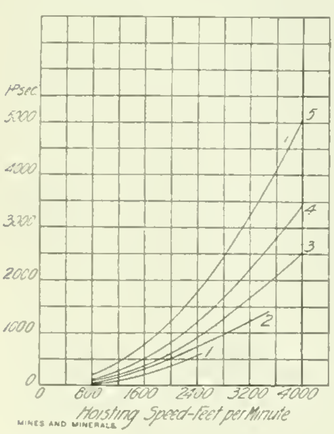

Fig. 3

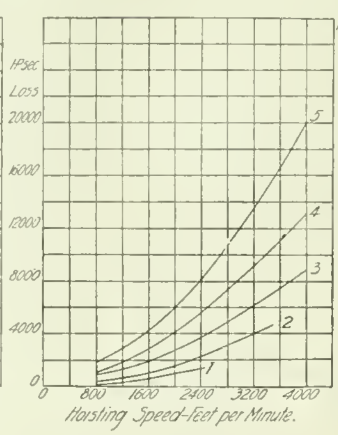

Fig. 4

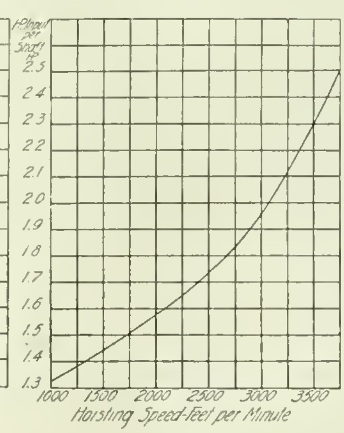

Fig. 5

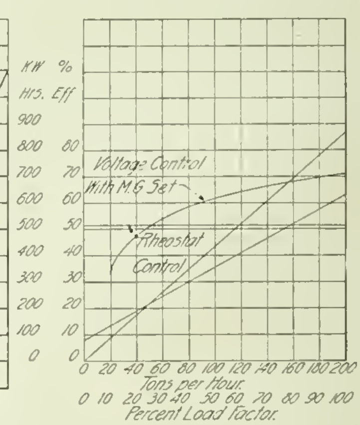

Fig. 6

In Fig. 2 is shown a characteristic load diagram hoist without tail-rope, for a deep shaft. In this case, the weight of the rope is more than that of the load lifted, so that there will be a negative torque before the load reaches the surface. This acts against economy in two ways; in the first case, the total torque at starting is very great in relation to the load lifted, and consequently, the rheostatic loss due to the static load at starting is very great. When there is negative torque, it is not possible to regain some of the energy during retardation, and consequently the whole of the area below the zero point represents lost energy, which must be absorbed in the brakes under ordinary conditions. If the hoist is stopped by reversing the motor, the losses will be further increased by an amount represented by the area below the zero line.

In Fig. 3 is shown some curves based upon average results with double-drum hoists working balanced without tail-ropes. Curves have been drawn for hoists designed for 500 to 4,000 feet total depth, and it will be seen that with the increase in the depth for which the hoist is designed the power required for acceleration increases very rapidly, owing to the fact that the weight of the rope and all the parts of the hoist increases at a greater rate than the depth.

These curves show the horsepower seconds required for each ton of net load for which the hoist is designed. For instance, a hoist built for 3,000 feet, running at the speed of 4,000 feet maximum, requires about 3,500 horsepower seconds per ton, so that for a 5-ton hoist the power required for acceleration would be about 17,500 horsepower seconds. These curves are based on average hoists, and are representative of normal conditions. It will be understood that the power required per ton of load will decrease as the load increases, as the weight of the parts does not increase in proportion to the net load; but for average loads these curves are approximately correct.

Fig. 4 shows the results of a considerable number of tests giving loss in the rheostat for various conditions. It will be seen that in general these curves are similar to those in Fig. 3. The hoists built for the greater depths, on account of the greater mass to be accelerated and the greater static load at starting, require considerably more power per ton.

It is not intended that these curves should be taken as representing absolute conditions, as a considerable variation may be caused by local conditions, but they indicate the relation between the loss and the depth of mine and the speed.

Figs. 3 and 4 show very clearly the price that must be paid for high speed, and it is clear that in order to obtain the best economy, the hoisting speed should be as low as possible. As the depth increases, the rheostatic loss is also increased on account of the greater weight of the moving parts required to handle the load; but the net load is also generally increased for the greater depths, so the loss per ton remains about the same. With the increasing speed, the loss naturally increases on account of the greater time the rheostat is in circuit; and an examination of a number of tests shows that the efficiency is practically controlled by the maximum speed of hoisting in the case of the cylindrical-drum hoist.

In Fig. 5 is shown the average of some test results, which indicate that for high speeds hoists with rheostatic control are not particularly economical. It is seldom, however, that rheostatic control is used for such hoists, as generally high-speed hoists are only used for great depths and the size usually warrants a more economical arrangement.

The results given in the three preceding curves, it should be understood, apply only to balanced, cylindrical-drum hoists without tail-ropes. In the case of conical or cylindroconical drums or reels, the starting conditions are more favorable to

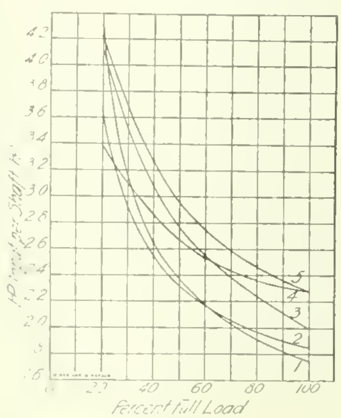

Fig. 7

rheostatic control, but these types of hoists are only used to a very limited extent.

The curve shown in Fig. 5, indicates that where high speed is required some type of control other than rheostatic should be adopted. In case power input equalization is not required, an ordinary motor generator can be used with a direct-current hoist motor, the speed of the latter being controlled by varying the field of the generator. With this type of control, which has been used for some very large installations; the rheostatic losses are eliminated; and under conditions where there is a negative torque, or in other words where the hoist tends to drive the motor, energy can be returned to the line. The losses in the motor-generator set, however, tend to offset to some extent these savings, and the over-all efficiency depends upon the degree to which the hoist is utilized. If the hoist is running almost continuously, the losses due to the motor-generator set will be comparatively small, whereas, if the operations are infrequent, and the motor-generator set is kept running continuously, the losses will represent a very much greater percentage.

In Fig. 6 are shown some comparative figures for a hoist operating from a depth of 3,000 feet at a maximum speed of 3,000 feet per minute. These curves show the total power required when hoisting at various rates, and it will be seen that the over-all efficiency of the motor-generator equipment is appreciably higher than the rheostatic control, when the hoist is working fairly well loaded; whereas at the light loads, the rheostatic control is more economical. They are equal at about 25 per cent. of the maximum capacity.

In cases where it is required to equalize the power input to the hoist, by mounting a flywheel on the shaft of the motor-generator set, causing this flywheel to deliver energy as required, the losses are naturally increased. This increase is due to the extra friction and windage of the flywheel, which may be considerable; and in case the motor-generator set is driven by the alternating-current motor, there is a certain loss due to the resistance, which it is necessary to insert in the motor in order to obtain the required speed variation. The resistance loss varies with the amount of work that the hoist performs, but the loss due to the flywheel is practically constant, independent of the rate of operation. It is therefore obvious that the over-all efficiency will vary according to the rate at which the hoist is used. This is a very important feature and it is common practice to determine the capacity of the hoist more upon its capacity for a short period than upon the average daily capacity required, it not being generally appreciated that this increase in the capacity for short periods, means a considerable reduction in the all-day efficiency.

In Fig. 7 is shown the result of a number of tests on such equipments, operating both in this country and in Europe. These curves show that the power consumption increases rapidly for the lower capacities.

In the case of the curves *3* and *5*, it should be noted that these tests were made when the hoists were operating from approximately half the depth for which they were designed, so that the flywheels are very much larger than required and the machines also have a far greater capacity than necessary, hence the operating conditions are decidedly unfavorable. Curve *4* indicates that the losses in the machine are a great percentage of the total loss, as from the shape it is obvious that the fixed losses are not very great. The high transformation losses are due to the rapid acceleration and retardation necessary with the comparatively high speed for this depth.

In order to improve the efficiency of this hoist, it is necessary to make a careful study of the distribution of losses. In case the hoist is used near its full capacity regularly, it will be generally more economical to use a comparatively large flywheel and reduce the rheostatic losses in the slip regulator in the case of motor-generator sets driven by induction motors. When the average work is considerably below the maximum capacity, it will be found advantageous to decrease the size of the flywheel, allowing a greater slip, and increase the the rheostatic losses.

The bearing friction may be appreciably reduced by decreasing the number of bearings and their size, providing, if necessary, forced lubrication with suitable oil cooling arrangements. The excitation should be reduced as much as possible, and when the hoist is at a standstill, means should be taken to either reduce the current flowing in the hoist-motor fields or to cut them off altogether. Comparatively little improvement in economy can be obtained by increasing the efficiency of the machine above ordinary commercial values, as it is the constant losses that mainly effect the all-day efficiency.

(To be continued)

Turquoise in Arizona

The turquoise mining district is situated on the east flank of the Dragoon Mountains, in Cochise County, Ariz., about 14 miles east of Tombstone. The district is reached by a branch of the El Paso & Southwestern Railroad from Douglas. As described by F. L. Ransome in Bulletin 530-C, United States Geological Survey, it contains two small settlements, Courtland and Gleason. The turquoise mines, from which the district gets its name, are on the west side of Turquoise Hill, northwest from Courtland. They are said to have been fairly productive, but are now idle and very little could be learned of their history.

The turquoise occurs in joints and small irregular fractures in a bed of Cambrian quartzite that outcrops along the west side of Turquoise Hill a few feet above the contact with decomposed granitic rock. At the opening examined the bed had been stoped to a width of 4 feet and a depth of 75 feet or more, the bottom of the shaft being now filled with water. A short distance north of this opening and near the western boundary of the area mapped, other workings, perhaps a little more extensive than those visited, have been opened on the same bed of quartzite.

According to a report by A. B. Frenzel, part of which appeared in the *Mineral Industry* in 1899, there was considerable activity in turquoise mining at Turquoise Mountain in 1898. This mountain is 18 miles from Kingman in Mohave County, where Aztec or Indian workings were reopened. Veins of turquoise showed from the commencement of operations, increasing in width as the work progressed. Near the surface the stone was of poor color and quality, but as depth was gained the rock became firm and the turquoise solid and of better color.

The Leasing of Metal Mines

An abstract from a recent editorial in the *Salt Lake Mining Review* needs some qualification. While admitting some of the good points made in favor of leasing mining properties, still serious objections may be raised against the system. The *Review* says:

"A great many mining men—men who work in the mines and who know how to polish off the head of a drill—could make a great deal more than regular wages if they would take a working lease on some property of known value; and more than one mining company, if it could be brought to believe it, would derive a greater revenue by leasing its properties than by working them.

"Lessees can often accomplish more than a mining company. The lessee is working for himself, individually, and knows no hours.

"The mining company has fixed charges to meet, such as office rent, and salaries to secretary, manager, and office boy. The lessee works hard all the time, because he is working for himself. The pick-and-shovel miner, in the employ of a company, has no interest at stake but to put in his time, and this often at an actual loss to the company. The lessee has but few wants and demands no luxuries. He can live and carry on his work at half the expense that a company can. A lessee will get along with less equipment than a company, with its big ideas. His automobile is often nothing but a burro, and his champagne merely good spring water. Therefore his expense account is not padded, and he has no need to tear his hair and wonder what his manager is doing that so much money is needed in outputting a few tons of ore.

"The leasing system is good for any camp. A miner who is fortunate in securing a good lease is much better off than if he were working in a company mine for so much per day. He is a benefactor to his camp, for he buys his supplies of local merchants and the men he employs spend the major portion of their earnings among the business men of the district. The lessee is oftentimes more successful and independent than a mining company, and perchance may develop a small mine into a great producer."

We do not believe it to be universally advisable for a company to let out its ground under leases. There are, as stated, very peculiar features of economy attaching to the system of leasing. But, on the other hand, the very fact that a lessee gives little heed to many of the things that would give a company superintendent or manager serious concern, introduces a weak point. A lessee will spend just as little as possible in timbering, in tracklaying, and in ventilating. He will not exert himself nor spend his money in making the mine workings safe or workable longer than he is required to occupy them. His work is therefore not of the standard most large mining companies are obliged to maintain. He will take chances on his life or health that our very worthy laws will not sanction in the wage practise. He will submit to adverse conditions and to inconveniences that he would not stand were he working under day's pay in the same property. Naturally, he is straining every point to get the largest returns with the very minimum of cost, and he is not devoting any consideration to the wreckage that may prove a sequel to his operations. Therefore many companies, while realizing and appreciating the arguments set forth by the advocates of the leasing system, prefer to keep on the "company" basis until they have exhausted all the known available ore bodies. When a mine has reached this point, and the owners are sure that they, themselves, shall never wish to work it again, then it may be advisable to give the lessee a chance to gouge and rob the mine all he can. In this manner the life of many a mine has been materially prolonged.

Very often, mines are bonded and leased. When this is the case, the holders of leases have intentions of purchasing the property and they will accordingly conduct their operations in a manner to retain the mines in good condition.

It has been said that the Cripple Creek District has had two periods in its history. During the early years of the district's activity, it was known as a high-grade camp. As depth was gained the kind and grade of the ore changed, and this was simultaneous with a general business depression pervading the whole nation, so that stagnation faced the district.

Many well-known mines closed down. But, soon, there set about a very general request, from miners and prospectors, for leases on blocks of patented ground and in developed mines. These being granted, the hard-working miners set to work upon economical scales and actually accomplished the profitable mining and treatment of the refractory and low-grade stuff that had not been "ore" when these mines had been on company basis. Thus the district, as a whole, was tided over this critical period during which metallurgists wrought out the solution of profitably treating the low-grade telluride and sulphide ores.

Therefore, while hearty recognition of the value of the leasing system should be given, still there are always conditions to be considered in each individual instance in which leasing is suggested.

Gold Dredging Up to Date

The Characteristics of a Gold-Dredging Field—Conditions to be Noted in Examining, and Their Influence on Costs

Written for Mines and Minerals by Arthur Lakes

In selecting a field for gold-dredging there are several considerations, amongst which are:

1. Obviously, the assurance of the presence of gold in the ground of sufficient value to warrant dredging.
2. The surface contour of the land, liability or not to freshets or floods.
3. Nature of gravels.
4. Depth of gravels.
5. Character and contour of bed rock.
6. Water and power facilities.
7. Climatic conditions.

The first is determined by intelligent examination and prospecting.

The surface contour should be comparatively regular and gentle.

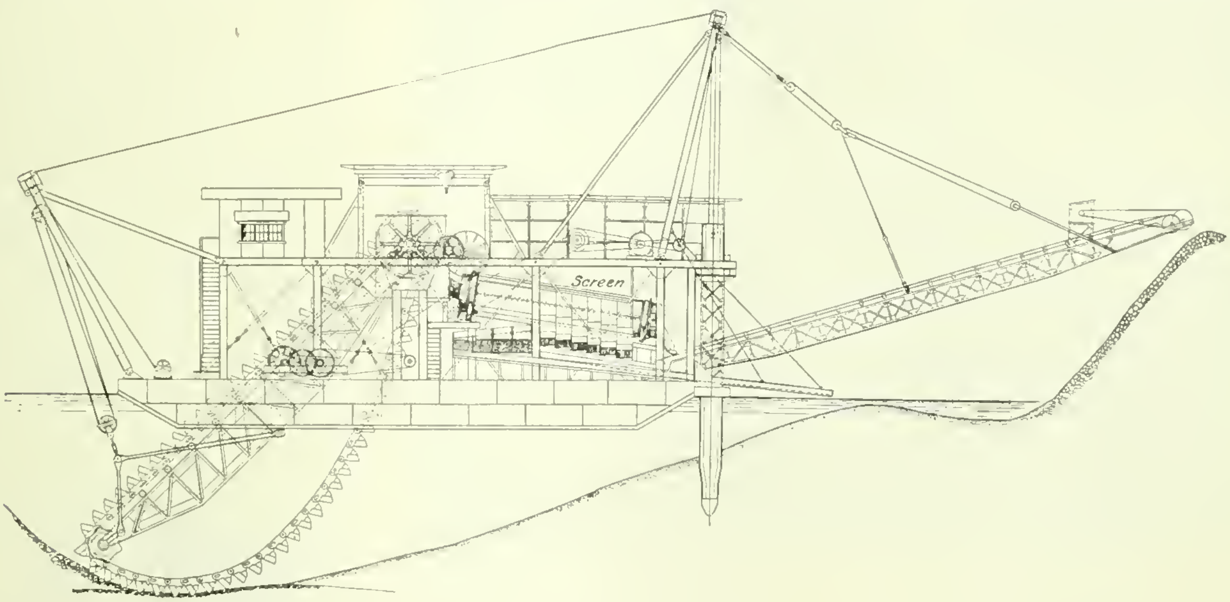

Fig. 1. Sectional View of Dredge

The depth of gravels to bed rock is limited from 10 to 70 feet. A superabundance of large boulders such as would be difficult for ordinary buckets to handle has resulted in the failure of many dredges, owing to their build and machinery being inadequate. A large amount of clay or fine material in the gravels tends to clog the gold-saving tables and by rolling up into balls "steals" the gold and prevents its amalgamation.

The character of bed rock is important as the largest proportion of gold generally settles on it or penetrates it a little way. Hence it should be soft enough to be easily scraped or dug into by the buckets. Bed rock is commonly a decomposed igneous rock, such as granite or porphyry, a soft volcanic tufa, or a shale.

Occasionally a hard quartz vein or a reef of quartzite or some other very hard rock may be met with and temporarily put the buckets to a severe test. Hitherto unknown quartz leads carrying ore have sometimes been discovered on dredging and have led to profitable mining, or the decomposed outcrop of the continuation of a known vein has been uncovered and resulted for a space in rich dredging ground. When an abnormally large boulder or a high reef of hard rock is met with, it is usually possible for the dredge to pass over it and resume operations on the other side. A fairly even soft bed rock is much preferred to the contrary. Preliminary testing will show the nature of bed rock prior to dredging.

Sufficient water is necessary to float the dredge, also to wash and winnow the material. Dredging areas being usually along the courses of or in the vicinity of rivers, water is easily obtainable for dredging purposes as well as for supplying electric power used in the present day in place of steam used formerly. Areas of gold-bearing gravels called "dry placers" in regions totally inaccessible to water could not be dredged.

Climatic conditions in some regions may, in the winter season, affect the period of active work by freezing the gravels, cutting off the flowing water and obstructing the machinery. These natural obstacles are being overcome by artificial means and in many cases dredging is being carried through the severest winters and the year through without cessation. In some tropical countries in swampy areas near sea level, malaria and other tropical diseases are a hindrance to dredging by white labor, natives then may learn the business and take their place efficiently.

Testing Ground

Besides surface shallow placer gravels and hydraulic workings, with possibly some known gold veins and gold-bearing rocks and working gold mines affording a reasonable presumption that the area is generally gold bearing and a probability that the deep gravels will be found likewise auriferous, it is customary for a company contemplating dredging to prove positively the gold-bearing character of the gravels to be dredged by putting down test shafts and test drill holes to bed rock systematically over the field, on an average one hole to every 2 acres. In this way a reasonable approximation of the prospective value of the entire area can be attained before any steps are taken in actual dredging or before a dredge is built.

In this respect dredging for gold is far more certain and sure than ordinary lode mining. Values can be figured up and approximated before any costly operations are undertaken. The cost of building and installing the dredge can be estimated exactly. The amortization factor is known, and approximately the gold values, together with the reasonable profits. Thus the gravels by testing are known to contain so many cents to the cubic yard and the cost of working them can be estimated to a reasonable certainty. Hence, when an investor goes into dredging he knows more than in most lines of business what he going into, and what will be his expenditure and profit. In the case of ordinary precious-metal mining no man can see but a few feet ahead of the actual workings; but in dredging, by careful testing, it is known for many square miles what the field will produce and the element of speculation is reduced to a minimum. The gold value may be of less importance than various physical and other conditions in the ground to be prospected. Such may be a hard uneven bed rock with a great depth of gravel to reach it, many large boulders, much clay, a rough surface contour, dikes and ridges of hard rock crossing the field, gold contents small and unevenly distributed, and a severe winter climate, against the opposite and more favorable conditions.

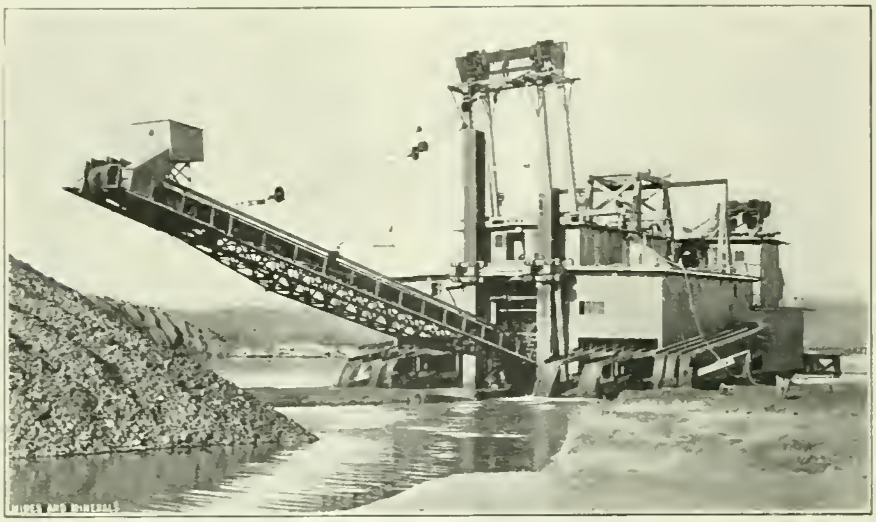

Fig. 2. Dredge, Showing Tailing Stacker and Discharge Launder

To learn the value and character of gravel, depth to, and nature of bed rock, if the gravels are not too deep, pits may be sunk to bed rock, at intervals systematically arranged. This is often done as preliminary. If the depth exceeds 20 feet or thereabouts to bed rock, prospecting by churn drills is expedient and cheapest.

The following are the commonly accepted conditions for examining ground for dredging.

1. Value, character, and distribution of gold content.
2. Depth, character, quantity of ground to be worked.
3. Contour and character of bed rock.
4. Water level and available supply.
6. Labor, transportation, supplies, etc.
5. Surface contour of property.
7. Operating costs.
6. Labor, transportation, supplies, etc.
9. Climatic conditions.

The recovery by the dredge is generally less than the gold content indicated by prospecting.

A modern gold dredge of Californian type is a big boat, hull, or pontoon commonly over 100 feet long by 30 or 40 feet wide and 8 to 10 feet deep. It is built very strongly of thick heavy timbers firmly bolted together and strengthened by trusses and steel work to support and withstand the strain of its powerful machinery and the heavy work. Its complement consists principally of a digging ladder with an endless chain of buckets, screening apparatus, gold-saving tables and devices, pumps, and stacker. It floats in a pond of its own excavating of convenient size for it to turn around in and deploy. As it advances upon the bank in front of its bow it leaves at a safe distance behind its stern a train of boulders and debris from 20 to 40 feet high, sometimes several miles in length.

A gold dredge has been described as a floating mill with apparatus for excavating and elevating the gold-bearing gravels and winnowing them of their values. The power plant, usually run by electricity, is aboard the boat. The hull is built in scow form with the forward part divided in the middle so as to form a well in which the ladder and bucket chain can be raised and lowered. Taking the gold-dredging boats at Breckenridge, Colo., and the California pattern as a type, the hull is 115 feet long 40 feet 6 inches wide and 9 feet deep. The sides are curved at the forward, or bow, and the well is about 6½ feet wide extending back from the bow about half the length of the hull.

The dredge is anchored, or held to its work if excavating, by means of spuds. These are beams firmly held in a vertical position in casings on the stern gantry and attached to the stern of the boat. In these they are raised by winding on a winch drum and dropped by releasing the same. The steel point of the spud is driven by its weight into the bottom of the pond. One spud is called the "digging," the other the "walking" spud. The walking spud, which may be of wood or steel, is used in advancing the dredge. This is accomplished by winding the starboard side line and dropping the starboard spud, then by loosening the starboard line and winding the other side. The dredge is swung from side to side by side lines attached to the shore by "deadmen" or buried logs and passing through sheaves on the dredge to winches winding the rope on the side to where the dredge is swung. The "digging" spud, usually of steel, is used to anchor the dredge whilst digging, and answers as a pivot around which the boat is swung in an arc.

As the machinery is constantly renewed the hull should be built strong enough to outlast all parts. Strength and stiffness to withstand the machinery vibrations are essentials. Timbers, as far as possible, should be in one piece without jointing or splicing, especially the main trusses and frame timbers. Oregon pine is commonly used.

The sides of the hull are extended from midships to the stern of the boat and from bulkheads aft.

There are also two bulkheads running the length of the boat, tied together by drift bolts some 30 inches long driven through the edge of the planking and binding the whole hull as a unit.

Lateral trusses prevent the boat from sagging, whilst the back guy connections prevent torsion. Three frames or gantries, strongly built of thick timber strengthened by steel plates, are erected on the hull to support the machinery. The middle gantry supports the upper tumbler and upper end of the digging ladder. The chain of revolving buckets passes from the upper tumbler round the lower tumb-

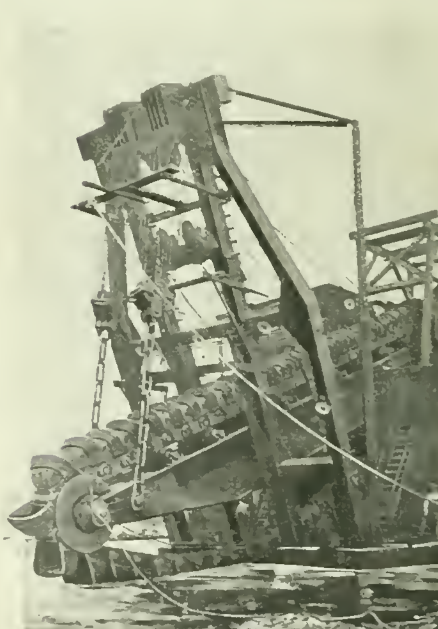

Fig. 3. Lower Tumbler and Bucket Line, 13-Foot Dredge

ler at the bottom end of the digging ladder. The bow gantry hoists and lowers the digging or bucket ladder. The stern gantry suspends the stacker ladder, hoists and lowers spuds, and provides guides for them. Gantries may be of wood or steel or of both combined.

The digging apparatus includes ladder, buckets, rollers, and tumblers. The ladder and bucket line varies in length, size, and capacity according to depth and nature of the ground worked. The ladder may be from 60 to over 100 feet. It is made of structural steel angles and plates. Angle-iron braces are used. Truss rods are fastened from each end on the bottom to give extra strength. Steel rollers on the upper side of the ladder reduce the friction of bucket line and prevent excessive wear on the ladder.

Tumblers are massive revolving castings of open-hearth steel one at the top, the other at the bottom of the ladder around which the chain of buckets revolves. They may be square, pentagonal, or hexagonal. They are protected by wearing plates. Their shafts are 10 to 12 inches diameter of the hardest manganese or nickel steel. The bucket line is the most destructible and costly part of the dredge, subject to the greatest wear and tear, and needing constant repair. The bucket line of modern dredges is close connected. The bottom is of solid casting. The size of a bucket as well as the dredge to which it belongs is estimated by its cubic capacity, this may be from 3 to 15 cubic feet. Buckets from 3 to 13 cubic feet vary in weight from 500 to 2,150 pounds.

The buckets dump over the upper tumbler into a hopper where jets of water assist emptying and dissipate clay. Thence the material passes to the revolving screen which disintegrates and classifies it. The stacker receives the oversize from the screen, and carrying it along over a rubber belt conveyer dumps it well behind the boat. The length of the stacker varies with the depth of the ground dug and the amount of gravel to be handled. The motive power is nowadays commonly electricity in place of steam formerly used. Electric current at Folsom, Cal., is taken aboard the dredges at 2,000 volts for motors of 50 horsepower and stepped down by transformers to secondary 440 voltage. Transformers are sometimes on shore with a cable to the boat. The digging face of the pit is kept from 150 to 250 feet wide and the boat passed from side to side of the pond by sidelines. The bank is cut in terraces or a sloping face. The whole width of the cut in alternate sections is carried forward to the limit of the property. The dredge is then turned around and in return makes a similar cut. When the ground is very hard, frozen, or cemented, steam points, blasting and monitors may be used ahead of the dredge. Property to be dredged is sometimes laid off in lettered squares. The yardage is periodically measured or surveyed as the dredge advances.

Gold-saving appliances used on a dredge are revolving screens, tables, and sluices.

The revolving screen disintegrates the material so that particles of gold may not be carried off over the stacker in lumps of clay or cemented gravel. These screens may be 6 feet wide by 32 to 35 feet long; the diameter of perforations vary from 5-16 inch to ½ inch inside the upper part of the screen and from ½ inch to ⅝ inch at the lower end.

Wooden bar riffles capped with iron or angle irons are used accompanied by quicksilver. The gold-saving tables slope toward each side of the boat at right angles to the slope of the screens. Cocoa matting is sometimes used for catching fine gold, only coarse gold settles behind the metal or wood riffles; 1½ inches per foot is a good slope for tables and sluices. Too much and too swift water may carry off and lose fine gold. Too flat a grade is apt to cover the mercury with sand. Gold may be coated with a film of iron oxide or be influenced by arsenic from arsenical pyrites and fail to amalgamate. Tailings are periodically tested. "Clean-ups" are made at intervals by a gang of three experts or gold men on both sides of the boat simultaneously. Riffles are loosened with a bar and washed on the table, each man takes a section above the stops till all side tables are finished. Amalgam, black sand, and "quick" are scraped into buckets and emptied into a tank of water. 90 per cent. of amalgam is caught above the stop and mercury trap. Material is further treated by Long Tom sluices. A "clean-up" is usually completed in two or three hours and may occur every 6 or 8 days. At Oroville, Cal., there are two products for the melting room. One consists of amalgam with some mercury; the other of black sand containing also nails, lead, and sometimes Chinese coins, with much shot lead from generations of sportsmen. Some of this second product passing over the tables acts as "sluice robber." With the black sand are traces of platinum, osmium, and iridium. Amalgam is placed in an iron vessel and retorted, smelted, and poured into iron molds. Mercury is cleaned at intervals by retorting, it may leave a white residue carrying $16 per ounce of gold. Black sand is separated with nails, etc., from second product by a magnet. Black sand is sometimes said to be worth $140 per ton. It may be barren magnetite or may carry a small per cent. of gold.

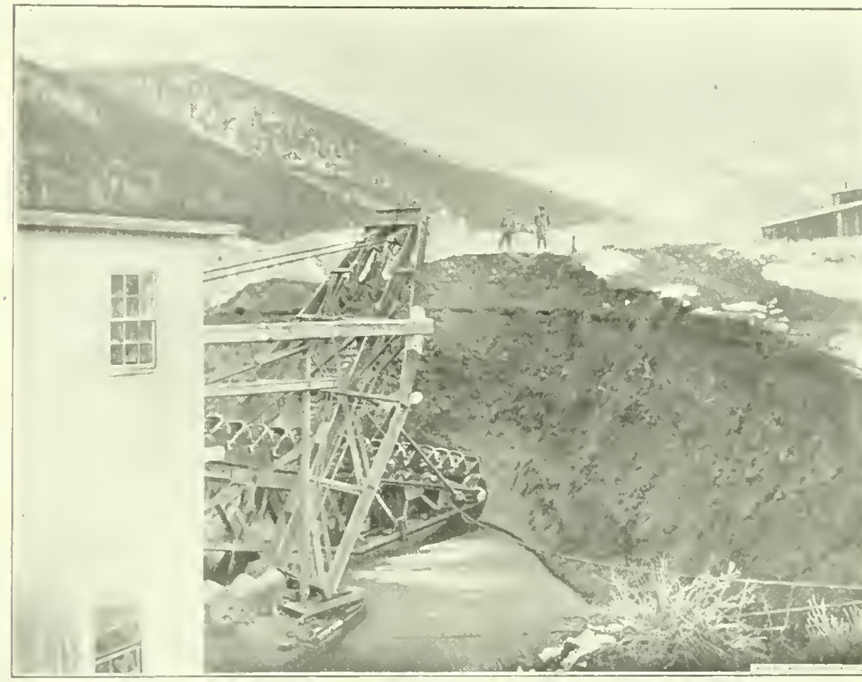

Fig. 4. Dredge Attacking High Bank on French Creek

Dredges aim to obtain the greatest output is a given time, to maintain the highest per cent. of working time and secure the highest extraction. The cost of dredges is from $40,000 or $50,000 to $225,000, according to the gauge of the buckets. Boats with buckets of 3-cubic-feet capacity dig about 40,000 cubic yards monthly, larger ones up to 200,000 or more. Fixed costs of dredging form a large per cent. of the total operating costs, hence a large relative output is desirable. Production is limited by mechanical difficulties and increasing percentage of gold lost in the boats digging more than a certain yardage. Screens cannot treat and prepare for gold-saving tables more than a certain quantity per day irrespective of the digging capacity of the boat and if this ratio is exceeded there follows an increasing loss in gold per yard dredged. Though a certain amount of gold is lost, by increasing the output more net profit may be made. Among factors of loss is when expenses are going on, but temporarily no gold is being produced. The constant need of repairs and stoppages of the buckets is a chief cost and loser of time. A dredge at Oroville, replaced all buckets on a dredge in 12 months. Wearing of pins is another loss of time and cost. Wearing plates or tumblers, a set costing $600, may be needed in a few months. Tumblers as well as spuds are not unfrequently cracked or broken by the intense strain to which they are exposed and have the be repaired or discarded.

The costs of dredging again depend on various local circumstances and conditions, such as:

Average depth of ground and character of gravels.

Favorable or unfavorable conditions on rich or poor ground.

Number of cubic yards excavated and average daily yardage. Number of acres dredged.

Whether working by headlines on easy ground or by spuds on difficult ground.

Whether land is subject to overflows or not at high water.

Whether gravel is a compact clean gravel with little clay and few large boulders, or the opposite.

Gravel shallow, deep, or medium.

Character of bed rock, hard, soft or decomposed, granite, shale, or volcanic tufa with even or uneven contours.

Whether dredge is an old-fashioned double-lift or a modern single-lift, whether with open or close-connected bucket line.

Surface of ground covered or not by thick growth of small timber which must be cleaned before dredging. Whether fired trees or large stumps abound or not.

Much clay and fine stuff with heavy overburden of sandy loam or light soil.

Expenses connected with installing machinery, repairing, or remodeling old ones.

Difficulties from working against a high bank above the surface of the pond and from raising bed rock and cemented gravel, the former sometimes requiring cutting through if it rises above water level, to a sufficient depth to float the dredge and enable it to maintain its course.

In costs and expenditure are included: operating, material, and labor; electricity; repairs; general expenses; taxes and insurance.

Under the above conditions the costs of dredging around Oroville appear to lie between 3 cents per cubic yard as a minimum and 10 cents as a maximum with an average of from 5 to 6 or 7 cents. Dredging expenses there are reduced by putting many boats under one management and not duplicating departments. Three shifts are employed, the crew consists of dredge master, winchman, and two oilers.

Wages at Oroville are: Foreman, $125 monthly; winchman, $3 per day; oilers, $2.50 per day; other labor, $2 per day.

Improvements in the Caving System

A Few Suggestions Looking to the More Economical Mining and Treatment of the Brown Ores of Virginia

*Written for Mines and Minerals by Charlton Dixon**

IN previous articles† the writer endeavored to make plain the methods of mining Virginia brown ores, as practiced above and below ground. In this article attempt is made to show how practice may be altered and modified to produce larger profits, more particularly from the under ground operations.

The caving system is, and always has been, applied as inflexibly as the laws of the Medes and Persians, often inflicting an avoidable expense on the operators. As practiced, the upper level is always driven to the boundary before any robbing can be done. This is not necessary in 90 per cent. of the cases.

In coal mining, as soon as a room is driven its pillars may be extracted. The effect of letting all of them stand until the last room is finished can easily be imagined. This is exactly the procedure in the ore field today. It is no more necessary in the one case than the other.

The custom of retarding the car levels in a shaft opening or drift, on account of the supposed impossibility of robbing, is wrong in every way. From the commencement of a shaft operation, all help required to handle a full capacity on top is employed. On this account, and the retardation process practiced, development cost is high.

What should and can be done is to rush the car level, the 12-foot or 24-foot levels, incessantly by three 8-hour shifts, three men to a turn, having always plenty of cars ready for them to load direct, thus avoiding casting the fall back from the face in order to hasten the drilling. Planks or sheet iron should be laid at the face before blasting. This facilitates the shoveling.

In the meantime, the upraises should be started as soon as the proper distance is obtained. When the boundary or other limit is reached, the last two should be rushed to the outcrop, using the three shifts until this is done. One of them, even if the ore does not reach to daylight, should be worked out to daylight for temporary ventilation, timber, etc. The upper levels may now be driven back toward the opening, meeting those being worked from the upraises behind. Just as soon as connection is made to the nearest chute, robbing can be commenced at once, precisely where it would and does after say 2 years of procrastination. This method would shorten the life of the ordinary mine at least 2 years out of 5, which is about their average life. In other words, as much ore would be won by the above method in 3 years as can be done in 5 by the present one. This means 2 years' salaries and wages, and 2 years' pumping, besides hundreds of dollars in timber, etc., saved. An objection might be offered to this double-end method, as it may be named, on account of the difficulty of elevating the necessary timbers at the "in end." That is more imaginary than real, because, as has been said in a previous article, if there are six levels to begin with, in a distance of 2,000 feet two of them will be pinched out. The reason is, the ore is never so accommodating as to rise in the same ratio as the car level. Considerable timber may be brought down the temporary air hole and stowed in the lower levels for use in the first robbing.

Another variation, or modification, to the caving system can be applied, which would also reduce the cost of timber changing, besides that of developing. That is, to rob each alternate block down to the 24-foot level, leaving the other as a barrier pillar. This would give a large amount of cheap ore at an early stage and would alleviate the hardship of development to a very considerable extent.

The barrier pillar can be mined in retreating, thus maintaining a good output to the end.

These two modifications might be combined—there is nothing to prevent it—and they would form an ideal plan of operation in this ore. There is no doubt about the caving system being an expensive one as practiced, but if the plans suggested are applied profitable results will be produced.

The upraises are driven every 50 feet and these add very much to the cost of operation. The object of such a short distance between them is to accommodate the wheelbarrow, to save time in pushing it back and forward.

Were the levels straighter, a 2-foot gauge

* Pittsburg, Pa.

† Mines and Minerals, Vol. 32, pages 483 and 553

track and a car of 1,000 pounds capacity could be used on all of them. This would obviate the necessity of one-half of the upraises, besides saving much of the time now wasted in traveling to and fro with an insignificant load. By substituting cars for the wheelbarrows the cost of mining will inevitably drop. The truth of the foregoing has been sufficiently demonstrated at some of the operations during the last 4 years. Wherever the change was effected the men preferred the cars to the more primitive vehicle.

Generally speaking, the ventilation is very deficient. The fans are invariably small, antiquated, and necessarily very inefficient. Air-courses are contracted, besides being extremely crooked; in fact the whole question does not receive much attention. The necessity of it is manifest; the temperature of the robbing rooms is nearly always far above that in which a human being should be required to exert himself. Much black damp (CO_2) is also generated, which, owing to poor ventilation, is an important factor of expense, as lamps will not burn and men are not efficient in semidarkness, not to mention headaches, etc. Better fans should be used by all means, air-courses might, with very little extra cost, be kept in better condition. Not a fan in the district is cased to reverse the current; although the shafts and slopes accumulate ice very rapidly during cold weather. This also adds an avoidable cost. Dynamite being the only explosive used to any extent underground, the amount of time lost waiting until the fumes are carried off after a blast, is almost incredible. Of course, the better the ventilation, the less this loss becomes.

The custom of sinking shafts and steep slopes in the ore is uneconomical, as thousands of tons of what should be the cheapest ore are lost. Textbooks give no instructions concerning robbing shafts. Openings should be made in the waste; by so doing all the ore is recovered.

Another saving can be effected by connecting some of the upper levels to the shaft as intermediate hoisting stations. At present the ore is chuted from the top levels to the car level, then hauled back again. This congests traffic to the detriment of all concerned.

In many instances an arrangement of this sort would pay if for no other purpose than to handle the timber. It is costly, besides being very laborious, to elevate this material through a narrow manway to a height varying from 40 to 90 feet. Were this distance halved, the cost would also be cut in two.

Large two-compartment shafts are the rule, which is an outlay not justified by the conditions; not one of them has an output to exceed the capacity of a single hoist. A single shaft with room for a counterbalance would satisfy the requirements. A self-dumping cage would add to the profits.

At the shaft bottom only one track would be necessary, the loads running direct to the cage, the empties to a kick-back, thence to a side track parallel to the loaded one, but with a pillar between. A shaft of the above description is now in operation. It is very satisfactory.

Owing to the inclination being insufficient to chute the ore from the upper to the lower levels at many places, transferring must be resorted to. This is probably responsible for more extra cost than any other single cause. It often requires the employment of three to four men to handle the ore ordinarily taken care of by one where the pitch is favorable. To elucidate, ore from the 48-foot level is wheeled to the chute connecting it with the 36-foot level; at the bottom of this it is caught in another wheelbarrow. This is repeated on the 24-foot and 12-foot levels.

To avoid this trouble the territory should be closely drilled, every hole going to the flint, and the levels figured closely. If found too flat for a gravity flow, where the vein comes to within a reasonable distance of the surface a slope should be sunk in the foot-wall at an angle sufficient to keep it from touching the ore until the required depth is reached. This where the pitch of slope is between 10 degrees and 30 degrees; where less than 10 degrees, the slope should go down on the ore, as the ordinary mine car can be used, in conjunction with side-tracks at the mouth of the different levels. On the steeper pitches a 2-ton dump car should be used, drawing its load from the chutes at the different levels. Where the depth from the surface precludes the adoption of this method, transferring may still be avoided by driving a heading straight up the pitch in the foot-wall, using a counterbalance or small winze engine to take care of the ore; a surface engine with the rope running in one of the bore holes could also do the work.

Concerning the method generally practiced in surface operations, there is not much to be suggested by way of change. These are mostly all confined to the outcrop ore running with the strike. After the ore has been extracted the trench left acts as receiver general for the drainage from the mountains above them. The water caught in it is subsequently pumped from the lower levels.

Occasionally a serious loss is brought about by this feature, as a stratum of loose sand is often found between the ore and flint from 3 inches to 12 inches thick. This is washed out, causing the whole hill to settle down. In one shaft operation, one side of the mine was ruined entirely. Much money was wasted in attempts to counteract it, and it was finally abandoned.

This can also be avoided by driving drainage drifts from the hillside when the cuts are exhausted.

Only after a thorough drilling and most careful leveling combined with ore of good quality, and where the stripping does not exceed 2 feet to every foot of ore, should open work be indulged in.

The preparation of the ore for the furnace is in many cases susceptible of much improvement. A large percentage of it occurs in hemispherical form, the cavity nearly always containing sand, either loose or solidified, generally the latter. The ore encloses it like the tentacles of an octopus. Apparently there is no cure for this but to crush the whole of the product to pig size, the largest not to exceed $1\frac{1}{4}$ inch. There is nothing impossible about this from a mechanical standpoint, for the cost would be largely compensated for by the reduction of the number of handpickers needed, and by the higher percentage of ore recovered.

Rubber picking belts are responsible for much waste reaching the furnace. They are too narrow and channel too easily when carrying a full burden; only the waste seen on the surface can be picked off. At one washer, steel conveyers $2\frac{1}{2}$ feet wide were installed; these provided spreading space for the load, exposing all sand, etc. Being of large capacity, they necessarily travel much slower, thus giving the pickers time to eliminate all extraneous matter. Washers should be arranged in a way to permit washing and concentrating to be carried on independently, with at least one-half day's storage for each.

The largest and by far the most costly washer in the district is built on the continuous plan, a derangement of any of its multitudinous parts affects the whole. Much loss has been entailed thereby.

Bleaching Powder

Bleaching powder is also commonly known as chloride of lime. It is soluble in about 20 parts of water. When brought into contact with sulphuric or hydrochloric acid it gives up its chlorine. With the sulphuric acid, the sulphur unites with the lime to form calcium sulphate, leaving the chlorine free. It is used in the barrel chlorination process. In making the charge it is customary to first charge the "bleach," as it is called, which is followed by the ore, which completely covers the bleaching powder. Then the water and acid are introduced, the barrel is quickly closed and the cover secured The barrel is then rotated, which results in a thorough admixture of the several ingredients of the charge. The chlorine is liberated, as above indicated, and attacks the gold present in the ore. The process was quite extensively employed some years since at Deadwood, S. Dak., in the treatment of the telluride gold ores of that district, but has since been superseded by the less expensive cyanide process. There are ores, however, which may be successfully treated by the barrel chlorination process which are not readily amenable to cyanide treatment.

Random Thoughts on Prospecting

Written for Mines and Minerals by A. J. Hoskins

Persons who take an interest in metal mining are occasionally asked by friends why it is that there are not more Mother Lodes, Leadvilles, Comstock Lodes, or Cripple Creeks being found. They also are requested to admit that it is probably true that there remain no great undiscovered mining regions in our great West.

It is true that very little of the public domain has been absolutely overlooked by prospectors. Such pioneers have pretty well traversed the earth. But the fact should be recognized that there are large sections of country that have been either too casually investigated or that have been so radically different in character from previously known mineralized regions as to have deceived the seekers for mineral wealth.

The Cripple Creek district was for years utilized only as a cattle-grazing and ranching country. During the occupancy of the region, there were two distinct excitements in quest of gold, but no real finds were made for a number of years thereafter. One of the rushes was founded upon an actually fraudulent attempt, on the part of a notorious character, to sell a salted gravel bed to gullible gold seekers. The other rush, however, was inspired by a report of ore discovered in place, but this was proved to be false rumor. These unfortunate incidents combined to discourage investigation in that region to such an extent that prospectors were wary of following their calling therein for fear of being discredited. In fact, so pronounced became the stigma on this area, that men of science denounced the country, declaring the formations were such that nothing good could emanate therefrom. So, when one or two honest prospectors finally reported good luck, wise heads were shaken and the district condemned as being absolutely "impossible" from a mineralogical standpoint. Purely because of preconceived prejudice concerning geological occurrences, this area was shunned; but the discoveries just mentioned could not be denied, and the rest is history.

Our knowledge of natural conditions has reached such a stage that it is almost permissible to paraphrase the old phrase into "metals and valuable minerals are where one finds them," not restricting the statement to the single metal, gold. Prospecting has come to be a scientific pursuit rather than the gambling game of chance that it formerly assumed. Whereas the miner of today appreciates the environments in which past discoveries have been made and is thereby encouraged to seek minerals or metals in similar places, he will not allow himself to confine his search to such formations or regions alone, but he will investigate possibilities that are presented in any geological structures that may, so far as he is aware, never have produced ore bodies.

Prospecting is going on all over the world; the United States is not excepted from this assertion. It must, however, be realized that there are areas in which climatic conditions seriously impede the prospector. Some areas seem always to remain invulnerable to his search, while others may be investigated during only certain, and often brief, seasons. One might imagine that those sections of the West that are arid, because they have almost no precipitation, summer nor winter, would be absolutely forbidding to the prospector; but such is not true, for this ubiquitous individual is usually thereby permitted to ply his vocation ceaselessly. On the other hand, we think of regions that never have dry seasons—places with heavy falls of snow or rain the year through—and we find it hard to conceive how a mine could ever be disclosed under such adversity. The past winter and spring have been unusually severe as regards the fall of snow in the mountains of the West and Northwest.

Much has been said by the press of the High Grade district, in the northeastern corner of California. Opinions vary as to the virtue of the area, but the present season will probably settle the question. Still, erroneous conceptions might be arrived at, and the prospectors there must be ready to investigate formations which, to them, may seem quite forbidding.

Among the areas to come in for attention from prospectors this season, is the northwestern portion of Colorado. The three large counties of Grand, Jackson, and Routt are said to contain over 1,000 square miles of unclaimed, mineralized, government land. The winters here are always long, and prospecting has always been more or less restricted on that account. The greatest handicap, however, has, until within the past 2 or 3 years, been the absence of any railway lines in this domain. The so-called Moffat road is now constructed and operated from Denver over the Continental Divide to Steamboat Springs, the metropolis of this region. Hunters, a few ranchmen, and straggling prospectors have roamed this wilderness for many years and have, from time to time found "mineral"; but as time went by with no improvement in the transportation conditions, all such finds were of necessity abandoned. During past years there have been numerous rumors of gold discoveries in the vicinity of Hahn's Peak, and well-posted mining engineers have frequently made favorable estimates of this region's mineral wealth in many of the metals. There is a very great variety of rocks and they are so mutually related, physically, as to offer inducement to the prospector. The coal resources of this section have been well exploited and good coal mines are in operation along the new railroad; but as yet, there is very little known, generally, concerning the other natural resources.

It must be admitted that there has been a rather general depression in some of the metal-mining lines during the past few years, but there are now unmistakable signs of an awakening interest in the industry, and there are being sent forth numerous inquiries for desirable mining properties by persons who never before have been known to possess such interests. This is creating work for not only the prospector but the mining engineer, who usually follows on the trail of the prospector. During the past 12 months, many old-time mines have been revivified throughout the West, while many prospects that were never before exploited are being developed into mines.

One feature of this search for mines is the present-day practice of financially large concerns in maintaining staffs of skilled men who devote practically their entire time to the investigation of finds reported by the common prospector. As a general thing, mineral finds are made by men who lack money to develop mines. The only hope for such men, therefore, lies in selling out all or part of their rights to others who can provide the required capital to equip and develop these properties into productive mines. Perhaps this fact has been accentuated too strongly at times, with the resulting discouragement of prospecting, temporarily. We have been passing through such an unfortunate period. In but one country of the world, so far as known, has legislation ever been sought on this economic problem. At present, there is some agitation being carried on in New South Wales whereby the State Minister of Mines is urged to offer prospectors protection from the unscrupulous schemes of investors who combine to control prices of prospects.

We, in this country, do not face such monopolistic control of the selling prices of new mining property. Instead, our prospectors have a good chance to sell or finance their projects, providing they are reasonable in their demands. A decade or two ago, American capital could be enlisted in new mining enterprises in return for small fractional interests, but the man who now puts his money into such a deal feels that this money is just as essential to the success of the mines as was the discovery of the ore. He reasons that the two prerequisites in the establishment of any mine lie in the finding and in the financing, and that therefore these two factors should be granted practically equal importance in the apportionment of interests. The prospector of today is obliged to bring himself so far out from his naturally selfish instincts as to deny himself the right to a lion's share in his discoveries. Possibly he can settle each particular instance to his own satisfaction by pondering upon the query as to which is the more valuable: all, or most, of an undeveloped, non-producing prospect; or one-half, or less, of a real, dividend-earning mine.

Mines and Minerals

Vol. XXXIII.—No. 2. SCRANTON, PA.—SEPTEMBER, 1912—DENVER, COLO. Price, 25 Cents

PUBLISHED MONTHLY AT SCRANTON, PA.
ESTABLISHED 1881

SUBSCRIPTION RATES

Single Copies .... 25 cents
Yearly Subscription, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines. $2.00
To Canada 2.50
To all other countries 3.00

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us.
Notice to discontinue or change of address should be sent to the Scranton office.
When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

THE poet who wrote "'Hope springs eternal in the human heart" must have had a wide acquaintance among prospectors.

~~~

A WITTY old Irishman once said: "The world's not much to a man whin his wife is a widdy." If mine workers who jeopardize their lives by inattention to the condition of the roof in their working places would remember that witty remark, the number of accidents due to "falls of coal or roof" reported annually by the mine inspectors would not comprise the greater portion of deaths reported.

~~~

THERE is a vast difference between a mine surveyor and a mining engineer. Every man who possesses the degree of Engineer of Mines conferred by some college or university because he completed a certain course of study, is not necessarily a mining engineer. This is not the fault of the institution which conferred the degree. Sometimes it is due to nature, but in most cases it is due to lack of application, and an appreciation of the fact that it takes study and mental effort to apply principles learned in a general way to detailed conditions met with in actual practice.

~~~

A CORRESPONDENT sends us a clipping from a journal whose name we have not been able to ascertain. We should be very glad to give due credit to this paper in copying this remarkable paragraph; but our readers may agree with us that it is merciful to not divulge its identity. This is the paragraph:

"The geological formation is briefly described by stating that the Permian limestones have intruded and overlapped the Mezozoic. The Carboniferous formation covers the entire field. The metallic deposition is in the crystallized limestones and usually accompanied upon the hanging wall with porphyritic dikes."

~~~

PROF. H. H. STOEK, head of the mining department of the University of Illinois, and formerly editor of MINES AND MINERALS, at the close of the last term of the University took some examination papers home for inspection. Seated in his library, busy with the work, Mrs. Stoek, who was present, suddenly heard him break the silence with a hearty laugh. When she inquired the cause of it, the Professor said: "Listen to the answer to this question—'After the hole is tamped and the squib is inserted, what should the miner do next?' 'Yell *fire!* light the squib and git—the powder will do the rest'." In answer to Mrs. Stock's query as to what credit he would give for such an answer, the Professor said: "One hundred per cent. The answer, while laconic, is absolutely correct." The student who made that answer, after acquiring a mining education under Professor Stock, will undoubtedly know how to practically apply his knowledge.

Krebs, Indian Territory, Explosion

We are indebted to Mr. E. W. Parker for the following information to be added to the list of explosions printed in the July issue of Mines and Minerals. The Krebs, Indian Territory, explosion was attributed to dust. It occurred at 5:03 p. m., January 7, 1892, and 67 were killed. Over 100 of the injured ultimately recovered and some of those who lost their lives might have been saved had it not been for lack of proper care and sanitation in their homes, and the unusual severity of the weather at the time of the accident.

Uniformity in Mine Inspectors' Reports

The Mine Inspectors Institute is an organization with which every State Coal Mine Inspector in the United States should be affiliated. As an organization of inspectors it should not in any way encroach on the field covered by the several institutes composed of mine officials and mining engineers, as it has a broad enough field in originating and discussing plans to make the inspection service of each state most efficient. As an important preliminary to a proper consideration of the relative conditions existing in each state, Mines and Minerals respectfully suggests that the tabulated information in each state's annual reports be made uniform in arrangement, and be made to cover the same calendar months of each year. By this means the value of the reports will be greatly enhanced and both inspectors and mine officials will be better able to determine the relative efficiency of the methods employed to conserve life and property under conditions met with in the various coal fields. We trust the suggestion will meet the approval of the membership, and that the Institute will see the wisdom of using its knowledge and influence to bring about such uniformity. Mines and Minerals will be pleased to publish the opinions of both inspectors and mine officials on the advisability of such a system of reports.

"Laying Up Treasures"

According to the Goldfield (Nev.) *News*, the Mother Lode Mining Co. is operating its 340 acres of mineralized lands at Cherry Creek, in White Pine County, Nev. What distinguishes this from the ordinary mining company is the fact that it is owned and controlled by ministers. The president is the Rev. A. F. Dotterer, of Philadelphia, Pa. Eight of the ten directors are, or have been, active preachers. These men have been managing the company's affairs for over 3 years, and five of the men have personally visited and inspected the property.

There can be no reasonable objection to doctors of divinity extracting zinc from the bowels of the earth, but when they attempt to extract gold from the bowels of the ocean as did the dominie in Maine it is unfair to their parishoners.

If ministers are entirely dependent on salaries, they are not to be blamed for trying to lay up treasures in some other way; and what offers greater opportunities than metal mining if you use judgment before investing?

The Scientific Management of Mines

Mining is not a haphazard undertaking, and at scientifically managed mines the business and the work move forward with regularity and smoothness unsurpassed in any industry that requires the physical exertion of men. To scientifically manage mines the manager must be technically educated, broad gauged, and experienced in the many phases of the business. The manager who depends on the education of others to carry on the work, or who holds in supreme contempt the educated engineer and will state that he can hire all the college engineers he wants for $60 per month, can never develop into a scientific manager, no matter how practical he may be. Scientifically educated managers are those who have learned the theory of mining and who have by experience developed into practical men, or vice versa. The scientific mine manager does not hesitate to call in the consulting engineer, whenever a problem involving considerable expense arises, not to ascertain what is to be done but how best to do it. This policy is based on the broad-gauged man's belief that two good heads are better than one good one.

The new doctor who proclaims his calling as "efficiency engineer" might find some employment in mining, provided he can induce the practical manager to believe he is an expert in mining. It is doubtful, however, if the scientific manager will ever have need for him, for in order to be of any use he must determine, by systemic observation and analysis, conditions as they are, and study how to improve them. The question then arises, is the "efficiency engineer" as capable of improving matters as the scientific engineer who is continually advocating improvements as the changing conditions arise and warrant.

Systematic arrangement of the departments originates with the manager, but each is improved by departmental heads, provided they are inclined to receive suggestions from their men and are in sympathy with the management's policy. For example, many economic ideas have originated with miners, who have discussed them with foremen, and the latter with the managers. There is scarcely a large or small colliery where there is not some labor-saving device that originated with the workmen. It is quite true that where there is one valuable idea advanced there are many worthless ones; however, the intent of the men should be encouraged. It does not follow that all educated mining engineers will make scientific managers; there is an inherent quality about the successful man which conforms to the conditions with which he is surrounded and to the kind of men with whom he is obliged to work. This is a branch of scientific management which, if overlooked, is fairly sure to result in failure.

Mr. S. A. Taylor, who is connected with the University of Pittsburg, has prevailed upon the Faculty to consent to a course of instruction in the Scientific Management of Mines. This course is only open to graduates in mining after 2 years' experience in the field.

The Civil Service Idea of a "Mine Technologist"

THE United States Civil Service Commission announces an examination to fill a vacancy in the position of mine technologist in the Bureau of Mines, field service, at a salary ranging from $1,800 to $2,400 per annum, and vacancies requiring similar qualifications as they may occur, unless it is found to be in the interest of the service to fill the vacancy by reinstatement, transfer, or promotion.

The duties of the person appointed to this position will be a general study of mine conditions with reference to economic problems with a view to the improvement of these conditions, especially in the coal fields of the United States, and a study of these conditions as affecting the welfare of the miners.

The applicants for the position must have had graduate work in economics in some college of good standing, especially along the line of industrial economics.

Competitors will not be required to appear at any place for examination.

The examination will consist of the subjects mentioned below, weighted as indicated:

Subjects	Weights
1. General education and scientific training	35
2. Professional experience along industrial lines, and fitness	30
3. Publications, theses, etc.	35
Total	100

In furnishing material under Subject 3 any published works, unpublished manuscripts, or theses may be submitted. Letters of recommendation from teachers or colleagues may also be submitted under this subject.

All statements relating to training, experience, and fitness are subject to verification.

Age limit, 24 to 40 years, inclusive, on date of examination.

The above circular issued by the United States Civil Service Commission was no doubt penned as a serious production by its author, but to practical educated mining men, and to those who have been eminently successful notwithstanding a lack of college training, it is a very humorous production.

In the first place the larger mining corporations and many of the larger individual mine owners will pay more money than our respected "Uncle Samuel" offers for approved talent.

In the second place the man who can pass the examination in Subjects 1 and 3, and who has had any successful extended "experience along industrial lines" is not looking for a job paying $1,800 to $2,400 per annum.

It looks to an outsider, as if the United States Bureau of Mines considered a higher education in the "ologies" of greater importance than broad practical mining knowledge in the personnel of its force.

If the Bureau of Mines is to command the respect and cooperation of the managements of large mining interests, it will have to employ men who, by experience as well as education, have at least as much practical knowledge of mining methods and mining conditions as the subordinate officials of the companies engaged in the industry. Many an eminently successful mine manager cannot spell correctly with a pen, but as a rule he has in his mental storehouse a fund of information that is of greatest value; and if he could dictate what he knows and what he learns by observation to a clerk with sufficient education to put it in proper English for publication, it would be of greater value than improved theories suggested by men of greater education but less knowledge. We do not want to be understood, in this connection, as believing that a technical collegiate education is not of value, for we know that it is, and that when possessed by an active industrious man who knows how to apply it, it makes him of superior ability. What we do want to emphasize is the fact that the Bureau of Mines will never be of real service till its officers recognize the fact that "book education" alone is not the prime requisite in a man to enable him to study mining conditions and to work out economic problems connected therewith.

Convict-Mined Coal

THE Southern Appalachian Coal Operators Association has decided to take an active part in the coming election of governor and members of the legislature of Tennessee, in an effort to secure the abolishment of state mines worked by convicts. The state mine has been a political asset, and the large tonnage which it produced has been thrown on the market at prices far under the market ruling, thus completely demoralizing the market, especially when in its worst condition.

The state of Tennessee has a Railroad Commission, and it is claimed that whenever a shortage of cars is noted at the state mine there is little delay in correcting it. The operators of course do not enjoy such privileges. It is also stated that a coal broker who is handling convict-mined coal and compelled to take the coal according to contract, as the mine works every day, sold screened coal at 45 cents, and in fact gave away some coal on the payment of freight and demurrage.

The operators have decided to secure from every candidate for the offices above mentioned an expression of their opinion in the matter of doing away with the state mine.

Premiums for Yards and Gardens

In accordance with notices published under date of April 15, 1912, premiums for the best kept yards and gardens at the plants of the United States Coal and Coke Co., Gary, W. Va., were awarded to householders on July 23 and 24. The awards were made by a committee consisting of Prof. C. R. Titloe, Director of Agricultural Extension, College of Agriculture, West Virginia University, Morgantown, W. Va.; Dr. E. A. Schubert, traveling agent of the Agricultural and Industrial Department of the Norfolk & Western Railway Co., Roanoke, Va.; and Professor Hanifan, State Superintendent of Rural Schools, Charleston, W. Va. Colonel and Mrs. Swope, of Welch, accompanied the party.

The prize given was $10 for the best kept garden and $5 for the best kept yard at each plant, with an additional prize of a fine lawn swing, which was awarded by the Agricultural Department of the Norfolk & Western Railway Co. for the best kept garden and premises generally at all the plants, which was awarded to John Wolfe (German) at No. 9 plant.

Premiums were awarded by the committee as follows:

Works No.	Yard: House No.	Yard: Name	Yard: Nationality	Garden: House No.	Garden: Name	Garden: Nationality
2	62	Jim Marcelli	Italian	84	Rufus Tatum	Colored
3	23	Mike Wasso	Slavish	210	Each Socosh	Hungarian
4	7	P. L. Gillespie	American	50	Paul Conchia	Slavish
5	44	Hugh Jennings	American	2	Andy Saxon	Hungarian
6	126	Jacob Brown	Colored	77	Arthur Gray	Colored
7	36	Jim Rose	American	52	Wm. Deush	German
8	40	W. A. Graham	American	48	Mike Dutsie	Polish
9	147	M. Grobelink	German	142	John Wolfe	German
10	61	H. C. Mann	American	76	Joe Wassus	Hungarian
11	114	J. W. Lester	American	110	A. P. Mitchell	American
12	76	J. E. Money	American	26	S. T. Spencer	American

Honorable mention was also made of 21 others.

House No. 142, at No. 9 works, was awarded special premium of lawn swing, given by the Agricultural Department of the Norfolk & Western Railway Co.

In making the awards, the location and natural conditions were taken into consideration, as well as the general appearance of the yards and gardens.

The interest and pride taken by the householders in their yards and gardens proved a revelation to the entire committee, and aside from a monetary standpoint, it gives the householder fresh vegetables throughout the greater part of the year. After seeing the gardens, the committee estimated that from a monetary view alone, the gardens will average at least $100 per garden, while a number of them will greatly exceed this amount, and an estimate of the gardens as a whole was placed at from $15,000 to $20,000. The manner in which the gardens and yards are kept at the various works shows that the householders are becoming awakened and getting to know what good gardens mean to them. Improvements in the yards and gardens also lead to sanitary improvements, and great benefit is derived from this source.

Doctor Schubert, who served on the committee last year, said that in his opinion the sanitation had improved and that the gardens had improved at least 200 per cent.

These premiums will be awarded from year to year, as improvements in the yards and gardens will be of vast benefit to the householders, the company, and the surrounding community.

Personals

C. W. Purington, of London, is now in Alaska.

D. C. Jackling, of Salt Lake City, is in Alaska.

B. J. Latimer is with the Buena Tierra Mining Co., at Santa Eulalia, Chi., Mex.

E. P. Earle is a director of the Tri-Bullion Smelting and Development Co.

Alfred L. Johns has left Victor, Colo., and is now located at Guadalajara, Jalisco, Mex.

R. H. Elliott has recently become superintendent of the Liberty Bell mine at Telluride, Colo.

Edward Meents, of Battle Creek, Iowa, has been visiting mining properties in Colorado.

Geo. L. Crawford has opened an office at 315 Ideal Building, Denver, Colo., as a consulting engineer.

J. M. Bovee is manager of the Shawnee Copper Co., instituting operations in Carbon County, Wyo.

E. C. Van Diest, of Colorado Springs, Colo., is now a member of the board of trustees of the Colorado School of Mines.

Arthur H. Carpenter, Denver, is a new member of the technical staff of The American Vanadium Co., of Pittsburg, Pa.

Walter L. Reid, mill superintendent for the Smuggler-Union Mining Co., of Telluride, Colo., has been in Oregon on business.

J. B. Carman is with the American Smelting and Refining Co., at Velardena, Durango.

John V. Harvey is engineer for the Peregrina Mining Co., at Guanajuato, Mex.

W. A. Townsend left Denver, Colo., in July to take charge of the Ingersoll-Rand office at El Paso, Tex.

Prof. Frank D. Adams, D. Sc., F. R. S., Dean of the Faculty of Applied Science, and Logan Professor of Geology at McGill University, Montreal, has been appointed president of the executive committee of the twelfth session of the International Geological Congress, to be held in Canada in August, 1913.

J. W. Merritt, assistant in mineralogy at Northwestern University, has been appointed instructor in geology at Dartmouth College.

R. E. Garrett, of the University of Oklahoma, and the Oklahoma Geological Survey, has been appointed assistant in mineralogy at Northwestern University.

Alexander N. Winchell has resigned from the United States Geological Survey to resume work as a consulting mining geologist. He has recently returned to his office in Madison, Wis., after spending several weeks in Nevada in connection with litigation regarding the ownership of the remarkable ore deposits of the National mine in that state.

Manager for Illinois Mine Rescue Station

The position of Manager of Mine Rescue Stations, for the State of Illinois, made vacant by the resignation of Mr. Richard Newsam, will be filled by means of an examination to be conducted at Springfield by the State Civil Service Commission, on October 3 and 4, 1912. This examinatioin will include a statement of the applicant's experience in mining, and will cover a knowledge of first aid and mine rescue apparatus, general mine operations, including mine maps, ventilation, mine gases, safety lamps and general methods of work, the organization and administration of mine rescue work, and a knowledge of the State laws relating to this work. This position, which is open to residents of Illinois, has a salary of $3,000 per year, all necessary traveling expenses being allowed in addition. Applicants must be between the ages of 30 and 60 years. In order to qualify, a candidate must not only be familiar with rescue apparatus and methods, but must have ability as an organizer, for while the actual work of training is mainly in the hands of the men living at each station, the manager must coordinate all the work and must have power to interest both operators and miners in mine rescue and first aid work.

Illinois is the only State having a thoroughly organized service of this kind. Up to the present time, about 1,500 men have taken rescue and first aid training in Illinois. Applicants for the position should write immediately to the State Civil Service Commission, Springfield, Ill.

COAL MINING & PREPARATION

Southern Kentucky Coal Field

Geology—Description of the Coal Beds, Mining Methods, and Surface Plant of the Stearns Coal Co.

Written for Mines and Minerals

IN the progress report of the Geological Survey of Kentucky, 1906 and 1907, A. R. Crandall has written a meager account of the southern central coal field of Kentucky or, as some might call it, the southeastern coal field, which extends into northern Tennessee.

With this exception, one of the most interesting coal fields in the United States, from a geological standpoint, has been neglected. It seems to have been separated from the Jellico field by the upheaval which formed the Pine and Log Mountains.

Starting from the town of Stearns, which is virtually located on the top of the mountain, the Kentucky and Tennessee Railroad goes slightly southwest on the hillside to Paunch Creek, which it follows to the Big South Fork of the Cumberland River, whence it turns and follows the river almost due north to Yamacraw. The descending grade of the railroad is steeper than the pitch of the strata, consequently the geological sections are exposed, both by the railroad cuts and the creek erosion.

At Barthell the Lea conglomerate begins to rise in high cliffs above the railroad, while rocks the size of houses have fallen from them in places so as to choke up the creek. In addition to these exposures, the old streams made deep undercuts here and there in the cliffs that almost resemble caves. At Yamacraw the railroad crosses the Big South Fork on a $75,000 concrete bridge and follows Rock Creek toward the southwest to Rock Creek station. Between Yamacraw and Oz, beyond No. 10 mine, the Subcarboniferous strata are represented by the variegated Mauch Chunk or Chester shales and below them is the Subcarboniferous or St. Louis limestone. The Lea conglomerate corresponds geologically to the Pottsville conglomerate, it being the lowest member of the Carboniferous series; further, it contains large rounded quartz pebbles, thus forming the closest approximation to the structure of its counterpart in northeastern Pennsylvania the writer has observed in any bituminous coal field. Owing to the natural advantages offered for observation and the railroad cuts, the bedding planes or parting lines between the strata are clearly shown; particularly is this so between the conglomerate, red shales, and limestone where railroad cuts have been recently made and weathering has not obliterated these marks. The coal seams, three in number, are found in the Lea conglomerate.

Fig. 1. Concrete Tipple at Mine of Stearns Coal Co.

It seems somewhat peculiar that coal beds existing in the Pottsville conglomerate should have exceptional qualities that make them in some particulars more valuable than the general run of bituminous coal beds. In the counties of Whitley, Wayne, and Pulaski in Kentucky, and in Scott, Pickett, and Fentress counties, Tennessee, the three coal beds vary in thickness from 2.5 feet to 7 feet, averaging, however, between 4 and 5½ feet. Numbering from the base of the conglomerate upwards, No. 1 coal bed occurs about 20 feet above the Chester formation, and according to Crandall has the following analysis:

Moisture, 3 per cent.; volatile matter, 36 per cent.; fixed carbon, 57 per cent.; ash, 5 per cent.; sulphur, .79 per cent.

The top coal so far as followed is 3 feet thick, while the rock between the beds increases from nothing up to 12 feet. This mine ships 600 tons daily, but the development is such that the quantity can be greatly increased. Analysis of coke made from the nut and slack of No. 1 seam by the Dayton (Tennessee) Coal and Iron Co. is as follows: Moisture and volatile matter, .54; fixed carbon, 87.06; sulphur, .91; specific gravity, 1.88; pore space, 45.10; ash, 11.39.

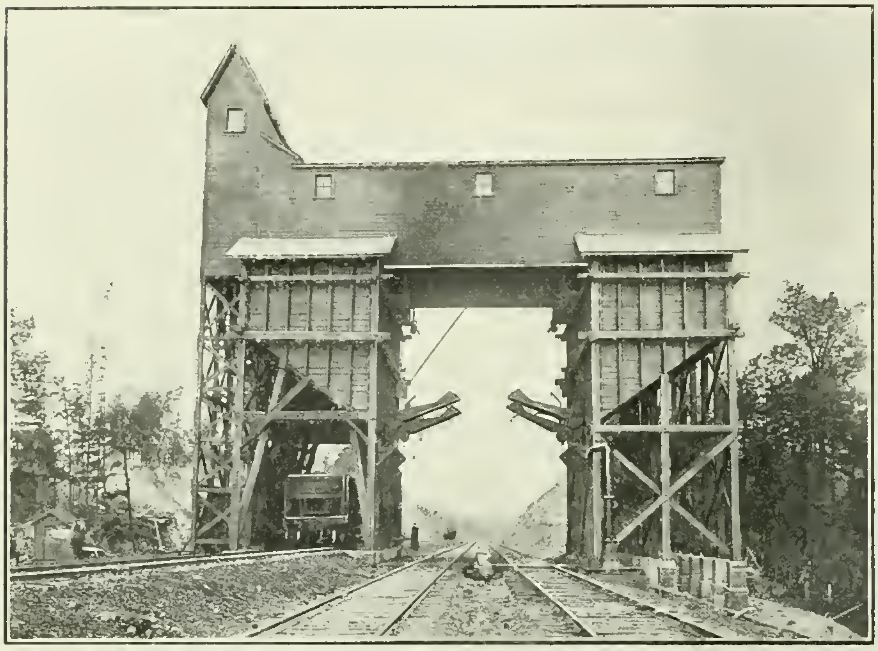

FIG. 2. COALING STATION AT STEARNS, KY.

From this it is assumed that the coal should produce an excellent coke in retort ovens, and furnish a good amount of by-products owing to its richness in oily hydrocarbons.

So many irregularities in thickness and so many local "raises" and "swags" were found that in many cases it was not possible to gather with motors. The combination of mules and motors was then tried and the plan works tolerably well. The coal is gathered from the room partings with mules and delivered to sidings on the main entries, where it is picked up in trips and taken to the tipple. Previous to introducing the motors every effort consistent with economy was made to reduce gradients to a minimum and to ease curves and straighten roads. The track was then relaid with 25-foot and 35-foot steel on white oak ties 5 inches by 6 inches by 5½ feet, spaced 18-inch centers. The compressed terminal bond, consisting of a head on the end of a copper conductor, is used. This head is compressed in a drill hole in the rail by means of a screw jack, which exerts a pressure of from 10 to 20 tons on the head of the bond, causing the copper to expand in the hole and form an intimate contact. These bonds have thus far eliminated the troubles arising from poor bond contacts. The trolley wire is 4-0 V grooved; the machine wire is No. 4; the clamps are the "Sure Grip" of the Electric Railway Equipment Co. On the outside hauls the trolley wire is strung on 8-inch round chestnut poles set 30 feet apart with 3" x 5" white oak cross-arms. Power is obtained from a Jeffrey 150-kilowatt generator, to which is directly connected an induction motor, forming a motor generator set. Three haulage motors are used, one 8-ton and two 5-ton, all Jeffrey equipment. The plant, while small and compact, is built in a substantial manner and has to date fulfilled requirements.

This coal bed at Worley varies from 4 feet to 7 feet in thickness, and is particularly interesting because, without any reason so far discovered, soft coal will suddenly change to cannel coal, and vice versa. Sometimes there will be soft coal above the cannel coal, which may increase from nothing to almost the entire thickness of the seam and then decrease. There is no parting between the two varieties; they merge into each other, and consequently no endeavor is made to separate them for shipping purposes. No. 4 mine is worked by Sullivan punchers and chain machines and has electric haulage. The rooms are made 40 feet wide with 20-foot pillars where the roof is good; where it is soft, however, the rooms are made single, 24 feet wide with 16-foot pillars. The entries are driven 12 feet wide; cross-entries are turned every 400 feet. The mine contains some gas but no explosion has yet resulted.

Mine No. 3 has been driven so as to connect with Mine No. 4, 1,000 feet away, and thus has lost its identity. It was assumed when driving the two mines toward each other that they would meet; it happened, however, in this case, that a horse of rock split the two beds, as shown in Fig. 3, slightly upsetting the nicely prognosticated plans.

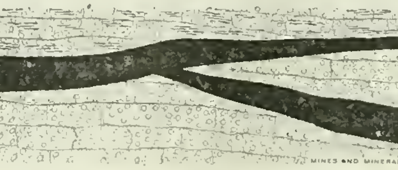

FIG. 3. SPLIT IN COAL SEAM

When constructing the Kentucky and Tennessee Railroad in 1903, the No. 2 coal bed, which is 90 feet above No. 1 coal bed, was found at suitable tipple height above the railroad to commence mining operations, at the place called Barthell. Here mines No. 1 and No. 2 are opened. No. 1 mine being the more extensive, it is probable the No. 2 mine will be merged in No. 1 when the two excavations meet. The No. 2 coal seam is not so free burning as No. 1 coal seam, but for steam locomotive purposes it is preferable. About 130,000 tons of coal from No. 2 bed is sold yearly to the Cincinnati, New Orleans and Texas Pacific Railroad, which has one of Roberts & Schaefer's coaling stations at Stearns, shown in Fig. 2. The elevating capacity of this two-track coaling station is 125 tons of coal per hour, with storage capacity of 500 tons in two equal sized bins. The machinery, driven by electric power obtained from the Stearns Coal Co.'s power plant, includes not only the elevating and distributing coal system, but an electric compressor and machinery for sand house. This plant also has complete fire protection equipment, consisting of fire pump, hydrants, fire hose, and sprinkling devices above the bins.

The mines are worked double entry, with double and single rooms as explained for Nos. 3 and 4 mines. At present coal is shot off the solid and haulage is accomplished by mules and electric locomotives.

Mine openings Nos. 5, 6, 7, 8, and 9 of the Stearns Coal Co. are merely prospects on Rock Creek and will not be developed for some time, as a long spur track will need to be built to connect them with the Kentucky and Tennessee Railroad; besides, the operating mines are capable of producing more than twice the coal being shipped, which in 1912 will amount to over 400,000 tons.

Mine No. 10 is a short distance beyond Yamacraw on Rock Creek, and is destined to be a mine of large capacity. It has two openings some distance apart but at such height above railroad track that when the cars come from the main entry they are run directly on the tipple and dumped. The tipple, which is shown in Fig. 1, is probably the pioneer concrete tipple; and if not, it is the pioneer of its kind. The Stearns Coal Co. have abundance of the best white oak and long-leaf yellow pine for tipple construction, yet it was believed that a concrete tipple if properly constructed would last enough longer than a wooden tipple to pay for the difference in first cost, and in any circumstance it would not burn and so interfere with coal shipments. The construction of the tipple was an experimental venture, because there were no all-concrete tipples to use as patterns and to develop weak points for improvement, besides the anthracite breakers were partly concrete and wood or concrete and steel, the all-concrete breaker of the D., L. & W. Co. at Taylor, Pa., not having been finished. The No. 10 tipple, which has been in use over 1 year and 4 months, has not so far developed any weakness and has given general satisfaction. The tipple was constructed and the screens furnished by the Associated Engineering Co.

The tipple is a remarkably neat looking structure, braces and housing being reduced to a minimum, thus making its simplicity more glaring. If a tipple is to last, it must have solid foundations, with every part of the superstructure bound together to form a rigid mass. In testing for foundations, it was found that the ground under the shaking screens and loading chutes was yellow clay, making it necessary to enlarge the foundation piers for the tipple columns and keep the pressure on them under 1,000 pounds per square foot. The reinforced-concrete columns have 4 square feet sectional area and necessarily differ in length; the third or longest pair are 44 feet high and are reinforced with extra steel rods in order to bind them to the tipple floor above the screen floor below. The columns are braced at all corners and junction points, to add stiffness, and the three lower bents are tied with a beam and braced in order to furnish mass and resist the strains produced by vibration of the shaking screens.

All concrete beams on the tipple and shaker frame floors are 2 feet deep and 1 foot thick. The tipple floor is of concrete 4 inches thick. This has a grade of 1.5 per cent. for the loaded cars going to the dump and 1.7 per cent. for the empty cars going away from the dump. In the tipple floorbeams regular trussed reinforcing was used. The shaker-frame beams were specially reinforced for concentrated loads at points where the screen pedestals were fastened. The floors were reinforced with ½-inch round bars placed 6 inches apart and bent in truss form to reach from beam to beam. Special steel chairs placed 2.5 feet apart were embedded in the concrete tipple floor to hold the track rails in place. The arrangement of the tracks on the tipple floor is shown in Fig. 4.

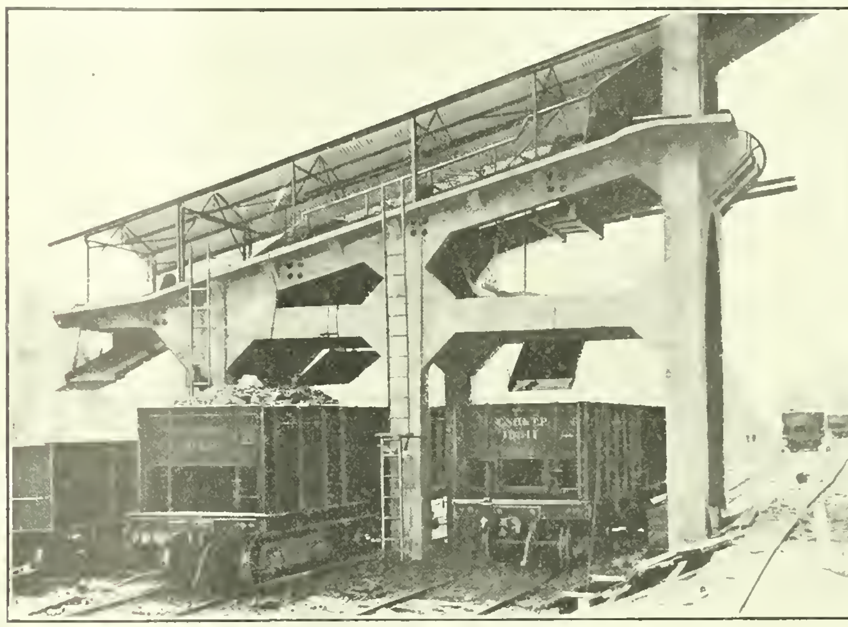

Fig. 5. Stearns Tipple, Chute End

The loaded cars come from the weigh scales on track *a*; at *b* there is a switch thrown by hand to direct the cars to one of the two Phillips kick-back dumps at *c*; at *d* there is a movable rail which the loaded car pushes in place so as to cross the return tracks *e* at the frog point. The track *a* has a higher elevation and the removable rail, which in place forms part of it, swings over and rests on the return track at *f*; but so soon as the loaded car has passed over the movable rail, a weight fastened to it by a chain swings it back and holds it in the position shown. At *g* there is a spring switch which is always set for directing the empty cars on the track *c*.

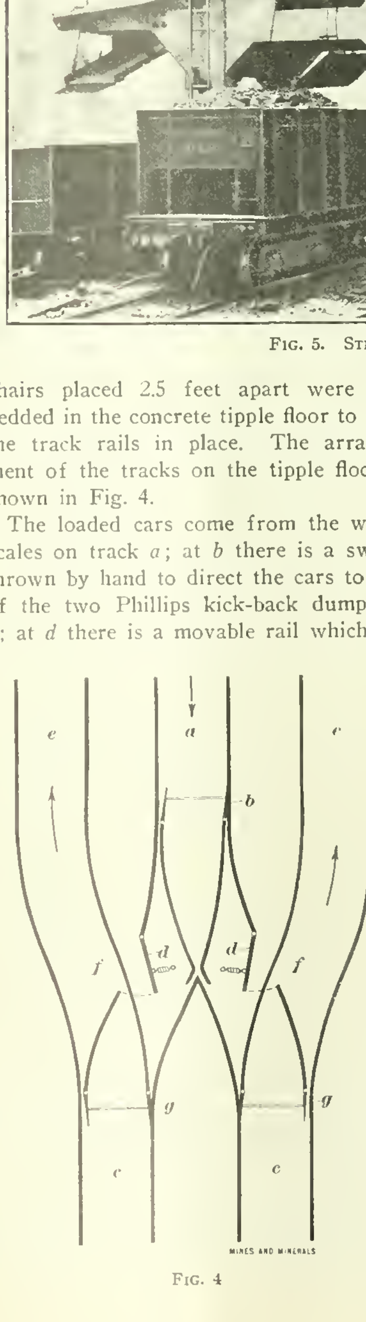

Fig. 4

The shaker screen is of new design, and does away with the long suspension rods, and spring boards of the old style; there is also an absence of long reach rods between the screen and eccentric, thus economizing considerably in space. In the new screen the suspension rods are links 6 inches long and on these the screen swings full stroke without the attendant vibration that accompanies other shaking screens. The screen at Stearns No. 10 mine is 72 inches wide, and effectively separates the coal into 4 or 5 grades if desired at the rate of 200 tons per hour with a consumption of 6 horsepower. The little building shown beneath the tipple floor in Fig. 1 contains the motor which drives the shaker screens by a belt that passes over the delivery main railway track to the eccentric shaft pulley shown on the third bent of the tipple. The screen frames are of steel, and the screens are two-decked, consequently it requires only the opening or closing of valves to make a number of different coal sizes, a matter which is accomplished quickly. The upper screen plate is of sheet steel .25 inch thick, perforated with 2-inch diameter holes; all coal which passes over this screen can be separated into sizes by passing it over bars. The under screen plate, made of the same thickness of steel, is punched with 1-inch diameter holes, the oversize going to bar screen which separates any coal over 1 inch. The screen is run at about 110 revolutions of the eccentric per minute, which is equivalent to 220 shakes; at the same time it is accomplishing more work with less horsepower and less vibration than shakers having larger area.

About 2 years ago the mine designated as No. 11 was opened at Yamacraw on the west bank of the South Fork of the Cumberland River. As the railroad is on the east bank, it became necessary to provide means for transporting the coal across the river temporarily for the development and construction period, and later for the regular operation of the mine.

Temporarily an old steam log-loading machine was set up near the railroad, and a 1¼-inch plow-steel cable was strung over the river and anchored in solid rock on either side. To this was suspended from a trolley, a sheet-iron bucket of 2 tons capacity. The coal was dumped from the mine car through a short chute directly into the bucket, pulled across the river by means of the log loader, dropped into railway cars and shipped as run-of-mine. With this equipment a capacity of 150 tons in 9 hours was obtained at a cost of not to exceed 10 cents per ton, and the wasteful practice of stocking the development coal in the mine yard was avoided.

The permanent equipment consists of a reciprocating aerial tramway of 550-foot clear span operated by a 35-horsepower General Electric variable-speed motor, geared to the main driving wheel of the tramway. The 1¾-inch lock coil track rope cables reach from cliff to cliff across the river, and are anchored in solid rock and concrete. The traction cables are ⅝-inch plow steel. The buckets are 52 cubic feet capacity and travel at a speed of 800 feet per minute.

The writer is indebted to Mr. J. E. Butler, Manager of the Stearns Coal Co., for the material in this article.

Barometric Pressure and Mine Gas

Observations Showing the Effect of Variations of Barometric Pressure on the Composition of Return Air

In volume XXVIII, No. 2 of the Proceedings of The South Wales Institute of Engineers, J. W. Hutchinson and Edgar C. Evans have a joint paper on "Analyses of Mine Air," which will prove interesting reading. We have abstracted parts of this paper relative to the firebosses test for firedamp and to the effect which variation in barometric pressure has on the flow of gas into a mine. —Editor.]

The new English Mine Act of 1911 stated for the first time that definite percentages of various gases in the ventilating current must not be exceeded. Previous provisions with regard to ventilation stated that "an adequate amount of ventilation shall be constantly produced in every mine to dilute and render harmless noxious gases." The law now is that, "a place shall not be deemed to be in a fit state for working or passing through if the air contains less than 19 per cent. oxygen or more than 1¼ per cent. carbon dioxide; and an intake airway shall not be deemed to be normally kept free from inflammable gas if the average percentage of inflammable gas found in six samples of air taken by an inspector in the air-current in that airway at intervals of not less than a fortnight exceeds ¼ per cent." The Act also states that "workmen must be withdrawn and a place shall be deemed to be dangerous if the percentage of inflammable gas in the general body of the air in that place is found to be 2½ and upwards—or if in a part of the mine worked with naked lights 1¼ or upwards." With the statutory limit of 2½ per cent. of methane it has become absolutely necessary that the fireman should be able to detect the presence of low percentages of firedamp by means of the safety lamp. With careful training it is possible for skilled men to detect as low as 1½ per cent. of methane and we believe even so low as 1 per cent. We have been training a number of firemen in the detection of low percentages of methane. They have, by means of hundreds of analyses made, become familiar with the caps showing the various percentages. Each fireman after making a cap test in the mine notes down the percentage which he thinks is present. He then immediately takes a sample of the air which is afterwards analyzed in his presence. The notes he has made are collected previous to the analysis, so that there can be no question as to the fairness of his observations.

The tests are made with an ordinary bonneted Clanny lamp fitted with round wick. In making a test the fireman lowers his flame until the luminous tip is barely visible; he then bases his estimate on the appearance of the cap, the height, density, and condition of tip all being taken into account. The firemen in their reports rarely state the height of a cap, but definitely state that a place contains a certain percentage of gas, and in most cases with considerable accuracy.

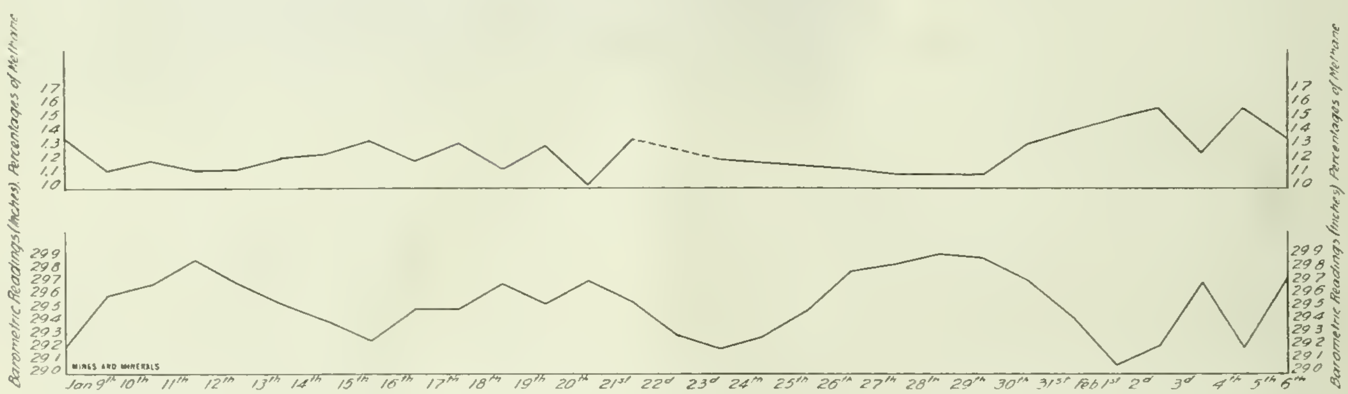

Fig. 1. Influence of Barometric Pressure on Percentage of Methane

The chemical analysis of the return aircourse is of the highest importance, since this airway is the main sewer, as it were, and contains the gases from the various working districts and places ventilated. Systematic analysis of the return air is also a check on the ventilation, and calls the manager's attention to any increase in the quantity of gas, such as may be due to increased blowers of gas or decreased speed and efficiency of the fan; and if the analyses are combined with anemometer readings the quantity of gas produced by a colliery can be directly ascertained. The original clause in the Mines Bill stated that the percentage of methane in return airways used for hauling coal should not exceed .5 per cent. Had this clause been persisted in, it would have closed a large number of collieries in South Wales, with a consequent loss of coal output of enormous dimensions.

The results of our analyses were interesting, and systematic analyses were continued with a view to accounting for the variations which were found taking place. The first and most obvious influence to be looked for was the variation in barometric pressure. Daily examinations of the air were made in the main returns of two mines, with a view to finding how far barometric variation affected the amount of methane given off from coal. To this end samples were taken daily at four places and the barometric pressure noted. The results showing the influence of barometric pressure on the percentage of methane in the return airways are given in Fig. 2. It will be noted that, *a substantial rise in the barometer is accompanied by a drop in the percentage of methane and vice versa*, but a close examination will show several local variations which cannot be accounted for by barometric variations. The amount of gas released is influenced by the rate at which the coal is worked, and thus varies at different periods of the shift. Again, variation in the speed of the fan causes a variation in the quantity of air passing along an air-course and consequently a distinct influence on the percentage of methane.

In Fig. 1 is shown the curves of variations of methane relative to variations of the barometer, at the second mine, and which confirm the influence of barometric pressure on the percentage of methane in the return airways. The seam at this colliery gives off large quantities of gas wherever it is worked. Samples of the return air were taken daily with extreme care by the colliery surveyor. The samples were taken at the same spot each day at the same time, the barometric pressure being recorded simultaneously. This curve shows in an unmistakable manner the enormous influence the barometer has on the quantity of methane given off by the coal, with the consequent variation in the percentage of gas found in the return air.

The results on the whole are exceedingly consistent. A drop in the barometric pressure is accompanied by a rise in the methane percentage, and a barometric rise with a corresponding fall in percentage throughout the period observed. There is no doubt in this case but that the fan was working at a regular fixed speed and a constant water gauge. While the experiments shown in Fig. 1 were going on an attempt was made to find whether the time at which the return air was sampled had any effect on the percentage of methane, apart from that due to barometric changes in pressure but due to the working shift. These experiments were carried on in another colliery. Samples were taken four times daily at 6 and 10 A. M. and 3 and 10 P. M., readings of the barometer being made simultaneously. During the first two days the barometer remained practically stationary and its influence was practically eliminated. Thus any variation in the methane percentage, assuming of course that other factors remained constant, was due to mining the coal. It will be seen in Fig. 3 that the percentage of methane is at a minimum at 6 A. M., before the day shift starts, but increases throughout the period of the working shift until the end at 3 P. M.; then it falls gradually throughout the night to a minimum on the following morning. This is repeated periodically day by day throughout the period taken. Thus the peaks of the curves all represent the methane percentage at the end of the working shift; the troughs—the minima—represent the periods when no coal was being worked. The influence of the barometer is also plainly marked. Corresponding with the sudden fall in the barometer the methane curve, as a whole, takes an upward tendency, fluctuates on Thursday in accordance with the fluctuating barometer and rises again on Saturday in agreement with the falling barometer.

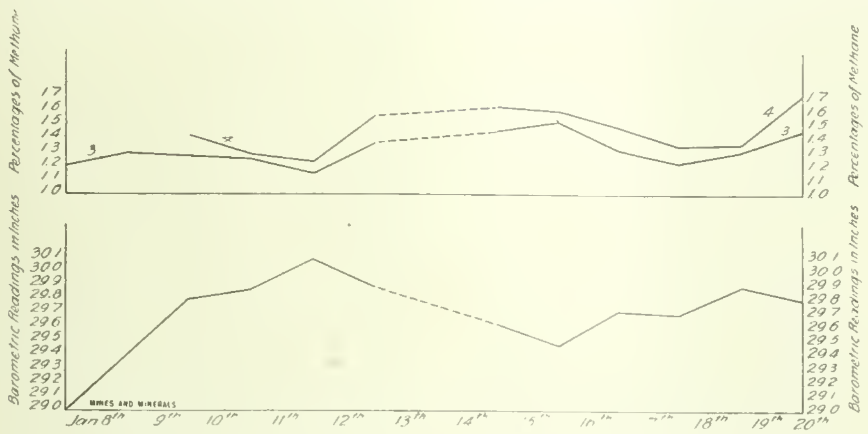

FIG. 2. INFLUENCE OF BAROMETRIC PRESSURE ON PERCENTAGE OF METHANE

FIG. 3. INFLUENCE OF WORKING AND BAROMETRIC PRESSURE ON PERCENTAGE OF METHANE

Power and Quantity Air

The relative amounts of power required to pass equal quantities of air through air-courses of the same length but different areas and perimeters are found by the formula: Power varies as $\frac{\text{Perimeter}}{\text{Cube of Area}}$.

The following table shows the results of using different sizes of airways:

Size of Airway	*P*	*A*	Relative Power, Making the Road 6×6 = 1
6×6	24	36	1.00
5×5	20	25	2.29
4×4	16	1	7.59
3×3	12	9	32.00

It will be noted from above that while the area of the airway 3 x 3 is one-fourth of the 6 x 6, yet it requires 32 times as much power to force the same quantity of air through it. This illustrates the great importance of keeping the airways large and explains why ventilation is often poor or an excessive amount of power is required to furnish sufficient air for the needs of the men and animals in the mine.

First-Aid Contest at Gary, W. Va.

The first-aid contest held on the Athletic Grounds, at Gary, W. Va., on July 4, under the auspices of the United States Coal and Coke Co., was a brilliant success. While the contest was open for all first-aid teams in the Pocahontas coal field, only three teams reported, as follows:

Team No. 1, from the plants of the United States Coal and Coke Co., on Tug River, above Gary; team No. 2, from plants on Sand Lick Creek, above Gary; and team No. 3, from Gary and Wilcoc.

The contestants were very fortunate in being able to procure the services of Dr. J. J. Rutledge, Mining Engineer of the National Bureau of Mines, Pittsburg, Pa., and Dr. J. Howard Anderson, of Marytown W. Va., to act as judges. Before the opening of the contest, Doctor Rutledge made a short address in which he outlined the great progress being made in first-aid work throughout the country, particularly in the soft-coal districts. He also stated that in all first-aid contests it was customary to penalize each contestant by giving certain discounts for failure to observe certain precautions necessary to first-aid work. The discounts decided upon for the contest were as follows:

	Per Cent.
For improper control of team	15
For failure to reduce shock	15
For failure to stop bleeding	15
Failure to observe aseptic precautions	5
Appearance of team	5
Not observing proper sequence in rendering first aid	10
For careless handling of fractured bones	15
Time	5
Failure of rescuer to protect self	5
Improper application of splints, tourniquets, and bandages	10

The schedule of contests was as follows, which were performed by each team in turn:

1. Man unconscious from electric shock or gas. Remove from wire; perform artificial respiration for 1 minute.

2. Small injuries. Dress wound of right temple; dress wound on back of left hand. Apply torniquet for severe hemorrhage of leg below knee and arm.

3. Compound fracture of right arm below elbow. Control bleeding, dress wound, apply splints, and dress complete.

4. Man injured, simple fracture of left leg below knee. Apply splints. Make stretcher with two coats and two mine drills. Place injured man on stretcher and carry 50 feet.

The manner in which the contesting teams went through the different events showed the efficient training they had received, and Doctor Rutledge said that they would compare favorably with contesting teams in the various state contests. The points made by the different teams were as follows: Team No. 2, 83⅓; team No. 1, 82½; team No. 3, 77½.

The following prizes were awarded: First prize, $40 in gold; second prize, $30 in gold; third prize, $20 in gold. Each contestant also received a solid-gold first-aid button. Fully 500 persons were present and enjoyed the contest.

The contesting teams, as well as everybody present, were very much pleased by the efficient manner in which the judges rendered their decisions, and their knowledge of first-aid work, as they took particular interest in observing each and every point in favor or against the different teams, and they were judged by individual points scored for or against them, instead of being judged as a whole; and everybody connected with the contest expressed their thanks to Doctors Rutledge and Anderson for the very capable manner in which they officiated.

Cadeby Mine Explosion

The Cadeby mine, in which an explosion occurred on July 9, is one of the two large collieries owned by the Denaby & Cadeby Colliery Co. The Cadeby shaft is sunk to the Barnsley coal seam, which at Conisborough, in Yorkshire, has a depth of 2,250 feet from the surface. At the time of the explosion about 200 men were in the mine, and in the district which exploded about 35 men, instead of the usual 136, when the explosion occurred at 4:30 A. M. while the night shift was at work. Only two of the men in the first explosion escaped. When the mine began to clear, rescuers went into the pit and were searching for the bodies when a second explosion occurred, much more severe than the first. Other rescuers were summoned and made their way as far as possible and by 8 o'clock six bodies had been recovered. These bore evidence of the severity of the blast. Coal dust was burned on them and it was apparent that in most instances death had been almost instantaneous. The work of the rescue parties was seriously hampered by the heavy fall of coal and stone which followed the explosion.

Mr. W. H. Pickering, Chief Inspector of Mines for Yorkshire and the North Midlands, and Mr. Hewitt and Mr. Pickle, two other mine inspectors, went down into the mine. In the absence of the managing director of the company, Mr. Douglas Chambers, of the Denaby mine, joined the party, as did Mr. Douglas Pickering, son of the Government Inspector. These men were superintending the operations below when another explosion occurred followed by two others. These men were soon brought up in a state of collapse, overcome by the fumes. From these it was learned that most of the rescue party, the mine inspectors and the officials had been caught by one of the last two explosions and many of them had perished.

Despite the tragic sequence of events, men were still ready to descend as rescuers, and later in the afternoon the work of rescue was resumed. By 5 o'clock 31 bodies had been recovered. Percy Murgatroyd, who was the last man to see Mr. Pickering and the other members of the rescue party alive, wore a helmet. He stated that it was about 11:30 o'clock when the exploring party undertook to find out what had been the cause of the explosion. He was the only one who wore a respirator because the air seemed good and there was no need of one, but it was his business to penetrate into any part of the workings that the others might direct him to go. He was talking quite casually when all at once there was a trembling of the air. There was no time to seek a place of safety, there was a fearful crash, then clouds of dust and smoke all around. He remembered seeing Mr. Pickering and Mr. Hewitt lying on the ground as if asleep, and did not think they could have lived more than two minutes in that atmosphere. He staggered about in the darkness and tried to find his way out, but suddenly realized that he was lost. He came to a great fall and was so exhausted that he collapsed. After a minute or two it occurred to him that he might find a telephone. He found one and rang up and suddenly heard footsteps approaching and two rescuers came upon him and brought him out.

Two surveyors who escaped were a mile and a half away from the shaft and carried the first news of the explosion through the shaft. Edward Humphries, one of them, stated that his first impression of the explosion was a puff of air in his face and a moment later the place was filled with dust. He with two others went steadily on an investigating tour, doing all they could to locate the mischief, but it was not until they came to level known as 14 that they found any serious marks of the disaster. Cars were smashed, girders twisted in all shapes, and everything scattered about showing the force of the explosion. Word was sent to the pit manager and it was about 5 o'clock after the first puff of air that the real trouble was located. Foul air prevented further investigation for a while and then the men traveled some distance and came across the body of a man half buried in dirt. In all it is thought that 87 men lost their lives in this disaster. The seat of explosion was sealed in order to prevent further explosions, which are supposed to originate from gob fires that are prevalent in Yorkshire mines.

The coroner's jury returned a verdict of "accidental death," caused by two gas explosions on July 9. Fourteen bodies were sealed in the affected area and the coroner intimated that a formal inquiry was to be held by the Home Office.

The Flooding of Superba Mine

Tremendous Downpour of Water Wrecking Surface Structures and Bursting Into the Mines

Written for Mines and Minerals

On July 24 a tremendous downpour of rain occurred in the vicinity of Uniontown, Pa., that found its way into the Superba mine and trapped 14 men. At about the same time the flood found its way into the Lemont mine about 1 mile away, drowning three men.

Through the kindness of Joseph S. Hagans, a photographer of Uniontown, it has been possible to obtain illustrations which show one of the difficulties the entrapped men had to overcome to escape.

Both the operations are in Fayette County, a few miles northeast from Uniontown, Pa. Superba, the smaller mine, is at Evans Station, and is purely a coal-shipping proposition working on one of the upper measures known as the Sewickley coal, a bed about 5 feet in average thickness and separated from the Pittsburg, or Connellsville coking seam by some 90 feet of intervening strata.

The mine has not been in operation long enough to be rated among the older plants and probably 50 acres have been developed up to date. The Lemont mine, however, has been in operation a number of years, and operates solely in the Pittsburg seam. Both these plants occupy in part, the same superficial outlines; the Lemont workings on the western end, partly exhausted, lying directly beneath those of the smaller mine. The dip or inclination of both seams in this particular location is to the westward, and the general trend of both operations is practically in the same direction; odd as it may appear, the main openings of each plant are more than a mile apart and are on opposite sides of the same main valley. The Lemont openings enter direct on the outcrop and with the inclination of the seam; the Superba inlets, in the opposite hillside, swing around in several consecutive angles until they get the natural bearing and follow the same inclinations as the Lemont workings. The dip on the main slope of the Superba mine is about 7 per cent.; the Lemont opening is more on a local "backbone" in the basin, consequently somewhat flatter.

The conformity of the surface area covered by the recent flood is not one that would naturally cause apprehension or anticipation of this unusual disaster, save in the fact that the coal outcrops along the bottom of the foot-hills defining the valley; but the latter is one of ample width and extent, with several miles of gently rolling or undulating country to the base of the regular mountain chain on the east (Laurel Ridge). It is well cleared and has been cultivated in the past; and while the watershed exposure is considerable, there is ordinarily ample clearance for the spread of excessive rainfalls.

It is a well-populated section with the inhabitants located so as to be at any time quickly notified of and protected against impending dangers from floods. Yet all the misfortune took place in mid-day, when all were in position to realize and see for themselves; which proves how entirely unusual the occurrence was and how little it was apprehended. While ample assistance of all sorts was readily available for an ordinary outbreak, the community was overwhelmed and helpless before the suddenness and power of such volume of water as descended during the few hours covering the period of disaster. It has been stated by good authority that the rainfall during these few hours amounted to more than 2 inches.

Further confirmation of the helplessness and horror of those involved lay in the fact that the waters did not enter either mine through the natural or expected sources, the regular mine openings, but in each place broke through the surface in the low places of the main valley and where the old workings had been driven up almost to the crop of the coal, leaving but a few feet of surface to cover these excavations. Flowing into these old excavations, it sought its own course, spread in all directions, and was simply beyond human control for the time being.

Eventually the body of water covering the valley did rise sufficiently high to flow into the manways of both plants, and in this rise, sections of low country for miles around were covered and impassible, indicating the suddenness and extent of the storm.

The northeastern corner and high point of the Superba operations crops in the valley close to the railroads' right of way; both the Pennsylvania and the Baltimore & Ohio Railroads traverse this valley in parallel lines and near together; the mine workings stop at the boundary of the right of way, and the coal at this point has only 6 feet of cover. But previous to the day of the accident, no indication of fracture or settling of this surface had been noted, although for some years heavy train traffic with its vibrations and pressures had been constantly passing this point. At Lemont, the same condition applied—differing only in the fact that the railroad actually crossed the excavated portion and the thin cover was on the opposite side of it, a mile further eastward than the break at Superba; nor had there been any indication of break or settling at this second hole.

The first sign of serious trouble took place about 1 P. M. in the sudden disappearance of a heavy stream of water that flowed along the western ditch of the railroad; immediate investigation showed the water to have broken through the surface at the point above referred to at the Superba mine; and from all reports a similar break occurred at the Lemont mine at about the same hour. Sixty odd men were at work in the Su-

SUPERBA MINE SURFACE PLANT

Superba Slope Mouth

perba mine and a full quota of employes at the adjoining plant.

Messengers acquainted with the workings were at once dispatched to notify the men of their danger and to hurry them out as rapidly as possible; and after strenuous effort on the part of the messengers and many narrow escapes, all but 14 of the total in Superba and 3 in Lemont made their way to safety. That effective and very rapid work was done by the messengers is illustrated in one case where a Superba trackman, working in the extreme dip and farthest point in the mine, was rescued along with many others. Of the other 14 men lost, several were within rescue distance, but the rush of the water carrying with it timber and heavy debris, finally battered and beat them back until they were totally exhausted and lost. Much of this final overpowering was due to the additional stream flowing into the traveling way shortly after the messengers started on their journey to notify the men; this new stream caught even the messengers on their return trip and in their then exhausted condition, their escape was only short of miraculous. Also, in this mine, with only 5 feet of height in which to travel, all the men were handicapped, due to the crouched position necessarily maintained; and as the water continued to rise, their space for air supply became rapidly contracted, and all the way through they suffered many physical disadvantages in the strenuous endeavor to make their way to safety through the strong current of water, laden with debris, and with the usual passageways blocked with foreign matter.

The manways in each case were several feet higher in elevation than the ordinary storm stages of water; and also in wide parts of the valley barriers or covers built around the openings were swept away by the sudden rise; the ventilation regulating and controlling doors and stoppings were burst open by the inrush of water; timbers dislodged, mine tracks thrown out of place and pushed up to the roof, and all loose timbers, materials, and other debris were swept along the main outlets and escape ways. At this most crucial moment, while most heroic endeavors were being made to dam back the flow of water in the mines, on the surface and within a few miles on both sides of the plants, bridges and standard railroad track and work were being swept away, heavy stone abutments were battered and damaged, house foundations washed out and the buildings dislodged and several of the larger towns suffered great loss of property; traffic was entirely suspended; even the highways were impassable and a complete demoralization of the whole district for a length of 12 miles lasted until the following day.

While a dip of 7 per cent. is rather heavy in the usually flat beds of coal in this section, such pitch does not afford, as has frequently been the case in the heavy pitching anthracite seams, highly elevated places to which men can retreat in case of flooding, and where for a limited time they will likewise find air storage sufficient to maintain life, if quick rescue can be accomplished. But in the present case, as the water flowed in the main openings or even the new breaks, it would rapidly fill up all the excavations, and those who could not keep ahead of this rise, would be trapped and covered. As the men were all probably on their way out from the various parts of the mine, where those who became victims met their end it would be difficult to state; many of them would likely be floated off to other parts from where they met the water until they lodged on some obstruction. The only definite statement that can be made is that most of them were employed in the most recently developed part of the mine. This is on the southern side of the slope, away from the old workings in which the break originally took place. Two new main flats are being pushed in this lower section, and there is not much difference in elevation at these points between the slope dip and the headings mentioned; the greater body of the coal lies in this part of the mine and it was the endeavor of the management to get ample development in this solid portion to take care of their shipments without having to depend on the old section near the crop.

View of Manway, Superba Mine, After Flood

While two adjoining mines have been unfortunate at the same time in losing employes through the same means, what happened at each plant was by no means effected through the mishap to its neighbor. The water into Superba followed a westward course; and while directly over the western end of the Lemont operations, even had the breaks and fissures of the intervening strata been sufficient to allow this water to pass down into the workings of the latter mine, very little damage would have been done to Lemont; but there is little indication that the water followed such a direction, as after subsiding on the surface the volume in the Superba remained about stationary, indicating very little leakage or subdrainage. On the contrary at Lemont, its body of water appears to have taken the eastern course due to the "backbone" referred to, and other operations along the main axis of the same basin, but in the opposite direction from the Superba and operating in the Pittsburg seam, were getting high water through this source.

There are several small valleys, laterals they might be called, branching out at almost right angles from this main valley and extending back to the Laurel Ridge; these valleys are the natural water courses for the mountain streams and are about 2 miles apart; one of them is just west of Evans Station; the other nearly opposite Lemont. It was at first thought and so reported that one of the large storage reservoirs at the foot of the mountain had given way, but afterwards was found not to be the case; the forces of several storms circling around the affected district must have suddenly concentrated and fallen in a deluge; the meeting of the waters through the two lateral valleys into the main valley then caused the sudden rise. Something worthy of note is the fact that in the lateral at Evans Station, and about a mile southward from it (much nearer to the base of the mountain) is another mine operation with a manway opened within a hundred feet of the creek bed and its own small reservoir. This manway is not much elevated above the surface and only a railroad fill intervenes between it and the flow of water; yet the water rushed by this point, tore its way through huge ash dumps from the ovens, upset tracks and bridges, and very little of it eventually reached the manway to do any serious damage. This miracle simply kept down the list of the storm's victims and even looks providential.

Many harrowing tales are told by the survivors; of course they vary widely in their narratives, due mainly to the disconnected events occurring in rapid succession and as they remember them in fleeting space; but the full horror of this unusual accident can be somewhat realized by one who is experienced in mining practice and posted in the lore of the man who works underground.

In the Superba mine there are probably 40 acres of exhausted territory now full of water, and the length of time required to pump it out is problematic, depending on the success with which persistent endeavor will be met, and the amount of repair work to be done as the work advances. While one might figure out the cubic feet of water to be discharged per day to eventually displace the quantity involved, the unforseen features cannot be estimated; however, this work of pumping and eventual recovery of the bodies was put under way as quickly as the conditions would allow.

The inundated portion is one of much commercial activity; several railroads, a street railway, and numerous mines and industries, as well as the homes of the employes, are strung along the valley for some miles. Moreover, while excessively high waters are not necessarily apprehended, the clear spaces through its length have been somewhat blocked with such industries and by the deposit of much refuse matter. Some attempt has been made to retain the natural water courses, but in an indifferent way; much of the refuse, light in character, is easily disturbed or washed into the streams during heavy rainfalls and liable in this case to add to the blockade. Bridges are numerous both on highway and rail, indicating the tortuous course of the streams; and the stoppage of water through a few of these at a critical time becomes a serious matter. It would appear to the casual observer that it might be good policy for the numerous industries to come to some arrangement for establishing of definite water channels, and this must be done with a full cognizance of what has been done under the surface in the way of mining operations as well as the exterior or surface arrangements. While the possibilities of a similar flood are equally for and against its occurrence, an investment of the kind here referred to will be of much smaller moment than the many thousand dollars lost in a few hours during this recent downpour; and the guarantee of safety to the men working underground will be a feature far more commendable and of greater moment than any monetary consideration. The importance of such water courses must necessarily rank with efficiency, conservation, safety, and good roads.

Dr. Holmes says that during the past year in producing 500,000,000 tons of coal in the United States, there were wasted or left underground in such condition that it probably will not be recovered in the future, 250,000,000 tons of coal.

The Horsepower and Kilowatt

There was, before 1911, no precise definition of the horsepower that was generally accepted and authoritative, and different equivalents of this unit in watts are given by various books. The most frequently used equivalent in watts, both in the United States and England, has been the round number, 746 watts; and in 1911 the American Institute of Electrical Engineers adopted this as the exact value of the horsepower. It is obviously desirable that a unit of power should not vary from place to place, and the horsepower thus defined as a fixed number of watts does indeed represent the same rate of work at all places. Inasmuch as the "pound" weight, as a unit of force, varies in value as g the acceleration of gravity varies, the number of foot-pounds per second in a horsepower accordingly varies with the latitude and altitude. It is equal to 550 foot-pounds per second at 50 degrees latitude and sea level, approximately the location of London.

The "continental horsepower," which is used on the continent of Europe, differs from the English and American horsepower by more than 1 per cent., its usual equivalent in watts being 736. This difference is historically due to the confusion existing in weights and measures about 100 years ago. After the metric system had come into use in Europe, the various values of the horsepower in terms of local feet and pounds were reduced to metric units and were rounded off to 75 kilogram-meters per second, although the original English value was equivalent to 76.041 kilogram-meters per second. Since a unit of power should represent the same rate of work at all places, the "continental horsepower" is best defined as 736 watts; this is equivalent to 75 kilogram-meters per second at latitude 52° 30′, or Berlin. Circular of the Bureau of Standards, No. 34, June 1, 1912, gives tables showing the variation with latitude and altitude of the number of foot-pounds per second and of kilogram-meters per second in the two different horsepowers.

These values, 746 and 736 watts, were adopted as early as 1873 by a committee of the British Association for the Advancement of Science. The value, .746 kilowatt, will be used in future publications of the Bureau of Standards as the exact equivalent of the English and American horsepower. It is recognized, however, that modern engineering practice is constantly tending away from the horsepower and toward the kilowatt. The Bureau of Standards of the Department of Commerce and Labor and the Standards Committee of the American Institute of Electrical Engineers recommend the kilowatt for use generally instead of the horsepower.

Fires in Mines and Some of Their Causes

The following non-technical address by Prof. W. H. Minor, of the Department of Mining Engineering, Ohio State University, was delivered to the Sugar Creek, Ohio, Mining Institute:

A mine fire is sometimes a very serious matter. The importance of a mine fire depends upon its position in the mine to a considerable extent, and if steps are not taken at once to dam it off or put it out it will spread over a large area in a short time. Frequently it is very difficult to get to the fire because of the poisonous gases evolved together with the high heat generated. While mine fires do not usually result in a large loss of life, they frequently reduce the output of a mine, because they contract the area which is in a workable condition. Each fire must be dealt with according to the circumstances which surround it, consequently there is no set of rules which will apply to every mine fire.

Of the many causes for mine fires probably the chief one is the firing of coal, timber, or other combustible material in the mine, which may happen in ordinary working or by accident. Fires have been started by furnaces or boilers in the mine, used for pumping or ventilation. Timber may be fired by naked lights, gas ignited by an open light, heat generated by steam pipes, oxidation of coal, or some other material. Coal may take fire spontaneously through oxidation; it may be fired by coming in contact with an electric cable; or in firing a shot. An explosion may start a fire by lighting the gas when present. Firing shots at quitting time and then not going back to the face to see if the gas is burning sometimes leads to mine fires, particularly in the anthracite field. Probably the greatest cause of fires in the bituminous coal mines is spontaneous combustion due to the oxidation of fine coal, or to the oxidation of pyrite. Associated with the oxidation of coal, the sulphur in connection with the coal also oxidizes. Moisture favors the oxidation of sulphur, but it impedes the oxidation of coal. The part which the sulphur plays seems to be to increase its volume, thereby creating a pressure in the coal which tends to break it up. This chemical action creates heat, causing gas to be given off, which, with its lower temperature of ignition, aids in the start of a fire at any given point. Associated with the oxidation of coal and sulphur in a pillar of coal, is pressure due to the weight of the overlying mass which tends to crack and fissure the pillar, exposing large surfaces to oxidation. The last condition would probably never start a fire directly. The coals which are most liable to spontaneous combustion are the lignites and closely associated bituminous coals which carry oxygen and volatile constituents. A fire would be preceded by a rise in temperature, a sort of musty smell, a sweating of the coal, gas will be given off in quantities until finally explosions of gas would be noticed after the fire has started.

Prevention is usually a matter of care and foresight, but in case a given seam is liable to fires, they may be avoided by removing all fine coal from the mine, or sometimes by excluding the air from the gob or adopting a special system of working.

A fire of small extent, especially in entries, may be put out by applying water and pulling down the burning mass, loading it into cars and taking it to the surface when it has been thoroughly quenched. The air in this case may require the erection of partitions or some especially designed ventilating apparatus. Oftentimes a road may be driven above the seam, and having erected dams previously the fire area may be flooded. The most efficient method is by stopping off the fire. This is, of course, to prevent air from reaching the fire. Considerable argument goes on from time to time as to which end should be closed first. Fires have been handled by closing either end, but the outlet should be closed first, because in so doing the gas given off from the fire is bottled and a mixture is formed containing more than 10 to 12 per cent. of blackdamp, which would not permit of an explosion taking place. After the outlet has been closed there is no great hurry in sealing the inlet until the smoke or gas is detected rolling back from the fire. The first partitions erected may be of canvas, or bags filled with sand. If these seem to suffice, a masonry dam seated in the walls on all sides should be erected. In this dam should be placed a large pipe which may or may not contain a valve. The end of this pipe should be placed in a barrel filled with water and gas allowed to bubble up through the water at such times as seem to suit the working conditions. As the fire gradually dies out the water will be drawn back into the fire area and more water will have to be supplied to the barrel. This avoids any air reaching the fire area. Sometimes instead of using this trap a flap valve is placed over the end of the pipe and this works fairly well under certain conditions.

The fire may be extinguished by chemical methods; either the use of blackdamp or sulphur dioxide is recommended, but the method is a costly one. Finally a fire may be put out by flooding the entire mine, but the cure is almost as bad as the ailment, and this heroic treatment should only be applied as a last resort. Chemical fire extinguishers may be employed effectively in a mine at the very start of the fire. It is to be remembered that a fire generates explosive gases and oftentimes small explosions occur at regular intervals provided conditions remain constant. Having observed the intervals when these explosions occur, it is possible to work at the fire between explosions. This does not always take place, but it is well to note the fact that it is the usual occurrence. In reopening a fire territory the outlet should be opened first. When there is a fan which is easily reversible, advantage may be taken of this condition in connection with the fire oftentimes to great advantage.

The various rescue appliances and helmets may be used in connection with fire fighting and in opening fire territory. It is advisable in this connection that five men wearing the equipment should always travel in a body. This necessary precaution should be taken so that if any accident should happen there would be plenty of help for the one who met with the accident or otherwise.

In quenching a gob fire a piece of canvas should be placed over the material and water thrown on the bagging. It is dangerous to throw water from buckets on such a fire unless the fire-fighters are protected with oxygen helmets. Water from a hose may be used effectively if the fire-fighters are on the intake side of the fire, in fact at the present time water is better for all mine fires, large or small, unless it be a chemical fire engine. Those mine fires which are most difficult to extinguish are near the crop and consequently are fed by oxygen to a limited extent. The oxygen keeps the coal glowing and the carbon dioxide is split up into oxygen and carbon monoxide, thus continuing the fire indefinitely.

A New English Coal Field

By J. J. Baines, Manchester, England

The first output of coal from a completely new coal field, the existence of which was entirely unknown some years ago, is an event both of importance and interest. There are no indications on the surface, or in the surroundings to suggest coal-measure rocks in the southeast of England; their existence at a considerable depth was surmised by reasoning, on the faith of which a large amount of capital has been raised and invested. Bore holes were sunk, and the expected seams ultimately found. England, Wales, and Scotland, considered as one large island, is made up, toward the west and north of primary rocks, and toward the east and south, of secondary and tertiary rock formations. The existing coal fields are in the west and north, in Wales, around Bristol, in the Midlands, Lancashire, Yorkshire, the northeast, and in Scotland. Many of these coal fields are detached areas, which were probably once continuous, the intervening portions having been removed by erosion. In Belgium and the north of France, about the same latitude as the south of England, there are extensive coal fields and it was suggested some 12 or 15 years ago that the Continental fields continued in a great saucer-like formation below the sea, below the secondary rocks of the south of

England, and cropped up in the known coal fields of the west of England, the distance between the Belgian and French outcrop on the east, and the English outcrop in the west being approximately 200 miles. It was suggested that if in the southeast corner of England, now covered with chalk, shafts were sunk, this supposed great trough of coal-measure rocks would be pierced. Now a first train of 12 trucks carrying 120 tons of coal has just been dispatched to London. It is the commencement of a great industry, which will convert a hitherto agricultural district into a mining center, with the greatest market of the world within 50 miles. London is now supplied with coal partly by water from the Newcastle district, in the extreme north of England, and from the great Midland coal fields; now coal can be obtained almost at its gates. Bore holes were sunk through the chalk near Dover about 1901 at the foot of the Shakespeare Cliffs; this chalk covers not only a considerable area of the southeast of England, it occurs also on the French coast and is probably continuous below the shallow sea forming the Straits, and has been deposited on a continuous sheet of Carboniferous rocks. The problem experts had to solve was to select a locality where these newer beds could be pierced with the greatest possibility of reaching the older rocks. The discovery of coal has shown the skill with which the problem was considered and solved. Other bore holes were sunk further inland and control was obtained over large areas of land.

Coal was not the only mineral found, for about 600 feet down an iron ore deposit was found 16 feet thick, which is also to be developed, so that two industries may be developed in an area where the last generation would have considered them impossible. The shaft from which coal is now being obtained is in mid Kent, about 15 miles or so east of Canterbury. For several years following 1901 the work was limited to bore holes; there were difficulties with regard to capital; during the last two years or so shaft sinking has been in progress and now the harvest has commenced. The first mine is known as the Shakespeare colliery, situated beside the main line of the Southeastern and Chatham Railway. Two shafts have been sunk, and a bore hole at Ropersole, 7 miles away. The deepest shaft extends to 1,632 feet and taps six seams of coal, four of which are workable; the shallowest seam is said to produce highly bituminous coal of good general commercial value and two deeper seams yield a bright house coal of good quality. Still deeper borings beneath the second shaft have revealed a seam of coal suitable for steam raising purposes.

There are two separate areas where bore holes and shafts have been sunk; the first, from which the coal supply mentioned above has been obtained is near the seashore, at the foot of the great chalk cliff, and the other at a place inland called Waldershare, where the first bore hole was commenced during 1906 and at least five seams of coal of high quality, at workable depths and of workable thickness have been discovered. Another bore hole at a place called Fredville has also been sunk, in all at least six bore holes have been made and coal proved in all cases. One shaft at Tilmanstone colliery is 14 feet in diameter; considerable difficulties occurred, not so much from the quantity of water as with the strata, which almost dissolved in water and ran at the sides whenever given the least opportunity.

The extent to which the new coal field is being developed may be realized from the fact that there are at least 10 companies interested of which four are so-called mother companies, whose business it is to take up the mineral areas and lease them to tenants; three of the others are colliery companies, which act as tenants. The reason that there are four of the former is due to the very large area under which coal has been proved. One company limits itself to boring; and another to sinking shafts. The largest seam found has a thickness of 6 feet and the area of the coal field fully proved is 70 square miles. Outside the known limits the accumulations of secondary and tertiary rocks may render the coal seams too deep to be reached, and there may of course be areas not at present known where these thin out. It has been estimated that there are 1,000 million tons of coal in the proved area. Many of the underlying fireclays are stated to be suitable for industrial purposes. An important and interesting point is that some of the coal is suitable for navigation, equal to the best South Wales navigation smokeless coal and there has been hitherto no coal found anywhere similar to the South Wales coal, except in New Zealand. Now a third source of supply will become available.

The saucer-like trough formed by the coal-measure rocks, extending from Belgium and France to the west of England, is not an isolated phenomenon. The coal field of South Wales is a precisely similar formation, rendered more interesting as the lip of the saucer can be traced all round. Further north a precisely similar basin occurs, the coal-measure rocks cropping up in North Wales on the west and in Derbyshire in the east, the trough being filled up with secondary new red sandstone containing salt deposits, representing an inland sea. The reverse formation also occurs.

Trade Notices

New Storage Battery Mine Locomotive. A new type of storage-battery locomotive has been recently put on the market by The Atlas Car & Mfg. Co., of Cleveland, Ohio. It has a narrow frame, and is especially well adapted for use in low veins without the cutting away of the roof. It is built in various lengths, widths, and heights to meet requirements, the minimum height being about 36 inches. The frame is of steel, thoroughly braced, and is carried on four ground tread wheels which are of either chilled cast iron or rolled steel. The machinery and batteries are protected by steel plates; the top plate is removable, thus giving immediate access to all parts of the mechanism. The wiring is carried in conduit and attached to the frame to prevent injury. Four sizes are made, weighing 2, 2½, 3, and 4 tons each, and in track gauges ranging from 24 inches to 48 inches. However, the 2- and 2½-ton sizes can be furnished to accommodate 18-inch and 22-inch if required. A controller and hand brake are placed at either end, permitting of operation from either end, the speed being the same in either direction. The battery capacity is sufficient to run the locomotive through a 10-hour day with one charging on ordinary service with usual shut-downs for switching, etc. A special type of motor is used, so that no current is wasted in overcoming resistance while running, and the full draw-bar pull can be secured at the start with only the normal current from the battery. An ampere-hour meter is furnished with the locomotive; by its use in connection with the circuit breaker, the storage battery cannot be injured by overcharging. At the zero point on the dial there is a platinum-tipped insulated contact pin, connected to one side of an auxiliary circuit leading from the meter, the other side of this circuit is connected with the indicating hand. When the hand goes back on charging the battery and touches the point at zero, this action operates a shunt trip coil circuit breaker, which opens the circuit with which it is connected. The meter also shows the condition of the battery in regard to charge and discharge. If desired, a combination volt ammeter is furnished in place of the ampere-hour meter. A headlight is placed at each end of the locomotive and an electric gong is included in the equipment. This company is also prepared to furnish a portable charging outfit complete with generator, engine, switchboard, and fuel tank. This charging outfit does away with the purchase of a large amount of expensive machinery, which is usually thought necessary for the charging of storage batteries. When not in use for charging the batteries, this outfit can be used for other purposes such as running motors, mine lighting, etc.

The Atlas Car & Mfg. Co. also manufactures a full line of mine cars and surface hauling locomotives of various kinds. Catalogs of the various lines will be sent upon request.

The Hyatt Way is the title of a booklet issued by the Hyatt Roller Bearing Co., of Newark, N. J. This is the first number of a series which will appear monthly, and contains principally reprints of advertisements used by that company in different papers. The advertising of the Hyatt Roller Bearing Co. has been a good example of the "reason why" style, and the assembled advertisements therefore tell an interesting story and give a good idea of the varied purposes for which their roller bearings may be used.

New Branch Office.—The Taylor Iron and Steel Co., of High Bridge, N. J., announces the opening of an office in Pittsburg, Pa., at 301 Oliver Building. The office will be in charge of Mr. James S. Morrison. In order to handle matters expeditiously, they request that all inquiries and orders for Tisco manganese steel castings from customers in the immediate vicinity be sent through the Pittsburg office.

A Section Insulator Switch.—The Electric Service Supplies Co. has placed upon the market a section insulator switch which has a valuable additional patented feature by which the closing of the switch closes the dead section of the breaker. In this way the switch protects the breaker, because the closing of the dead section prevents arcing. Consequently, injury and strain to the motors when the trolley wheel breaks and remakes the circuit is eliminated. The switches not only protect the breaker by closing the dead section simultaneously with the closing of the switch, but they save the time of the motorman because he does not have to stop or leave his position to close the switch, and the switch is mounted so that the motion in closing is in the direction of the traffic. A saving in expenditure for unnecessary power is also affected, as the section of the line which it is desired to insulate is dead when it is not in use, and hence there is no danger in the section, as there are no live wires. The motorman can throw the switch when he again desires to enter the section without stopping or leaving his position. The switches are made for currents up to 1,000 amperes, are tapped for $\frac{5}{8}$-inch stud, and are provided with feeder connections at each end.

New House Organ.—*The Keystone Traveler* is the bimonthly house organ published by the Electric Service Supplies Co. The July number is devoted to an illustrative description of the new building now occupied by that company, explanation of the various departments, their work and method of carrying it out, and a detailed résumé of the organization and growth of The Electric Service Supplies Co. The theme of the little introductory talk on this issue is "service," the title being "Service is Success." This theme is dealt with briefly but neatly, some of the suggestions and statements made being extremely good ones. "The story of any success is service," is the concluding and summarizing sentence of the article.

Universal Mine Hanger.—A new trolley wire hanger, made by the Ohio Brass Co., of Mansfield, Ohio, is designed to be installed either directly to the mine roof by means of an expansion bolt or to the roof timbers by means of a hanger screw. It has an especially broad top which bears directly against the surface from which it is supported, a feature which is desirable at all times and particularly so on curves where a heavy side strain is thrown upon the hanger. The shell of the hanger is made of sherardized malleable iron and is provided with a hole for draining off moisture which may collect at the bottom of the expansion bolt. The stud is insulated from the body by heavy layers of mica and is molded into the Dirigo insulation which is formed into a triple petticoat to minimize surface leakage in wet mines. The use of this hanger obviates the necessity of carrying two kinds of hangers in stock at the mines and also simplifies installation, since all hangers can be put in place by screwing them on to the bolt or screw. A portion of the body is made hexagonal, so that a wrench may be used for this purpose.

Transportation in Industrial Plants. Large manufacturing plants often present a difficult transportation problem, due to their unsymmetrical growth, owing to expansion not being provided for in the original conception. The Jeffrey Mfg. Co., of Columbus, Ohio, is spread out over an area of approximately 26 acres, with 18 acres of floor space, and manufactures a large line of electrical locomotives, electric storage-battery trucks, coal-mining, elevating, and conveying machinery of all descriptions, structural-steel work, etc. Formerly the raw and finished material was transported to and from cars in and about the shops and the departments by two-wheeled warehouse trucks, four-wheeled trucks, and industrial cars. Also, part of the territory was served by a Jeffrey storage-battery truck working on a 36-inch gauge industrial track. A study of conditions made it plain that a material saving could be effected by a more efficient transportation system. Accordingly, the industrial railway was extended to take in all departments, a systematic method of car dispatching was established, and instructions were issued that no material was to be transported by other means than by the storage-battery trucks and industrial cars. It was immediately found possible to dispense with the services of a two-horse team, 28 two-wheeled warehouse trucks, 13 four-wheeled trucks, eight wheelbarrows, and 18 men whose whole time had been devoted to this purpose, effecting a saving of more than $600 per month. The Jeffrey storage-battery truck does not require the service of skilled operators, and the maintenance and operating costs are extremely low. Full descriptions and information will be furnished on request.

Largest Electric Mine Hoist in America. In the mine of the Christopher Coal Mining Co., at Christopher, Franklin County, Ill., will be installed the largest electric mine hoist in America. The mine, including 32 locomotives for haulage, is to be operated entirely by electric power, and about half the capacity of the plant will be required for the hoist. Power for the several operations will be generated at the mine by two 750-kilowatt, three-phase, 60-cycle, 2,300-volt Curtis turbogenerators. Above ground practically all the machinery, except the hoist, will be operated by alternating current; while all the underground equipment is to be operated by 250- to 275-volt direct current. The hoist operates on the Ilgner system and is of the double-drum type, having 7-foot drums designed for an effective load of 9,000 pounds in a car and cage, the combined weight of which is 11,000 pounds. Wire hoisting rope $1\frac{3}{8}$-inch diameter is used. The equipment is designed to make 1,000 trips from 600 feet depth in 7 hours, with a maximum rope speed of 2,400 feet per minute. A 1,150-horsepower, 550-volt, direct-current motor drives the hoist and is direct connected to the drum shaft by a flexible coupling. This motor is designed especially for hoisting service and has large overload capacity. Power will be supplied to the motor by a flywheel motor-generator set. The speed and direction of rotation of the hoist will be governed by a controller at the operating platform, by means of which the voltage and polarity of the generator will be governed. The efficiency of this form of control, called the Leonard control, is very high, as there are no rheostatic losses except the comparatively small ones in the field circuit of the generator. The torque of the regulating motor varies with the line current and when this current tends to exceed a predetermined value, the torque of the regulating motor will overcome the weight of the moving parts of the rheostat, introducing resistance into the rotor circuits of the main induction motor, thereby causing the motor to slow down and allowing the flywheel to give up its energy. When the current falls below the predetermined value, the weight of the moving parts of the rheostat will exceed the torque of the motor and the resistance will be cut out automatically. In the control equipment are also devices to guard against damage from overwinding, failure of alternating-current supply, loss of exciter voltage, loss of air pressure for the brakes, as well as extreme overloads. Both service and emergency air brakes are provided. The hoist is to be of the Ottumwa Iron Works make, and all the electrical apparatus, including the mine locomotives, is being furnished by the General Electric Co.

Gasoline Motors in Mines

With Special Reference to the Advantages and Disadvantages of Gasoline Locomotives for Mine Haulage Work

By A. F. King, E. M., Charleston, W. Va.*

FOR possibly 30 years gasoline motors have been used for various purposes on the Pacific Coast and in the metal mines of the West, this development being brought about by the high cost of steam generation and, in many cases, scarcity of water in arid regions.

Stationary gasoline motors were first used in the mines of West Virginia about 15 years ago, and at about the same time the Prouty Company, of Chicago, was advertising its manufacture of gasoline haulage motors of different capacities for mine work.

It has been since the advent of the automobile, and during the past 6 years, that manufacturers have seriously tried to develop a gasoline haulage motor that would satisfactorily meet mining conditions; and, I am now given to understand that there are about 300 in actual service.

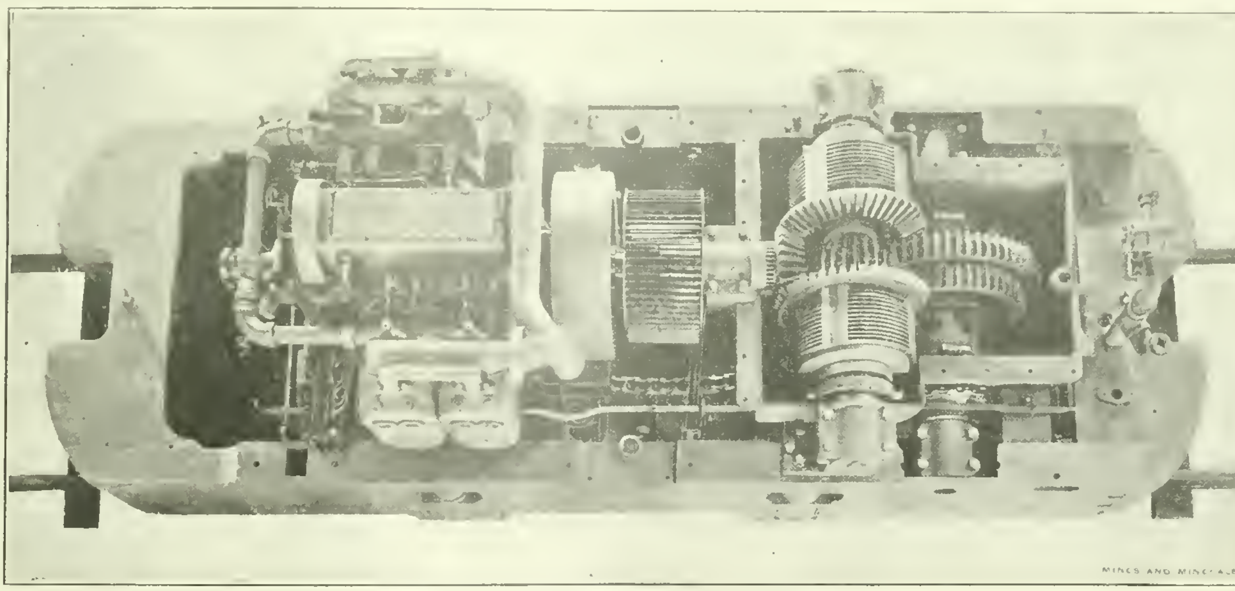

FIG. 1. TOP VIEW OF GASOLINE LOCOMOTIVE, STRIPPED

In shape and appearance the gasoline locomotive closely resembles the electric locomotive, except that it has no trolley pole. The larger types of the gasoline motor require more height than an electric motor of the same weight.

The cylinders, or combustion chambers, are water-jacketted, to prevent undue heating and consequent sticking or binding of the piston. Excessive cooling of the cylinders, however, reduces the efficiency.

Rotation is always in one direction, so that the reversing is done by means of clutches and miter gears. They are usually constructed so as to run on full and on half speed.

Each motor is equipped with a carbureter whose office is to properly mix the air and the gasoline in the cylinder. They are also equipped with an electric igniting device, which is so connected as to operate from a storage battery when the motor is starting, and thereafter from a magneto.

Some manufacturers also equip the motors with absorption chambers, the types and capacities of which differ with the size of the motor. The absorption chambers are intended to absorb the carbon dioxide (CO_2) generated, and to cool the gases given off. It is also claimed that this absorption chamber is a protection against the ignition of explosive mine gas or coal dust in case the engine "back fires."

The gasoline storage tanks are placed, in some makes, in the side of the frame of the motor, Fig. 1, while in other types they are suspended within the frame of the motor or placed in a more or less exposed position.

The repairs are said to cost about the same as for electric motors of the same power, but, on account of the gasoline motor having reciprocating parts, the writer is inclined to believe that they cost more.

The advantages of the gasoline motor are:

1. No power plant is needed to operate them, the power-generating apparatus being a part of the motor. This means that power-plant fuel, labor in operating, and maintenance of the same, are not required.

2. There are no transmission-wire lines or pipe lines needed, and line losses and line maintenance are dispensed with.

3. The use of the motor is not affected or interrupted by short circuits, bursted pipe lines, or drains upon the transmission lines by other motors.

4. No trolley lines, hangers, bonds, or cables are required, thus saving the labor for their installation, their cost, and maintenance.

5. It aids in the humidification of the mine air.

6. It is safer than a trolley-wire equipment; that is, the mine employes are less liable to meet with injury through contact with the motor or its transmission lines.

7. No time is lost in handling the trolley pole or wires; and in gathering it is unnecessary to attach and detach either transmission or haulage cables.

The disadvantages of the gasoline motor are:

1. In the use of gasoline in the mines there is an element of danger, from the fact that it readily volatilizes, and when mixed with air forms a very explosive gas.

2. The combustion of gasoline in the combustion chamber extracts oxygen from the mine air.

3. Carbon dioxide and free nitrogen are the products of the perfect combustion of gasoline.

4. The carbureter is usually adjusted to furnish, as nearly as possible, the proper mixture of gasoline vapor and air when the motor is doing its heaviest work, and if it is assumed that, under these conditions, perfect combustion is obtained, it is evident that when the engine is running with the motor standing, or when it is doing light work, there is a more or less imperfect combustion, which means that carbon monoxide (CO) is given off.

5. I am of the opinion that the absorption chambers do not eliminate all of the carbon dioxide which is produced, nor do they prevent the carbon monoxide or free nitrogen from being given off.

*Paper read before the Coal Mining Institute of West Virginia.

33—2—4

6. When the coal must be cut by mining machines, a power plant, though not necessarily so large, must be operated and maintained, and transmission lines, both outside and inside the mines, must be erected and maintained.

7. The gasoline motor costs from 25 per cent. to 50 per cent. more than an electric motor of the same power.

8. It is also said that, due to its having but two speeds, the gasoline motor will not start as large a trip as the electric motor.

9. One complaint heard is that it will not take an overload, as do electric motors; but it seems to me that the tractive effort in either case is dependent upon the weight of the motor, and in the case of the gasoline motor, it is simply a question of designing the engines large enough to produce the effect.

10. At the present time the gasoline motor cannot safely be used in a gaseous mine.

Gasoline is of the hydrocarbon series, whose typical formula is $CnH_{2}n+_{2}$. Assuming a specific gravity of .70 at zero, centigrade, its formula would approximately be C_7H_{16}, which is called heptane. A gallon of this oil will weigh about 5.85 pounds.

Assuming that there is perfect combustion in the engine, the following chemical changes would take place:

$$C_7H_{16}+22O=7CO_2+8H_2O$$
$$100 \quad 352 \quad 308 \quad 144$$

which means that for every 100 pounds of gasoline used there are produced 308 pounds of CO_2; that 352 pounds of oxygen are abstracted from the mine air, and that 1,178.4 pounds of free nitrogen are given off; neglecting other constituents of mine air, and assuming that oxygen and nitrogen exist in the proportion of 23 per cent. and 77 per cent., respectively, by weight.

Let us further assume that a 5-ton gathering motor is used, and that the consumption of gasoline per day is $2\frac{1}{2}$ gallons per ton weight of motor; this motor would consume $12\frac{1}{2}$ gallons, or 73.1 pounds.

This motor would then produce 225 pounds, or 1,921 cubic feet, of CO_2, 861.4 pounds, or 11,570 cubic feet, of nitrogen, and 105.26 pounds of H_2O. It would rob the mine air of 257.3 pounds, or 3,026 cubic feet, of oxygen.

Doctor Haldane has found that what we know as blackdamp does not entirely consist of carbon dioxide, but that the greater part of it is composed of nitrogen. There would, therefore, be produced 1,086 pounds, or 13,491 cubic feet per 8-hour day, 1,686 cubic feet per hour, or 28.1 cubic feet of blackdamp per minute.

To keep the percentage of blackdamp below 1 would require a volume of 3,000 cubic feet of air passing per minute.

If, however, there is incomplete combustion in the engine, carbon monoxide (CO) is produced, and the very dangerous character of this gas, even .1 of 1 per cent. being very injurious and poisonous if breathed for any length of time, makes it imperative that additional air be provided to make ventilation exceptionally good, and it is suggested that the quantity of air to be provided for the particular motor under consideration be made 5,000 cubic feet per minute, say, 1,000 cubic feet per ton of motor.

There are conditions in the mines under which the gasoline motor will operate satisfactorily, but its many advantages should not cause us to neglect or overlook the dangers incident to its use.

When manufacturers practically eliminate any danger from carbon monoxide poisoning by building an engine that will have perfect combustion under varying loads, and when the mine operator using them realizes that he must provide ample ventilation to carry away and dilute the noxious gases generated, then it may be said with more assurance that the gasoline mine motor has come to stay.

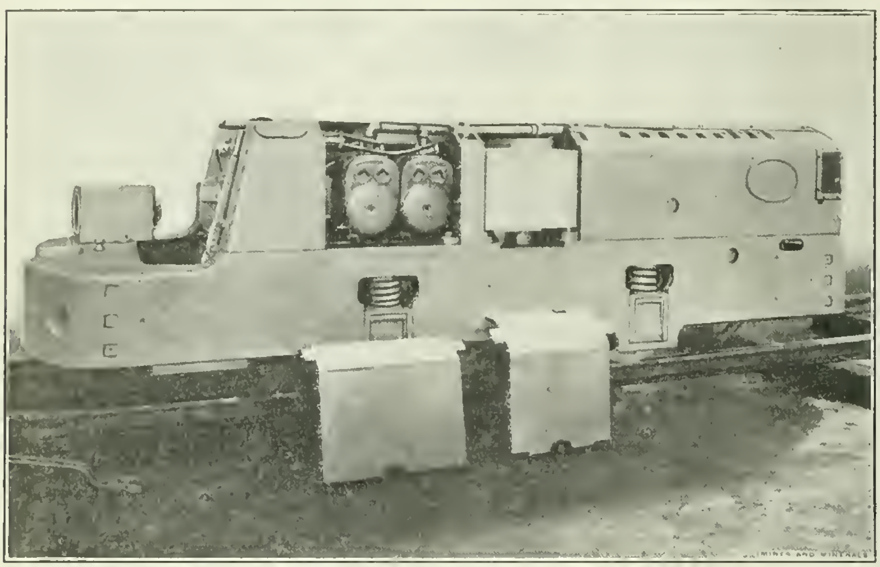

Fig. 2. Locomotive With Gasoline Tank Doors Removed

Discussion by E. B. Wilson

Mr. A. F. King's paper on the "Use of Gasoline Motors in Coal Mines" is of particular importance at this time, when many mine managers are considering seriously their introduction. It is also of as much importance to metal as to coal miners, because of the poorer systems of ventilation in metal mines and the greater need for some system of comparatively cheap haulage. The Institute is to be congratulated on having what is probably the first impartial article on this subject presented to its members; and what is here added is not in the way of criticism, so much as to furnish further information on the subject. In Fig. 1 is shown one make of gasoline locomotive, stripped so as to show engine, cooling fan, and transmission gear. It is a four-cylinder engine, with two sets of gears, one for a speed of 4 miles an hour and one for a speed of 8 miles an hour. These gears are thrown in and out of mesh by levers.

In Fig. 2 is shown the locomotive with the engine door and the gasoline tank door removed on one side for inspection. Fig. 3 shows the driver's end of the Whitcomb gasoline locomotive and the carbureter. With an occasional glance at these three illustrations it will be possible for the uninitiated to follow the discussion.

The idea of the introduction of such volatile and highly inflammable liquid as gasoline into coal mines is rather startling at first, but the difficulties and dangers have been so far overcome that they are used in the deep mines of Westphalia and elsewhere, and almost daily their number is increasing. In Austria they are allowed in fiery mines if their construction complies with certain regulations relative to ignition. Some German machines are made without carbureters, the vaporizing and ignition of the fuel taking place in the cylinder.*

Attempts have been made to prevent the carbon dioxide resulting from the combustion of gasoline escaping into the mine atmosphere. It can be accomplished provided sufficient lime water is carried on the locomotive, but if the solution is not changed often, or is allowed to reach the boiling point, 1 gallon of lime water will absorb but approximately 3.2 cubic feet of carbon dioxide, and any additional quantity will be expelled by the heat. The chemical reactions taking place are as follows:

(1) $Ca(OH)_2+2CO_2=Ca(HCO_3)_2$
(2) $Ca(HCO_3)_2=CaCO_3+H_2O+CO_2$

In equation (1) calcium hydrate and carbon dioxide form acid calcium carbonate, which is broken up as shown in equation (2) so soon as heat is added from the exhaust. It, of course, is understood that

*Mines and Minerals, Vol. XXXI, page 30.

gasoline locomotives are unsafe in dead entries or in an entry where insufficient air is stirring; and Mr. King is right in his contention that 1,000 cubic feet of air per minute should be supplied per ton weight of motor, for this is abundantly on the safe side. D. H. Trowbridge* in March, 1911, made some careful experiments to ascertain the number of cubic feet of carbon dioxide in 1 pound of gasoline. He found that 26.5 cubic feet of carbon dioxide was evolved when there was complete combustion, which is 8 per cent. more than the volume given by Mr. King. However, Mr. King's figures for gasoline consumption, $2\frac{1}{2}$ pounds per ton, are somewhat high, about 2 pounds being a fair average. There is no fixed rule in regard to fuel consumption, which necessarily varies with the grade, the speed of the motor, and the intelligence of the operator. With a gasoline engine there is a medium where just sufficient gasoline gives the most power, and if less or more is used the power is reduced.

It is a comparatively simple matter to adjust the carbureter to obtain this result and if the same attention is bestowed on points of this kind as is given the adjustment of electric motors, the results will be at least equal. Again, with the regulation of the fuel the carbureter is adjusted to provide for a fair range of speed of the engine. The gasoline locomotive engine has a uniform speed and the size of the engine is proportioned to the weight of the motor, so that the engine has power at even lower speeds than normal, which is 500 to 550 revolutions per minute. In the majority of motors the engine has ample power at speeds ranging from 300 to 350 revolutions per minute up. The range of speed is from 200 revolutions per minute, when the engine is running light and not pulling, up to 800 to 1,000 revolutions per minute, depending upon the size of the engine. Again, with the modern carbureter the throttle valve in the carbureter is opened and closed just the same as the steam valve on a steam locomotive, and when the engine is running light or pulling a light load the throttle valve is not wide open; therefore, more air is drawn in, less gasoline is consumed, and the volume of carbon dioxide and nitrogen will vary almost directly with the quantity of gasoline used.

The Whitcomb company had the question of carbon dioxide fully investigated and had between 30 and 40 different analyses made of the mine air in which the locomotive was hauling. In all of them the percentage of carbon dioxide was so low that the ventilating current was little vitiated.

Various authorities, among them Doctor Haldane, quoted by Mr. King, affirm that there could be quite a percentage of carbon dioxide in air and not be injurious to the health of the men working in the air. In fact, some authorities claim that there could be 3 per cent. or 4 per cent. of carbon dioxide in the air without being dangerous, while, according to the analyses made by Mr. Trowbridge, the percentage of carbon dioxide in the air was as a rule only a small portion of 1 per cent. However, as Mr. King states, .1 of 1 per cent. of carbon monoxide would be dangerous.

Recently, from one of the 10-ton gasoline locomotives in operation in the mines of the Jamison Coal and Coke Co., a test sample was taken directly from the exhaust pipe of the engine. This engine is a machine of the four-cylinder, four-cycle type, with cylinders 8 inches in diameter. The engine was running 600 revolutions per minute and the motor was hooked to a trip of cars whose wheels were spragged so that the engine was slipping its wheels, although the rail was sanded; therefore, the engine was working up to its full capacity. This engine has a double exhaust, the exhaust from two cylinders going off one side and the exhaust from the other two cylinders going off the other side. On one side the exhaust showed about 7 per cent. of carbon dioxide with about .1 of 1 per cent. of carbon monoxide. The exhaust from the other two cylinders showed about $4\frac{1}{2}$ per cent. of carbon dioxide and about .2 of 1 per cent. of carbon monoxide. This engine would throw off a total volume of about 241 cubic feet of exhaust per minute when running 600 revolutions per minute; therefore, if the rule suggested by Mr. King is followed, there would be 10,000 cubic feet of air passing in this entry and into this air there would be an exhaust of 17 cubic feet of carbon dioxide and .49 cubic foot of carbon monoxide per minute. The carbon dioxide given off under such conditions is hardly worth considering from a toxic standpoint, and the percentage of carbon monoxide would be so small that it would not be detectable by any ordinary analysis.

If a ruling could be made that these gasoline motors were permissible in any mine or any entry, provided there was a volume of air of say 500 to 750 cubic feet per minute to each ton of weight of motor, it would make a safe regulation and would put the gasoline motors on a better understood basis. In fact, it would not be any particular hardship if a provision was made even as high as 1,000 cubic feet per ton of weight, as suggested by Mr. King, provided that for a gathering motor due consideration be given to the fact that in many cases a motor would only be in any given air-current for a very few minutes. For instance, with a motor running up into a room the motor would probably not be in that room over 3 or 4 minutes out of an hour, and in a good many cases an hour and a half. The average "turn" will run probably not over five to seven cars per day; therefore, a motor would only enter a working place from five to seven times in a day of 8 hours.

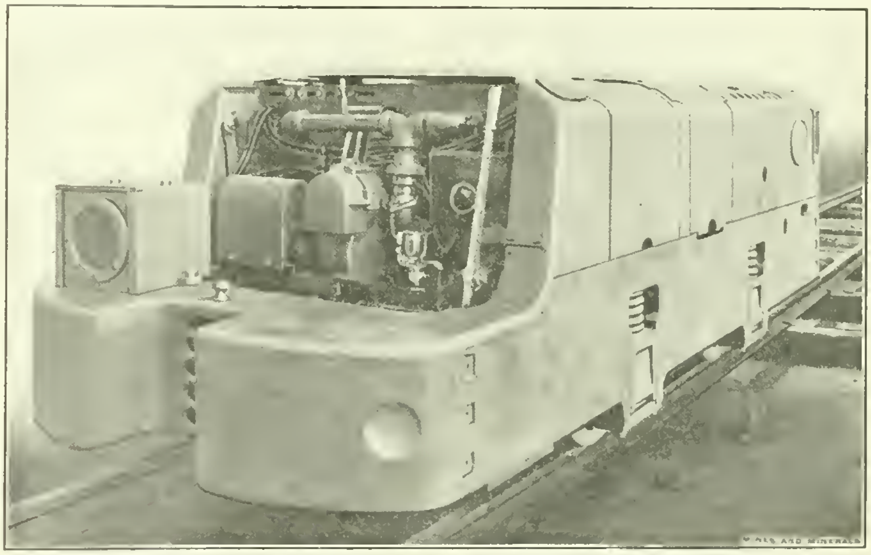

Fig. 3. Rear View of Gasoline Locomotive, Carbureter Alongside Brake Lever

In regard to the hauling capacity of the gasoline locomotive, any machines should have engine power enough to slip the wheels without stalling the engine, when in low gear. With any locomotive the hauling capacity is governed by the traction on the rail, and this in turn is governed to a very large extent by the weight on the drive wheels. Therefore, a gasoline locomotive will pull as much as it is possible for any locomotive of the same weight; it will also pick up a load with less jerk and jar than any other traction motor.

In Fig. 2 it will be seen that the gasoline tanks are housed within the frames of the motor, remote from the carbureter, and thoroughly protected in every way. In a number of cases the carbureter, through the carelessness of the operator, has gotten to leaking and on fire. On each side of the carbureter there is a shut-off valve, one from each gasoline tank, and there is a

* Lewis Institute, Chicago, Ill.

shut-off valve on each tank; therefore, there is a double shut-off on each side. In case the carbureter gets on fire, the operator can shut off the gasoline either at the shut-off valves each side of the carbureter, or if the fire is too hot at this point, he can shut off the gasoline at the tanks, and the only damage that can be done is possibly to burn the cork float in the carbureter. However, there is a very small quantity of gasoline in the carbureter at any one time, and the pipes leading from the tanks to the carbureter are small; therefore, even in case it should happen from any cause that the carbureter did get on fire, it would be unlikely to cause any considerable damage.

Attention is directed to the fact that there is no universal system of mine haulage, but that one system is better adapted to certain governing conditions than some of the others. The gasoline locomotive is no exception to the rule, consequently it has its limitations; with conditions favorable, it is one of the great strides made in recent mining improvements. That this is so is attested by the number of mine-supply machine shops which are experimenting in its construction.

Obituary

GEORGE MAXWELL JESSUP

George Maxwell Jessup, a young mining engineer, of Wilkes-Barre, Pa , and a younger brother of Albert Jessup, E. M., general manager of the G. B. Markle & Co collieries, at Jeddo, Pa., died of ptomaine poisoning at the Hahnemann Hospital, in Scranton, on August 1, aged 27 years. "Max" Jessup was a young man of much promise, and was prominent socially in the northern anthracite field. After graduating from the Scranton High School he entered Lehigh University, leaving that institution before graduating to take up practical work in his chosen profession.

A Colorado First-Aid Contest

First Annual Contest of the Colorado Division of the Victor American Fuel Co.'s First-Aid Team

*Written for Mines and Minerals by G. F. Whitside**

The first-aid work attempted under the auspices of the company had its beginning in May, 1910. Like any work of this nature, there was considerable enthusiasm manifested at the start among those who more fully realized the benefits to be obtained. It soon became evident that it was a more difficult matter to arouse and retain the interest of the miners and company men, who were the most greatly to be benefited by this instruction. But the faithful persevered, however, and a gradual but certain gain in attendance and proficiency was attained, so that when the Government Rescue Car made its appearance in November of that year, the work was established upon a permanent basis.

To further stimulate the interest in the first-aid classes, the officials of the company decided to hold an annual contest for picked teams representing the various company properties. The first Colorado contest was scheduled to take place in the baseball park at Walsenburg, on June 22, of this year. On account of the unfortunate accident at Hastings mine on June 18, the contest was postponed until July 13.

Great interest was manifested by the many people who packed the grandstand and entirely surrounded the roped enclosure in which the events were held. Dr. John R. Espey, chief surgeon for the company, prepared the program and was in direct charge. The judges were Capt. C. L. Cole, Medical Corps, U. S. A., Dr. John W. Amesse, and Dr. Harold G. Garwood, both of the Colorado National Guard. Mr. E. P. Linskey was announcer of events.

*Chief Engineer Victor American Fuel Co., Denver, Colo.

Past experiences in other gatherings of this character have demonstrated that the proper handling of the audience, especially that portion which is on its feet and moving about, is of prime importance. Unless people can be kept back of certain fixed lines, they will crowd about the subjects, interfering with the work of the teams, and obstructing the view of others in the audience. By referring to Fig. 3, it will be seen how the people were handled so that at no time during the progress of the work was there the least difficulty for any one to obtain a full view of any one of the teams.

The following is the list of events. Owing to the lateness of the hour, the sixth and seventh events were omitted when their time came:

First Event.—(*a*) One man. Man partially overcome by gas. Can stand but cannot walk. Carry 100 feet to good air. This event is shown in Fig. 1.

(*b*) Two men. Left hand caught by drilling machine. Bones of hand broken and palm lacerated. Sharp hemorrhage, blood bright red and spurting. Dress and carry 50 feet to stretcher.

Second Event.—Four men. Rock fall. Right arm nearly severed in arm pit by sharp rock. Pectoral muscles, chest to arm, cut off, but no bones broken. Top of shoulder uninjured. No serious hemorrhage, vessels escaped or lacerated and clotted. Simple fracture of both bones of left forearm. Dress and carry 50 feet on stretcher.

Third Event.—Two men. Man lying unconscious, right leg over live wire, not grounded, but dry. Remove man from

FIG. 1. CARRYING DISABLED MAN

FIG. 2 MAITLAND TEAM, WINNERS OF FIRST PRIZE

wire and attempt to restore him. Three minutes for efforts.

Fourth Event.—Full team. Premature explosion. Compound fracture of lower jaw. Chest crushed, with probable simple fracture of several ribs on both sides. Shock considerable. Dress and carry 50 feet.

Fifth Event.—Full team. Man squeezed between pit car and rib of tunnel. Compound fracture of left femur in middle third. No serious hemorrhage. Pelvic bones broken, simple fracture. Dress and carry on stretcher over obstacles.

Sixth Event.—Three men. Rock fall. Compound fracture of both bones of right leg. Severe hemorrhage. Tissues about right eye lacerated and swollen; possible injury to eye. Dress and carry 50 feet.

Seventh Event.—Full team. Face, arms, hands, and chest burned by powder explosion. Dress and carry 50 feet.

With a view of making possible suggestions to others interested in this work, the following taken from the report of the judges to Doctor Espey is given to show in what particulars the greater number of mistakes and imperfections occurred: Artificial respiration faulty, first and third events; seven cases. The treatment was usually too rapid.

Not doing the most important thing first, all events, 15 cases.

Awkward handling of patient, all events, seven cases.

Captain's failure to command, all events, eight cases.

Not treating shock, all events, 10 cases.

Not stopping hemorrhage, second event, four cases.

Failure to be aseptic, second event, two cases.

A few other minor criticisms were noted, but the foregoing cover the most important ones. While the events were timed, this was done as a check rather than with an idea of making or breaking speed records. When, in the opinion of the judges, a team was unnecessarily slow, it was discounted. However, when the work done was first class and showed proficiency and skill, the fact that this particular team did not call first for inspection did not lower its percentage.

The following scores were made: Maitland, 94$\frac{1}{6}$; Delagua, 92$\frac{1}{2}$; Gray Creek, 88$\frac{1}{3}$; Hastings, 88; Chandler, 87$\frac{1}{2}$; Radiant, 86$\frac{2}{3}$; Bowen, 85$\frac{5}{6}$; Ravenwood, 82$\frac{1}{2}$.

In keeping these scores, the following discounts governed in each event where they were applicable: For not stopping bleeding, 10; for not treating shock, 10; for not doing the most important thing first, 5; for a loose or "granny" knot, 5; for a loose bandage, 5; for a loose splint, 5; for wrong artificial respiration, 5; for slowness in work, 5; for captain's failure to properly command, 5; for awkward handling of patient or stretcher, 5; for failure to be aseptic, 5; for failure to entirely cover wound, 5; for unfairness or for outside coaching, a forfeiture of all credit for that event.

The specifications for each event were typewritten upon eight separate sheets, each in a sealed envelope. As each event was called, the envelopes were distributed to the captains of the teams, who then read the statement of the work to be performed for the first time. When all captains had declared themselves ready, the word was given to proceed with the event.

In the fifth event, after all the subjects were prepared to be carried over and through the obstacles, all teams but the first to make the trial were retired from the field, that they might in no way profit by the experience of those going before them. As each team passed through the curtain at the left of Fig. 3, the next in order was admitted to carry its subject through the passage representing an entry.

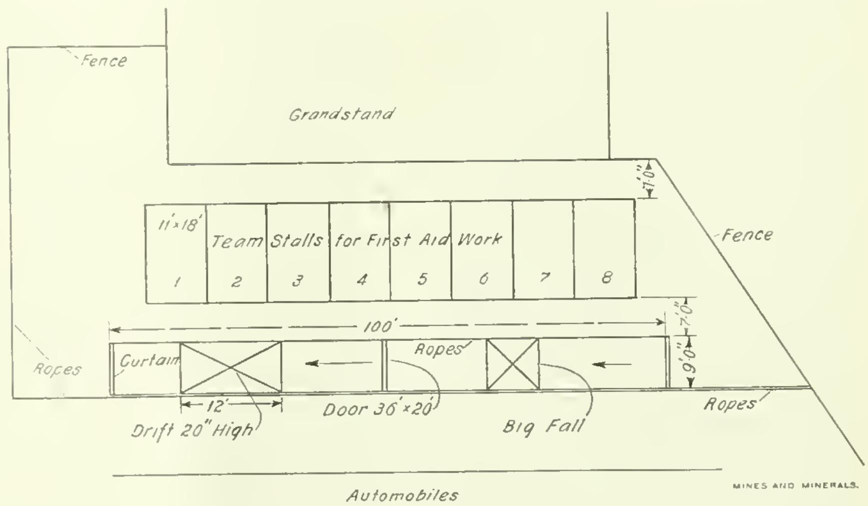

Fig. 3. Diagram for Field for First-Aid Contest

The prizes consisted of a handsome silver loving cup, presented by the company, which is to remain in permanent possession of the team which shall take first place three times; a handsome cut-glass punch bowl, with ladle and set of cups, given by the First National Bank of Walsenburg, which remains in permanent possession of the Delagua team; and as a third prize, the Baxter Hardware Co. presented each member of the Gray Creek team with a handsome pocket knife.

The judges acted with absolute impartiality and marked with no leniency whatever. The high scores made by all the teams, therefore, indicate the greatness of their proficiency in the work. The most disinterested spectator could not fail to be interested in, and impressed with the value of instruction of this character. It should be taken up by all the mines, all the railroads, and rapid-transit companies; indeed, we may live to see it taught in all our public schools, for lives are frequently lost for lack of proper treatment in case of accidents due to everday causes.

Lake Commerce for June 1912

The iron ore shipments from Lake Superior and Lake Michigan ports during June, 1912, amounted to 7,274,732 long tons, an increase of 58 per cent. when compared with the shipments in June, 1911. Iron ore shipments since the beginning of the year, 13,394,964 long tons, were about 54½ per cent. greater than during the corresponding period of 1911. Increases in shipments were reported at all the important iron ore shipping ports, namely, Duluth-Superior, Two Harbors, Escanaba, Ashland, and Marquette.

The receipts of iron ore show a corresponding increase from 4,460,764 long tons in June, 1911, to 7,219,093 long tons in June, 1912, or nearly 62 per cent. The receipts since the beginning of the year show an increase from 7,959,822 long tons in 1911 to 12,343,667 long tons, or 55 per cent. Over 80 per cent. of the iron ore receipts are credited to Lake Erie ports, the remainder to Lake Michigan ports.

The June shipments of coal, 3,623,745 short tons, show an increase of 13½ per cent. over the shipments in June a year ago. Of the June, 1912, shipments, 2,836,934 short tons were soft coal and 491,941 short tons hard coal, the remainder being bunker coal supplied to vessels engaged in the domestic trade. The shipments of soft coal showed an increase of 27 per cent., while those of hard coal showed a decrease of over 32 per cent., when compared with the June shipments in 1911. Over 97 per cent. of the soft coal was shipped from Lake Erie ports. Of the domestic soft coal shipments on the Great Lakes in June, 1912, 1,521,490 tons were received at Lake Superior ports; 1,084,644 tons at Lake Michigan ports; and 89,119 tons at Lake Huron ports. The total domestic shipments on the Great Lakes during the present year (including hard and soft coal and bunker coal) were 6,765,173 tons.

Answers to Examination Questions

Examinations for Fire Boss Held in the Bituminous Regions of Pennsylvania, April 12, 1912

Ques. A.—Are you a citizen of the U. S. of A.?

Ans.—While this may be answered by a simple "yes," or "no," it is well to qualify by saying "yes, native born," or "yes, naturalized," or "no, but first papers applied for," etc.

Ques. B.—What is your age?

Ans.—This had better be answered by giving the date and place of birth, if known, thus: Age, 32; born, July 16, 1880, in McKeesport, Pa.

Ques. C.—If a naturalized citizen, produce proof of your citizenship.

Ans.—Either the final or the declaration papers should be handed to the Examining Board.

Ques. D.—Have you testimonials of character?

Ans.—These should be obtained from former employers, superintendents, and the like for whom the candidate has worked, or from well-known and reliable business men, and should be handed to some member of the Examining Board if asked for. These testimonials are meant to show more particularly the fact that the candidate is sober, honest, hard working, and ambitious, rather than that he was a good tracklayer, driver, or machine runner, and the like.

Ques. E.—How many years practical experience have you had in the bituminous mines of this state and other states and countries? State fully when, where, and by whom employed, and the length of time of such employment in each case.

Ans.—This should be answered similarly to the following: "Worked as trapper at the Rolling Mill mine of the Cambria Steel Co., Johnstown, Pa., from August, 1894, to December, 1898; employed as driver at the same mine from December, 1898, to January, 1900; tracklayer and timberman, Lick Branch mine, Norfolk Coal and Coke Co., Lick Branch, W. Va., February, 1900, to April, 1906; machine runner, Pittsburg-Buffalo Co., Marianna, Pa., August, 1907, until the present time." The candidate is not supposed to account for every month of his time, as it is probable that at intervals he has been out of work, sick, or the like. If the month of beginning or ending employment at any place is not known, give the total number of months or years worked and the date as near as possible.

Ques. F.—Have you ever obtained a fire-boss certificate prior to this examination?

Ans.—To be answered by "no," or if you have a certificate by stating what kind (mine foreman's, fire boss, or the like), and where and when secured. It would be well to have the certificate with you to show the Examining Board.

Ques. 1.—What are the legal duties of a fire boss?

Ans.—These are set out in Article V of the mine law approved June 9, 1911, copies of which may be obtained from the Department of Mines, Harrisburg, Pa. The article is not very long and as it is of prime importance it would be well for the candidate, although not at all necessary, to commit its contents to memory. Briefly stated, its provisions are:

Section 1. In mines generating explosive gas in sufficient quantities to be detected by an "approved safety lamp" the mine foreman must employ one or more fire bosses whose competency is evidenced by a "certificate of qualification" from the Department of Mines upon recommendation of the Examining Board. This certificate is granted after successfully passing an examination, such as the one supposed to be before the candidate. The fire bosses' daily examination must begin within 3 hours of the time the shift is due to enter the mine and no light must be used for this purpose "other than that enclosed in an approved safety lamp." Before beginning the examination the fire boss must first see that the air-current is traveling in its proper, regular course. This determined, he must "examine carefully every working place without exception, all places adjacent to live workings, every roadway, and every unfenced road to abandoned workings and falls in the mine." He must not only examine for gas but "for all dangers in all portions of the mine under his charge," and "shall leave at the face and side of every place examined, the date of the examination." He must also "examine the entrance or entrances of all worked-out and abandoned portions adjacent to the roadways and working places where explosive gas is likely to accumulate"; and across the mouth of any place, whether working or not, where explosive gas or any other "immediate danger" is discovered, he shall place a danger signal which "shall be sufficient warning for persons not to enter." He, the mine foreman, or the assistant mine foreman, "through an interpreter," shall explain to "the non-English speaking employes of the mine," and in his or their own language, the meaning of all danger signals.

Section 2.—Immediately after making an examination of all, or any part, of the mine the results of this examination must be entered in ink and signed in the permanent record book at the mine office on the surface. The record must show the time taken in making the examination and must state clearly the nature and location of any and all dangers found in any part of the mine, which dangers must be reported at once to the mine foreman. If an inside station has been established in the mine a second record book must be kept there which the fire boss must fill up and sign in addition to the one at the office on the surface, and these record books must be open during working hours to the inspector or to any employe of the mine. No person shall be allowed to enter the mine until the fire boss has returned to the office on the surface, or to the underground station (if there is one) on the intake entry of the mine, and has reported to the mine foreman, or assistant mine foreman, "that the mine is in safe condition for the men to enter."

Section 3.—This provides for a second examination during working hours of "every working place" by the first fire boss or another acting in his place.

Section 4.—"The mine foreman and the fire boss" must maintain a permanent station at or near the main entrance to the mine, with a proper danger signal, designated by suitable letters and colors placed thereon." When the working places are "1 mile or more" from the drift mouth or from the foot of the shaft or slope, a permanent station may (it is not compulsory) be erected by the mine foreman (provided the location is approved by the mine inspector) for the use of the fire bosses, in which "a fireproof vault of ample strength shall be erected of brick, stone, or concrete, in which the temporary record book of the fire bosses (as described in Section 2) shall be kept." It is unlawful for any person except the mine foreman and "in case of necessity such other persons as may be designated by him, to pass beyond said permanent station and danger signal until the mine has been examined by a fire boss, and the mine, or certain portions thereof, reported by him to be safe." The fire boss shall not allow any one "to enter or remain in any portion of the mine through which a dangerous accumulation of gas is being passed by the ventilating current from any other part of the mine," and any violation of this rule must at once be reported to the mine foreman.

Section 5.—Any person, except those in real or delegated authority, who passes a danger signal into the mine, or who, when inside goes past a danger signal into any other portion of the mine, or who removes a danger signal before the mine has been examined and reported safe, or any person who passes a danger signal placed at the entrance of a place, whether the place is working or not, or removes the danger signal without permission of the mine foreman, assistant mine foreman, or fire boss, is guilty of a misdemeanor. The mine foreman shall notify the inspector for the district, and the inspector shall enter proceedings against the guilty party. If the mine foreman fails to report violations of the law which he has seen or which have been reported to him, he is guilty of a misdemeanor, and is liable to punishment.

SECTION 6. A fire boss who neglects any or all of his duties or who makes a false report as to the conditions of any portion of the mine examined by him is guilty of a misdemeanor and shall be suspended by the mine foreman and his name given to the mine inspector that he may be prosecuted. If found guilty, his certificate must be returned to the Department of Mines. At the end of 6 months, during which time he cannot act as fire boss, he may be granted a new certificate after passing another regular examination. If found guilty a second time, his certificate is again surrendered to the Department of Mines, but in such a case he is not allowed to take another examination. This will prevent him forever from serving as a fire boss in the state of Pennsylvania.

SECTION 7. In an emergency a regularly employed fire boss may act as a first-grade assistant mine foreman.

QUES. 2.—If a portion of the mine was worked with locked safety lamps and approved powder used for blasting, how would you light the shots, and what precautions would you take if called upon to perform this duty?

ANS.—Sec. 14, Art. IV, which describes the method of firing shots in gaseous mines is not at all clear. After authorizing the employment of shot firers in mines generating explosive gases and defining their duties and stating how shots may be fired, it proceeds to state "no shot firer or any other person shall fire a shot in any working place or *in any mine* if his safety lamp can detect explosive gas at the roof." After thus prohibiting the firing of shots in working places or *in mines* in which explosive gases may be detected, the section again sets forth how shots may be fired in gaseous and *dusty* mines. The authors of the law presumably meant that in mines generating explosive gases shot firers must be employed, but that a shot firer should not shoot a hole in a room or other place where his safety lamp showed gas at the roof, but must first remove the gas. With this understanding the fire boss' duties, if called upon to take the place of a shot firer, would be:

To test the roof for gas and if any was found to remove the same by bratticing up to the face or otherwise. Whether the coal be undercut, or sheared, or shot off the solid, he must see that the holes are properly placed so that they will do the work expected of them and not result in blown-out or windy shots. If the holes are not properly placed, he must decline to fire them. The holes are to be charged with permissible powder and tamped with some incombustible material, such as clay, of which a supply must be kept at convenient places underground. "Under no condition shall the shot firer use coal dust or other combustible material for tamping." If the mine is dusty as well as gaseous, the entry or room where a shot is about to be fired must be "so thoroughly wetted as to prevent the existence of any dry dust for a distance of at least 80 feet from the hole to be fired." All shots must be fired by electrical apparatus (the kind is provided by law), and "no person other than the shot firer shall connect the wires of or operate said apparatus." After firing one or more shots, he must return to the place or places before leaving the mine "to see that there is no fire or any other danger existing." If the coal is shot from the solid he must see that all men are out of the mine except the shot firers and those "delegated by the mine foreman to safeguard property." A record must be kept and a report made to the mine foreman of every hole that he has refused to charge, every blown-out shot, and every hole that has missed fire.

QUES. 3.—Give the names, symbols, and specific gravities of explosive and other gases found in coal mines; where is each found; where and how produced, and what effect has each on the health and safety of the workmen, and how can they be removed?

ANS.—Nitrogen, symbol N, specific gravity .9713, is the chief constituent of the atmosphere and, consequently, the most abundant gas in mines. It is also found to a small extent occluded in the pores of coal and is sometimes produced by the explosion of certain classes of powder. The gas is not actively poisonous, but as an increase in its amount is accompanied by a decrease in the amount of oxygen present in the air, it eventually causes death by suffocation. Oxygen, symbol O, specific gravity 1.1056, is the second most common gas in the air and, naturally, in mines. It is the great supporter of life and combustion and occurs occluded in the pores of some coals. Carbon dioxide, at one time called carbonic acid, and some times known as blackdamp, symbol CO_2, specific gravity 1.529, results from the complete combustion of carbon. It is formed in mines from the breathing of men and animals, from the burning of lamps, and the explosion of powder, and from gob and other mine fires, and more or less is occluded in the pores of the coal and in the rocks overlying and underlying the coal seam. It is an inert and non-poisonous gas and, as does nitrogen, causes death by suffocation by reducing the oxygen content of the air below the amount that will support life. As it is heavier than air, it is generally found near the floor and in dip workings. Methane, formerly called light carbureted hydrogen, or marsh gas, symbol CH_4, specific gravity .559, occurs as an occluded gas in coal and in the overlying and underlying rocks, from which it is given off as the coal is mined. It is also given off by both active and abandoned gas or oil wells which have not been properly cased off below the coal. As it is much lighter than air it is generally found near the roof, on tops of falls, and the like. It is a non-poisonous gas, and like nitrogen and carbon dioxide, may cause death by suffocation through diminishing the proportion of oxygen in the air. It and carbon monoxide are the explosive gases common to mines. Carbon monoxide, formerly called carbonic oxide or whitedamp, symbol CO, specific gravity .967, is formed through the slow combustion of carbonaceous material in the gob or abandoned parts of the mine; by the imperfect combustion of carbon in mine fires; by the explosion of most kinds of blasting powder, and by explosions of coal dust. Carbon monoxide is unquestionably the most dangerous gas met in mines, not only because it is highly explosive, but also and more particulary because it is highly poisonous even in very small amounts. Under any circumstances .2 per cent. is fatal in a short time and much smaller amounts if a man is exposed for a greater period of time. The oxygen of the air forms with the red corpuscles of the blood an unstable chemical compound which is conveyed through the arteries and veins to all parts of the body for the needs of the various tissues. It appears that these red corpuscles have about 250 times the affinity for CO as for O and, consequently, if any of the former gas is present it is absorbed instead of oxygen with fatal results; the patient really dying from the substitution of carbon monoxide for oxygen in the blood. As this gas is a little lighter than air it has a tendency to collect near the roof, but its specific gravity is so nearly that of the atmosphere that it is readily diffused. All the gases just described are common in afterdamp of all kinds. Sulphureted hydrogen, symbol H_2S, specific gravity 1.191, is one of the rare gases met in coal mines, and results from the decomposition of iron pyrites (sulphide of iron) in the presence of moisture, and from the explosion of some classes of powder, especially if the charge is damp. It is explosive and far more poisonous than carbon monoxide. Owing to its weight it is apt to be found near the floor.

The above are the more common gases met in mines. In addition, there are certain rare gases always present in the air, such as argon, xenon, etc.; a number of gases consisting of carbon and hydrogen in the same series as methane given off by the coal, and some compounds of nitrogen and oxygen formed by the explosion of powder.

The method of removing these and any other gases from mine workings is to supply a sufficient quantity of fresh air moving at sufficient speed to dilute them to a point where they are no longer dangerous and remove them from the mine.

Ques. 4.—If there is 5,000 cubic feet of air, containing 5 per cent. of marsh gas, measured at the last cut-through in an entry, how much more air should be added to reduce the amount of gas to 1 per cent.?

Ans.—The amount of marsh gas in the air is $5,000 \times .05 = 250$ cubic feet. That this total amount (250 cubic feet) of gas may make but 1 per cent., the volume of gas and air must be $\frac{250}{.01} = 25,000$ cubic feet. As there are already 5,000 cubic feet of air and gas present, the amount to be added is $25,000 - 5,000 = 20,000$ cubic feet of air.

Ques. 5.—What is the principle of the safety lamp? Describe its construction.

Ans.—The principle of the safety lamp is the isolation of the flame from the outer air by means of a wire gauze. The mixture of gas and air passes through the gauze and (if enough gas is present) burns within the lamp. The products of combustion pass out through the gauze and being split up by the holes (meshes) therein, are cooled below the temperature at which they would ignite a dangerous mixture of gas and air outside the lamp. In its principal features the lamp consists of a metal receptacle to hold oil or other illuminating fluid, which constitutes the lamp. Above this is the wire gauze, the lower portion of which in all modern lamps is replaced with heavy glass to increase the amount of light. The upper portion of the gauze is surrounded by a sheet-metal covering, known as the bonnet, intended to prevent the flame being blown through the gauze (and thus igniting the firedamp) when the lamp is carried in an air-current of high velocity. Some lamps, such as the Wolf, in common use in Pennsylvania, are provided with a device by which they may be relighted if extinguished in the mine, as well as with magnetic locks so that they may not be opened except by the lamp tender at the lamp house, where a powerful magnet is kept.

Ques. 6.—How would you prepare your safety lamp before commencing your examination of the mine, and what kind of a lamp would you use, and in what direction would you travel through the mine? If a door was found open by you in a section of the mine known to generate explosive gas, what would you do in such a case?

Ans.—The lamp should be cleaned, filled, and trimmed. The gauze should be examined for any possible flaws and holes or for grease or dirt that may have lodged upon it. Extreme care should be taken to see that it is put together properly and, if possible, it should be tested in a box containing explosive gas before it is carried into the mine. In event of more than one fire boss going on shift at the same time it would be well for each to examine the others' lamp, thus affording a check upon any possible mistakes. The kind of lamp used should be according to law "an approved safety lamp," the Wolf being probably the most common type in use in Pennsylvania. Lamps used for testing for gas are usually more delicate than those used for working purposes. There are many types, some provided with indicators that tell approximately the percentage of gas present. The inspection should be made "with the air," that is, in the same direction the air travels.

In the event of a door being found open it has probably been left in that position by the shift of the previous day, in which event the particular section of the mine may have been without air for 9 or more hours. In any case, the door should be closed and a warning or danger signal posted. If the mine makes a great deal of gas it may be necessary to speed up the fan in order to remove it. If the mine makes some gas it would be well to defer the examination of this section until the last, that the gas may be as far as possible removed, or a special examination should be made after the first one and just before the shift goes on. Extra precautions should always be taken in testing and examining after a district has been cut off from air for some time, and no one should be allowed to enter until absolutely sure that no more than the usual amount of gas is present.

Ques. 7.—Are there any conditions under which the flame will pass through the gauze of a safety lamp? Explain fully.

Ans.—Yes. If the lamp is held too long in a gaseous atmosphere the gauze will become heated and pass the flame; or if the lamp be held in an air-current the flame may be blown through; or holding the lamp in a slanting position causing the flame to heat the gauze, will communicate flame to the outside; or if there is grease or soot on the gauze it will, being a good conductor, permit the wires to be more rapidly heated, destroying their power to cool the flame of the burning gas below its point of ignition. Other ways by which flame may be passed are by breaking the glass as the result of a fall or by water falling upon it when hot, or by an explosion of gas within the lamp suddenly forcing the flame through.

Ques 8.—If 20,000 cubic feet of gas at the greatest explosive point is passing through the mine, what is the quantity of gas given off and what quantity of air should be added to make it non-explosive?

Ans.—The percentage of gas at the maximum explosive point is 9.46. Hence, the 20,000 cubic feet of mixed air and gas contains $20,000 \times .0946 = 1,892$ cubic feet of gas, and $20,000 - 1,892 = 18,108$ cubic feet of air. The lower explosive limit is reached when the mixture of gas and air contains 7.14 per cent. of gas. We may assume that the mixture contains .01 per cent. less, or 7.13 per cent. The total volume of mixed gas and air should then amount to $\frac{1,892}{.0713} = 26,536$ cubic feet. As the original volume of mixed gas and air was 20,000 cubic feet, it will be necessary to add $26,536 - 20,000 = 6,536$ cubic feet of air.

It is understood, of course, that these figures are intensely theoretical. No one would consider a mine with 7.13 per cent. of gas in the air at all safe, as this mixture, while theoretically non-explosive, would burn. In the presence of the explosive dust found in practically all the bituminous coal mines of Pennsylvania, the allowable percentage of marsh gas in the air should be well under 1 per cent. Assuming, however, that with all precautions, such as undercutting the coal, using permissible powder, systematic sprinkling, the employment of skilled shot firers, and the like, that 1 per cent. of marsh gas is allowable, the total volume of gas and air would then be $\frac{1,892}{.01} = 189,200$ cubic feet, and the amount of air to be added would be $189,200 - 20,000 = 169,200$ cubic feet.

Ques. 9.—What qualifications other than those required by law, should a man possess in order to make an efficient fire boss?

Ans.—If he possesses what is wrongly called "common sense," combined with a realization that upon his skill and watchfulness may depend the lives of all in the mine, he should make a good fire boss. If he possesses common sense, he will be a good observer and close reasoner, cool in the presence of danger, and will almost unconsciously "do the right thing at the right time." If he fully realizes all the responsibilities of his position, he will be sober, industrious, and willing to learn.

Ques. 10.—Explain why some safety lamps are more sensitive to gas than others?

Ans.—Any lamp that admits air freely below the flame and has a good draft that at once carries away the products of combustion is more sensitive than one where the air is admitted above the flame and the draft is poor, as the circulation within the lamp is poor and it is apt to go out when most needed. Lamps burning naptha, or any substance giving a flame with the least amount of light, and when they have no reflecting surface behind the flame, will show a smaller percentage of gas and that more plainly than lamps using the heavy, light-giving oils, and particularly so when the lamp is provided with a reflector.

Ques. 11.—How would you proceed to enter a place supposed to contain firedamp, and where and how would you hold your lamp to find it?

Ans.—The place should be entered cautiously and slowly to avoid walking under, or into, or disturbing a large body of gas. In making tests the lamp should be held upright, and, beginning near the floor, should be slowly raised toward the roof until gas, if present, shows a cap on the flame of the lamp. If there are holes in the roof or "high" places between timbers, etc., the lamp should be raised into them.

Preservation of Mine Timbers

Relative Life of Treated and Untreated Timbers—Different Methods and Cost of Plant for Treating

At the 1909 summer meeting of the Coal Mining Institute of America, John M. Nelson, Jr., read a paper on the "Preservation of Mine Timbers," and recently the United States Department of Agriculture issued Forest Service Bulletin 107, having the same title. The latter is by E. W. Peters, and both are herewith abstracted ad libitum to bring out the valuable suggestions incorporated therein.

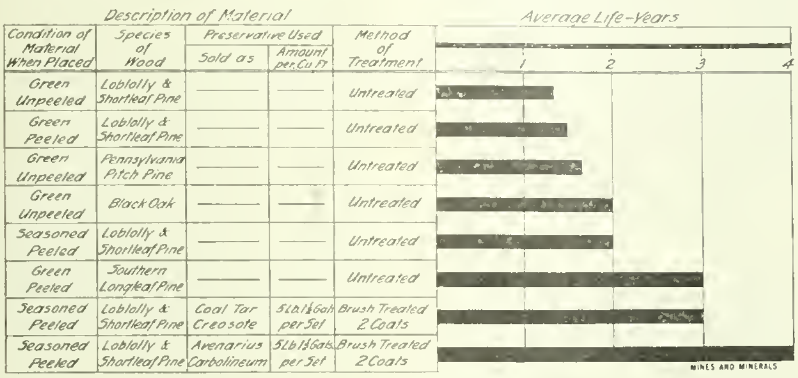

FIG 1. SHOWING LIFE OF TREATED AND UNTREATED GANGWAY SETS

In 1907 mining operations the cost of round prop timber alone was $10,000,000, while additional expenditures were necessary for lagging, planks, ties, and other lumber extensively used in mines. It is not stated whether this included the timber used in metal mines, but it is assumed that it does.

Concrete and steel have to some extent taken the place of timber in mines, but their high cost and the difficulty of installing them will restrict their use to work that is permanent.

The Philadelphia & Reading Coal and Iron Co., the coal mining department of the Delaware, Lackawanna & Western Railroad Co., in Pennsylvania; the Tennessee Coal, Iron, and Railroad Co. in Alabama; the Bunker Hill & Sullivan Mining and Concentrating Co. in Idaho; the Homestake Mining Co. in South Dakota; and the Anaconda Copper Mining Co. in Montana, have installed wood-treatment plants to secure authentic data on the efficiency of various methods of preserving mine timbers from decay.

The Forest Service is obtaining data from these companies with the object of determining suitable methods for treating timber used in mines, and to determine the durability of treated and untreated timber.* In mines, 5 per cent. of the timber used is destroyed by wear; 20 per cent. by breakage and fire; 50 per cent. by decay and insects; 25 per cent. is wasted from all causes.

The practical methods of increasing the durability of timbers in mines are: Peeling off the bark; seasoning, and preservative treatment. While under certain conditions peeling and seasoning increase the durability of timber, chemical preservatives give the best results.

Before timber is treated with preservatives it must be peeled and seasoned, and all timbers should be cut and framed to their final dimensions and form before treatment.

There are three questions which every mine manager will ask as soon as the subject of wood preservation is mentioned: (*a*) What will the treatment plant cost? (*b*) What will it cost to treat timbers? (*c*) What will be the economy in treating timbers?

To answer (*a*) it must be understood that there are two general methods of timber treatment, besides the brush treatment.

The brush treatment is fairly effective and consists in applying two or three coats of hot creosote or other preservative to timbers, care being taken to get the preservative into all checks and knot holes, so that fermentation cannot set up decay. The amount of preservative for this kind of treatment is relatively small and no special equipment is needed.

Brush treatment is advisable at small operations where the quantity of timber used will not warrant the erection of a treatment plant. The main disadvantage to brush treatment is that the slight penetration of the antiseptic material does not secure the protection of the interior of the timber for a considerable period, and the thin coating may be broken so as to leave the interior exposed to fungus spores.

Fig. 1 shows graphically the comparative cost of untreated and of brush-treated loblolly pine gangway sets after various periods of service. The charge includes the cost of installation and maintenance, plus simple interest at 5 per cent. on the investment; and was derived from the cost data given in Table 1; and the figures for average life were secured from the experimental sets placed in the mines of the Philadelphia & Reading Coal and Iron Co., as shown in Fig. 2. The broken lines show the actual expenditures for a gangway set of average life.

Thus, the original cost of a green, unpeeled, and untreated loblolly pine gangway set, including removal of old timber

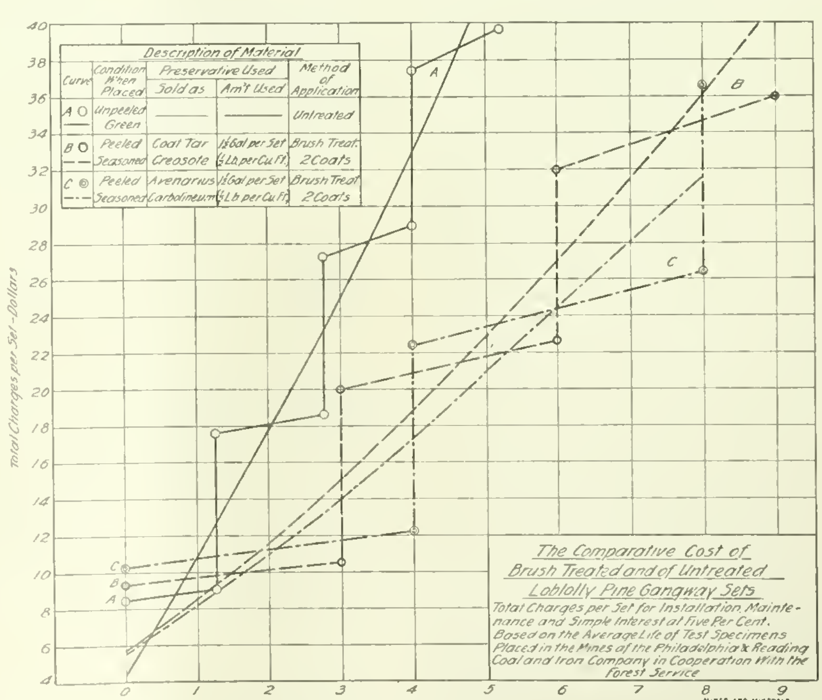

FIG. 2

*Vol. XXXII, p. 706, MINES AND MINERALS.

and placement of new one, amounts to about $8.50. The average life of such a set is about 1 year and 4 months. At the end of this period the simple interest charges on the expenditure amount to 57 cents, making the total cost up to that time $9.07, as indicated on line *A*. To this must be added a replacement charge of $8.50, which is represented by the vertical rise in this line, the total charges for the two installations and the maintenance and simple interest on the first installation up to this time amounting to $17.57. After a period of 2 years and 8 months the interest charges on the cost of the first installation amount to $1.14, and on the first replacement to 57 cents, making the total cost up to this time $18.71. A second replacement is then necessary, the cost of which is again shown by the second vertical rise in the line. Thus the increased interest charges are represented by the increase in the slope of the lines connecting the vertical rises in the broken line, while the vertical rises represent the successive replacement charges. Lines *B* and *C*, showing the cost of brush-treated sets, are derived in a similar manner.

If a number of sets are considered, it is unlikely that all of them will fail at the same time, and for this reason the average expenditures are better represented by the smooth curves shown in the diagram. These also show better the saving which may be realized by the use of brush-treated timber. Thus in 2 years the average total charges against the untreated set, as read from the curve, amount to about $18.10. With a set brush-treated with creosote, on the other hand, the charges amount to $11.60, a saving of $6.50 due to the treatment. In 4 years this saving amounts to $13.80, which represents the difference between $33, the total cost of the untreated sets, and $19.20, the total cost of the brush-treated sets, for that period. The curves further indicate that brush treatment with carbolineum proved more economical than brush treatment with creosote. The fact that the initial cost of the timber at different periods is considered to be the same makes the curves very conservative, since the price of mine timbers will unquestionably continue to rise. On the other hand, a certain salvage might have been allowed for removed props, which may be utilized for fuel or sawed into lagging. Since, under the conditions of the experiment, failure from mechanical causes, such as crush and squeeze, was more common in treated than untreated props, the former would have a greater salvage value, and the relative saving resulting from their use would be greater than that shown in the diagram.

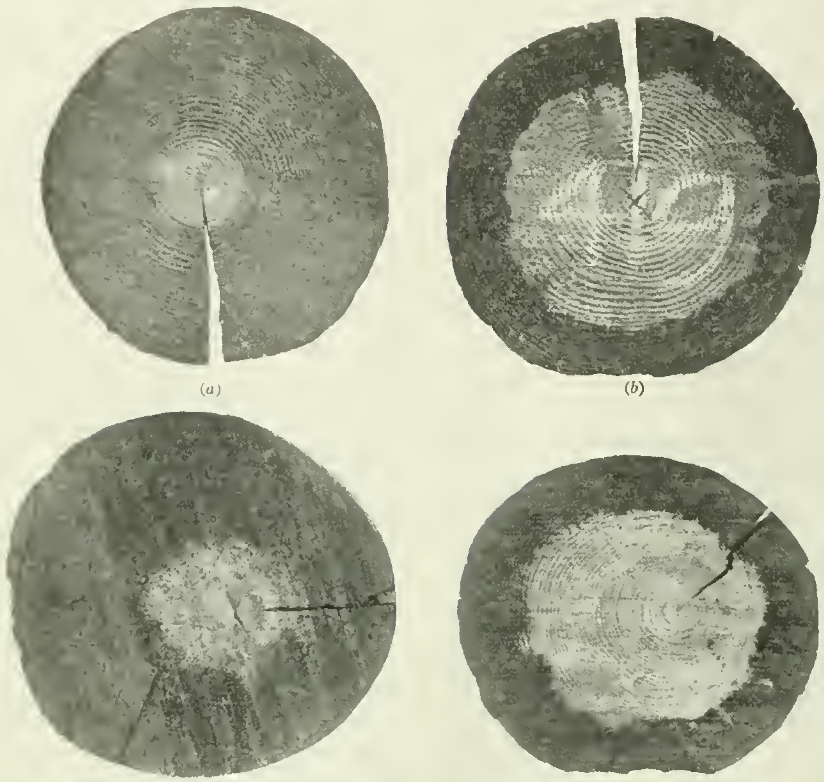

Fig. 3. Sections From Round Timber After Treatment

Concerning the comparative life of brush-treated timber and untreated timber, the following is given:

All of the untreated material failed within from 1 to 3 years, while brush-treated timber remained serviceable for from 3 to 4 years.

The life of untreated peeled loblolly and short-leaf pine was from 10 to 15 per cent. greater than that of similar unpeeled material.*

In dry, well-ventilated workings the average life of untreated seasoned loblolly pine was approximately 25 per cent. greater than that of similar green material. In wet locations seasoned timber did not appear to outlast unseasoned material.

Loblolly and short-leaf pine, brush-treated with coal-tar creosote and Avenarius carbolineum, proved to be from 50 to 100 per cent. more durable than similar untreated material. Moreover, brush-treated loblolly and short-leaf pine proved more serviceable than untreated long-leaf pine, pitch pine, and red and black oak. Brush treatment with Avenarius carbolineum was somewhat more effective than similar treatment with coal-tar creosote.

Another process of applying preservatives to mine timbers is known as the open-tank process, where the atmosphere is the

*Most of the timbers were placed in fairly dry situations.

Table 1. Cost of Untreated and Treated Loblolly Pine Gangway and Entry Sets Placed by the Philadelphia & Reading Coal and Iron Co.

Condition of Material Before Treatment	Method of Treatment	Preservatives Used, Sold as–	Unit Cost of Preservative	Amount of Preservative Used Per Set	Cost Preservative Per Set	Cost Per Set of Peeling, Seasoning, and Treating Timber*	Total Cost of Set in Workings
Green unpeeled.	Untreated						$8.50
Green peeled....	Untreated					$ .28	8.78
Seasoned peeled.	Brush treated, two coats	Coal-tar creosote	8 cents per gallon†	1½ gallons per set, .5 pound per cubic foot	$ .12	.65	9.27
Seasoned peeled.	(same as above)	Avenarius carbolineum	70 cents per gallon‡	(same as above)	1.05	.65	10.20
Seasoned peeled.	Impregnated	Water-gas-tar creosote	7 cents per gallon†	10 pounds per cubic foot or 30 gallons per set	2.10	.94	11.54
Seasoned peeled.	Impregnated	Coal-tar creosote	8 cents per gallon†	(same as above)	2.40	.94	11.84
Seasoned peeled.	Impregnated	Zinc chloride	4 cents per pound dry salt	½ pound dry salt per cubic foot or 13 pounds per set	.52	.94	9.96

* Cost of treating includes cost of labor, fuel, and interest and depreciation on plant.
† Unit cost of creosote based on price of tank car lots of from 8,000 to 10,000 gallons.
‡ Unit cost of carbolineum based on price of barrel lots.

pressure used to force the preservative into the pores of the timber. This differs materially from the process where artificial pressure is used for penetrating the pores. The non-pressure, or open-tank process, is much simpler and less expensive than the pressure process, but it is not so well suited for the treatment of a variety of species and forms of timber. The process is as follows: After seasoning, the wood structure becomes more porous, and in this condition is placed in a bath of the preservative. The heat causes the air in the wood structure to expand and much of it is expelled After a time the hot liquid is run out of the treating tank and cooler preservative admitted; or the timber is removed from the hot bath and quickly plunged in a cooler one; or the heat may be shut off and the timber allowed to cool with the preservative. These operations cause a contraction of the air and a condensation of moisture to take place within the timber; a partial vacuum is consequently created and the preservative is forced into the timber under atmospheric pressure.

The preservative process best suited for the treatment of round timber by mining companies depends upon the form and species of timber handled and the proportion of sapwood it contains. A porous wood, such as sap pine or red oak, is more easily impregnated with a preservative than is a dense species, such as white oak or chestnut. A less expensive non-pressure treatment is therefore more suitable for the treatment of these porous woods. Moreover, sapwood is more easily treated than heartwood. When the timber to be treated is round there is always a well-defined band of porous sapwood encircling and enclosing the interior dense heartwood. The presence of the surrounding sapwood insures a satisfactory and even penetration of the preservative fluid applied by either method of treatment, inasmuch as the sapwood of almost any species of timber may be penetrated without the application of artificial pressure. However, when the timber to be treated is partly square or rectangular, as a railroad tie, both sapwood and heartwood surfaces may be exposed. As a rule, this dense heartwood can be treated more thoroughly by the application of artificial pressure. When treated, the sides of the tie covered with layers of sapwood may be thoroughly impregnated, with the other two sides barely penetrated with the preservative liquid. The side of the tie on which the rails rest and into which the spikes are driven, is usually heartwood, and it is here that a preservative treatment is most desired. Moisture collects beneath the base of the rail and around the spikes, forming an excellent opportunity for the development of decay. If such a tie is not treated uniformly on all sides, the money invested in the treatment of the sap portion may be partial loss. Of course some species of wood contain a much larger proportion of sapwood than do others. For instance, southern pine contains a great deal of sapwood, while white oak and chestnut contain a very small proportion. In consequence, a non-pressure method of application may be suitable for the treatment of the former species and not desirable for the treatment of the latter. Numerous variations in the kind and form of timber should influence the consumer in selecting a method of treatment, but space will not permit of giving them in detail.

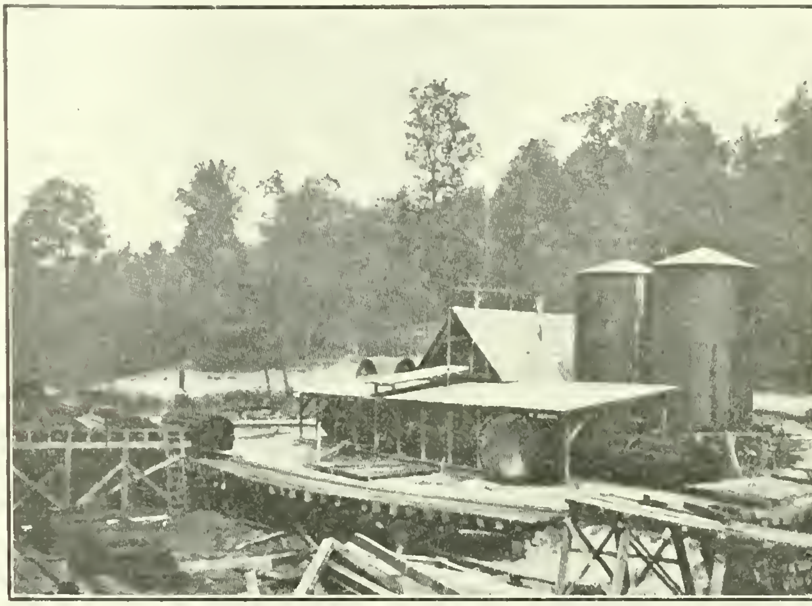

FIG. 4. WOOD-PRESERVING PLANT AT MCADORY, ALA.

For the treatment of round mine timbers a non-pressure method of application may be the better.

A non-pressure plant with a daily capacity of 30 sets of collar timber or 800 linear feet of 12-inch timber may be installed complete for about $6,000. This plant could treat about 400 flat ties in a day of 12 hours, and a proportionate number of standard-gauge railroad ties. An open-tank plant, having a capacity of 100,000 cubic feet per year of 250 days, may be erected at a cost of from $1,500 to $2,500.

The low cost of an open-tank plant places it within the reach of many mine operators. Fig. 3 shows sections of round mine timber sawed from the center of sticks 10 feet long. Fig. 3 (*a*) is loblolly pine seasoned 3 months. It was treated in an open tank for 2 hours, at 185° to 195° F., cooled to 160° F., then heated for 3 hours at 210° F. It absorbed 6.2 pounds of preservative per cubic foot, and had a penetration of 3.5 inches. Fig. 3 (*b*) is loblolly pine that was seasoned 2 months and then subjected to 3 hours at 180° F., cooled to 140° F., and then heated for 2 hours at 215° F. The absorption of preservative was 3.1 pounds per cubic foot and the penetration 1.5 inches. Fig. 3 (*c*) is seasoned pitch pine that has been treated 5 hours at 230° F. and cooled to 170° F. The preservative penetrated 3.7 inches and was absorbed at the rate of 18 pounds per cubic foot. Fig. 3 (*d*) is loblolly pine seasoned 3 months, treated 2 hours in preservative at 215° F., cooled to 175° F., and then heated 2 hours longer at 230° F. The stick absorbed 3.7 pounds of preservative per cubic foot, and was penetrated 1.5 inches.

The unit cost of handling timber at open-tank plants is from 3 to 4 cents per cubic foot. In Table 1 is shown the cost of the open-tank treated and the untreated loblolly pine gangway and entry sets. Each set in this table consists of one 7-foot collar, one 9-foot leg, and one 10-foot leg. Each member of the set was 13 inches in diameter and approximately, there are 26 cubic feet in a set.

The condition of timber treated by the open-tank process with sodium and magnesium chloride, although not comparing favorably with that of timber similarly treated with other preservatives, was better than that of the brush-treated timbers.

Open-tank treatment of green timber with zinc chloride proved fairly effective, but the tests indicate that better results will be secured with seasoned material, since about 13 per cent. of the green timber treated with zinc chloride by the open-tank process showed marked signs of decay after 4 years, while no decay was found after the same period of service in seasoned material similarly treated.

With many species of wood a satisfactory treatment can be secured only by the pressure process. The essential difference between the open-tank process and the pressure process is that in the former atmospheric pressure is relied upon to secure the penetration of the wood, while in the latter the preservative is forced into the timber pores by artificial means.

Pressure processes may be employed for either full-cell or empty-cell treatment; the former leaves the treated portion of the wood completely filled with preservative, while the latter aims to inject the preservative as deep into the timber, but leave no free antiseptic in the wood cells. The oldest process of full-cell treatment with creosote is termed "Bethellizing." A similar treatment with zinc-chloride solution is called "Burnettizing." Fig. 4 shows the plant of the Tennessee Coal, Iron, and Railroad Co., at McAdory, Ala. Its capacity is 830 cubic feet of timber per run; it being possible to make three runs daily if necessary. The total cost of the plant, including the necessary yard construction, was approximately $12,000. The plant erected by the Anaconda Copper Mining Co., at Rocker, Mont., cost $15,000.

The cost of pressure plants depends chiefly upon their capacity. Fig. 5 shows the general arrangement of a small pressure plant, having a capacity of approximately 1,000 cubic feet per run, or 750,000 cubic feet per year.* The total cost of such a plant will amount to from $12,000 to $20,000. The following is a list of the main items of equipment:

One horizontal treating cylinder 65 feet long, with inside diameter of 6 feet 2 inches, capable of withstanding an internal pressure of 175 pounds per square inch.

Two vertical measuring tanks, each of 15,000 gallons capacity.

One storage tank of 50,000 gallons capacity.

One hoist engine.

One pressure pump, capacity 150 gallons per minute at 175 pounds pressure per square inch.

One air compressor, capacity 460 cubic feet of free air per minute at 20 pounds pressure per square inch.

Sixteen cylinder cars.

One zinc-chloride mixing tank of 2,000 gallons capacity.

Special attention should be given to the design and construction of a storage yard of adequate capacity for both treated and untreated material, since handling the timber before and after treatment is an important factor in the cost of operation. It is also important to locate the plant at a convenient point in the mining district, so that treated timber may be readily distributed to points where it is to be used

*Annual capacity based on three runs per day for 250 days.

Since the impregnated timbers have not been in service long enough to enable their average life to be determined, most of them being still sound when last inspected, it is impossible to show the ultimate saving in money resulting from their use. Even for the period since their installation, however, they have proved more economical than untreated or brush-treated material.

Below is given in detail the cost of the untreated and creosoted 16'×8" Douglas fir shaft sets placed in the mines of the Anaconda Copper Mining Co. These sets contain 1,127 feet board measure of Douglas fir squared timbers from the Pacific Coast, and 393 feet board measure of lagging. The average absorption secured in the treatment of these timbers amounted to 4.5 pounds of creosote per cubic foot:

Cost of untreated sets:	
1,127 feet b. m. squared timbers, at $20.50 per M b. m.	$25.36
Framing timbers	13.50
Cost of lagging, at $15 per M b. m.	5.90
Switching and unloading charges	.85
Cost of placing set	18.00
Total cost of untreated set in place	$63.61
Cost of treatment:	
Cost of treating, including interest, depreciation, fuel, and labor charges	$ 3.34
Cost of creosote, at 15.6 cents per gallon; absorption 4.5 pounds per cubic foot	8.03
Loading and unloading charges	1.23
Total cost of treatment	$12.60
Total cost of treated set in place	$76.21

In concluding, attention is called to the article on the antiseptic treatment of mine timber in the July, 1912, issue of Mines and Minerals, as the points raised have not been covered in the sources from which the above information has been abstracted.

From what has been stated it may be inferred that not only will proper preservative treatment result in a direct saving in money, but it will make less timber necessary for any given working. Furthermore, the use of treated timber makes it possible to utilize many of the inferior and more rapid-growing species, which, though possessing most of the requirements of high-grade structural timber, lack durability. Treated timber of these species has in many cases proved more serviceable than high-grade untreated material. Thus, in the eastern and southern states, treated loblolly and short-leaf pines may take the place of untreated long-leaf pine, while treated red and black oaks may be substituted for untreated white oak. Douglas fir, which is now extensively used in the West, may in turn be replaced by treated hemlock, larch, or western yellow pine. Inferior grades of timber can usually be bought for less than higher grades, and an additional saving thus realized.

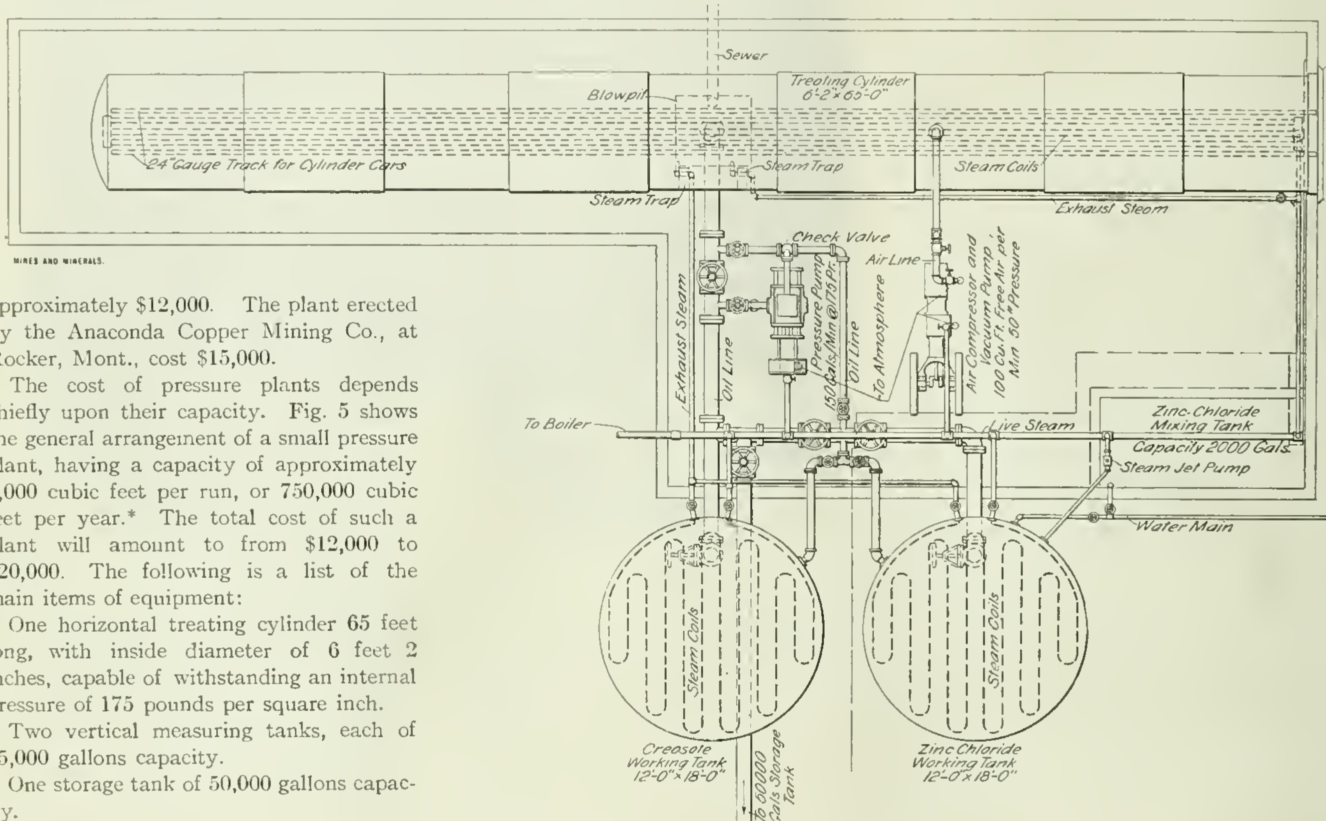

Fig. 5. Plan of Pressure Plant for Treating Timbers

New Jersey Mineral Production

The total value of the mineral products of New Jersey in 1911 amounted to $37,716,411. Of this amount 23.4 per cent. was zinc; 3.7 per cent. was iron ore; 5.7 per cent. was mineral paints, coke, and by-products; and 8.6 was Portland cement. The average value of the iron ore was $3.22 per ton.

Wind Blasts

Editor Mines and Minerals:

Sir:—I would like to have you explain to me the cause of these so-called wind blasts that occur here. I have been employed by the Federal Mining and Smelting Co. at the Standard mine. Within the last month these wind blasts have killed two men and crippled four. The cause no one knows. The level they occur on is the 18th, which is fairly dry. If they were dust explosions, to my idea they would wreck the timbers. If they were created by carbon dioxide the men could not work because the candles would not stay lighted. I have talked with most of the men that worked on the level and they all agree that the explosion sounds like some one shooting before time, and the explosion is on the inside of the wall or the force is behind the walls or roof, which forces slabs of rock out with considerable force, enough to wreck timbers, etc. The foot-wall or the hanging is not of limestone. I have talked with the superintendent and foreman. They think that there is a cavity formed by the slipping of the ground and gas accumulates which causes the explosion. These are lead-silver mines located in the Coeur d'Alene district. Can you enlighten me on this subject?

Henry Hoard

Kellogg, Idaho

Treatment of Broken Hill Ores

Editor Mines and Minerals:

Sir:—My paper on the "Treatment of Broken Hill Ores" which you published in your issues of November, 1911, to March, 1912, was written early in 1908. Many important processes have materially altered since that date. Unfortunately I have not visited Broken Hill and Port Pirie since then, but so far as I can gather from private information and published statements the following have been the chief alterations in practice:

Sizing.—Revolving trommels have in part or whole been superseded by various types of shaking and moving screens. Screen sizing has also been much more extensively used in connection with concentration on jigs, tables, and runners.

Grinding.—The grinding pan superseded other types of fine grinding; e. g., rolls, Heberli mills, and ball mills, and the grinding pans are in turn being superseded by tube mills. In order to prevent overgrinding of galena and blende, which are more friable and heavier than silicious gold ores, it was found necessary to reduce the height of discharge of the grinding pans and shorten the length of the tube mills as compared with those commonly used in gold fields.

Flotation Processes.—Despite the wide initial difference of modus operandi of the various patented processes, they have rapidly approached a common usage in emulsifying and aerating the pulp, using very small amounts of sulphuric acid and oil. The methods employed to separate the "mineral scum" from the rest of the pulp still differ considerably, owing to patent rights. Owing to the large amount of litigation respecting flotation processes that has taken place and is still considered probable, it is difficult to obtain authentic details of the workings of the various plants. It has just been announced that the rights of the Potter, De Bavay, Sulman-Pickard, Cattermole, and Bellot patents have been consolidated. This will probably be followed by the processes in several plants being made more uniform in practice.

Roasting Concentrates. — Since the above-mentioned paper was written, the Ropp roasting furnaces at Port Pirie were heated by producer gas instead of by direct coal firing. More recently a Dwight-Lloyd blast roasting plant has been installed, superseding in whole or in part the Huntington-Heberlein pot roasting plant previously in use.

Zinc Smelting.—A zinc roasting and smelting plant has been erected at Port Pirie, where Broken Hill zinc concentrates are being successfully treated.

The importance of Broken Hill should not be overlooked. It is the largest producer in the world of both lead and zinc and one of the largest, if not the largest, producer of silver.

William Poole

An Air Blast, or Earth Movement

Editor Mines and Minerals:

Sir:—Last December, while engaged in the examination of a mine, near Wallace, in the Coeur d'Alene district, Idaho, it was my fortune to experience the shock of an "air blast" and to observe, thereafter its effect on the underground workings of the mine. I am writing the experience with the expectation that some readers of Mines and Minerals will be able to describe and explain the phenomenon.

The mine in question is opened by a tunnel and, from a point about one-half mile in from the mouth, a main working shaft 1,800 feet in depth has been sunk. The level on which I was at the time is at a depth of about 2,000 feet from the surface and I was more than 1,500 feet away from the shaft station.

About 3 o'clock in the afternoon, a time when we knew there was no blasting in the mine, we heard a dull, heavy boom, like a distant blast but not preceded by the usual "knock" of shots.

Our lights were blown and we felt the rush of air. Going to a point some distance out in the same drift we met the assistant engineer who was cutting down samples and he stated that he had felt the strong outward rush of air. To him the sound had appeared near, so that his first thought was to go in and see if anything had happened at the face of the drift where miners were working.

Half an hour later, one of the shift bosses came in and stated that the force of air had been strong enough to put out the candles of himself and another man who was with him, knocking the latter down. The apparent explosion, as we learned later, had occurred 200 feet above these men and 400 feet above the level on which my assistants and I were working.

Later we learned that a good many men working in places above and below the level on which the plainest evidence of the earth movement was visible, had experienced about the same shock.

A visit to the level, 400 feet above our working point, showed three broken posts and a pile of dirt 2 feet high along the drift for 2 sets. This dirt had come from the sides, not above, and the lagging overhead was not broken. It was apparently a settlement of a large rock mass, not a giving way of the timbering nor a distortion of the level.

When we left the mine, at the end of shift, I met State Mine Inspector Bell who, with Superintendent Davis, had been at the shaft station on the tunnel level, half a mile underground from the tunnel mouth. Neither of them (nor any one else at that point) had noticed any noise or air movement. However, on going to the mine office, about 300 yards from the tunnel mouth, I was asked by the bookkeeper as to what had happened. He stated that he had felt the building shaking and rocking in a manner similar to a slight earthquake, but the movement lasted only a few seconds. He also had had a telephone message immediately from another mine office more than a mile away, where about as much of a shock had been felt, and where it was believed at first that it must be an earthquake.

If it had been entirely an air movement, one would suppose that the force of it would have been felt at all points in and around the shaft and particularly at the collar of shaft where some of the many men stationed could not have failed to observe it.

While talking the matter over, I learned that a similar "air blast" had occurred 17 days previously in the same mine. The strongest evidences had been noted by the superintendent at nearly the same place in the level, but they did not extend into the stopes over the level nor was there any material settlement of timbers.

Allowable Error in Closing Survey

Editor Mines and Minerals:

SIR:—In the matter of the inquiry of C. G. O. in your February issue concerning the allowable error of closure in a mine survey, it seems to me that the care with which any survey, whether surface or underground, is made, depends entirely upon circumstances; that is, each survey must be considered as a separate problem. Where land is worth, as it is in some parts of the Connellsville region, as high as $3,000 an acre, or where mining operations have been extended under a large city as at, say, Scranton, Pa., vastly more care must be taken both above and below ground than where the land in fee is worth $50 an acre and the value of the surface improvements is insignificant.

I do not consider that error in closure is to be measured by the number of minutes the survey is "out" upon occupying the first station, but rather by the failure of the survey to close, when calculated, in latitudes and departures. I have been advised by engineers from the anthracite region of Pennsylvania that it is their custom to allow an error of 1 minute in a closure of 12 stations. This seems to me all wrong, as there are instances where an error of 4 or 6 minutes in this number of stations will have no effect upon the practical value of the survey, and there are other cases where even an error of 1 minute is not allowable. A survey of 12 stations may extend but 1,000 feet in flat workings or it may cover 5,000 feet in pitching ones. While an error of 1 minute might mean very good work in the second case, it would not be extraordinary in the first. On the other hand, in the first case, there should be no error of distance measurement between stations to exceed .01 foot, while in the second, errors of .05 foot may reasonably be expected. For these reasons and because stations are located by linear as well as angular measurements, failure to balance in latitude and departure is the only test as to the accuracy of a survey.

In my own work in the rolling, submountainous districts of the Appalachian region, I find no difficulty in securing a closure of 1 in 5,000. That is, in running a traverse of one mile (practically), the initial stake is missed by 1 foot, which, if platted on the ordinary mine scale of 100 feet to the inch, is but .01 inch. If the error in closure was, say, 1 in 4,000 or even as high as 1 in 2,500, whether the survey should be rerun is a matter of judgment. If the land is low-priced or if discovering the error involved transporting the corps a long distance at a considerable outlay, I would not consider the gain in accuracy offset by the increased expense. On the other hand, were the land valuable or were other and extensive surveys to be based upon the one in question, then the work should be rerun.

In the matter of inside surveys the same reasoning applies. In the nearly horizontal, well-conditioned mines of Pennsylvania and West Virginia, with thick coal, any underground survey should close within 1 foot in 10,000 feet and in many instances the error will be but 1 foot in 20,000 or 25,000 feet. Personally I always rerun a mine survey (under the above conditions) when the error exceeds 1 in 10,000; that is, I rerun the survey if of the main heading or of any workings that will be greatly extended. For short butt headings driven to the line, with a 10-foot, or more, barrier pillar to the next operating property, an error of 1 in 2,500 is allowable.

In other words, surveying is a business proposition in which it is poor policy to spend $25 worth of time to save $5 worth of land. To my mind nothing so plainly shows the skill, experience, and judgment of the engineer as a knowledge as to when his work is sufficiently well done.

FRANCIS G. WELLES
Chicago, Ill.

Humidifying Mine Air

Editor Mines and Minerals:

SIR:—In answer to James Ashworth's article on humidifying mine air, and in contradiction to a letter of mine published in MINES AND MINERALS, in April issue, where he claims it is misleading to state the humidity of a mine in percentage of humidity, I do not see anything misleading, because it is not the actual weight of water contained in a given quantity of air that determines its humidity, or hygrometric condition, but its approach to saturation, or its capacity to hold moisture.

Percentage of humidity is used by the United States Weather Bureau, the Bureau of Mines, and other authorities.

In reference to Mr. Ashworth taking my temperatures and grains of water contained per cubic foot, to prove his assertion, I wish to say that such results are to be expected, because the first temperature was the outside temperature, the second temperature was underground, outside of radiator, but close enough to it so that there was an increase in temperature; the third temperature was taken inside of radiator, but outside of steam pipes, and at this point the temperature had been raised from 26 degrees to 61 degrees, and being outside of the steam pipes, the decrease in the degree of saturation was to be expected.

He also claims that water vapor has no value as a restrainer of an explosive flame until after the air contains 25 grains of water per cubic foot of the mixture. The temperature of air capable of carrying this amount of moisture would be such as to prevent a person from performing hard labor.

I believe that moisture in the form of water vapor is a restrainer of dust explosions, or of dust taking part in a gas explosion, to the extent of the moisture present, because the greater the degree of saturation of the mine atmosphere, the more damp the surrounding and there is no danger from dust until raised into suspension. The more damp the dust is, the more difficult it is to raise it, also to ignite it, as the moisture contained has to be extracted before distillation takes place.

JAMES DALRYMPLE,
State Inspector of Coal Mines
Denver, Colo.

ORE MINING & METALLURGY

Tin Ore Dressing and Metallurgy

A Discription of the Mining, Concentrating, and Smelting Processes in Use in Australia and Tasmania

Written for Mines and Minerals

As assistant geologist of New South Wales, Mr. Carne has made a study of the tin deposits and metallurgy of that country. His researches have been incorporated in "Mineral Resources No. 14," published by the Department of Mines, Geological Survey of New South Wales, Australia, and constitute a classic on the mineralogy, geology, dressing, and metallurgy of tin. According to more than one authority, tin ore occurs in acid granite. In the United States it has been found in coarse pegmatite, termed "greisen." Unless petrological evidence is at fault the acid granite of the Tingha district coincides with those of Cornwall, England, South Dakota, and North Carolina, where tin is found. These are considered to be the ore bearers.—Editor.]

A typical Middle Creek Tingha, New South Wales, acid granite carrying tin is medium to coarse grained. Orthoclase is the predominant mineral, and gives the granite a pink color. A lesser amount of white felspar is also present; a little biotite, and patches of a yellowish alteration product cause a speckled appearance. An analysis by H. P. White furnishes the following composition:

	Per Cent.
Silica	76.28
Alumina	11.41
Ferric oxide	1.60
Ferrous oxide	.72
Manganous oxide	.06
Magnesia	.15
Lime	.62
Soda	3.97
Potash	4.54
Carbon dioxide	.04
Titanium dioxide	.20
Phosphoric anhydride	.17

The norm is determined by Mr. Card as follows: Quartz, 34.9; orthoclase, 26.7; albite, 33.0; anorthite, .3; diopside, .8; akermanite, .4; iron oxide, 2.5; apatite, .3.

Mining tin in New South Wales is confined to stream mining by sluicing or dredging alluvial deposits; to mining old stream beds covered with basalt by shafts and drifts; and to tin-vein mining. The dressing of tin-bearing rock is confined chiefly to material obtained from vein mines. Fortunately for the miner of small means, tin ore is of such value it is salable in small quantities; therefore, pockets can be worked and the material treated in primitive ways. In some pockets the material is so rich as to need no dressing, others produce material that is dressed with spalling and bucking hammers on a flat-rock surface after preliminary roasting if the material is hard and tough. Improvements on this method take the form of raised bucking tables built of rough-dressed stone and capped by a single slab or iron plate.

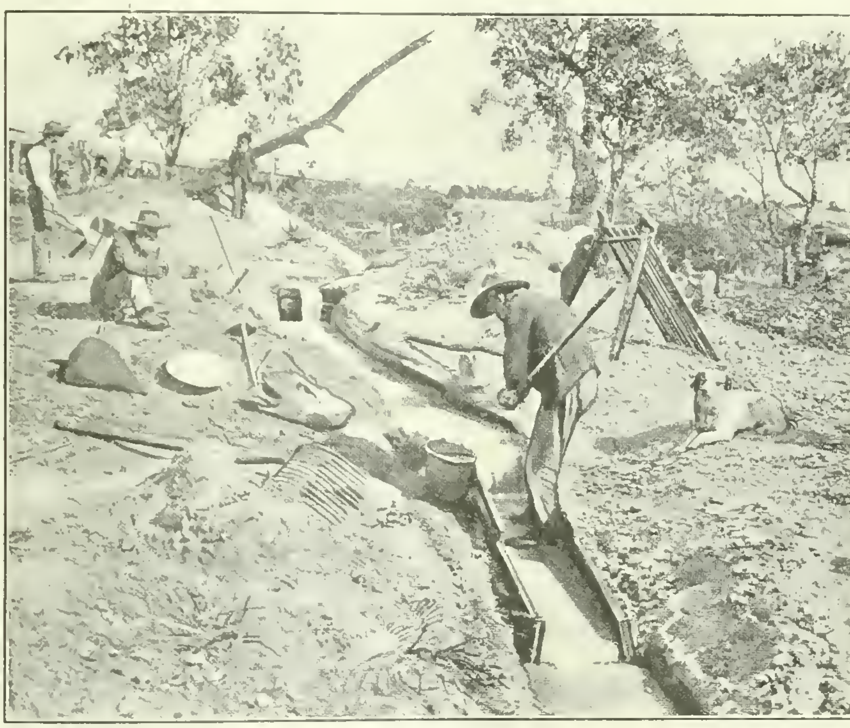

Fig. 1. Tin Sluicing

Intermediate between these primary forms and the modern stamp battery is the "spring dolly," an iron-shod wooden stamp worked by means of a spring pole. In some instances horsepower gearing was attached. To the spring dollies are sometimes added small hand-power rolls for fine crushing. At one place adjustable rolls with flywheel geared for hand power are in use. The tin material is returned for recrushing through closer adjustment, and finally sieved.

The most favored crushing machine is the stamp mill, although rock breakers, rolls, Huntington mills, Fig. 3, and Chilian mills, Fig. 2, have been tried. Fig. 5 shows an ingenious local adaptation of the Chilian mill principle, in which granite wheels take the place of steel wheels for grinders, and the rock floor takes the place of the pan and die. Breakers and rolls with jigs and concentrating tables do not always prove satisfactory, owing to the large tough mica plates in the greisen.

In a paper read before the Scientific Society, Broken Hill, New South Wales, R. H. Couran states: "The method of treatment at the mill taking the ores from the Clitters group is practically the last word in Cornish milling practice. The ore contains cassiterite, wolfram, and copper sulphides. After passing over grizzlies, it is broken by rock crushers and fed by suspended automatic Challenge ore feeders, to a battery of twenty-five 1,100-pound California stamps, and crushed through 20-mesh gunmetal woven screens. It is then classified in spitzlutten, giving three spigot products and an overflow. Each of the spigot products is taken to a concentrating table, the middling from which is ground and afterwards treated on a vanner.

"The overflow from the spitzlutten goes to a 10-compartment condensing and classifying spitzkasten. The various spigot products from the spitzkasten are taken to the distributing boxes of double vanners, the product of the first three pairs of compartments going to three double vanners, and the last two to one double vanner. The middlings from these four machines are

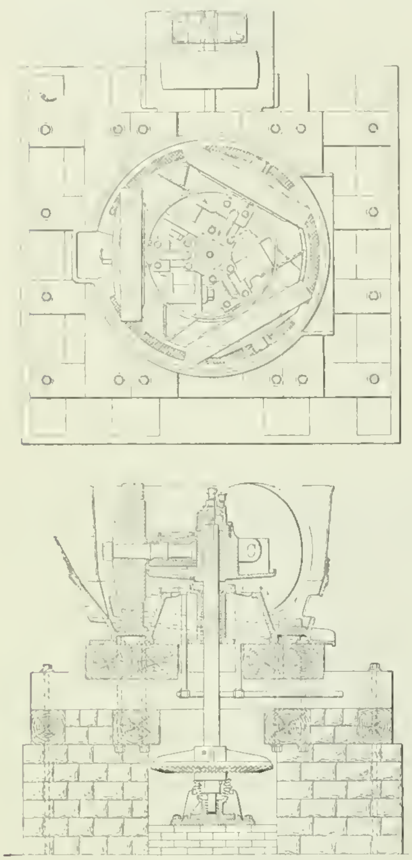

Fig. 2. Chilian Mill

treated on a fifth one, after some of the water has been eliminated in a spitzkasten. All the tailing passes to an eight-compartment spitzkasten 40 feet long, where a quantity of lime is added. A large quantity of the water is removed and pumped back to the storage tanks. The tailing passes on to dams where it is settled; it being illegal to run solids into the neighboring river.

"The concentrate from the table being coarser than that from the vanners, is roasted separately, and then passes to a magnetic separator of the cross-belt type, which gives five products. In the first and weakest field, magnetic oxide of iron is removed; in the second field, oxide of iron with adhering oxide of copper; in the third, oxide of iron and wolfram; in the fourth, wolfram; the non-magnetic product is oxide of tin and some silica. The copper and iron product is sold to copper smelters. It contains 10 per cent. copper and a high percentage of iron oxide, thus commanding a good price. If there is too much tin and wolfram in the first two products they are crushed dry in a ball mill and then retreated.

"The wolfram products are finished in kieves or tossing tubs and sold. The vanner concentrates are roasted and treated in buddles, then dried in a reverberatory furnace, and treated on the magnetic separator, giving a similar product to the table concentrates. The preliminary "buddling" or washing is necessary owing to the limited capacity of the magnetic separator. The secret of the success of magnetic separation is in the roasting, it being desirable to produce the greatest possible quantity of the higher oxides of iron and at the same time eliminate the arsenic and sulphur. If the ore is rich in copper, the iron and copper products of the separator are treated with hot sulphuric acid in a lead-lined vat, and the copper in the solution is precipitated on scrap iron. All the water used in treating the roasted products is passed through precipitation tanks."

The following notes on the treatment of Mt. Bischoff tin mine, Tasmania, have been supplied by J. D. Millen, G. M.:

"The flow sheet, Fig. 4, is of the plant under erection, and embodies the results of numerous experiments that have been carried out during the past 3 years.

"The present mill treats 19,000 tons of ore per month, containing .56 per cent. of tin oxide; and of this, 82 per cent. is saved by concentration. In the two adjoining mills there are 25 and 60 stamps, respectively. These stamps crush surface ore, but also a large quantity that comes from underground, where the vein varies from 18 inches to 18 feet, with an average width of 3 feet.

"The process of recovering alluvial tin ore from channel drifts, surfacing, etc., is a simple one, owing to the specific gravity of the mineral, which is from 6.4 to 7.1, and yet it requires considerable skill in the final cleaning stage. All the methods of ground and box sluicing, puddling, etc., in vogue in alluvial gold mining were naturally applied to alluvial tin mining, when the rush for the mineral ensued in 1872. Altered conditions and greater experience led to modifications in the size of sluice boxes, but the main features of mining and dressing remained unchanged.

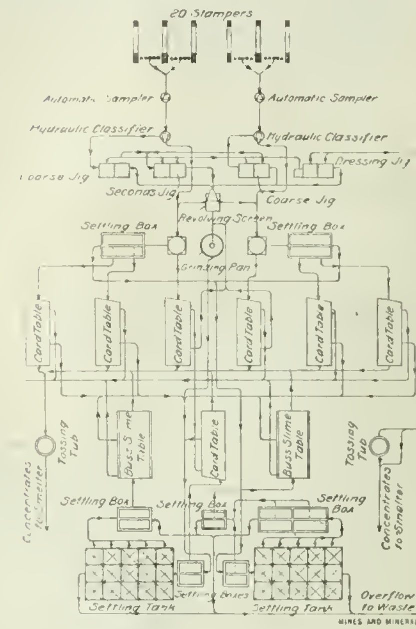

Fig 4

The advent of the modern systems of sluicing and dredging led to new methods of maintaining efficient hydraulic pressure head for breaking down, and the development of power for excavating and elevating, the dressing and concentration of the mineral being effected as before, but on a scale proportionate to the increased power. Fig. 1 shows men actively engaged in tin sluicing. The introduction of steam pumps to force water, instead of the rare and seldom continuous head of water from a

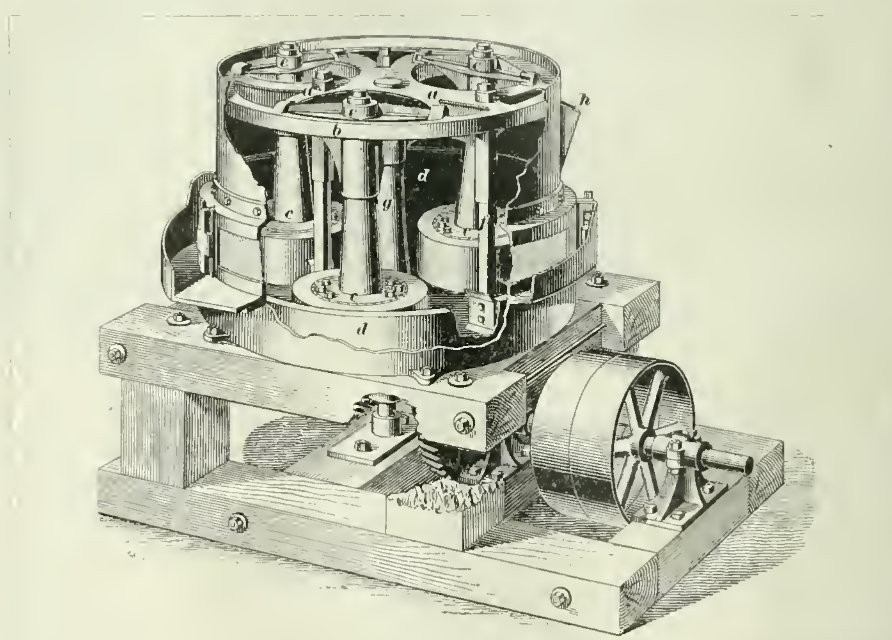

Fig. 3 Huntington Mill

natural flow, revolutionized tin mining in the principal tin centers and led to the recovery of not only a large percentage of the tin lost in previous working, but of much ore thinly scattered through the overburden, the channel banks, and adjacent flats, which could not be remuneratively recovered by other means.

"The efficiency of a powerful stream of water issuing from a nozzle, in breaking down and thoroughly disintegrating the wash and overburden, even when explosives are necessary to burst cemented layers, has rendered suction or pump dredges most favored by the miners, 31 being in operation during 1909, and but two bucket dredges. In gold mining the order is reversed, bucket dredges being the favorites. Bucket dredges are not so efficient against the high bars in a channel and clay wash. The presence of high bars in a channel would be equally objectionable in the case of a floating suction dredge, but the nature of the conditions allows choice between a floating or stationary plant. The absence of any puddling power in the bucket type of dredge is a marked disadvantage compared with the suction."

Smelting Tin Ores.—The smelting practice at the Glen Smelting Works, Tent Hill, in 1887, was described by David as follows:*

"The reduction of the ore is effected in three reverberatory furnaces. These are constructed on the usual plan of an ore chamber, separated from the fireplace by a fire-bridge, 1 foot high. The ore chambers, which have oval-shaped hearths, are from 14 to 16 feet long, and from 6 to 8 feet in width. Their floors sink slightly toward the center, and the arch, which is 2 feet high near the fire-bridge, slopes downwards toward the far end of the chamber, the object of this being to keep the flames from the furnace as close down upon the ore as possible. A flue at the far end of the chamber communicates with one of two brick chimneys, which are respectively 50 and 60 feet high. The outer walls of the furnaces are built of common brick, the sides, crown, bottom, flues, and all exposed parts, being firebrick. Owing to the greater wear and tear of the bottoms and sides, the former are so placed upon iron supports as to be easily removed. The charge for each furnace is 4 tons, 3 tons of ore being mixed with 1 ton of ground charcoal. The charge, having been previously moistened with water, is shoveled into the ore chamber, in which heat is maintained by burning wood in the fireplace. The ore is then spread over the bottom of the furnace with a large iron rake or rabble, until it acquires a thickness of about 12 inches at the center. The heat of the furnace is then gradually raised, the flames from the fireplace playing upon the surface of the ore, and passing through the flue at the far end up the chimney. The charge is stirred from time to time with a rake, especially during the last part of the smelting, and in 12 hours is thoroughly reduced. At the expiration of that time the furnace is tapped, the contents running into a cauldron or float of firebrick, which is large enough to hold all the metal and a small quantity of slag. The furnace, having drained, is ready for another charge, and by the time that has been attended to the temperature of the molten metal has decreased to a point that will admit of removing the slight covering of the slag, without the risk of extensive oxidation. From this it is conveyed in iron ladles direct to the refining pots. These are cauldrons of cast iron, three in number, capable of holding 5 tons of molten tin. The highly heated metal (previously placed in the 2½-ton cauldron) is allowed to settle for some 2 hours, after which the upper portion of the metal is ladled into two smaller cauldrons, where, the temperature being lowered, boiling by the immersion of green billets of stringy bark is resorted to. The green billets are kept immersed by an iron lever, and the steam escapes and causes a violent ebullition of the metal, thus oxidizing any impurities, as also a large percentage of tin, which is afterwards recovered by furnace treatment. The metal, after having been boiled for 4 hours, is, when cold, generally soft enough to stand the bending test—this being always taken as the standard of quality. It is then ladled into cast-iron molds, giving it the ingot shape. Each ingot so cast weighs 50 pounds, and assays 99.5 to 99.8 per cent. of metallic tin. The ingots, having been carefully weighed, are packed, placed on drays, and forwarded to Glen Innes. The load taken by each dray varies, of course, according to the state of the roads; the average load being 5 tons, drawn by eight horses."

"Since the year 1875, these works have been under the management of Mr. J. Reid, to whom I am indebted for much of the above information."

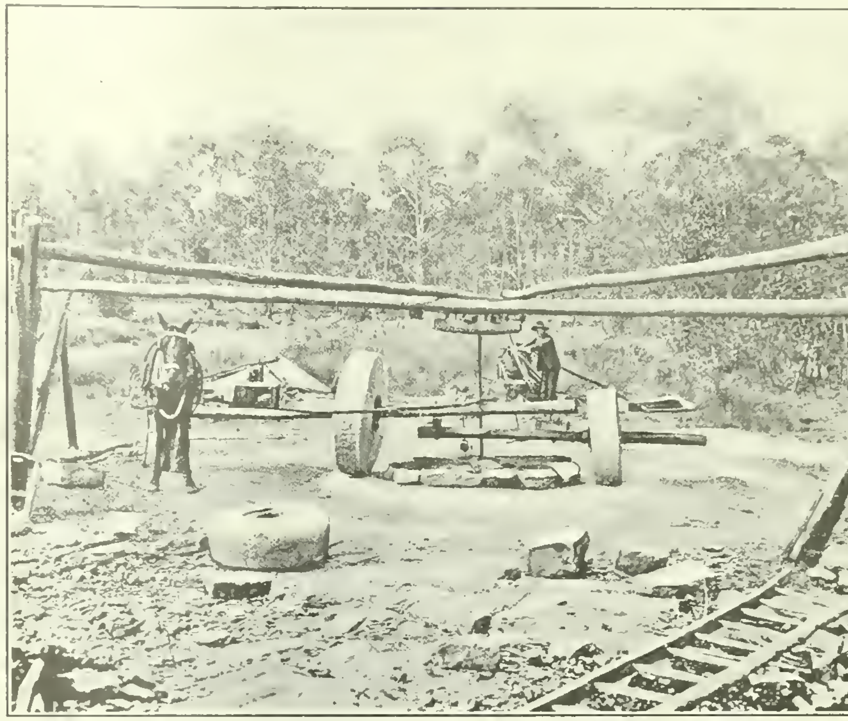

FIG. 5. HOME-MADE CHILIAN MILL

Sulphur Mines in Mexico

The great bulk of Mexican sulphur is obtained from the mines near Cerritos, in the State of San Luis Potosi, about 50 miles east of the capital. The deposit is one of the largest and richest in the world. Other Mexican deposits have been worked to some extent; but until political matters become more settled the output is likely to be irregular.

As stated in a recent U. S. Consular Report, the production of the mines is about 800 metric tons (metric ton = 2,204.6 pounds) of refined sulphur per month. The sulphur is encountered at a depth of 20 feet below the surface, and the lowest present workings are 190 feet deep. The mines are at an elevation of about 5,800 feet above sea level. The indications are that the sulphur extends downward in chimney form. The ore runs 37 to 90 per cent. pure and is smelted by the steaming process.

The mines employ some 700 men. The property is owned by the Virginia-Carolina Chemical Co., an American concern, but is under lease to German interests. The excess over home-market demands is shipped to Germany.

Churn-Drill Examination of Placers

Description of Drill and Tools, Method of Setting Up, Driving Casing, Pumping, Sampling, and Calculations

*By James E. Dick, E. M.**

Testing or prospecting placer deposits is accomplished by the use of churn drills, by sinking shafts, or by test runs which involve small operations. This paper is descriptive of the churn-drill method, as it is generally conceded to be the most desirable and, at present, the most universally used.

Churn drilling is subdivided into hand drilling and steam drilling; however, the hand drill has, as yet, not received the universal indorsement of placer miners, and for this reason, it will not be considered in this article.

All American percussive drill rigs are practically the same in principle, their only differences being in the minor features of construction. They depend for drilling on reciprocating up-and-down motion furnished by attaching the drills and rods to machines operated by steam power.

The object of drilling placer ground is, primarily, to determine its average gold value. However, there are other important features of any deposit that must be determined, which the drilling will reveal, if properly interpreted. To know these conditions is fully as important as to know the quantity of gold, since certain of them may increase operating costs to such an extent as to make the ground worthless. Or, they might make it unworkable by ordinary methods and, in extreme cases, by any method. From the data obtained by drilling, the anticipated profits may be calculated.

The following are some of the important features to be ascertained by the drill: Value of gold per cubic yard or per square foot of bed rock; distribution of gold—laterally and vertically; depth of gravel to bed rock; position of the level of ground water; nature of the bed rock; slope of the bed rock; amount of clay in the gravel; presence, size, and distribution of boulders; whether or not the gravel is frozen (in northern countries).

For ordinary ground, up to 50 feet in depth, the drilling tools (or, as they are commonly called, "the string of tools") consist of a rope socket, stem, and bit. For ground deeper than this, it is customary to insert a set of jars between the rope socket and stem.

All of these tools have tapered joints and are cylindrical, except where squared for the tool wrenches. The rope is attached to the rope socket by forcing it into the hole at one end and then driving soft iron pins through the holes on the side and through the rope. These pins are then clinched at both ends. The other end of the socket has a box into which is screwed the pin on one end of the stem.

The function of the stem is to add weight to the string of tools, and forms a connecting link between the bit and the socket. It is 4 inches in diameter and 10 feet long, but may be purchased in a greater or less length if a different weight is desired. On the lower end of the stem is a box into which the pin of the bit screws.

Fig. 1. Driving Casing

When prospecting placer ground with a traction driller three different kinds of bits are used; the placer bit, the fluted rock bit, and the Mother Hubbard bit. Each is for a different purpose. The placer bit is designed especially for placer prospecting and is used almost continually. For this reason, it is always well to have two on hand so that one may be sharpened while the other is being used. It has a thin long blade and is made to cut rather than to crush, as is the case with each of the other two types.

The rock bit is used for breaking up large rocks and boulders and for drilling into bed rock or hard pan. It is heavy and blunt and strikes a crushing blow. The Mother Hubbard bit may be used in place of the rock bit, but it is lighter and is used only at times when there is a possibility of the thin placer bit slipping off sideways and thus causing a crooked hole. This cannot take place with the Mother Hubbard bit, since it is so thick as to nearly fill up the hole.

The pulling jars are for the purpose of pulling up the casing when a hole has been completed or abandoned. The cap screws on to the top of the casing in the place of the drive head. The device works like a piston; the hammer or piston part, on its upward motion inside the casing, striking the cap a heavy blow that loosens the casing and pulls it up a little at each blow.

A vacuum sand pump is used for removing the cuttings from the hole. This is a simple suction or sludge pump, and consists of a 4-inch steel cylinder, 8 feet long, in which a piston works. The piston is drawn up rapidly, producing a vacuum inside the pump. This causes the cuttings at the bottom of the drill hole to be drawn in, and the valve is then closed by the weight of material in the pump.

A special casing is made for use in churn-drill holes, it differing from ordinary merchant pipe in that it is made with straight threads and the ends are cut off square so as to meet in the center of each coupling. It can be obtained in lengths of from 5 to 7 feet. Except in soft ground, where the drilling and driving are very rapid, the short lengths are found to be the most convenient. Casing is made in two different weights, light and extra heavy. Under ordinary conditions, the light is always used. Its thickness of 5-16 inch is sufficient to withstand the ordinary stress placed upon it. The extra heavy is used only where the conditions are the most severe and additional strength is required. It has a thickness of ½ inch. The inside diameter of the light weight is 6 inches, and the outside diameter of the extra heavy is the same as that of the light weight. This makes its inside diameter 5⅝ inches.

The drive shoe is attached to the bottom of the casing to protect it from the wear and tear of driving. It is made of wrought steel and is 7½ inches in diameter at the cutting edge. It has a shoulder against which the end of the pipe is screwed to protect the threads from the jar of driving.

The drive heads are made of solid steel and they also have shoulders against which the pipe is screwed. Each has two holes in its side and at points directly opposite one another, so that the head may be turned on or off by means of a steel bar.

*Akron, Ohio.

Setting Up.—When the location of the hole has been decided, the drilling machine is moved by its own power to this point and "set up." A proper setting up is essential from the standpoints of economy and accuracy. A poor set-up

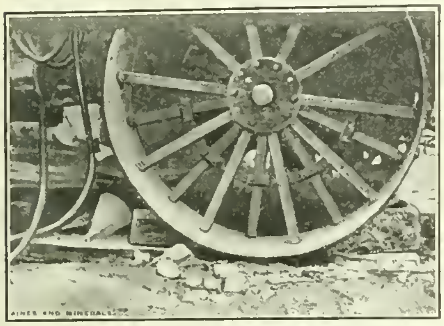

FIG. 2. REAR WHEEL CHOCKED

usually results in a crooked hole and crooked casing must often be pulled up before the hole is completed, thus necessarily incurring a considerable loss of time. If the hole is very crooked, the tools and pump will fitcher or bind, and this may result in the loss of them and the hole as well. If a deep hole is crooked, the apparent location of the hole on the surface may not be its actual location at bed rock, and this may cause a material error in estimates where a rich narrow pay streak is being blocked out. For these reasons, it is well to set up the machine properly in the first place. It will have to be done, sooner or later.

Fig. 2 shows the method used in chocking rear wheels of the driller. They rest on 4-inch planks and are chocked by wooden, wedge-shaped blocks. These blocks are driven with a sledge, after the machine has been run on to the planks, and are then nailed to the planks to prevent their slipping from the vibrations of the engine. The ground must be leveled before these planks are laid in position.

In Fig. 3 is shown the manner in which the front or derrick end of the machine is braced. A number of planks of length slightly less than the distance between the inside of the two front wheels are placed in the position shown and are built up to such a height that jack-screws may be placed between them and the bottom of the derrick ladder, and the machine raised so high that the front wheels are free to revolve. By raising one jack-screw and lowering the other, the top of the ladder is moved to the right or left until the rope hangs in the middle and over the point at which the hole is to be placed. By raising or lowering both of them simultaneously, the rope may be made to hang closer to, or farther from, the machine, as desired. The customary position is such that the machine tips slightly forward. The casing should stand at least a foot away from the front end of the wagon bed. Wedge-shaped blocks are driven between the axle and the wagon bed to take weight off the ball and socket of the axle and to steady the front wheels.

Starting Hole and Driving.—After setting up the machine, a hole is dug a couple of feet deep and the tools then let down to get the exact location of the center of the proposed drill hole. A joint of casing, with a shoe on one end and a drive head on the other, is then placed directly over this point with the shoe down, is plumbed, and the dirt filled around it.

The next operation depends somewhat upon the nature of the ground. Where there is no overburden, the method of first drilling immediately beneath the shoe is used. The casing settles as the drilling proceeds; if it does not, it is driven afterwards.

However, the usual method is to drive first. This is done in almost every kind of ground, and always when the overburden is deep. The driving blocks are

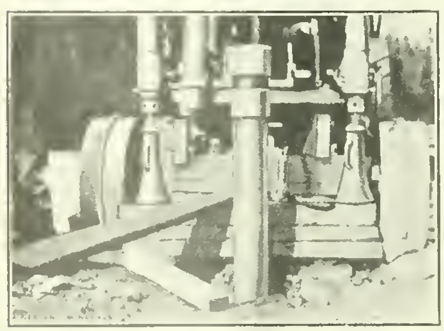

FIG. 3. BRACING FOR FRONT OF DERRICK

clamped to the lowest square on the stem and the stem lowered to such a point that, when the walking beam is up, the blocks come about 3 or 4 inches above the top of the drive head. The walking beam is thrown into gear and driving begins. The casing is steadied by two or three men on different sides, and by means of a level, the direction in which it leans, (if not plumb) can be determined. By a little pressure on the proper side, the casing may be brought into a vertical position. While this is going on, it is well to have a man on the ladder steadying the stem, as shown in Fig. 1. After the first length is down, it is usually unnecessary to steady the stem but, occasionally, the level should be applied, and if the casing is found to be out of plumb, the various methods described later may be used to straighten it.

In order to get the fastest results in driving, the length of the rope must be correct. The clamps should strike the head with a sharp blow while coming down on the spring of the rope. The clamps should rest only a fraction of a second on the head, and should immediately spring back after striking the blow. If this rule is carefully observed, the fastest driving will result. The drill rope is let out, from time to time, as the casing descends, and is kept at the proper length. Under ordinary conditions, driving is done 1 foot at a time. After the casing has been driven a foot, the core is drilled and pumped; and then the driving repeated. When the first joint has been driven down to the head, the head is removed, the threads of the casing cleaned and greased, and the second joint screwed on, and the driving continued. Since there should always be at least one length of casing ready, this means that the threads should be cleaned and greased and that a coupling should be on one end.

Drilling.—Each time, after the casing has been driven as far as desired, the driving clamps are removed, the stem and bit are lowered into the casing, and drilling is begun. In starting the drilling, or at any time, if the hole is dry, water should be poured down the casing.

The proper length of rope for drilling is about the same as for driving. The blow must be struck, as before, while the tools are taking up the spring in the rope, and the bit must rest on the bottom for the smallest fraction of a second only. This cannot be seen, of course, and the drill man must tell by the "feel" of the rope. This ability to know by the sense of feeling, whether the drill is working properly, distinguishes a good drill man from a poor one. There are certain times when a longer rope is used, as when drilling through rocks or boulders with the rock bit. In these cases, a crushing, rather than a cutting, effect is desired.

Drilling is always done inside the casing, that is, the bit never gets below the bottom of the shoe—except when clearing a way for the casing, in drilling through boulders, in exceedingly tight

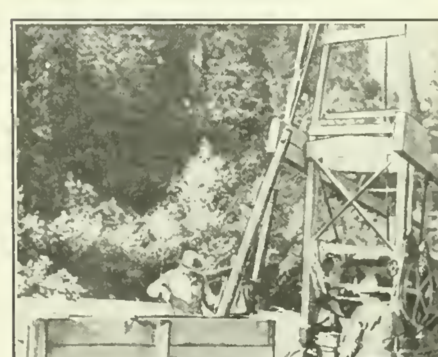

FIG. 4. DUMPING SLUDGE

or cemented gravel, or into bed rock. Drilling is more important than driving, or pumping, since, upon its proper execution, depends the accuracy and speed of the work.

Pumping.—The sand or sludge pump works on the vacuum principle. When the plunger is suddenly raised, the vacuum formed within the pump barrel draws the cuttings in through the valve at the bottom. It naturally follows that the greater the speed at which the plunger is raised, the greater will be the vacuum produced. It usually requires three or four pumpings to get all the material out when the pump is operated slowly, so the object of bringing up the plunger rapidly is apparent. Therefore, when the pump is lowered and reaches the bottom, 6 to 8 feet more of rope is let out and allowed to hang loosely over the top of the casing. The engine is speeded up and the pump reel thrown into gear. The taking up of this slack rope gives the engine time to get under full speed, and when the plunger comes up in the pump it does so with considerable speed.

It is customary to raise the pump a few feet from the bottom of the hole and to then lower it, repeating this operation two or three times before pulling up and dumping. In this way, the pump will be full each time that it is brought to the surface.

The contents of the pump are dumped into a box, the valve is washed out by water thrown into it, and the pumping operation is continued, or the pump is hung up, depending upon the conditions of the work.

Dumping.—There are various methods of handling the sample, after it is recovered from the hole. The usual method is to empty the pump sludge directly into a box. This box is from 10 to 12 feet long, made of 12-inch smooth planks, open at the top and with a gate at one end. The joints should be calked. The box is set on a couple of saw horses conveniently close for dumping from the pump, and with the gate end away from the machine. As shown in Fig. 4, the box should be set to slope slightly toward the gate end.

Rocking, Panning, and Cleaning Up. From the dump box, the material passes to the rocker, which may be either directly under the gate end of the dump box or to one side. If placed to one side, the material must be moved to it with a shovel or a pan. A pan may be so placed under the gate end of the box that the rocked material will drain into it while the water is allowed to drain over its side. If the rocker is placed directly under the end of the box, it must necessarily be built on a low, broad plan.

The rocker should be constructed with two trays, each having two, and preferably three, pockets which are best made by using a piece of canvas on the frame and by lapping it back. It is always advisable to use amalgamating plates at the ends of the rockers.

The concentrate from each foot of pump sludge is washed from the trays into a pan, but is screened to approximately ⅛-inch size before panning. The screening cuts down the work of the panner, enabling him to keep ahead of the work during fast drilling, and to use his spare time assisting the helper. The screening is best done under water in a tub and the screened material should be carefully examined before discarding, especially when it is obtained near, or on, bed rock.

All rejected stuff, both from the rocker and the pan, should be preserved and put through a small sluice at the completion of each hole. All the black sand recovered is amalgamated by any convenient thorough method, and a sample taken for assay. These sands sometimes run very high in gold and where this is true they are saved and shipped, or are worked over by other methods.

The gold resulting from the panning is dried, annealed, weighed, placed in a phial, labeled, and filed for future reference.

Calculations for Single Hole.—The inside diameter of the casing is 5⅞ inches. The outside diameter is 6½ inches. Some engineers hold that it is the displacement of the pipe rather than its cubical content that ought to be used in calculating. Others believe vice versa. However, when the cubical content is taken, it is found to be much too small and this gives a calculated value that is too high. The cubic content, per foot of 6½-inch pipe, is .23 cubic foot. To make allowance for the observed discrepancies, .25 to .27 cubic foot is used. The latter, .27, is called Radford's factor, it having been determined by a mining engineer of wide experience in this kind of work and who compared results from drill holes and shafts.

This factor is generally accepted as the most convenient and accurate. With .27 as a factor, 100 cubic feet of core make 1 cubic yard, so that 100 divided by the length of the core and multiplied by the value, in cents, of gold recovered from the hole, gives the value of the gravel per cubic yard. As an example take a hole 29½ feet deep, yielding 8.79 cents in gold.

$$\frac{100\times 8.79}{29.5} = 29.8 \text{ cents per cubic yard}$$

A system of factors is sometimes used by samplers when accuracy is desired. Different factors are selected for varying conditions of ground; and when passing from one stratum to another of a different texture the factor is changed. The following are the factors: For compact gravel, .010; for medium gravel, .011; for loose gravel, .012; for loose gravel and sand, much water, .013.

To calculate with the above factors, multiply feet drilled by the factor selected, and divide the value (in cents) of the gold derived from the sample by the result. Thus for compact gravel:

$$\frac{8.79}{29.5\times .01} = 29.4 \text{ cents per cubic yard}$$

By the use of a different factor, as .012, for a layer of loose gravel, the result is arrived at:

$$\frac{8.79}{29.5\times .012} = 24.6 \text{ cents per cubic yard}$$

In other words, as the compactness of the gravel decreases, the amount of the sample or core increases but the value decreases.

Although this method has much merit, and seems to be used successfully in the California dredging areas where it originated, conditions in other districts are so varied that a more universally applicable method is described later, under the heading of "Records." By this method, simple calculation is used, but the actual amount of sample is used rather than the depth of the casing, as in the foregoing cases and therefore the results are usually considered to be of greater accuracy.

Calculations for an Area.—To estimate the value of an entire area under examination, the value per cubic yard, as found above at each hole, is multiplied by the depth of the hole in feet. The sum of products from all the holes, in "foot cents", is divided by the sum of the depths of all the holes, in feet. This will give a unit value, in cents per cubic yard, relative to the whole mass.

Sometimes it is possible to segregate certain desirable sections of the property. Again it may be possible to cut out certain portions at the ends or sides, so that the remainder will be of sufficient area and value to warrant operations, whereas the total value shown might not be attractive. This applies especially to deposits suited to hydraulic treatment and where only the pay streak is worked. An instance is known wherein a portion of a property under examination was proved to be apparently a dredging proposition, but the necessity of securing this payable portion only, made it undesirable as a dredging investment.

In estimating the value of the gravel in a dredging area, it is necessary to consider only a certain percentage of the calculated value. The reason for this is that all the gold is not saved in actual operations. In the case of dredging, some of the gold never even reaches the gold-saving tables or sluices. Hence it is seen that the percentage adopted in calculations must depend upon the methods of handling and upon the nature of the gold. With fine, flaky gold, the loss in the sluices will be much higher than with the coarse.

(To be continued)

Barytes in Missouri

Description of the Mineral and the Conditions Under Which It Is Found—Methods of Mining and Preparing for Market

By Lucius L. Wittich

BARIUM was discovered by Sir Humphrey Davy when testing the mineral barite, which is found as gangue in the lead mines of Lancashire, England.

Barium is a pale-yellowish silvery metal; malleable, very hard to fuse, and having a specific gravity of about 4. Merck, of New York, quotes the metal obtained by electrolysis, probably from smelting some of the barium salts, such as the chloride. Barium, one of the three alkaline earth metals, decomposes water rapidly at common temperatures and oxidizes in the air readily. Its principal value is for the preparation of barium chemicals.

FIG. 1. BARITE READY TO SHIP

The ores of barium are barite or barium sulphate, $BaSO_4$, also called "heavy spar"; and witherite, or barium carbonate, $BaCO_3$.

Barytes, or barite, the chief ore is insoluble in water and most acids, and consequently has survived disintegration, while the original minerals and rocks with which it was associated have weathered and dissolved. Since it is found in clay and sandy deposits, its origin was doubtful until it was afterwards found associated with the lead ore, galena, in veins. Frequently crystals of galena are found encased in barite and not infrequently some blende. The mineral may be known by the following peculiarities: Color, white, gray, green, blue, or pink; when white it looks like calcite; it may be transparent or colorless; its specific gravity (4.5) will distinguish it from calcite and gypsum. Hardness, 3½; cleavage, basal and perfect. It colors the flame green, while strontium carbonate, or celestite, colors the flame red. Barite crystallizes in the rhombic system in diversified forms.

In Missouri barite occurs in the northwestern part of the Bonne Terre sheet and in the area which is underlain with the Potosi formation. This formation is a member of the Upper Cambrian. It is in or just beneath the residual red clay that the barite is found. Beneath the red clay, speaking generally for the entire barite district, residual material, consisting of drusy quartz, fragments of dense chert, and masses of barite occur. Both hematite and galena sometimes are associated with the barite. Where hematite is found it usually occurs as a thin layer, coating the drusy quartz. When lead is found it usually occurs in cubes disseminated through the barite. Where it occurs on the surface of the barite masses it is oxidized and usually covered with a thin coating of lead carbonate. When barite is found in conjunction with the calcite of zinc-bearing ground, separation is almost impossible unless expensive methods are adopted, and in such cases the barite is looked upon as a detriment. Instances have been reported where the presence of barite in zinc mines made milling impossible and operations were suspended through necessity.

In some portions of southern Missouri the zinc mining industry is materially handicapped through the presence of the mineral; and when an effectual method of separation is found, the zinc production from about ten counties may be materially increased. In the southwestern portion of the state, operators have been fortunate in finding the zinc and lead ores free from the troublesome barite, but in one instance at least, that of the Blue Jay mine on the Mexico-Joplin land, at Joplin, a big producer was short lived because an enormous pocket of the mineral was encountered and its association with the blende made it impossible to clean the latter.

Sulphate of barium ($BaSO_4$) occurs in several portions of the United States, but the principal district from which a commercial product is obtained lies 65 to 70 miles south, and slightly west, of St. Louis. The chief towns through which barite is handled are Mineral Point and Potosi, both in Washington County, Missouri. The output from Washington County represents more than 95 per cent. of the production of the United States; in fact, statistics show that virtually all of the yearly production of the United States, 35,000 to 40,000 short tons, comes from the district mentioned. The largest companies are the Potosi Lead, Barytes and Mercantile Co., of Potosi, represented by Mr. A. O. Nichols, to whom the writer is indebted for much of the information contained in this article; and the Point Milling and Mfg. Co., of Mineral Point.

From the lands of the Potosi company the monthly output of barite is about 1,000 tons; from the Point company about 200 tons. From other lands the monthly output ranges down to less than 10 tons. The value of the crude barite, as sold by the miner to the land-owning company, is from $2 to $3 a ton, depending on the distance from the railroad. The land-owning company pays the expense of hauling. The barite, in turn, is sold to grinding companies for approximately $4.50 a ton, meaning that the miner pays to the land-owning company about 40 per cent. royalty for the privilege of gouging out the product. A hard-working miner can clear $2 to $3 a day, while members of his family, his wife and children, can all aid in the work, and through their assistance the income to a single family sometimes reaches $5, or even more, depending largely on the size of the family and the diligence of the toilers.

There are about 50 localities in the Potosi-Mineral Point district where barite has been mined or is being mined. In a few of these galena occurs with the barite. Separation is easy by hand cobbing, one mine known as the Star shaft, in the Potosi field, having entered an

FIG. 2. WINDLASS AND ROCKER

unexpected pocket of galena which produced $10,000 worth of ore in a few weeks' time. The hope of encountering lead in large quantities is one of the never-fading dreams of the barite gougers, who toil day after day at their tedious work ever in the belief that sometime they may encounter the deposit that will make them independent.

The mining methods are crude in the extreme; the writer has visited many of the gouges on the 25,000 acres owned by the Potosi company and at no place did he find a mine greater than 30 feet in depth, save in a few isolated cases where greater depth had been attained in sinking into pockets of galena. Fig. 1 shows about a ton of cleaned barite, termed "tiff" by the gougers, while Fig. 2 gives an idea of the crude hand windlass employed. Often the windlass is even more crude than that shown, being merely a piece of tree trunk passed across supports made by placing cross sticks at either side of the shaft.

The visitor is impressed forcibly with the fact that the rule of the survival of the fittest is the law of the land where barite is mined. No leases of any specific size are given to the miners. They merely make application to "go to work," and, obtaining permission, proceed to mine whenever and wherever they please.

"Have you no system of blocking out claims or leases?" the writer asked of Joseph Deguna, one of the "old timers," who had gouged here and there in every direction from Potosi. At the time he and his wife and one son were busy at a "tiff" mine on a pretty hillside to the south of Potosi. Not 10 feet away, Anthony Declue and son, William Alonzo Declue, were producing "tiff" from a shallow gouge.

In broken English (most of the miners are of French descent) Mr. Deguna replied that no such system had ever been devised.

"If I get a good run of 'tiff'," he explained, "I can set up some little stakes in the ground where I think the boundaries of the deposit may be. There isn't any law here saying that my neighbor can't sink a hole into the heart of my 'tiff' if he wants to, but"—Deguna grinned as he clenched his fist and threw the muscles of his arm into play—"I don't think he will want to."

"But if you were a smaller man who couldn't defend himself, then the big, husky gouger could come along and steal your claim, is that it?" Deguna was asked.

"Yes," was the thoughtful reply, after a pause, "he might; but you don't hear of much of that. In fact, it is so easy to find the 'tiff' that when one of us gets a good thing we look upon it as a matter of course. We don't have to gouge very long before finding pay dirt."

Storekeepers in Potosi and other small towns of the eastern Missouri barite belt accept the "tiff" as currency much the same as merchants in a gold mining camp might take gold dust. It is not uncommon to see a barite miner trudging into town with a canvas sack of mineral which he trades for a pound or two of tobacco or possibly a sack of flour.

No fixed rules regulate the size of shafts that are sunk into the barite masses. They are almost invariably round and no effort is made at timbering. After the shaft has penetrated the barite horizon from 3 to 4 feet, the gouger digs out in every direction from the circumference

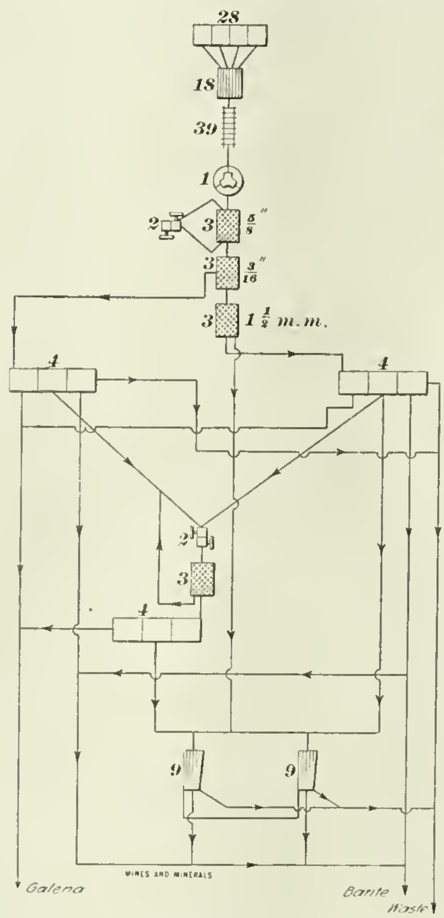

Fig. 3
1, Crusher; 2, Rolls; 3, Trommel; 4, Jigs; 9, Concentrating Tables; 14, Shaking Screen; 28, Ore Bin; 39, Picking Belt

of the shaft, thus leaving a great, rounded room into which the circular opening descends. The shafts vary in circumference from 3½ to 5 feet. The gouging process continues only so long as there is little danger from caving ground. It is considered wiser to abandon a shaft and sink a new one a few yards distant rather than carry the drifts too far and stand the risk of caving ground.

Sometimes a solitary miner will conduct all his own operations. He will dig his own shaft, tossing the dirt out with a shovel and when the shaft becomes too deep for this he will construct a flimsy ladder on which to descend and ascend, and will install a crude windlass. Going into the ground he will fill his bucket, then climb out by the ladder and hoist the dirt. Sometimes the product is almost pure barites; again it will be thickly coated with a gummy red clay, which must be dried to a crisp by the sun before it can be removed. No explosives are used in mining the barite, and because of the shallow workings no pumps are employed, although, at times, following heavy rains, the shallow gouges will become filled with water.

The clay-laden barite, after being taken from the ground, is scattered in thin layers over board platforms and thoroughly dried, after which the stuff is placed in shakers, also called cradles and rockers, Fig. 2, the average capacity of which is 150 pounds each. A shaker is built along no stereotyped lines; it may consist of a barrel, punched thoroughly with 1-inch holes, and so hung that it can be jerked backward and forward; or it may consist of a box with a metal bottom, in which holes have been cut, and which has been placed on rockers. Ten minutes to half an hour is required to shake the dried clay loose from the pieces of barite, which vary in size, some being as small as grains of rice while others may be as large as a man's head. Heaped into large, white piles, the barite is then ready to be loaded into wagons and transported to the nearest railroad, from which it is shipped to the grinding plants, when sufficient has accumulated.

At the property of the Wrisberg Mining and Milling Co., in Franklin County, Missouri, mill treatment of barite is being tried, a new plant having just been completed by the American Concentrator Co., a flow sheet of which is shown in Fig. 3.

At this property the chief mineral product is galena, *PbS*, the specific gravity of which is 7.4, compared to 4.5 for barite. Where this combination is encountered it is self-evident that the galena recovery must be made first.

The ore occurs in fissure veins and galena predominates. There is enough barite, however, to make the marketing of this product profitable; enough so at least to pay for the extra cost of milling. After the ore leaves the shaking grizzly, it is hand sorted before passing to the crusher. Oversize from the ⅝-inch screen goes back to the rolls; the undersize goes to the $\frac{3}{16}$-inch screen, the oversize in turn passing to a 30" × 42" jig while the undersize goes to 1½-millimeter screen; the oversize goes to a 24" × 36" jig while the undersize goes to tables. Middlings from both jigs mentioned go to 24-inch rolls, thence to ⅛-inch screen, the oversize returning to rolls and the undersize going to the 24" × 36" jig.

Where barite is found with zinc blende, the specific gravity of which is 3.9-4.1, the separation is, however, not so simple.

The treatment of blende carrying barite along elaborate lines has been tried at the Tahoma mine, in Benton County, Missouri, and has proved satisfactory, although the same principle adopted at another property has, strangely enough, failed signally.

At the Tahoma mine, a mill of 400 tons daily capacity is operated. Here the barite is separated from blende by a process requiring intense heat, the separator being comprised of a tube, 12 feet long by 8 inches in diameter, set in an oil-burning brick furnace. This tube is inclined slightly toward the end from which the discharge comes. A series of screens is at the discharge end, and a loose ring hopper is installed at the feed end. Although still finer screens may be utilized, the plan of using 20-, 30-, and 40-mesh screens, arranged concentrically, with the coarser one on the inside, has proven satisfactory. The barite will readily pass the 40-mesh screen, although little of the blende will do so. Before being dumped into the tube, which revolves slowly, the concentrate is dried partly. As the concentrate works down through the tube, the barite, coming in contact with the red-hot metal, explodes and this causes it to become decrepitated. Passing from the tube to the screens, very little of the blende will go through a 40-mesh screen, although the barite, now almost as fine as powder, would pass through a 200-mesh screen. From the 20- and 30-mesh screens the oversize goes to the bins; from the third screen an oversize middling product is procured. The undersize from the 40-mesh screen goes to a concrete vat where it passes over a 200-mesh screen, the blende being recovered as an oversize.

The bulk of the barite produced from the Washington County, Missouri, district, is reduced to a fine powder and utilized as an adulterant in white-lead paints. It is used also as a source of barium products.

At the grinding plants the barite is first run through crushers and rolls and reduced to a fine sand, then treated to a sulphuric-acid bath to remove all foreign coloring matter, after which it goes onto the 200-mesh screens for final separation, the undersize passing to the grinders which reduce it to a powder, ready for the acid bath and then the market, while the oversize returns to the rolls.

The Pelton Waterwheel

Principles of Construction of the Impulse Waterwheel—Methods of Calculating the Power and Speed

Written for Mines and Minerals

THE Pelton waterwheel, shown in Fig. 1, is an impulse wheel that is used for very high heads and comparatively small volumes of water. The jet from the nozzle A, which impinges on the raised center a of the cups c, is deflected to both sides, and finally leaves the cups in a direction tangent to their outer edges. In this way, the direction of the motion of the jet is changed nearly 180 degrees; and when the velocity of the cup is equal to one-half the velocity of the jet, the theoretical efficiency of the wheel is 100 per cent. Experiments have shown that the actual efficiency is sometimes nearly 90 per cent and that the best efficiency is obtained when the number of revolutions is such that the actual velocity of the cups corresponds nearly to the theoretical velocity.

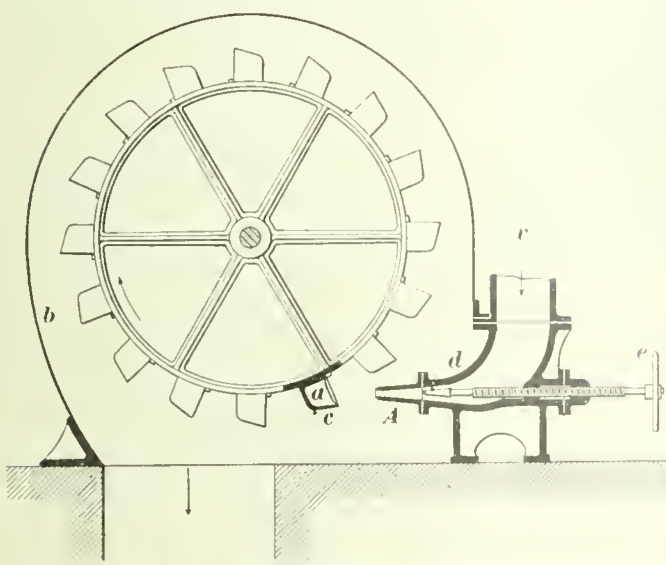

FIG. 1

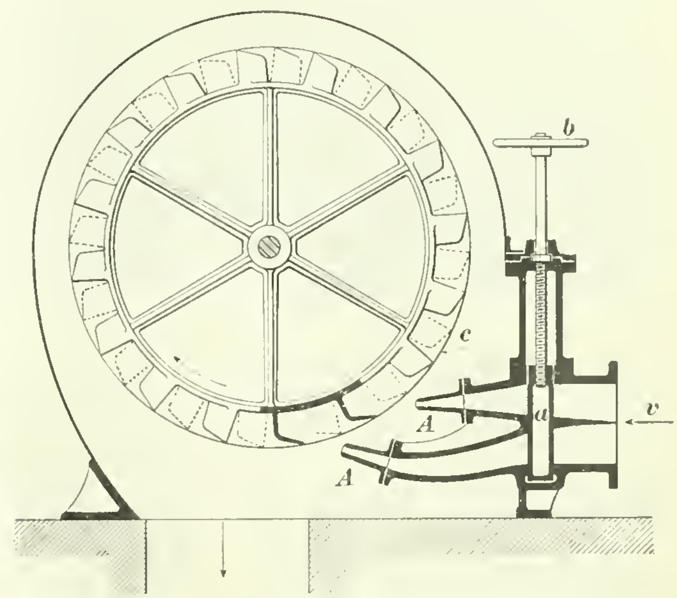

FIG. 3

The loss of efficiency is due to the friction of the water in the cups and the energy that is lost in the absolute velocity the water has when it leaves them.

Fig. 2 shows two sections of the cups and the common method of fastening them to the rim of a cast-iron wheel. The inclination of the edge a is such that the water as it leaves the cup flows clear off the wheel and offers no resistance to its motion. The faces of the cups are also inclined to the radius of the wheel, as shown, in order to give the water a slight tendency to flow from the center of the wheel as it reacts from the cups. The outer edges of the cups are made sharp, so as to offer as little resistance to the water as possible, and the inside surface is sometimes finished for the purpose of reducing the loss by friction.

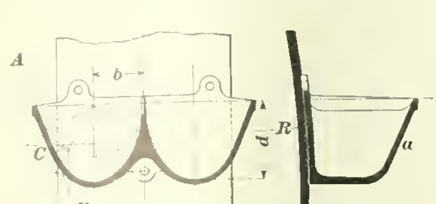

FIG. 2

The wheel must be provided with a cover or casing b, Fig. 1, to prevent spattering of the water.

The water for impulse wheels is discharged through nozzles, and in order to secure a high efficiency, it is necessary that the pressure head in the pipe be converted into velocity in the issuing jet with as little loss as possible. The ordinary method of reducing the flow of water by means of a valve in the pipe necessarily causes extra resistances and reduces the head. Fig. 1 shows a nozzle applied to a Pelton wheel, in which the flow of water is regulated by a conical plug *d* operated by the hand wheel *e*. This has the practical effect of varying the size of the nozzle and, hence, the quantity of water without a corresponding change in the velocity.

The power of a given size of impulse wheel may be increased by increasing the number of nozzles. This increases the amount of water used and gives the same efficiency for all the nozzles that would be obtained if only one were used. Fig. 3 shows a double nozzle *A, A* applied to a Leffel cascade impulse wheel, in which a gate valve *a*, operated by the hand wheel *b*, opens the orifices to the nozzle successively. By this means, as many of the nozzles may be opened as are required to furnish the necessary power and the water will be used without loss of head.

Another method, which is used when the supply of water is variable, is to have a number of nozzles of different sizes to correspond with the supply of water. When the water supply is small, a small nozzle can be used, and in this way the greatest efficiency can be obtained; and when the supply is increased, a larger nozzle enables the full power to be obtained without loss.

The circumferential velocity of an impulse wheel, i. e., the actual velocity of the cups, depends on the head, and hence the velocity of the jet. With a properly designed nozzle, the velocity of the jet will be nearly that due to the pressure head in the end of the pipe, and the best efficiency is obtained when the velocity of the cups is about one-half the velocity of the jet.

The number of revolutions, with a given velocity at the circumference, varies inversely as the diameter of the wheel; it is, therefore, possible to make the number of revolutions correspond to the speed of the machinery to be driven within certain limits. In accordance with this principle, wheels are often designed so as to run at a speed that enables them to be connected directly to the shafts of dynamos, centrifugal pumps, or similar machinery, without the use of belts or gearing. The Pelton wheels are seldom used for heads of less than 50 feet, but are applicable to falls of any greater height. A number of wheels are in use under heads of more than 2,000 feet.

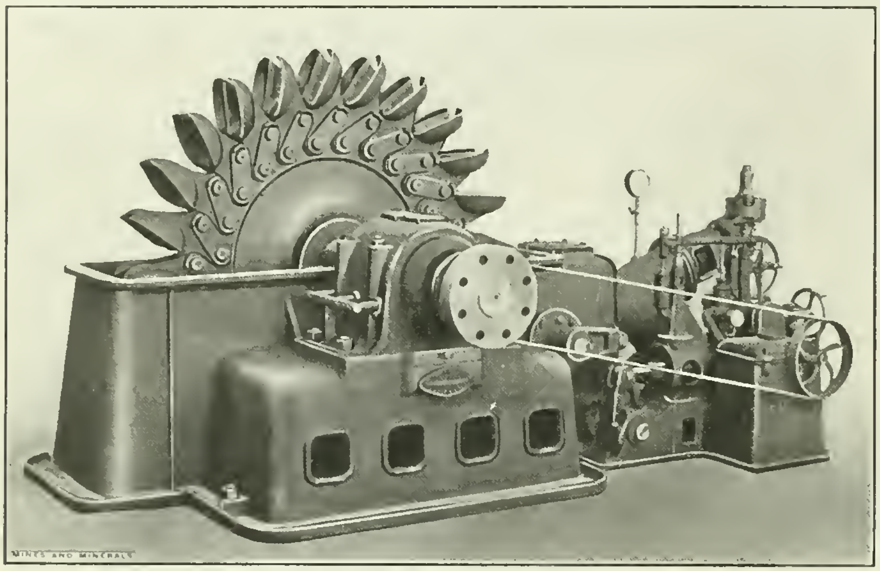

Fig. 4. Pelton Wheel for 2,395-Foot Head

Example.—What should be the diameter of an impulse wheel that is to be directly connected to the shaft of a dynamo, if the pressure head is 275 feet? The dynamo is required to make 850 revolutions per minute and the coefficient of velocity of the jet is .98.

Solution.—The velocity of the jet is $.98 \times 8.02\sqrt{275} = 130.34$ feet per second. The circumferential velocity of the wheel is, therefore, $130.34 \div 2 = 65.17$ feet per second, and the diameter required for 850 revolutions per minute is

$$d = \frac{65.17 \times 60}{850 \times 3.1416} = 1.464 \text{ feet, say 18 inches.}$$

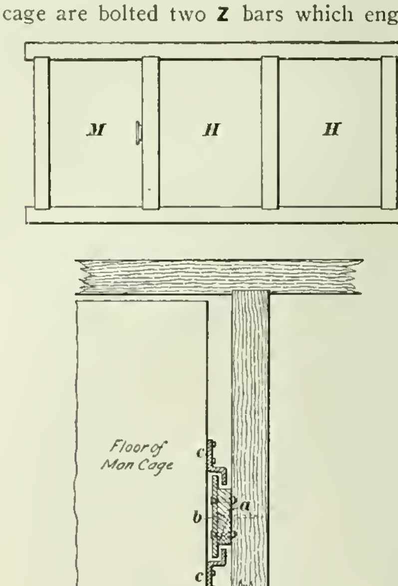
Ans.

In Fig. 4 is shown a Pelton waterwheel designed for operating under a head of 2,395 feet. This waterwheel was constructed at Geneva, Switzerland, to drive electric generators, and its speed is governed by the regulator shown to the rear of the wheel. This regulator is operated from the main shaft of the waterwheel by belt transmission, and by means of suitable mechanism controls the impinging stream of water striking the Pelton buckets. By this means the speed of the wheel and generators is held at 500 revolutions per minute, even under considerable variations of load. This Pelton wheel develops 5,500 horsepower and is in service at the hydro-electric plant, Viege Be Saas at Valais, in Switzerland. The special construction of the bucket on this steel impact waterwheel is of interest because of the cutting away of a portion of the bucket in order to increase the efficiency and satisfactory operation at this high head and consequent speed. This bucket construction was designed by a Swiss engineer.

In the West two mining companies were situated so as to use the same stream to generate power. In one instance the lower company brought suit to restrain the upper company from discharging mill tailing into the stream as it cut the buckets.

Single Shaft Guide

The accompanying sketch of a shaft guide, used at one of the mines of the Amalgamated Copper Co., Butte, Mont., is applicable where space does not permit of the use of the ordinary end, two-guide arrangement. It consists of a plank spiked to the shaft timbers to which is bolted a piece of heavy sheet iron. These form the guide which, of course, is continuous from the top to the bottom of the shaft. To the floor of the cage are bolted two **Z** bars which engage



Shaft Guide

the guide as shown. The arrangement is best adapted to slow-hoisting speeds, as in a manway, and gives excellent satisfaction.

Sand Filling on the Rand

Methods in Use on the Rand for Flushing Sand From Stamp Mills and Cyanide Works Into Mines

By Edgar Pam, A. R. S. M.

The following article, abstracted from the Journal of the Chemical, Metallurgical, and Mining Society of South Africa, is of considerable interest at this time to inhabitants in Northeastern Pennsylvania. It will be remembered that Engineers William Griffiths and Eli Conner suggested the use of sand to prevent mine caves. The paper is a good one and contains information on flushing the sand from stamp mills and from cyanide works into mines, and no doubt will be of interest to all metal miners where timber is expensive and conditions do not favor the caving system of mining. A second article on the same subject will cover the discussion on Mr. Pam's paper and will be found equally as important and interesting as the original.—Editor.

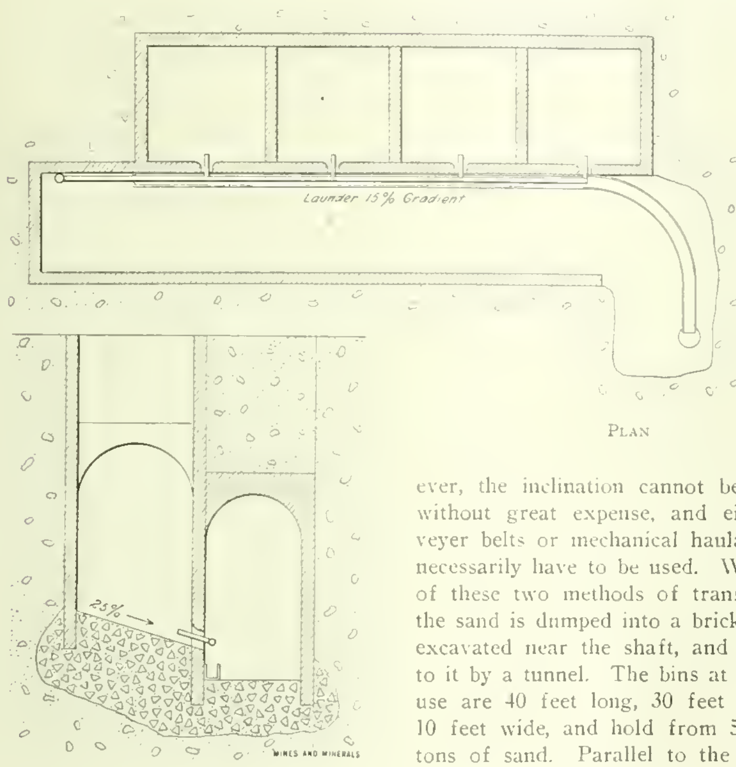


Fig. 1. Plan and End Elevation of Bins

Sand filling has been carried on for over a year at the Robinson Gold Mining Co.'s mine, but only on a small scale; and before commencing to lower large tonnages it was decided to secure the services of an engineer who had previous experience in this work. Mr. Waller, of Kaltowitz, Silesia, accepted the appointment, and the following is an account of the system recommended by him modified to suit local conditions:

The method of transporting the sand from the dump to the shaft is purely a mechanical question. Where there is a fall of 10 per cent. or more from the foot of the dump to the shaft, or where the ground can be readily excavated to obtain this fall, hydraulic sluicing is undoubtedly the best. More usually, however, the inclination cannot be obtained without great expense, and either conveyer belts or mechanical haulage would necessarily have to be used. With either of these two methods of transportation, the sand is dumped into a brick-lined bin excavated near the shaft, and connected to it by a tunnel. The bins at present in use are 40 feet long, 30 feet deep, and 10 feet wide, and hold from 500 to 600 tons of sand. Parallel to the long axis of the bin, and divided from it by a brick wall, is a tunnel 6 feet wide and 8 feet high. The bottom of the bin is built with a 25-per-cent. fall toward the tunnel, as shown in Fig. 1. Through the dividing wall are four openings 10 inches high and 6 inches broad into which water is sprayed, as shown in the plan. A mixture of sand and water comes out through the openings and falls into a launder which has a grade of from 12½ to 15 per cent. The sluice water, which is supplied under a pressure of 50 pounds per square inch, is forced through four one-half-inch nozzles and washes 200 tons of sand per hour down the mine. The mixture running into the launder is, by volume, equal parts of sand and water, or by weight, 60 parts of sand and 40 of water.

In addition to the four nozzles above mentioned there is one more which leads clean water direct into the launder. This is used for washing out the pipes before and after use and is an essential precaution against the pipes choking. The mixture of sand and water flows to the shaft and falls through a hopper into a pipe from 5 inches to 6 inches in diameter. Pipes without lining have been used so far, but owing to the combined action of sand and water are not expected to last long. Some special pipes have been ordered with 5-16-inch walls. These will be 7 inches in diameter and lined with Jarrah wood 1 inch thick. The lining will be inserted in lengths of about 8 inches, so that should even a section of the lining get loose it will not stick in the bends and cause a choke but go down the pipe and out with the sand. The pipes have loose flanges and are of such lengths that they can be turned or replaced easily. They will be turned at frequent intervals in order to equalize wear.

In inclined shafts and stopes the pipes may be replaced by launders, which are cheaper and less liable to be choked.

When debating the route of the pipe line, there was at first considerable discussion as to whether horizontal lengths could be used. The only objection to them was that a greater quantity of water must be used for washing out the line. The length of a horizontal pipe line must bear some ratio to the pressure in the column pipe. Mr. Waller says that the custom in Silesia is to allow 300 feet of horizontal pipes for every 100 feet of vertical head. For the installation so far planned it has not been necessary to approach this allowance, but 600 feet of horizontal pipes are working well at the 2,000-foot level. So far we have had no experience with up grades, but they are undoubtedly possible, although it is a question if they will prove expedient. The only valves on the pipe line are for diverting the stream of filling from one branch pipe to another, and one valve is always opened before the other is closed.

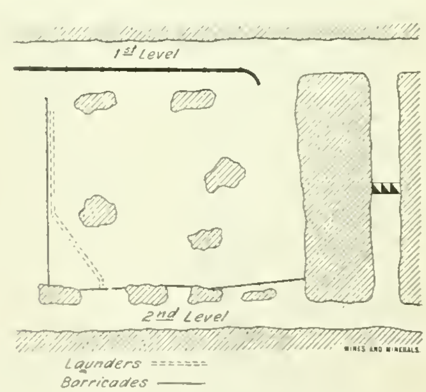

Fig. 2. Stope Ready for Filling

The flow of sand can only be started or stopped from the surface, and it is therefore necessary to install a reliable system of telephones so that instructions can be given from below.

To prepare a stope for filling, all box holes must be closed above the pillars by means of uprights well hitched and lagged with 1½-inch planks. The planks are of course nailed on from inside the stope and must be fitted closely on the pillars, foot-wall, and hanging wall. Any crevices are filled with grass, which is rammed in tight and kept in place by a piece of wood. Where possible the sand rests against a shaft or boundary pillar on one side, but the other is usually built similarly to the box holes, the uprights being 3 to 4 feet apart.

The chief point to keep in mind in filling a stope is to allow as little pressure as possible on the barricades, and for this reason the area to be filled should be as long as possible and the water should have a free flow. The outflow is usually through openings in the side barricade. These are 12 inches wide and the full height of the stope. As the sand rises, the openings are closed from the bottom so that only the water lying on the sand can get away. These openings are so placed on the barricade that water is flowing out at the bottom of one before the lower one is closed. This outflow is always as far as possible from the inflow, so that as much sand as possible settles along the bottom of the stope, but even when this length is considerable, even up to 500 feet, it is necessary to clear the overflow water by a series of weirs and settling sumps before it is allowed to reach the mine pump.

Filling is at present proceeding in old stopes only, but it is intended as soon as possible to fill directly behind the present stopes. It is possible that this method of packing may induce the miners to alter their present method of stoping, starting off from the drive. In this case a stope would be started by cutting away 50 or 60 feet up the dip, building a timber barricade, filling the area stoped with sand, laying rails on the sand, and then stopping up again and so on to the top of the drive.

Sand filling would be equally applicable to our present method of stoping, but the scheme mentioned would have the advantage that drive pillars would be saved and shoveling and tramming cheapened. However this is a matter for the future, and only experience will prove whether it is practicable or not. At present only sand from old dumps which contain no trace of cyanide is being sent into the mine. As an additional safeguard recommended by Doctor Moir the dumps are sampled ahead of that work, the idea being that by the time the sands have become acid all traces of cyanide will have disappeared. The chemical treatment at present is the addition of lime to save the pipes and pumps, but it is hoped that in the near future some process will enable the use of current sands with absolute safety.

The experiments made in concentration and gold recovery have not yet given results worth discussing, but it is hoped to pay some of the expenses by this means. Owing to the short time the work has been in progress no details as to the probable cost of the process are available, but the following are some of the advantages resulting from sand filling, even if it proves more expensive than the present method of supporting the excavation:

1. Sand filling greatly increases safety of the miners.

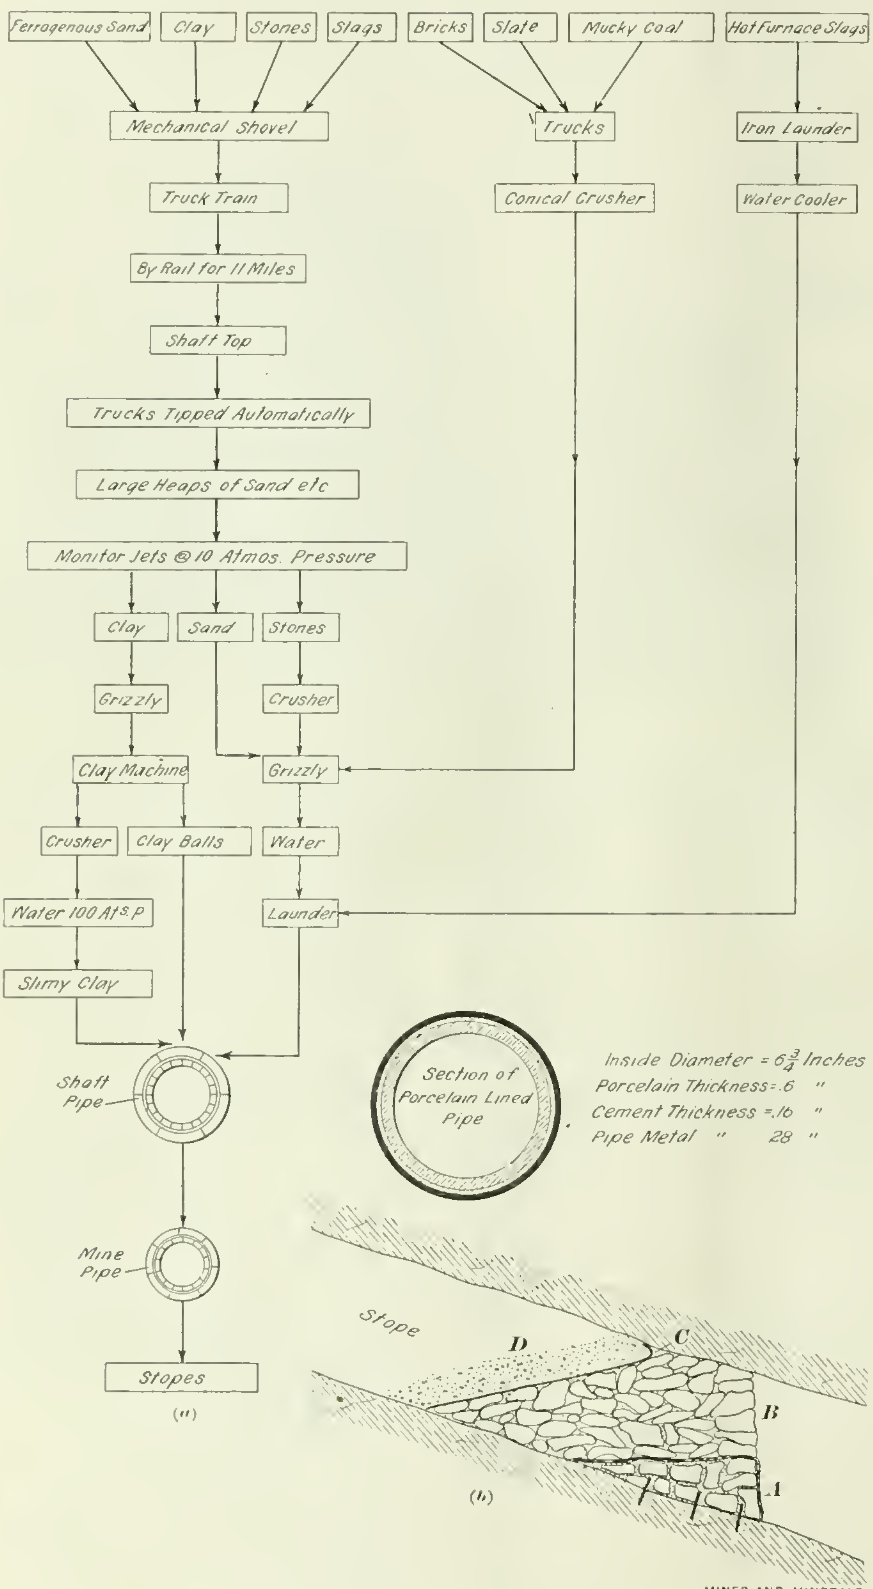

Fig. 3. Flow Sheet and Section of Barricade

2. It increases the security of shafts and mine workings, which are among the biggest assets in South Africa.

3. It improves ventilation underground; for since practically the same amount of air will pass through a smaller area, its velocity must increase. The air can be guided into the places where men are working and will not be dissipated in worked-out areas.

4. Increase of ore reserves, as fewer or no pillars will be left, and this feature becomes an asset to the country and to the shareholders.

5. Reclaiming old pillars and footwalls, which is impossible without a sound method of supporting the hanging walls.

6. Removal of dumps from the surface, thus diminishing the dust nuisance, improving the aspect of the town, and setting free large areas of ground for useful purposes.

7. Possibility of mining at great depths. When getting near the maximum crushing strength of quartzite, supporting ground by pillars, waste packs, and sticks is almost absurd except as a temporary measure.

DISCUSSION

Charles B. Saner said that at the Village Deep mine they have been running sand underground and at present can handle 1,200 tons per day. The pipe line goes down an old shaft through old stopes and drives, down the main incline, and along the top level. The pipe line has numerous twists, bends, and curves, yet the sand flows well to its destination. The secret is to first flow clear water through the pipe for 3 or 4 minutes before sending down sand, and always run clear water through the pipe for a similar period after shutting off the sand, otherwise the sand soon settles in any horizontal part of the pipe line and chokes it and so causes trouble.

Another essential for successful and smooth work is to have at least two separate places to fill into, so as to have continuous running. In old stopes the great trouble was found in making the pillars over the drives water and sand tight, as they have taken weight; and it will probably be found quicker and cheaper to go up the stope 15 or 20 feet and erect a barricade along the stope, continuously, ignoring all pillars. The drive pillars can be taken away and if practicable the barricade could be taken down and used again, the sand either remaining solid and vertical, or taking the natural angle of repose without falling into the drive, this of course depending upon the dip of the stope. The sand after 24 hours does not become solid, for as soon as water is put on again it becomes saturated and is like a quicksand or jelly. It is surprising the quantity of hay used to fill up old cracks in the foot and hanging walls, thus making one more instance of the mining industry materially benefiting the farmers.

It is believed that silting will benefit mining in several ways in the near future when it can be filled close behind the working faces. It will be possible then to guide the air to the working places instead of losing it in disused and worked-out stopes. The hanging wall will be supported throughout and everything will be excavated, and few, if any, pillars will be left, much less timber. Probably before long it will be possible to run the sand from the cyanide tanks, after treatment, by belts or other means, direct to the sluicing bins.

J. D. Marquard said: Much of the future good and safe mining on the Rand will depend greatly upon successful sand filling. Having spent some little time at Kaltowitz, in Silesia, where sand filling is largely in vogue, it will be just as well to remind you that sand filling has done much for Silesia. It was started there some 6 years ago by one of the cleverest engineers in the district. His ideas were largely criticized; however, he persevered under trying circumstances, for some of the difficulties were great. Most of these difficulties have now been practically overcome with the result that today one mine is putting down 7,500 tons of filling per day. The ultimate result is that his mines are working cheaper and are safer than others in the neighborhood. His critics are convinced and are now sand filling also. Numerous advantages have been gained in Germany by this system that do not directly affect us; however, the diagram Fig. 3 (*a*) shows the different stages of the system as there carried out, and is useful for reference.

The problems on the Rand are more complicated and present more difficulties and dangers than those of Silesia.

Surface transportation of filling material will vary at different mines, depending largely upon the respective elevations of the cyanide tanks and dumps above the shaft collars; however, the surface work on the whole will present no great difficulties. There is no reason why the sand cannot be sluiced with monitor jets from the old dumps into launders, and so transported to the shaft collars; or the current sand treated against cyanide may be lifted with water from a sump near the cyanide tank by means of elevator buckets, or centrifugal pumps. In some cases by starting up the disused tailing wheels the sand may be lifted to sufficient height to give it a drop to the shaft. It is very essential that the slush should be as thick as possible; a good mixture is 60 per cent. sand and 40 per cent. water by volume. A launder with 20-per-cent. grade will allow of this mixture flowing freely. At the Robinson mine these launders are lined with cement castings, a very good protection. These are made on the property comparatively cheaply. The chemical destruction of cyanide must be left to the cyanide managers, whose duty it will be to see that the slush is in a safe state for the mines.

From Fig. 3 it will be seen that the Silesian sand is sent down with various mixtures, such as clay, slags, stones, bricks, etc. These mixtures have beneficial and detrimental effects.

The beneficial effects are:

1. The clay lubricates the pipes, aiding transportation.

2. The clay with fine slags has a binding effect underground; and after 1 year the sand is as solid and compact as sandstone, requiring a hammer to break a piece off.

3. Slags and other materials give a certain amount of porosity to the mass, aiding drainage.

4. The sand particles are rounded, unlike Rand sand, which is angular.

5. The ferruginous mixtures also give binding effects, for some little chemical action takes place.

The detrimental effects are:

1. The clay causes trouble on the surface, sticking to the mechanical shovels and choking the crushers, grizzlies, etc.

2. Slags, bricks, etc., scour the pipes.

The material on the Rand is nearly pure silica with cyanide and cyanide compounds. It is not ferruginous, and there are no mixtures for binding or cohesion. On tunneling into the dumps, although the sand is subject to good pressure, there is found absolutely no cohesion. This non-cohesive difficulty is one of the greatest to be overcome. The sand packs very well, which can be seen at the mines now filling, and while moist it appears to have some cohesive power. Once it dries there will be no cohesion, and a portion of the resulting pressure of the overlying strata will be transmitted to the supporting barriers on highly inclined stopes. It certainly will be beneficial to get the sand as cohesive as possible behind the barriers. Around the mines there is a good thickness of red clayey soil. This is often used for brick making, and the following mixtures have been tried on the surface with fair success:

90 per cent. sand, 10 per cent. red soil plus water. Some cohesion and porosity.

80 per cent. sand, 10 per cent. red soil plus water plus 10 per cent. fine ash. Some cohesion and porosity.

80 per cent. sand, 20 per cent. red soil plus water. Good cohesion and porosity.

70 per cent. sand, 20 per cent. red soil plus water plus 10 per cent. rough ash. Good cohesion and good porosity.

Probably future experiments will find a good cohesive mixture. The red soil can be shoveled mechanically on sites where the excavations may be finally used for retaining slime.

The choice of suitable pipes for the transportation of material in the shafts and elsewhere is an important matter. The wood-lined pipes described by Mr. Pam are similar to those used in Silesia. In some mines there is a tendency to condemn these pipes. It would be well to give them a good trial, however, for they have been used quite successfully abroad. In the pipes in Silesia they have clay for lubrication, good inside diameter to lessen velocity, the sand is rounded, water is pure and not acid, and experience has shown that slags, bricks, etc., remain somewhat in the center of the pipes, while the sand is nearer the wood lining.

On the Rand the sand is angular and it has a greater scouring effect on pipes than the rounded sand would have. Porcelain-lined pipes are used in the shafts in Silesia; they last a fair time. It may be that Rand sand will not scour porcelain pipes too fast, therefore even if expensive they should be given a trial. A good sized pipe in the shaft is an important matter, for then the velocity of flow will not be too swift, thus obviating wear to some extent. An important point is that the pipes in shafts and elsewhere should remain reasonably full. The contents must be taken away below at the same rate as supplied at the top. For this purpose there must be a regulation valve in the mine pipe to which the shaft pipe line is directly connected. The hopper must hold a fair amount of slush, so as to keep the pipe full if there is a temporary hitch in the surface supply. Telephone communications allow of proper regulation by the operator below. Disregard of this precaution is one of the greatest causes of wear and tear in pipes, especially the shaft pipe. Often a sucking noise is heard at the top of the column and at the delivery end into the stope the slush comes out with spurts under high pressure. This is largely due to air being drawn into the pipe and causing alternately cushioning and releasing, with resultant excessive velocities and jerks or hammering in the pipe line, which results in the wear of the pipes and the loosening of the wood lining. The hopper will in a great measure prevent the sucking in of air. An important point to remember in connection with silting is to flush the pipes with water before and after use, and another point is never close the regulation valve.

The pipes in the shafts in Germany are always in duplicate. The system of sending the sand down in a paste through 8-inch bore holes, as at the Simmer and Jack, has many advantages for it saves piping, but unless this bore hole is used as a pressure column there will be some difficulty in getting the material to the far east and west portions of the mine. Very deep bore holes will cost a good deal, the expense increasing fast after the first 400 feet. There is also the disadvantage of passing through faulted ground or dykes which may cause future blocking of the bore hole. It may be that the pipes, etc., will be so costly eventually that bore holes will be the more economical for sand transportation. In the mine, wooden launders should be used wherever practicable.

Until it is certain that Rand sand coheres, or a proper cohesive mixture for filling purposes is devised, wooden barriers are not recommended; they serve in Silesia, but there the conditions are different. The barriers in Silesia are not nearly so extensive as those on the Rand will be; besides the filling coheres and hardens long before the barriers have time to rot. The Silesian stopes are flat, causing the resultant pressure on the barriers to be small. On the Rand the sand has to remain indefinitely, and if the lagging is wet on one side and dry on the other, two conditions arise which will rot timber soon. The overlying rock will crush, with the resultant pressure transmitted in part at least on the barrier, and this slope dripping water will permit much of the water to collect behind the barrier, another cause for anxiety. As a suggestion the barrier shown in Fig. 3 (*b*) might do well in service.

The masonry *A* is held with binding jumpers to the foot-wall. This will have a wedging effect on the overlying waste *B*, which must be packed well, the cavities being filled with ashes. If the ashes act as good filters then the matting *C* is not necessary. A 2-foot layer of the rough ash is represented by *D*. It is essential that all water be drained from the filling, therefore the barrier must be porous.

Much must be learned from future experience relative to stope filling and dewatering. In the mines which are now sand filling good progress has been made. It seems, however, that the more places there are to fill the better the filtering and dewatering of the sand can be regulated. There must be at least two stopes to work consecutively, day by day, each stope having a full day in which to prepare it for the next supply. It is an advantage to have a period between each filling, for then the sand can settle properly, and the water percolate through the sand, or clear above the sand.

It is best and cheapest to have no side barriers, but to keep boys heaping the free end up and letting it lie at its natural angle of repose, or less. The clear water is removed through old disused 3-inch pipes. These pipes have 1-inch holes drilled every 9 inches along their lengths. The pipes are laid on the foot-wall from bottom to top of the stope, and the holes have wooden plugs in them which are pulled out to let the clear water off. The following are some of the points to watch in stope filling and dewatering of sand:

1. Fill at the farthest point away from the drainage pipe.

2. Have no side barriers. The sand will lie at its natural angle of repose at the free end.

3. Where wooden side barriers are preferred, it would be best to have the filling pipe nearest to, and the discharge pipe farthest away from, the barrier; because all the coarse sand remains nearer the former pipe. This would make a better packing against the barrier. The other way will leave slimy sand against the barrier which often forces its way through during filling operations, generally slushing the drives, etc.

4. The sand must be so arranged in the stope that the water flows off at the junction of the foot-wall and the sand, and by no means against the hanging.

5. The supply launder should drop the slush from the hanging wall or as high as possible, and must be led right up to the sand. The slush must not be allowed to run in from the top of the stope on the foot-wall.

6. When starting a stope see that the first sands are well packed against the barrier. This is an important point and will prevent much slime, etc. getting into the drives at the commencement.

7. The length of the filling face must be as long as possible; the longer the better.

8. The discharge or drainage pipe can have more than one hole every 9 inches, say 3. This will allow of quick dewatering. After the clear water is off, the holes are again plugged and filling can be restarted.

9. Between the supply and discharge pipe, arrange small paddocks with bits of board. This will retard the flow, causing the sand to settle and the water to arrive reasonably clear at the discharge pipe.

In Australia stopes are being filled successfully with dry sand at a fairly low cost. Distribution takes place underground with chutes, traveling belts, etc. It will certainly do no harm to study their system. With the electrification of many mines power can be had cheaply and easily underground. Some of this power can be used for transporting appliances for sand. It would not be a bad idea to get the sand down the shaft pipe dry; it can be fed by means of a screw conveyer if near the dump, or otherwise into a strong square wooden pipe, 12 in. x 12 in., fixed in the corner of the pump compartment. Then dry sand may be sent down this square pipe into a funnel-shaped bin into which jets of water are playing. The funnel-shaped bin can be placed in such a position in the shaft as the mine distributing pipes demand. The mine pipes would be attached directly to the bin. This arrangement would have the extra length of piping in a shaft, which is so subject to wear, and pumping of sand filling water to the surface, the actual amount coming to the surface being what the mine makes.

Most of the remarks made here are suggestions only, and it is hoped that more will be heard in the society on sand filling. The subject is still partly in the experimental stage. It has to get out of that stage soon, for it is important that the overlying strata should be kept up. It is also important to fulfil all the advantages mentioned by Mr. Pam. There are many other advantages as well which will come up as soon as practical sand filling is an accomplished fact on the Rand. Practical knowledge is the outcome of experience; and with practical knowledge, sand filling will be successful, and with that success it will be possible to alter many of the present mining arrangements underground for the benefit of the Rand.

To Find Capacity of Cylindrical Tanks

Written for Mines and Minerals

Assume that the tank is 72 inches in diameter and 13 feet long with flat ends. On a piece of "squared" paper draw to scale a quarter of a circle 72 inches in diameter to represent one-half of the lower half of the head. If no "squared" paper is at hand the sheet may be ruled in squares. Each small space on a line in the figure represents 2 inches; consequently, each small square represents an area of 4 square inches of the head.

Consider that the tank is divided into 72 horizontal layers, or sections, each 1 inch in thickness. First take the lowest section, that is the one directly above the line OX. The matter may seem clearer by considering that the tank is filled to a depth of 1 inch. By the eye determine as nearly as possible where the sharp end of the lowest section of the head may be cut off and the end made square, without altering the area. This point is at A. OA is $5\frac{1}{2}$ inches, or one-half the width of the lowest section. The entire width is twice as great and the area of the lowest section is therefore 11 square inches. The tank is 13 feet, or 156 inches, in length. Then for each square inch of the head the tank has a capacity of 156 cubic inches, or $156 \div 231 = .675$ gallon. The quantity at the depth of 1 inch is therefore $11 \times .675 = 7.4$ gallons. The right-hand end of the second section after being squared off, is at B, 10 inches from the center line. Hence, the entire width is 20 inches, and the volume included between the depths of 1 and 2 inches is $20 \times .675 = 13.5$ gallons. In the same way the capacity for each additional inch can be obtained. The contents of any depth will be found by adding together the contents of the sections in that depth. It will be observed that the capacity of any section in the upper half of the tank will equal that of the corresponding section in the lower half. After the contents of the tank at each inch has been determined the quantities may be properly marked off on a measuring stick.

In the plan just given considerable multiplication is involved. This may be obviated by a simple graphical method. Choose some vertical line, say the one at 40 inches to the right, and lay off on it, starting at the horizontal line OX, a scale of gallons. Now find the number of gallons in a section extending to this line. If the width of the half section is 40 inches, the whole width of the section is

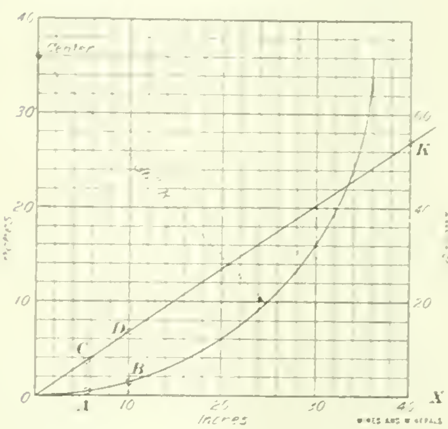

FIG. 1

80 inches and the corresponding capacity is $80 \times .675 = 54$ gallons. Mark K the point corresponding to 54 gallons, and join O to K by a straight line. Any scale that will be convenient may be chosen, but it is well to have OK make an angle of 45 degrees, approximately, with OX. In the figure each division represents 2 gallons.

To determine the number of gallons in any section, proceed as follows: A is the right-hand end of the first section. Directly above A locate C. Measuring the line from C to the base line OX according to the scale of gallons, we find it to be about 7 gallons. In a similar manner locate D above B, and observe that the corresponding capacity is about 13.5 gallons. In exactly the same way the capacity of each section can be readily determined. The correctness of this graphical method is easily seen because the capacity of any section is proportional to its width. It is suggested that the "average" end of each section be marked with a pencil and by the aid of a strip of paper the corresponding point in OK located. Should a scale be made for the imperial gallon, one must not forget that this measure contains 277.3 cubic inches.

In making the calculations for the matter in this article, no attempt has been made to be exact. However, if the drawing is carefully made, reasonably accurate results can be obtained. For illustration, suppose that an error should equal one-fourth of a small square, then the corresponding error would be one-fourth of .675 gallon = .17 gallon, or about two-thirds of a quart. The method here described brings to mind the fact that problems in mensuration may be solved with ease on "squared paper" or by means of a drawing. Should, for example, the tank have bumped ends, the volume of the ends could be found section by section by following the method given here.

The Markets for Joplin Ores

By A. J. Hoskins

The zinc-lead region surrounding the common point in the state boundaries of Missouri, Kansas, and Oklahoma is usually referred to as the Joplin district, the city of Joplin being about centrally situated in this area.

The bulk of the production of the mines in this region comes from the Missouri portion of the area. While outsiders may think of this output as originating "around Joplin," the local operators have a practice of subdividing the country into small districts that are respectively tributary to numerous little towns or railroad stations, in each of the three states. In the Missouri portion of the region, for instance, there are some 25 or more such imaginary districts, each holding a friendly rivalry with its neighbors along figures of production.

In these "camps," the ore as mined, must undergo concentration before it is marketable, and this is therefore always attended to at the mouths of the mines. Thus, every mine is found to possess its mill at the collar of one of its shafts, and this plant will contain the necessary crushers, rolls, and jigs. The flow sheet of such a mill is exceedingly simple.

The region contains two types of ore bodies that are locally termed "soft ground" and "sheet ground." The former type of ore body is usually the richer, and it was through the discovery and working of this kind of ore that the district became famed. The sheet ground is geologically deeper. During recent years, this formation has been extensively explored, and the production from it has been increasing so rapidly that it has surpassed the output from the soft ground. Thus, during 1911, the production of crude ore from these formations was 3,217,000 tons from the soft ground and 4,945,000 tons from the sheet ground.

As the ore comes from the soft ground, it averages about 4½ per cent. content in the sulphides of lead and zinc. In this content, the zinc mineral is about ten times as abundant as the lead mineral. In other words, according to Mr. J. P. Dunlop, of the U. S. Geological Survey, the crude ore from this formation carries about 4.1 per cent. sphalerite and .4 per cent. galena. After the concentration of this ore, the two mill products will average, respectively, 58.9 per cent. metallic zinc, and 79.9 per cent. metallic lead. From this, one will notice that the treatment given the run of mine, while exceedingly simple, is really very efficient.

The sheet ground carries, on the average, 2.1 per cent. of sphalerite, tersely termed "jack," and .5 per cent. of galena. After milling this ore, the two concentrated products average 79.8 per cent. metallic lead and 58.6 per cent. metallic zinc. These two figures compare closely with the averages of concentrates from the soft ground. Statistics covering a year show a small difference in the average prices paid for the corresponding products derived from the two kinds of ground, but the reason is not obvious.

Concentrate is purchased at the mill of the mining company by agents of the smelting companies and is loaded into the railroad cars by employes of the purchasers. The price paid for the concentrate is net to the mine operator, in the sense that there are no freight nor smelting charges to be deducted. The miners all agree, nevertheless, that "Jones pays the freight."

During 1911, the average price per ton paid for galena concentrate from the soft ground was $54.41. Taking 79.9 per cent. as the average grade of this product, the sellers received about 3.4 cents per pound for the lead contained in their ore, whereas the average market price for that metal during the same year was 4.4 cents. The difference, therefore, provided for the costs and profits in smelting and marketing.

Similarly, on the sphalerite concentrate from the soft ground, the average price paid last year was $40.80 per ton. Using the average figures for the grade of this material, it appears that about 3.46 cents was paid for a pound of zinc, although the average quotation on spelter for the year was 5.76 cents. It is generally admitted that zinc smelting is more expensive than lead smelting, but the differential in this case seems excessive. It appears from these figures that, although zinc was actually worth 30 per cent. more per pound than lead, the producers accepted practically the same price for both metals.

For the galena concentrate derived from sheet ground, the average price during 1911 was equivalent to 3.54 cents per pound of lead; while the jack concentrate from the same formation sold at prices that averaged 3.39 cents per pound of zinc.

Sealing Off a Loading Place

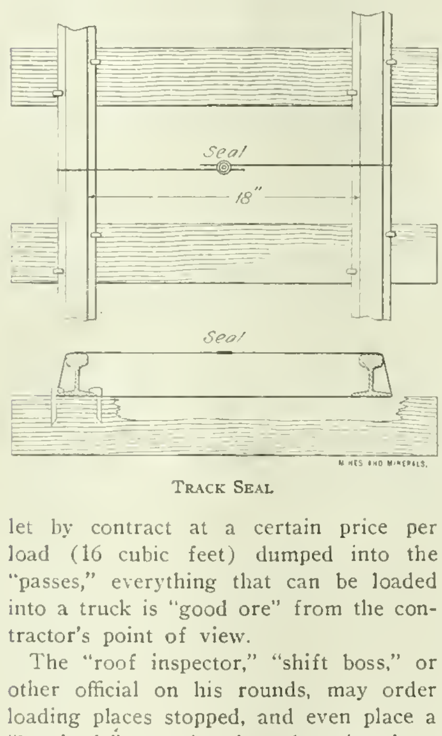
*By John T. Fuller, E. M.**

The simple device illustrated was used by the writer to seal off condemned "loading places," in the diamond mines at Kimberley, South Africa.

In these mines it is often necessary or advisable to temporarily stop the loading out of certain stopes or parts of stopes, either because waste rock has "come in" to the loading places or to prevent too much blue ground being removed from the stopes during the stoping operations.

A form of "shrinkage stopes" is used in these mines, the miners standing on the broken ore to reach and drill the "backs."

When the extraction of the "blue" is let by contract at a certain price per load (16 cubic feet) dumped into the "passes," everything that can be loaded into a truck is "good ore" from the contractor's point of view.



Track Seal

The "roof inspector," "shift boss," or other official on his rounds, may order loading places stopped, and even place a "barricade" at such points; but nine times out of ten loading would be resumed as soon as the official's back was turned.

Material once dumped in the "passes" was safe, so far as the contractor was concerned; because in most cases, though the waste was easily distinguishable from the "blue," it was impossible to trace it back to the level from which it had been dumped, owing to the fact that a number of different levels dumped into the same "passes."

It was very difficult to catch a contractor "red handed" loading waste, as they kept "natives" on the lookout for the "boss" and were generally warned in plenty of time to stop all illegal work.

In spite of the heavy penalties imposed on detection of such work it seemed impossible to stop it until the method of "sealing off" was tried.

Each "reef inspector" was supplied with a pocket reel of steel wire about 16 or 17 gauge, a pocketful of lead seals such as are used by the railroads for sealing freight cars, and special "pliers" that formed a combined wire cutter and seal stamp.

Whenever for any reason a loading place was condemned the inspector would wrap a wire around the rails just inside of the loading place, and after drawing it tight through the holes in the lead seal, would clamp it down tight on the wire with his pliers, at the same time leaving the imprint of the stamp on the lead.

All places thus sealed were reported to the inspector and shift boss of the succeeding shift, who inspected the seals and removed same if for any reason it had become advisable to resume loading.

It was soon found by the contractors that they could not tamper with these wires and seals in any way without leaving traces of such tampering and, of course, if a car was run in such a place the wire was broken.

All broken wires or tampered seals were considered as direct evidence of illegal loading and the maximum penalty immediately imposed.

In a very short time the practice of loading from condemned places was entirely eliminated.

*Consulting Engineer, Honesdale, Pa.

No Reward for Tin Discovery

The United States uses between 40 and 50 per cent. of the world's production of tin but mines only a small quantity. In 1911 the output of tin ore in this country was equivalent to 63 tons of metallic tin, valued at $54,013.

For some unknown reason there is a widely prevalent idea that the United States offers a reward for the discovery of a tin mine that can be worked at a profit. Where the rumor started is unknown, but it seems to be fostered by unscrupulous or ignorant persons who have mining stock to sell. The Geological Survey's officials state that the United States does not offer and so far as known to them never has offered a reward for the discovery of a tin mine, or any other mine.

So many letters are received by the Geological Survey asking where tin deposits can be found in the United States that a brief outline of the occurrences of the metal have been published in a report on the production of tin in 1911 by Frank L. Hess, a copy of which may be obtained free on application to the Director of the Geological Survey at Washington, D. C.

The Calculation of Areas

Short Methods of Determining Areas from Maps, with Special Reference to Areas of Irregular Outline

*By H. G. Henderson**

A VERY important portion of the office work of the mining engineer or surveyor is the calculation of areas as displayed on the mining map, and although the general principles underlying such calculations are understood by mining engineers, there are one or two special notes and ideas for facilitating work which may not be known generally. These are stated briefly for the purpose of assisting the mining surveyor in shortening and simplifying what is often a laborious undertaking.

For example, there is an interesting feature which does not appear to be generally known regarding what is called the 25-inch map, which makes it particularly fitted for the calculation of the areas, and this is that each square inch upon the map represents so approximately as to be practically true, 1 acre. For this reason the average breadth and length in inches of a mine claim which has been delineated on a 25-inch map may be taken with an ordinary 2-foot rule, and the product of these measurements will give the required area in acres. The reason for this is as follows:

The 25-inch map is laid down on a scale of $\frac{1}{2500}$, that is to say, every linear measurement on the map would, if made on the actual ground itself, be 2,500 times as long. Suppose now that a square inch is drawn on the map as at (*a*) Fig. 1; the real length from A to B would, of course, be 2,500 inches, and similarly the real length from A to C would be 2,500 inches. Now, 2,500" multiplied by 2,500" equals 6,250,000 square inches, and this number of square inches is practically equal to 1 acre. In reality, however, 6,272,640 inches make an acre, but the difference is almost negligible, as will be seen if a square inch is accurately drawn out on a piece of paper, and an acre is then put down on a piece of transparent paper on the $\frac{1}{2500}$ scale. If these are superimposed, the latter upon the former, the eye can detect no difference, and the above is a safe rule to form a guide to the mining surveyor.

Arising out of this, it may be of interest to mention a useful rough approximation for the calculation of areas which may not be known to all mine surveyors, and which may be noted in connection with plans and models. This consists in the measurement of such areas by the means of an ordinary 2-foot rule. If a representative fraction (R. F.) of the plan be given, any required area on such a plan can be approximately calculated by the eye, or at any rate by taking the average length and average breadth with the ordinary 2-foot rule. For example, supposing a mining claim is laid down on a scale of 100 feet to the inch. In this case the representative fraction would of course be $\frac{1}{1200}$. Now the number of square inches in the plan that are equal to 1 acre will be $\left(\frac{2500}{1200}\right)^2$ which equals 4.34, and in order to obtain the acreage of the claim the number of square inches contained in the plan must be divided by 4.34. The reason of this can best be seen by taking an area on a $\frac{1}{500}$ scale plan.

It is evident that if the area of the land occupying 1 square inch on the $\frac{1}{2500}$ plan be laid down to the same plan drawn to $\frac{1}{500}$ scale, 1 acre will occupy a square in the map of 25 square inches. That is to say, the number of square inches found by the 2-foot rule on the $\frac{1}{500}$ plan must be divided by 25 to give

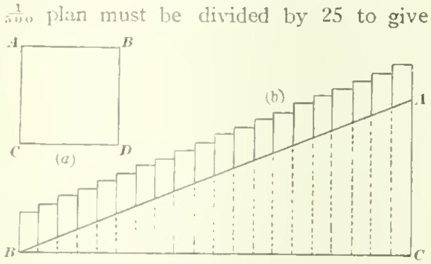


FIG. 1

the approximate acreage; but 25 equals $\left(\frac{2500}{500}\right)^2$; hence the rule will be found to be as follows:

Take the square of the denominator of $\frac{1}{2500}$ and divide it by the square of the denominator of the representative fraction of the plan before you and the result will be the number of square inches on that plan equivalent to 1 acre.

EXAMPLE 1.—A mining claim is marked out on a plan drawn to the scale of 3 chains or 198 feet to the inch

$$\left(\text{R. F.} = \frac{1}{2376}\right)$$

How many square inches go to the acre?

$$\left(\frac{2500}{2376}\right)^2 = \frac{6250000}{5645376} = 1.11. \text{ Ans.}$$

Suppose the concession to give under the 2-foot rule 437 square inches, its area would be $\frac{437}{1.11} = 394$ acres.

EXAMPLE 2.—A mining concession is laid down on a map the scale of which is 24 inches to the mile. How many square inches go to the acre?

Here the representative fraction is of course $\frac{24}{1760\times3\times12} = \frac{1}{2640}$, and the answer is $\left(\frac{2500}{2640}\right)^2 = \frac{6250000}{6969600} = .896$; and if the concession under the 2-foot rule yielded 437 square inches, the area would be

$$\frac{437}{.896} = 499 \text{ acres.}$$

It will be evident to those who carefully consider, the question that the formula to be perfectly true should be

$$\left(\frac{6272650}{\text{D. R. F.}}\right)^2, \text{ or } \left(\frac{2504.524}{\text{D. R. F.}}\right)^2.$$

But 2,500 is more easily remembered than 2504.524, and the result will be practically the same.

An interesting point arises in connection with the measurement of areas which on the actual surface formation are upon a slope. One of the cases in which a surface survey, for example, is rendered necessary is when a mining company has, as a result of its operations, to pay an amount as compensation to the owners or occupiers of the surface of the land under which their workings run, or more usually, of such sections of land as are required for the surface operations of the mine. In such cases, where the damage is computed in terms of the value of growing crops, it becomes necessary to survey the land and to calculate the area of the enclosure affected. This is a comparatively simple matter where the land is approximately horizontal, inasmuch as a survey is, of course, plotted on the flat, and the area is calculated in accordance with this.

More than one case of dispute has, however, arisen where the land lies on a hillside; and when it is agreed that compensation shall be paid for the growing crops, the mine surveyor should be careful to see that his company is not unjustly treated in the matter. In Fig. 1 (*b*), for example, the farmer may argue that if angle A B C is the slope of his field, the survey will show one side say of the area as length B C on the plan, whereas the actual area of his field in which say turnips are growing, should be calculated in terms of A B as more turnips can be grown in an area bounded by A B than in one of similar width bounded by B C.

If this principle were admitted, endless difficulties would be incurred in dealing with undulatory ground, as a surface plan would be valueless. That such complications need not occur, and that the surveyed plan must be accepted literally in such cases, may be seen by imagining for the sake of illustration that pine trees grow over the area as closely as they can be packed as shown by the vertical rectangles. If their number be counted it will be seen that quite as many can be grown on the level B C as on the slope A B, and this argument applies in full force where timber, corn, and practically

*Mining Engineer, London, England.

all cereals are concerned. There is a slight increase where flat growing crops such as turnips, cabbages, etc., are concerned, but the difference is negligible and does not correspond to the difference between A B and B C, inasmuch as the crop is not absolutely flat on the ground like a coat of paint, but has an appreciable depth vertically. Moreover, no

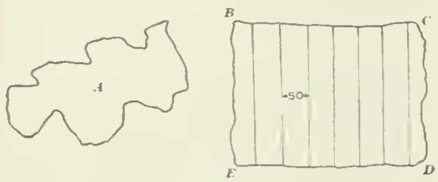

Fig. 2

more rain falls on the sloping surface than would impinge on it if the surface were flat, so that the value of a slope is no greater from a farmer's point of view than that of its corresponding projection on the horizontal. That this view is correct is borne out by the fact that farm leases are based on acreages calculated on the flat, so that it is manifestly unfair to claim compensation for surfaces on the slope on any other basis than on the level survey. A young surveyor, however, might easily be hoodwinked by the specious nature of the opposite argument.

If it becomes necessary to calculate in a rapid but accurate manner the area of a mining concession, deposit, stope, etc., as marked on a plan, there are, of course, many ways of doing this; but as a matter of experience it will probably be found that for simplicity and accuracy the method to be described is by far the best. Consider an irregular area such as A, Fig. 2 to be the boundaries of an ore deposit, as outlined on the map. A piece of tracing paper similar to B, C, D, E, should now be taken and upon the same should be ruled in red ink, parallel lines as shown, at convenient distances. By way of illustration the lines are shown in the diagram as drawn at distances apart corresponding to 50 feet on the ground to the scale of the plan. The tracing paper should then be placed over the plan of concession A, as shown in Fig. 3 (*a*) and a long strip of tracing paper should be marked off on some suitable round number or integer on the scale. The strip should then be taken and with it the distance from A to B, B to C, C to D, and so on should be marked off, and such distances should be marked and numbered on the strip as shown in Fig. 3 (*b*). It will then be found that sooner or later the 2,000-foot mark will fall upon the plan at X. From X the measurements should be recommenced and another 2,000-foot mark made, this process being continued until the whole of the concession area has been covered. Eventually the measurements will finish with a certain number of 2,000-foot distances and be either a trifle long or short, as the case may be. All that is necessary to do in order to start the computation is to count the number of 2,000-foot marks. For example, call these three in number. Then 2,000 multiplied by three, plus the trifle over, which is measured along the scale, multiplied again by 50, gives the area of the deposit in square feet.

The reason for numbering the marks on the edge of the strip of tracing paper is to prevent any mistake in the act of measuring and also to enable the strip to be used over and over again. Of course, with stopes and similar plan drawings, the parallel lines should be so many definite feet apart and in such a case the strip measurements are taken in feet also, giving the result in square feet. Although this method is so simple and quickly effected, it is surprising how accurate the results will be. The only trouble which may occur, apart from errors in measurements of computation which should be easily guarded against, is to be found where the outline of the deposit is very irregular. In such instances a "give and take" method must be adopted to compensate what may be termed the jagged ends of the widths to be measured.

It is, of course, a fundamental rule that measurements and computations connected with mining plans such as that described in the previous paragraphs should be most carefully checked, and in order to avoid the possibility of falling twice into the same error which might have occurred in the first computation, it is advisable that, wherever possible, the check should be carried out by a method or manner different from the one which was originally adopted. There are several ways of checking a computation of the area, and two or three of the most useful of these may be briefly described.

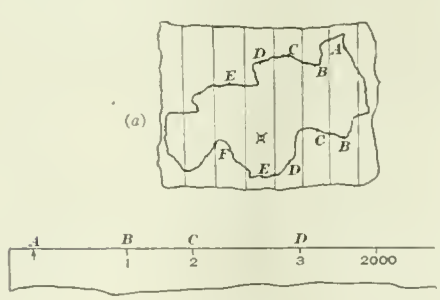

Fig. 3

With areas, the checking may be performed by using over again the lined tracing paper described in the previous paragraph, but in the second computation placing the lines at right angles to their previous position as indicated in Fig. 4. By computing the area by measurement of the strips so formed taken at right angles to the previous strips, it may be found that there is a slight difference in the result, more especially if, as pointed out above, the ends of the strips are irregular, and some means has to be taken of estimating the area of the jagged ends.

Another method of checking, and one that is very simple in application, is to transfer the area of the concession or deposit to a sheet of tracing paper, and

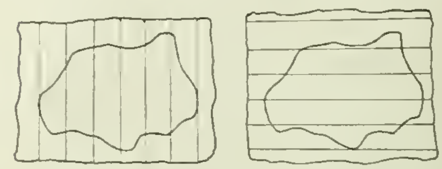

Fig. 4

by its side on the same sheet of paper to lay down according to the scale of the plan, a rectangle containing a whole number of acres, say, 10, 20, 50, as may be convenient. If, after doing this, the two outlines are carefully cut out from the tracing paper by means of a sharp knife or a pair of scissors, and then carefully weighed each in a very delicate balance, a simple rule of proportion will give the required answer. For example, if the tracing paper of the outline of the concession weighed ¼ ounce and the rectangle representing to scale 50 acres weighed, say, ½ ounce, it follows, assuming the specific gravity of the two pieces of paper to be the same, that the area of the concession will be 25 acres.

It very often occurs, however, that a mining engineer finds himself in a locality where he has no tracing paper, no balance, and, in short, nothing suitable for the purpose. He simply has his plan before him, and is required to calculate the area of a concession marked upon it. It may be presumed, however, that the plan has a scale upon it or attached to it. The best way to go to work under these conditions will be as follows: The engineer or surveyor should affix the plan and a sheet of paper on a board or table, and should construct a rectangle on the paper containing any given number of acres. He should then obtain from his cook a little dough and proceed to build a wall of this material round the concession and also round the rectangle, taking care that the dough accurately corresponds with the two outlines. Within these two enclosures dried peas or buckshot should be placed until there is a single layer all over each enclosure. The peas or buckshot contained in each of the two areas should then be carefully counted and the ratio of the two areas should correspond to a very near approximation to the numbers of peas or buckshot contained in each. As the area of the rectangle is accurately known, a simple application of the rule of three will give the area of the concession.

The foregoing observations do not include anything which is radically new or startling, but they have, it is hoped, a certain merit from the point of view that simplicity in operation always tends to success in surveying, whether this rule is applied to field or office work. Such simplifications tend to the elimination of those mechanical errors, which although they so easily creep in, are yet so difficult to detect, and which oftentimes throw work out of balance and lead to erroneous conclusions, and it is therefore hoped that the above practical hints may be of some value to mining engineers and surveyors.

Concrete Shaft Lining

Materials and Properties Used in Making Reinforced Concrete Sets Tests Showing Relative Strength of Concrete and Timber

*By E. R. Jones**

FOR a number of years solid concrete and reinforced concrete shaft collars and shafts have been in vogue where the conditions warranted a shaft of any degree of permanence, but not until 1909 was reinforced concrete tried as a substitute to take the form and similar methods of installation as the long-used timber sets for shaft purposes; namely, at the Nos. 3 and 4 shafts of the Ahmeek Mining Co.

In the beginning, two distinct kinds of material were used; a good grade of gravel and natural sand from a local pit; and the trap rock, through which the shafts were sinking, together with clean conglomerate sand from the C. & H. mill. Sets were molded from these two classes of material and installed with equal partiality, and subsequent service has proved both to be equal to the demands made upon them. Pieces set aside for the purpose were allowed to season sufficiently that they might be given a fair competitive test, and it was found, on comparing the fractures in the two combinations of material, that the sand and cement filling the spaces between the rounded pebbles broke away from them, while the fracture in the trap-conglomerate same combination continued through the larger elements of the mixture. The gravel mixture could doubtless be improved considerably by careful washing, but the cost of preparation, compared with the trap rock and conglomerate sand, prohibited its use in this particular case.

The materials finally used were as follows:

No. 1 Portland cement. Conglomerate sand. Trap rock trommeled over ¾-inch through screens.

The proportions used were 1–3–5 in wall plates, end plates, and dividings, and 1–2–4 in studdles. The reinforcement in wall and end plates consisted of three ¾-inch Monolith steel bars with ¼-inch webs, crimped on to them, together with two straight ¾-inch Monolith bars. The dividings were reinforced by four ½-inch Monolith steel bars wound spirally with ¼-inch steel wire, the whole presenting a column with square cross-section. Studdles were reinforced with two pieces of old wire rope 1¼-inch in diameter. Reinforced concrete slabs were molded for the shaft lining, the material used being fines of trap rock under ¾ inch, conglomerate sand, and Kahn expanded metal as reinforcement. The mixture used for slabs was 1–2–4. By way of experiment, the writer selected a piece of No. 1 hemlock plank of the same length, width, and thickness of a concrete slab, which had seasoned for 1 year, supported them at either end, and placed them side by side, and then applied an equal pressure across the center of each. Three failure cracks appeared in the concrete slab just previous to the breaking of the hemlock plank, although total collapse of the concrete slab did not occur until the pressure was considerably increased. While the method of the test employed was crude, it proved to the satisfaction of the writer that the concrete slab was much superior in strength. Considering the rapid decay of timber used as shaft lining, no further comparison of the two is necessary.

In the molding of the concrete sets, 2-inch No. 1 white pine was used in the construction of the forms. These were soaked in a wood preservative, and repainted with preservative on the interior each time before setting up, thus insuring them against warping and prolonging their lives indefinitely, as well as securing a smooth and easy parting from the concrete when removed. A barrel-type mixer was employed in preparing the charge for the forms. The amount of water used in the mix was such that, when the batch was piled, it settled rapidly without agitation. A drier mix was attempted by way of experiment, but due to the amount of reinforcement employed, it was found impossible to ram the drier mix into place.

The labor involved in the making consisted of two carpenters setting up forms and keeping them in repair; one man wheeling forms on to skidways ready for filling, returning used forms to shop and cleaning the same; one man feeding mixer from stock piles of rock, sand, and cement; one man delivering mix to forms and shoveling material into place; and one mason ramming charge into final position. With this combination of men as many as four complete sets, consisting of 64 separate pieces, have been molded in 1 day of 9 hours. In ordinary weather, the sides of the forms were allowed to remain in position over night, and then removed, while the bottoms were left in place another 24 hours. The bottoms were removed by turning the pieces on their sides, where they were left to harden 1 day longer before removal to the stock pile. All through the process of removal, the sets were handled with the greatest care in order to preserve the appearance of the set and prevent cracking, which might not develop to the eye until weathered. All skidways used in making and storing were brought to a level to prevent warping and bending while the sets were green, to insure a perfect fit under ground; for, unlike timber, the concrete set cannot be brought to place unless perfectly true. Sets should not have been used under 60 days after removing forms, although we, through the reduction of the stock piles, have been forced to install pieces of 14 days set, but the greatest care was observed in handling and putting in place underground. Concrete sets 1 year old, which have been subjected to all manner of weather, can be abused somewhat and handled almost as carelessly as timber.

As before stated, the above-mentioned sets were made for the Nos. 3 and 4 shafts of the Ahmeek Mining Co. The shafts are of the three-compartment variety—two skipways and one manway, dipping at an angle of 80 degrees. The outside dimensions of the compartments are:

Skipways, 7 feet 6 inches high, 6 feet 10 inches wide.

Manway, 7 feet 6 inches high, 3 feet wide, with the end plates and dividings, making the greatest span of 7 feet 6 inches. Offsets were molded in all plates 5 inches from the inside face to accommodate lining slabs. Also, holes were cored for the use of hanging bolts and bracket bolts. The wall plates, end plates, and studdles have a cross-section of 80 square inches; dividings, 81 square inches. The percentages of reinforcement are approximately as follows:

	Per Cent.
Wall and end plates	5
Dividings	5
Studdles	3

It was found advisable from the beginning, because of the great weight of the wall plates, to mold them in two sections, one section spanning the ladderway, and one skipway, and the other section spanning the remaining skip compartment. These two sections were connected when in place by two bolts passing through holes cored for the purpose, and two straps of iron spanning the splice. Studdles were made for 4-foot, 5-foot, and 6-foot sets, to accommodate the ground passed through.

* Read before the association of mining engineers of the copper country, The Michigan College of Mines Club at Houghton, Mich., February 25, 1912.

The weights of the different pieces comprising the set are as follows:

	Pounds
Long section of wall plate	1,035
Short section of wall plate	700
End plate	600
Divider	645
3-foot 3-inch studdles	268
Complete set of 16 pieces	8,104

Taking the weight of No. 1 western fir, which has been exposed to the weather in stock piles, as 33 pounds per cubic foot, the above concrete set weighs almost three times that of a 12"×12" timber set which the concrete set is intended to replace. Because of this additional weight of the concrete set, it was found necessary to increase the usual five or six men on the timber gang to seven in number. In a vertical shaft, to which the concrete sets are especially adapted, the number of men per gang might again be reduced. The sets are hung or built as the ordinary timber sets, only requiring an additional rope and block to swing the pieces in place. After the sets are wedged to line, bottoms are put in between the plates and the surrounding shaft wall, and the set is then tied to the shaft wall by means of concrete in the proportion of 1-3-5. The concrete slabs are then put in place and loose rock thrown behind them, filling up what space still remains between the set and the wall of the shaft.

After the set is in place, it is extremely important that it be well protected from the blast, for, unlike the timber set, concrete will not stand the blast. For this purpose, the writer used flat timber and steel plates chained to the under side of the plates and dividings, and even this precaution was at times inadequate. Where the ground was breaking easily, the sets have been as near as 12 feet to the miners, and again, when the ground was especially refractory, sets 40 feet from the blast have been cut out. It is obvious that it is well to keep as far behind the mining as the ground will permit. In dangerous ground, which required timbering close up to the sinking, timber sets were used, but, had not time played an important part in the sinking, no ground was met in which concrete sets could not have been installed. With a gang of seven men, one complete set can be installed in a 9-hour shift. This permits a sinking rate of better than 100 feet per month, which was accomplished at the Nos. 3 and 4 shafts.

The comparative cost of the concrete set and timber set, delivered at the shaft collar, is striking. The concrete set was delivered for $22.50, the timber set for $37.60. These figures are based on:

Western fir, $28 per 1,000 feet, f. o. b. car; crushed rock, 35 cents per yard, f. o. b. shaft; conglomerate sand, 60 cents per yard, f. o. b. shaft; No. 1 Portland cement, $1.15 per barrel, f. o. b. works; reinforcement, $12 per set, f. o. b. factory.

The Ahmeek Mining Co., I believe, was the first to adopt the concrete stringers, and the Mohawk Mining Co. soon followed with their use. At the Ahmeek, these stringers have been in continuous use since the beginning of operations and have required no repairs. Superintendent Smith, of the Mohawk, has informed me that soon after the stringers were installed, skip repairs increased about 100 per cent. The stringer being entirely rigid, and the skip also of rigid construction, the axles of the skips were found to be crystallized and the rivets working loose. This feature was overcome by molding 2-inch pine strips, after treating them with wood preservative to prevent decay, into the stringers at intervals of 3 feet, allowing them to project ½ inch above the face of the stringer, and resting the rail thereon. The pine strips have been in place 4 years, and none have been replaced to date, and skip repairs have been reduced to normal. Possibly because of a differently constructed skip, Ahmeek repairs were not abnormally high, but the same racking of the skip body occurred and the Ahmeek company has adopted the Mohawk feature and expects to profit accordingly.

Concrete plats, or stations, have been in use at both the Ahmeek and the Mohawk for some time. They differ from the timber plat in outward design only in the cross-section of the members, which are 9 in. × 12 in., and are reinforced with old rail and wire rope, and replace the 12"×12" and 12"×14" timber formerly used. Holes are cored to accommodate gates for skip and dump doors and tram rails are imbedded in the concrete, making the use of spikes unnecessary. When turntables are used on the back of the plat, the rigidness furnished by the concrete insures the trammers against derailed cars, resulting from a tilted table.

At the present time, our company is installing reinforced-concrete dividings to replace the practice of putting in 10-inch flat timber. In cross-section they are 9 in. × 12 in., and are reinforced by old rail. On the ladder road, they are placed 6 feet from center to center, and between the skip compartments are put in as often as the hanging requires. Since the casing along the ladder road performs no other office than the protection of the men while on the ladder, or in case of a fall, plank is used for the purpose, and a 3-inch hemlock strip is molded into the dividings to facilitate the fastening of this casing.

Quite often in the placing of concrete and reinforced concrete, both above and below ground, not enough attention is paid to the character of the men employed in charge of the mix and actual distribution of the material. It is not enough that the work shall look finished and neat on the removal of the mold boards, which any gang of men can accomplish with only this end in view. The placing of concrete where strength is desired, as well as weight and finish, requires care and judgment. Men should be selected who will see that the fines are uniformly distributed with the coarser material, for, unless the rock of the mixture is made to well overlap, congregation of coarse material and fines will accumulate which will result in a weakness, which often cannot be detected after the work is completed. The ideal method of placing the mix is by hand with shovel, but in shaft work this method is slow and requires extra labor where the work is situated some distance from the place of mixing. Where chutes are used to convey the mix to its destination, the larger material arrives in advance of the fines, making an even distribution difficult and at times impossible. The writer has eliminated this feature by placing traps at regular intervals in the conducting launders, for the purpose of retarding the larger particles, thus securing a more even mix at the end of the launders than at the beginning.

Concrete has long been used underground for bulkheads, forks, open gutters, and casings for firedoors, and cannot be surpassed for these purposes. As applied to shafts, the material is comparatively new, but each succeeding year marks its advance, and in the end timber will have been entirely superseded. For much of the underground construction, timber is still the rival of concrete, but, due to the increasing scarcity of the timber suitable for mine use, it cannot long remain as such, and must soon make way for the more plentiful materials, concrete and steel.

I wish to thank Mr. S. R. Smith, of the Ahmeek Mining Co., and Mr. Will Smith, of the Mohawk Mining Co., for information furnished me.

Monel Metal's Resistance to Corrosive Action

Recent experiment made at the laboratory of the Board of Water Supply, New York City, indicate that Monel metal possesses about the same resistance to corrosive action as the better known bronzes, while it had the additional advantage that it presented the least change in appearance as a result of the corrosive action. Specimens of several bronzes, Monel metal, and steel, were weighed and embedded in rich earth, which was kept wet for 6 months by periodical additions of very dilute solutions of corrosive salts. At the end of the test period all of the specimens were taken out, scrubbed, dried, and weighed to ascertain the comparative loss from corrosion. The results were as follows:

	Per Cent. Loss
Phosphor bronze	.09
Tobin bronze	.11
Monel metal	.12
Parsons manganese bronze	.12
Muntz metal	.33
Steel	1.04

Another test of the same kind under somewhat different conditions, but the same period, gave about the same relative results.

Practical Cyaniding—Part 2

Labaratory Equipment—Apparatus for Ore Testing and Methods of Operation—Roasting and Treatment of Concentrate

*By John Randall**

SINCE writing paragraph on "Determination of Reducing Agents," which appeared on page 45 in the August number, I have been using a better and more convenient method of determining reducing agents in cyanide solutions as follows:

Determination of Reducing Agents. By means of a pipette, transfer 10 cubic centimeters of the solution to be tested to a small flask or beaker and add 4 or 5 cubic centimeters of a 10-per-cent. solution of sulphuric acid. This acid solution is made by mixing 1 part by volume of sulphuric acid with 9 parts of water. Run the potassium permanganate test solution from a burette into the solution under examination until the reddish color of the permanganate just fails to be discharged. Next heat the solution in the flask or beaker over a spirit lamp until it is near the boiling point when the reddish color will probably be discharged. Carefully run in more of the permanganate test solution drop by drop, reheating the cyanide solution at intervals over the spirit lamp, until a pinkish tint of the permanganate remains. Each cubic centimeter of the permanganate solution used indicates that one-tenth of a gram per liter (two-tenths of a pound per ton) of oxygen must be combined in the solution to oxidize alkaline sulphides or other reducing agents. Ferrocyanides and thiocyanates discharge the color of permanganate, but their quantity in mill solutions is generally small and may be disregarded. If a bright piece of silver foil or a silver coin is placed in a cyanide solution containing a considerable amount of alkaline sulphides, the silver will be blackened.

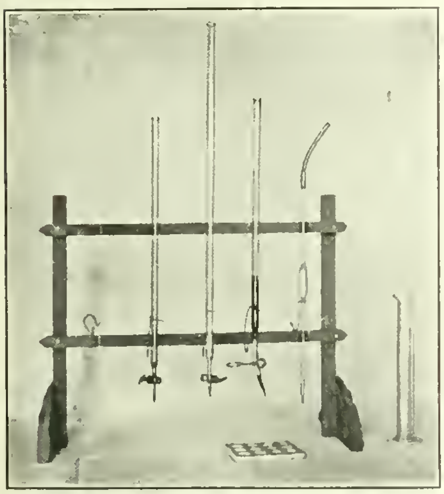

FIG. 1. BURETTE STAND

*Boulder, Colo. Part 1 appeared in August MINES AND MINERALS.

In addition to the apparatus needed for fire assaying, the laboratory should be equipped with burettes graduated to $\frac{1}{10}$ cubic centimeter, measuring pipettes, graduated cylinders, funnels, filters, etc., also a mixing flask (liter flask). A burette stand more convenient than those usually found on the market can be made on the premises. As many burettes as required are supported in notches cut in two horizontal bars, being held in their places by wire springs, the end of the spring being bent into a hook, as shown in Fig. 1.

In case the light is not good and it is necessary to set the burettes directly in front of a window, the cross-bars may be attached directly to the window frame.

The gold pan is an indispensable article. It is stamped from a single piece of sheet steel, and the diameter of the bottom should be four times the horizontal width of the flaring side.

A smaller pan made of sheet aluminum, 12 inches in diameter at the top and of the same proportions as the iron or steel pan, can be found on the market, and is very convenient on account of the ease with which sulphides can be seen against the white bottom. A large dishpan will answer for a panning tub.

The Hot Plate.—If the laboratory is not already equipped with a hot plate one can be made by fitting a two-burner gasoline stove into a small table, the top of the stove being flush with the table top. A piece of $\frac{3}{16}$-inch sheet steel 10 inches square is placed over each burner. A hole near the edge of each sheet to fit a stove-griddle lifter is convenient. To make it of a proper working height while standing, the table should be set on a platform 10 inches high. A hood leading to a flue to carry off fumes should be placed over the apparatus. If very much work is to be done the hot plate is quite indispensable in getting out the fire assays.

Scales.—An even-balance scale having a capacity of about 4 pounds should be provided, together with a set of brass metric weights, 1 gram to 1,000 grams.

Sieves.—A nest of 8-inch assayers seives, brass wire cloth in tin frames, of the following mesh, will be found useful: 10, 20, 30, 40, 60, 80, 100, 150, and 200. Coarser ones with wooden frames can be made as needed. Very serviceable round-hole sieves can be punched from tin pans on a block of end wood by carefully fitting a flat-faced steel punch to the required size. Sieves coarser than $\frac{5}{8}$-inch round hole will be seldom required.

Apparatus for Ore Testing.—Even after the method of treatment has been decided upon and the cyanide mill is in operation, ore-testing work should not be altogether abandoned, and in case the mill treats custom ore, testing work will be continually required. A room connected with the laboratory, and fitted up with appliances for ore testing, is one of the most important adjuncts of the milling plant. An agitator like the one shown in Fig. 2 can be made on the premises. The wood disk supporting the jars is mounted on a bicycle hub. A hexagonal block is secured to the center of the disk on which is mounted the sheet-metal clips that hold the 2-quart jars snugly in place. The plane in which the disk rotates is at an angle of about 27 degrees from the vertical, or a slope represented by the hypotenuse of a right-angled triangle having an altitude equal to twice its base.

The apparatus should turn at a speed of five to eight revolutions per minute. A small electric or water motor will furnish the power required.

After questions connected with the chemistry of the process have been decided by agitation tests, it is generally desirable to make tests on larger quantities of ore and under conditions more nearly approaching mill practice, at the same time ascertaining if there are any obstacles to zinc precipitation.

In Fig. 3 is shown an arrangement for a small testing plant composed of tubs *a* and *b*, a precipitating box *c*, and a sump *d* for receiving the filtrate. The top tub *a* will hold 100 pounds of ore and sufficient cyanide solution to leach out the gold. The gold cyanide solution is drawn from this tub *a* to the tub *b* below it, from which it passes into the precipitating box *c* that

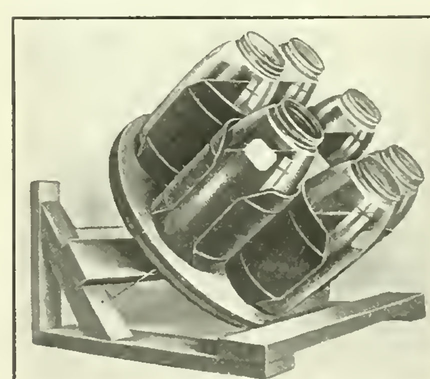

FIG. 2. AGITATOR

contains zinc shavings. After the gold is precipitated, the filtered liquor passes into the sump *d*, where it is tested for cyanide loss, then strengthened or standardized by the addition of cyanide, and, if needed, pumped back to the tub *a*. Sometimes two or more sets of these tubs may be arranged to drain into a precipitating box *c*, as shown.

Filters.—A good filter bottom can be made for small testing plants by placing slats 1 inch apart across a hoop. These slats do not reach down the entire width of the hoop, but stop about 1 inch above the bottom to allow a free circulation of the liquor. The upper surfaces of the slats are covered with a false bottom and canvas, and a strip of canvas should be tacked between the circumference of the hoop and the inside of the tub to prevent sand from washing under the false bottom.

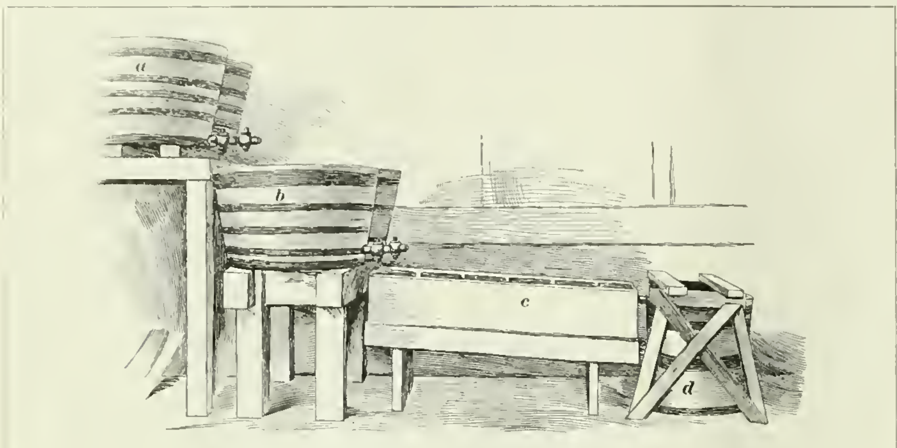

Fig. 3. Testing Plant

If it is desired to test the rate at which an ore will leach, this can be accomplished in a percolator made of 6-inch wrought-iron pipe of sufficient height to hold the depth of ore that it is desired to charge into the mill vats. Ore charges for leaching are from 5 to 8 feet in depth, and occasionally as much as 10 feet, where large tonnage is required. The pipe percolator is rigidly secured to the wall by brackets, the bottom being closed by an ordinary pipe flange and plug, the plug being tapped for an outlet nipple and valve. The filter cloth is placed between the halves of the flange coupling and the edges are made tight by the flange bolts. The tailing is discharged by separating the flange.

Crusher and Grinder.—A laboratory crusher and also a grinder should be provided, even if for no other use than the ordinary assay work. When a busy assayer is obliged to get along without such conveniences, poor sampling is not an uncommon result. Laboratory crushers of either the Blake or Dodge type are used, but these machines when built in laboratory sizes have small capacity. In the mill sizes, the comparatively heavy pieces of ore usually fall from the jaws as soon as crushed, but the laboratory size has a tendency to choke, even on dry ore. The question of capacity is not of great importance in dealing with hand samples in ordinary work about a mine; but in testing ores, considerable quantities are required to be handled, and the case is quite different. A machine is now manufactured which obviates this difficulty by giving the movable jaw a downward motion immediately after each crushing stroke, thus rubbing the packed ore from the face of the jaw. This machine will crush to about $\frac{1}{4}$-inch size, and the laboratory size machine is rated at 600 pounds of ore per hour.

In the laboratory pulverizer, or sample grinder, shown in Fig. 4, the ore is ground by a rubbing between two flat disks. The moving disk revolves upon an axis that is given a gyratory motion to assist in the grinding and promote even wear of the disks. These machines will grind to 200 mesh, can be opened for cleaning without changing the set for fineness of grinding, and require very little space.

The Jones ore sampler will be found quite indispensable in ore-testing work.

Lime Water.—Take 200 grams of lime, slack in water by the aid of heat, add about 2 liters of water and mix. The clear solution is used, leaving the undissolved lime in the bottom. More of the solution may be obtained by adding water. This solution is useful in making up cyanide solutions for ore tests.

Prepared Lime.—Crush 500 grams of lime of good quality on the bucking board and pass it through an 80-mesh seive. Roll it on the sample cloth and transfer to a salt-mouth (wide mouth) bottle that must be kept tightly corked. The alkaline strength of this lime should be determined, as lime often contains varying amounts of silica and other inert substances.

Alkaline Strength of Lime.—By the method about to be described, all the soluble alkalies and alkaline earths in the sample are reckoned as lime. Slack 1 gram of lime in a casserole by the aid of heat and mix it with 1 liter of distilled water. (Natural water of good quality may be made to answer the purpose by neutralizing with lime water until it strikes a pale pink color with phenolphthalein.) As 2 pounds of lime per ton of water has been added to the water, it is only necessary to titrate the mixture with H_2SO_4 test solution and compute the result in percentage of lime actually dissolved. The portion titrated must be clear and contain no undissolved lime in suspension.

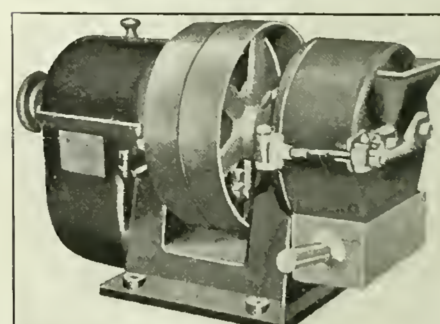
Computing Results.—All weighings are made by the metric system on account of its convenience and the saving of time. The chemist's glassware is graduated to this system. In order to become fluent in its use, it is merely necessary to forget a considerable number of long names applied to the useless number of units and thus boil the system down into workable form. The practical weights and measures of capacity are: 1,000 milligrams = 1 gram = 1 cubic centimeter of water; 1,000 grams = 1 kilo (about 2 pounds) = 1 liter of water (about a quart); 1,000 kilos (or liters of water) = 1 metric ton (2,204 pounds avoirdupois).

It will be seen from the above that the kilo bears the same relation to the metric ton that 2 pounds does to the short ton of 2,000 pounds.

Example.—It is desired to add to 100 grams of ore enough lime to make 2 pounds to the ton. Without stopping to "figure," weigh out 100 milligrams of lime. It is desired to make 5 liters of a 2-pound cyanide solution. Weigh out 5 grams of cyanide and add the water.

ORE TESTING WORK

The methods used by cyanide operators in making cyanide extraction tests vary considerably. Those herein suggested have stood the test of practice and when run alongside of mill work have been found to check quite closely. Some have a preference for percolation tests run in glass percolators of 1 pint to 1 quart capacity. These require more attention than agitation tests, but give good results on easily-treated ores. However, percolation tests



Closed

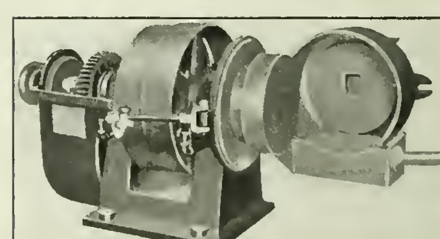


Fig. 4. Pulverizer Closed and Open

on some pyritous ores would be vitiated by allowing them to stand idle during the night, as of necessity one is obliged to do. Agitation tests require less time than percolation tests. They may be placed on the agitator near the close of the work period of the day, allowed to run 16 to 18 hours, and be ready for assay the next morning.

The Sample.—In preparing ore samples for testing, the ore should be kept as nearly as possible in the same condition in which it would be received at the mill. Drying is necessary in order to correctly estimate weights, but if the ore is to be crushed wet this may be omitted and the weight obtained from the moisture sample.

Artificial heat used in drying, even if quite moderate, is liable to cause marked changes in both pyritous and oxidized ores. Under the influence of warmth and moisture the pyrite is rapidly decomposed, ferrous compounds are oxidized to ferric, clayey material is partly dehydrated at quite a moderate dry heat, and in some cases the ore is changed so greatly as to render a test misleading. Samples may be thoroughly dried, and in mountain regions quite expeditiously, by exposing them in thin layers to air-currents of any ordinary temperature. Preliminary tests should be made on samples crushed moderately fine, say, to 40 mesh.

Making the Test.—Break 40 pounds of the ore to ¼-inch size. With the sampler cut out 10 pounds and break to 10 mesh. From this cut 2½ pounds and break this cut to 40 mesh, cutting from the 40-mesh ore a liberal sample for assay. The assay will determine the value of the entire lot. Assays in connection with ore testing should receive the same care and attention as bestowed on controls. The ¼-inch and 10-mesh lots will be reserved for future consideration and attention will now be directed to the 40-mesh ore.

Test for Soluble Acidity.—Place 10 grams of the ore on a filter in a 3-inch funnel, wash with distilled water, adding the water a little at a time from a wash bottle, collecting the filtrate in a beaker. Titrate the filtrate with decinormal (one-tenth normal strength) $NaOH$ test solution, using phenolphthalein indicator. One cubic centimeter of decinormal $NaOH$ test solution is equivalent to .004891 gram of H_2SO_4. The result of the titration may be computed thus:

Example. Suppose that 1.3 cubic centimeters of the $NaOH$ test solution was used. $1.3 \times .004891$ gram = .0063583 gram, the amount of acid (as H_2SO_4) washed out of the 10-gram sample by the water. Ten grams is $\frac{1}{100000}$ of a metric ton. The amount of acid in a ton of ore is therefore 100,000 times .0063583 gram, equal in round numbers to .6 kilo. A kilo per metric ton is the same as 2 pounds per short ton; therefore, if one desires to do his thinking in pounds he doubles the .6, making 1.2 pounds.

Ores do not usually contain enough soluble acidity to make a preliminary water wash advisable, but this condition occurs when treating old tailing.

Test for Total Acidity.—Ores not yielding acidity to water often contain substances easily decomposed by an alkaline solution, thus consuming considerable quantities of alkali. This is termed latent acidity. It is of little use to proceed with a cyanide test until these factors are determined. To determine total acidity, take two samples, 100 grams each, of the 40-mesh ore, and place each in a jar of the agitator. Prepare a clear solution of lime hydrate containing about 3 pounds of lime (CaO) per ton, and ascertain its strength by titrating 20 cubic centimeters. Place 500 cubic centimeters of this solution on one portion of the ore, and in the same manner prepare and place upon the other portion of ore a solution of about one-half the strength of the former. The reason for using five times as much solution as ore is to guard against any material drop in the strength of the solution during the test. At the end of 10 minutes titrate 20 cubic centimeters from each jar, also titrate at the end of 12 hours. In computing results, it must be remembered that, as there is five times as much solution as ore, the drop in the strength of the solution must be multiplied by five in order to indicate the amount of lime consumed per ton of ore. Fifty cubic centimeters may be used for the first and last titrations if greater accuracy is desired. The carbon dioxide in the air will consume some lime, but as that would occur in mill practice, no error is thereby introduced. If it is desired to know how much lime consumption is due to the air, the tests may be made in duplicate, one of the duplicates to be covered by the jar cap. It may be that the sample tested with the weaker solution will show a considerably lower lime consumption. This will give valuable information as to the total alkaline strength of cyanide solution to use.

Extraction Tests.—A test for gold extraction and cyanide consumption may now be made. Cut out and weigh into each of the six jars of the agitator 100 grams of the 40-mesh ore. Add a weighed amount of prepared lime to each charge. The lime consumption already determined will be a guide as to the amount of lime to add; but a different amount may be added to each charge, in order to note the effect of various amounts on the extraction. After the lime, add 500 cubic centimeters of cyanide solution varying in strength from 1 to 5 pounds of cyanide per ton, with protective alkalinity varying from ½ to 2 pounds of lime per ton. Start the agitator and carefully record all the particulars of each test. After the agitator has been running 16 to 18 hours, decant the solutions from the jars, carefully titrate them, and record results, examining the solutions for reducing agents. Transfer the ore to filters in 6-inch ribbed funnels and wash with water added in small portions, putting the washings into the solutions. Assay the solutions and dry and assay the several tailings. Study the record of each test. If the solution comes off with more protective alkali than it had at the beginning, it indicates that too much lime was added. If less, the reverse. Study the extraction and cyanide consumption; and if there is a material difference in the amount of cyanide consumed by the different tests, look for the probable cause and endeavor to make an improvement in the next series of tests.

After deciding the question of lime and solution strength, the matter of crushing may be gone into by means of samples crushed to various sizes from 10 to 150 mesh. Tests may be made on coarser material, if the appearance of the ore should warrant. The time of treatment beyond which no appreciable extraction occurs can be easily ascertained by putting on a number of like tests and taking them off after different intervals of time, up to 24 hours, remembering that the solution must be kept in proper condition. Do not be hasty in forming conclusions, but endeavor to verify the work by further experiment before accepting results. If there is reason to believe that reducing agents are interfering with extraction, a larger amount of solution may be used in the test and the jar may be tightly closed at intervals and vigorously shaken to incorporate air with the solution. At the end of the test note the effect when the solution is examined with $KMnO_4$. Air may be introduced into the solution during the entire time of the test in the following manner:

Aerating Device.—Procure a 60-gallon cask, set it on end, calk into the head a piece of ½-inch iron pipe reaching to the bottom head, having cut a notch across the bottom end of the pipe so that the cask bottom will not obstruct the opening. Insert a funnel in the top of the pipe and place it under a water supply. Screw a ⅛-inch gas-pipe nipple into the upper head of the cask. Water let into the cask through the funnel will force air through the nipple. Next, draw the end of a 3-foot piece of glass tubing to a fine point, placing the point of the tube in a jar of the agitator and reaching nearly to the bottom. By means of a flexible connection, secure the tubing near its other end so that the tube will be in line with the axis of rotation of the agitator. The pointed end of the tube will then easily follow the rotary movement of the jar. By means of a piece of rubber tubing, connect the glass tubing with the nipple in the head of the cask. To adjust the water coming into the cask so that the apparatus will run for a given length of time, hold a graduated cylinder under the stream above the funnel for 8.64 seconds ($\frac{1}{10000}$ of a day). Each 100 cubic centimeters of water caught in the cylinder represents a flow of 1 metric ton per 24-hour day.

Larger Tests.—After the agitation tests are concluded, leaching tests may be made in the tub plant, these tests to include precipitation of the gold upon the zinc shavings. Mechanical questions, such as the leachability of the ore, may be decided by the leaching tests. If there is doubt as to a fair leaching rate, the iron-pipe percolator may be used, being careful to fill the percolator in the same manner as the vat is proposed to be filled in mill practice—wet, semidry, or dry—to the end that the charge may have the same permeability. If the character of the ore is found to require separate treatment for sand and slime, the sand may be separated by panning. Pan in cyanide solution if it is proposed to crush in solution.

Concentration and Sizing Tests.—Ore may contain heavy minerals deleterious to cyanide, but become amenable to treatment after this mineral has been removed by concentration. Concentration tests are made by means of the miner's gold pan. As it is necessary to use the gold pan in order to make rapid and accurate sizing tests, concentrating and sizing will be described together. Weigh out 1 to 2 kilos of ore crushed to the proper mesh. Fill the panning tub about two-thirds full of water to which a little milk of lime has been added in order to settle slime. Place a convenient amount of ore in the pan, and with the pan dip some water from the tub and thoroughly wet the ore, breaking up lumps and slime with the fingers. Support the 200-mesh seive across the top of the tub by means of two sticks, or, better, by a frame made for the purpose. Have plenty of water in the pan, holding it level and shaking it from side to side. Do not be in a hurry to begin panning off the lighter material. After the pan has been at rest for a few seconds it will be noticed that the sand has packed. Shake the pan vigorously from side to side and note the effect. The sand is partly in suspension under the water and the heavy mineral is working its way to the bottom. Note the difference in the feel of the pan when in motion. It is more easily moved, the sand not moving with the pan. If there is too much water in the pan the sand will be broken up and mix with the water, and the concentrate raised from the bottom of the pan. Repeat these operations until you have become a little familiar with them. You are not losing any time, as the grains of sand are being rubbed and scoured from adhering slime and fine particles of sulphide. If the ore is very slimy, use extreme care to prevent wasting away sulphides with the slime, as the slime has the effect of buoying up the finer particles of sulphides. After shaking the pan, hold it stationary for 2 or 3 seconds and then slowly pour the slimy water through the screen. If quite slimy, leave from one-half to one-third of the water in the pan above the sand. Dip more water into the pan and repeat these operations, which may proceed more rapidly as the amount of slime in the pan decreases. The water in the tub will generally be sufficiently clear for panning, as the lime will flocculate the slime and cause it to settle rapidly to the bottom. The mineral is soon down under the sand and all the water above the sand may be drained from the pan each time the slime is poured into the seive. Finally the water poured from the pan will be practically clear. The sieve is then lowered into the tub so that the wire cloth will be a little under the water, the side of the sieve is tapped by the hand, and all the 200-mesh material remaining in the sieve is made to pass through. The oversize remaining on the sieve is returned to the gold pan. The slime in the tub is poured into a bucket, where it rapidly subsides, and a considerable portion of the water may, by means of a rubber tube, be decanted back to the tub for reuse. After further decantation the slime is transferred to a pan and dried.

If it is desired to separate the concentrate it will be best to size the sand into two portions. To do this, place in another gold pan a sieve of such mesh as will divide the sand into two nearly equal portions. Pour water into the second pan to a depth of $1\frac{1}{2}$ inches; place the sand upon the sieve a portion at a time, and by tapping and moving the sieve under the water, cause the finer sand to pass through. The two portions of sand are then separately panned, the operation being somewhat different from that described for the slime. The pan is shaken from side to side with a convenient amount of water, the operator tilting the pan from himself near the end of the operation so that the water nearly escapes over the edge of the pan. In panning off the sand the pan is more slowly moved from side to side while the water and lighter sand is running over the edge, the operation being assisted by the wave-like motion of the water from side to side, while the greater portion of the sand settles or "packs" in the pan. More water is added, and the shaking repeated until the sand is again in suspension and more of the gangue is panned off. No attempt should be made to separate the last portion of the gangue, as it will result in loss of mineral. The mineral remaining in the gold pan is washed into a small drying pan, and the sand again panned to make sure that no considerable amount of mineral has been panned over. After both sizes of sand have been panned, the sand and the mineral are separately dried. Only a very moderate degree of heat should be used in drying sulphides. The nest of sieves is arranged with the coarsest uppermost and the dried sand screened. A small scorifier placed in the uppermost sieve causes the wire cloth to vibrate as the sieve is shaken and greatly assists the operation. The sieves are taken off one by one and the scorifier transferred to the next lower as the operation proceeds. The material passing the last sieve and found in the pan bottom is added to the dried slime unless it is desired that it should be weighed separately. The concentrates and the different sizes are weighed and the percentage of each calculated. If it is attempted to size without first separating the slime, it will be found that a large amount of clayey material will adhere to the coarser particles, besides the passing of the finer particles through the 200-mesh sieve after drying will be extremely laborious. The following example from actual practice illustrates a good method of tabulating the results of a sizing or concentration test:

Sizing of M. H. No. 54, January 24, 19— From Puzzler Mine
Stamped to 12 mesh wire screen, No. 19 wire, the opening being approximately 20-mesh assayers sieve

Size of Mesh		Per Cent.	Assay	Total
	+ 20	1.8	$14.00	$ .252
− 20	+ 40	22.2	12.40	2.753
− 40	+ 80	24.0	12.40	2.976
− 80	+100	7.0	11.60	.812
−100	+200	8.0	12.80	1.024
−200		31.0	14.40	4.464
Concentrate		6.0	96.80	5.808
Heading assay, $18.40		100.0		$18.089

The column headed "total" is derived by multiplying the assay by the per cent. The assay of the different sizes shows that the ore was crushed to the right screen. A very little mineral was seen embedded in the +20 sand, which accounts for its slightly higher assay, $14. The remaining sand appeared white and clean. The higher assay of the −200 is accounted for by a little sulphide being panned off with the slime. As such losses always occur in concentrating mills, this does not introduce any error. A concentrate assaying $96.80 per ton was obtained, making a recovery of $5.80 from an $18-ore by concentration. Before methods were found for the treatment of ore after the free gold and concentrate had been recovered, large amounts of gold were allowed to go to waste in the tailing.

Separate Treatment.—Tests on comparatively large lots may be made by panning off the slime and leaching the sand, while the slime may be treated by repeated agitation and decantation with fresh portions of solution that may afterwards be passed through the sand. In making percolation tests it is best to keep the solution moving during the greater part of the time. To this end there should be sufficient solution above the leaching vessel at the end of the day and the leaching rate so regulated that it will run for a greater portion of the night. The ore should be kept covered with solution during the leaching. A good method of accomplishing this is to fill a 10-gallon tin can with solution and support it in an inverted position over the leaching tub, with its mouth just below the surface of the solution covering the ore, the can being partly closed by a stopper having a hole in it. As soon as the solution falls below the opening, air will enter the can, allowing a small portion of solution to run out. More than one of these cans may be used in the same vat if necessary. The rapidity of leaching is regulated by means of the valve outlet of the leaching tub.

Coarse Crushing.—If the ore is amenable to treatment at a coarse mesh, say, $\frac{1}{4}$- to $\frac{1}{2}$-inch size, it will not be necessary to separate the slime, provided the ore is crushed dry, but it need not be dried artificially. Some ore is successfully treated in this manner as it comes from the mine, containing quite an amount of moisture. The first solution is always put on from the bottom, which generally flocculates the slime-forming material so that no slime afterwards comes down upon the canvas filter. After preliminary agitation tests, it is always best to make leaching tests on coarsely-crushed ore, taking sufficiently large tailing samples to be certain of the percentage of extraction.

Modifications.—Laboratory extraction tests may be modified in a great variety of ways to suit special requirements. The operator must, to a considerable extent, decide for himself on these modifications; and in order to be successful he must have some originality and a knack for investigation and research. The outline here given is not expected to be followed in every detail, but as a general guide to a practical knowledge of the subject, which can only be gained by experience.

ROASTING TREATMENT OF CONCENTRATE

Ores containing gold in combination with tellurium and antimony are benefited by a preliminary roasting operation, as the loss of cyanide is thereby reduced and the extraction of gold is increased. In the Cripple Creek district, Colo., most of the telluride ores are unsuitable for cyaniding until after roasting, when a high extraction of gold has been obtained with a small consumption of cyanide. In some places, concentrates and pyritic ores that could not be treated economically in the raw state have been successfully treated after a dead roast. Roasting has the effect of decreasing the cyanicides in the ore by volatilization and oxidation. It seems also to break up refractory ore particles by freeing the gold, and to render the material more permeable to cyanide solutions.

After the ore has been tested, by the methods described, for total extraction and consumption of cyanide, if the extraction is low, finer crushing is tried; and, if the result is still unsatisfactory, the difficulty may be corrected by roasting. The sulphur tellurides of Kalgoorlie, West Australia, are first roasted and then ground in Wheeler pans.

Treatment of Concentrate.—Concentrate containing pyrite should be ground to slime and treated by agitation, if it will yield extraction without roasting. If the concentrate contains amalgam or coarse gold, this should be removed by means of a small amalgamating plate or like device, placed between the regrinding machine and the agitator. Some concentrate requires roasting in order to prepare it for cyanidation. The economy of doing this in preference to roasting the entire bulk of the ore is apparent.

Vacuum Filter Tests.—The leaf about to be described is of standard construction and will be found to answer general laboratory requirements. Make a frame of wood 12 in. × 12 in. inside. The top strip of the frame should be $1\frac{1}{2}$ in. × $\frac{7}{8}$ in., and the sides and bottom $\frac{7}{8}$ in. × $\frac{7}{8}$ in. Cover this frame on both sides with No. 8 cotton duck, stitching the two thicknesses of duck together by eight vertical seams $1\frac{1}{2}$ inches apart, reaching to within $\frac{3}{4}$ inch of the inner edges of the frame. The two outermost seams will be about $\frac{3}{4}$ inch from the side pieces of the frame. In the pockets between these stitchings, slip $\frac{3}{8}'' \times \frac{3}{8}''$ square sticks short enough to easily go inside the frame, leaving the stick out of the center pocket. Pass through the top frame and center pocket a piece of $\frac{1}{8}$-inch wrought-iron gas pipe, cutting some notches in the lower open end of the pipe so that it will not choke where it rests on the lower frame strip. Make an air-tight joint where the pipe passes through the upper frame strip, by means of lock-nuts and packing. Securely tack the canvas to the frame, lapping the two pieces on the outside of the frame. Cover and saturate the canvas with paraffin paint or shellac varnish where it comes in contact with the frame so that no cake will form on that portion. The filtering area will then be exactly 2 square feet. To the top of the pipe attach a small hose capable of withstanding a vacuum and attach to a receiver and air pump. If an accurate vacuum gauge is not at hand, attach a glass mercury tube to the suction hose and count the vacuum in inches of mercury. Have three vessels, one for the slime pulp provided with agitation, one for cyanide solution, and one for wash water. Run the pulp from the agitator into the first vessel and put in the filter leaf, keeping it all the time under the pulp and the vacuum in operation, and keep up enough agitation to prevent settling. Record the time and vacuum required to build a cake 1 inch in thickness. Remove to the cyanide solution, and draw through the cake twice as much solution as its contained moisture. Remove to the wash water, and draw through it half as much water as was drawn off the cyanide solution. If the leaf is kept entirely submerged the amount of wash drawn through can be known by measuring the fall of liquid in the vessel. If compressed air is not convenient, the cake may be blown off with water, using a pressure of not more than 10 pounds per square inch. On drying the discharged cake, its weight will give a basis on which to compute tonnage capacity. Diffusion loss in the wash water can be approximately determined by boiling down all the wash water left in the vessel after several cakes are washed and assaying as a solution assay, computing the result to the amount of dry slime washed. In order to more closely approach mill conditions, the solution wash may contain about 10 cents gold per ton. Diffusion into the wash solution is not serious, if known and the losses are guarded against by occasionally pumping out the wash vats and changing the solution. Experience seems to indicate that different ores present quite a wide difference in this respect.

(To be continued)

Eucalyptus Oil for Ore Dressing

According to the United States Consul at Hobart, Tasmania, local prices for eucalyptus oil have lately shown an advancing tendency, due, it is understood, to the demand which has arisen for the lower grades of such oil in concentrating sulphides of lead and zinc in Australia.

Eucalyptus-oil distillers are selling all the lower grades of oil to ore mills. Tasmanian eucalyptus oil ultilized in milling may be obtained easily from all kinds of eucalyptus leaves, but the leaves of the peppermint gum are at present the chief source of supply. This oil is selling for 16 to 20 cents per pound. It seems possible that its preparation may become an important by-product of the Tasmanian timber industry, and it is already announced that a mill for its extraction is to be erected at Scotsdale in northern Tasmania. The December (1911) issue of the *Australian Journal of Pharmacy* makes the following reference to this interesting use of eucalyptus oil:

"Enormous quantities of oil have been consumed in the mining districts in the processes of preparing sulphides of zinc and lead. About one-half pound of oil is emulsified by vigorously shaking it up with 100 gallons of water, and with this mixture the moistened or powdered ore is stirred up. The eucalyptus oil floats the sulphide particles and carries them to the surface, together with the gold and silver contained in them."

Power Consumption of Hoisting Plants

Relative Economies of Steam, Air, and Electric Hoists—Tests of Electric Hoists Under Varying Conditions

By S. W. Sykes. (Concluded from August)

In the case of electrically driven hoists, the efficiency is not as a rule very much affected by the method of operation, especially in the case of large hoists with voltage control. It is therefore more or less immaterial whether the operator is highly trained or not, so long as he has sufficient intelligence to operate the hoist in such a way as to obtain output and avoid accidents. In the case of steam hoists conditions are different, as it is possible by unskilled operation to very materially affect the economy. As already pointed out, the economy of a steam hoist is affected to a great extent by the steam pipe, which, for all practical purposes, should be considered as part of the hoist. The economy of a steam hoist is, as a rule, affected more by the proportion between the average duty and maximum capacity than electric hoists, even when the flywheel motor-generator system is used. This is due to the conditions limiting the design of steam hoists and the economical operation while running.

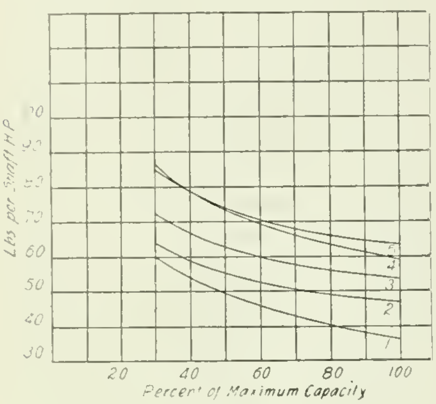

FIG. 8

An essential condition of a steam hoist is that it must start with the most unfavorable crank position. It is therefore necessary to use two cranks at 90 degrees to avoid dead centers, and generally the cylinders must be designed so that each is capable of exerting the maximum torque required to start. The consequence is that the engine is very large for the average work it must perform, and were it not for the starting conditions the result would be the equivalent of running an engine on very light load. At starting it is necessary to admit steam practically the whole of the stroke, and if the accelerating period is a large percentage of the time that steam is on the engine, it is obvious that the consumption will be high.

The steam hoist for main shaft hoisting has been greatly improved during the last few years, and with modern valve arrangements and favorable steam conditions, reasonable steam consumptions are obtainable. The great majority of hoists, however, are very uneconomical, owing to the lack of refinement in design, and they cannot be taken as representative of what can be accomplished. In Fig. 8 is shown the results of a number of tests on engines working under different conditions, these tests being made on engines which may be taken as representations of modern practice.

Curve *4* shows a test on a double tandem-compound hoisting engine, working with steam at 135 pounds per square inch non-condensing. In this case, the mine was not operating at the full depth and the engine was, consequently, somewhat too large.

Curve *1* shows an engine operating with considerable superheat and a moderate vacuum. The engine is working at about the conditions for which it was designed, and this is probably as low a steam consumption as can be obtained under working conditions.

Curve *2* shows a hoist working non-condensing, with saturated steam, at about the conditions for which it was designed; and it should be noted that this hoist has only a simple engine, but its economy is better than that of the double tandem-compound engine, shown by curve *4*. This is due to the load being nearer to the designed capacity, and it shows the waste caused by a hoist that is too large for the work.

The result shown in curve *5* represent very closely the average steam consumption of the usual type of simple hoist engine with a Corliss valve gear. This hoist was working at its designed capacity and is considered a first-class equipment, although it is about 6 years old. The curves *1* and *2* show considerably better results than usually obtained, and could be only duplicated under very favorable conditions with the latest design of engines.

Curves *1*, *2*, *4*, and *5* show steam actually used by the engine.

Curve *3* shows the steam consumption of the machine covered by curve *2*, including the loss in a pipe line 340 feet long, 12 inches in diameter, protected with ordinary insulating materials, and it will be seen that this loss is very considerable. It will be noticed that all of the curves show an increased consumption when the hoist is worked below full capacity. This is due to steam leakage and condensation in the engine, brakes, etc., and also to the method of handling.

Under the conditions shown in curve *1*, which indicates the steam consumption of 37 pounds per shaft horsepower at full capacity, an electric hoist of the flywheel motor-generator type, could be operated with a steam consumption at the generating plant of about 25 pounds per shaft horsepower hour.

Air Hoists.—The number of installations of air hoists is not very great, nor is it possible to obtain very much information regarding them. In Fig. 9, however, is shown some test results for an air hoist, operated by an electrically driven compressor, the compressor being provided with unloading devices and suitable receivers. It will be seen that the loss is very considerable and at the lower loads, the power consumption is very much in excess of the figures shown in the flywheel motor-generator set, Fig. 7. Very extravagant claims have been made for various systems of air hoists, but no information has been published that would justify the statements. It is quite possible to show that under certain conditions such hoists are economical, but practical results do not confirm these statements.

Summary.—It is impossible to draw any general conclusion as to the comparative cost of hoisting with different systems, as it is altogether controlled by local conditions, but the curves that have been given indicate to some extent the bases on which such comparisons can be made. The features affecting the economy of electric hoists have been considered in some detail so as to show the lines along which new installations should be designed to obtain best results.

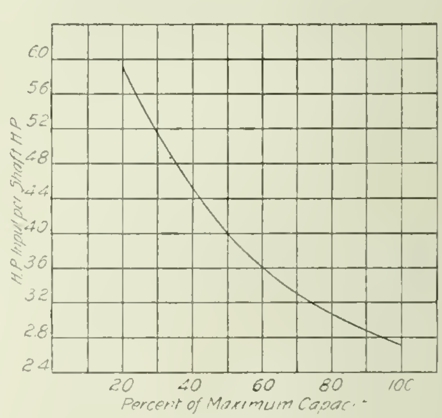

FIG. 9

There is one characteristic of the electric hoist that is of considerable importance from an operating standpoint; that is, the efficiency does not change with the age of the installation, except, perhaps, a little on account of wear of gears, etc. This is not the case with steam and air hoists, as constant attention is necessary to prevent leakage in pipes, valves, etc., and as a rule there is always more or less loss in this way. After a plant has been in operation for a few years, it is usually found that the economy has been materially reduced, except in a few cases where very great attention is given to maintenance, which is not the rule. Where air hoists are used it is practically impossible to maintain the piping free from leaks, and unless the leak is a bad one it is not discovered. The same applies to steam pipes to a lesser degree, but it must be remembered that each joint is a potential if not actual point of leakage. With steam lines, each foot of pipe is a source of loss due to condensation. The question of maintenance has not been discussed, as this is usually a matter of local conditions, but the figures given will indicate, in general, the bases on which cost estimates may be made.

Formation of Magmas

By Eugene B. Wilson

About 13 years ago one of the best geologists of our time stated that it was almost criminal to advance the ideas submitted in this paper. However preconception is as difficult to eradicate in this instance as in the case of observers who have absorbed ideas to which they endeavor to make the genesis of ore deposits conform.

Both Moses and David use the word Heaven before the word earth and as the fourth commandment was given direct to Moses, many accept the nebular hypothesis as the origin of the earth. This supposes that our planet in conjunction with the whole solar system originated in the separation and condensation of a small part of an enormous nebula or cloudy mass of vapors and gases, like the faint luminous star clouds which may be observed on clear dark nights. It also presumes that when any portion of those vapors and gases was thrown off or detached from the whole mass it began to arrange and consolidate as a globe.

Geologists, as a rule, have assumed that in the beginning the earth was a molten mass that cooled gradually until it became fit for the habitation of man. It is difficult to reconcile this assumption with the nebular hypothesis, or with the rocks that compose the basement complex. Vapors would not condense in burning material and certainly granite shows no sign of vulcanism, while it does show that it was a comparatively cool plastic magma to which the word plutonic has been assigned to distinguish it from slag or dry-heat formation.

This argument is apparently strengthened by the chemical law that the heat of formation is equivalent to the heat of separation, and from the fact that the minerals composing granite retain their water of crystallization, which, had vulcanism played a part, would have been impossible. Evidently the chemical heat of formation was gradually dissipated after the reactions ceased and then the earth formed a gigantic plastic magma. At the time the earth was forming there must have been moisture in abundance, and undoubtedly the mother liquor of the magma was hot, owing entirely, however, to wet chemical reactions.

Astronomers state that the sun shows indications of dry heat, also that it contains metals similar to those on the earth. However, our planet shows no past indications of heat other than can be duplicated by dynamic and chemical forces. The vulcanic appearance of some rocks influenced the early geologists to assume as a starting point that the earth was originally a fiery mass, and this assumption was strengthened by active volcanoes erupting fluid material that glowed on reaching the atmosphere. It is believed that geologists now discredit this theory, because similar phenomena can be reproduced on a small scale by chemical reactions, which with pressure will superheat a mass; and further, active volcanoes and eruptions discredit vulcanism or dry heat.

A close examination of the so-called igneous rocks of the eruptive class will disclose that their surfaces are glassy or slaggy where they have been exposed to the atmosphere, while their interiors show them to have been formed by wet heat. If the theory of vulcanism or dry-heat formation of the earth be rejected, and aqueo-igneous fusion as it is observed in natural eruptions substituted, it is possible to establish the hypothetical formation of magmas as herein outlined.

Geologists state that granite is the basement complex or primary rock from which other rocks were formed. They call it plutonic, meaning thereby it was deep seated and cooled slowly under pressure. That granite was formed by aqueo-igneous fusion is evident from the water of crystallization in the minerals composing it. Fissures in sedimentary rocks sometimes show intrinsic granites with angular pieces of the sedimentaries engulphed in it.

If the foregoing enunciation coincides with observed geological conditions, then the theory of formation of magmas depends for synthetical explanation upon the basement complex being the parent magma from which two other magmas were formed under widely varying conditions. These three magmas are named and defined as follows:

1. *Aquea-Igneaus Magma.*—This kind of magma formed rocks through the heat produced by chemical reactions augmented by pressure. Magmatic solution or mother liquor was a strong factor in the operation. Magmas of this kind produced the basement complex and later eruptive rocks.

According to J. D. Dana, all rock crystals contain on an average of 2.5 per cent. of water of crystallization, and, in addition, rocks in the zone of fracture contain quarry water. It is reasonable to presume that the heated magmatic solutions which were capable of forming and segregating rock minerals were equally capable of forming and separating metallic minerals and disseminating them through the magma as individual crystals. This segregation is typical of aqueo-igneous magmas whether of the basement complex or the Tertiary eruptive rocks, and will be noticed to some extent in aqueo-organic magmas; in fact it is "first concentration."

2. *Aqueo-Organic Magma.*—This magma had its origin in organisms that lived in water, and which afterwards were made plastic and consolidated by pressure. In the crystalline limestones of the early series, heat and magmatic solutions played their part. The oldest limestone, probably Cambrian (locally known as MacAfee limestone in New Jersey), is white and crystalline with scales of graphite here and there. It is found in juxtaposition with a magmatic deposit of Franklinite, a mineral that is magnetic and composed of iron, manganese, and zinc oxides. Daubreé states that Franklinite can be produced artficially by the action of perchloride of iron and chloride of zinc on lime, with heat as an adjunct.

Knox dolomite, a Cambrio-Silurian limestone, contains disseminated crystals of galena, sphalerite, and pyrite, and sometimes segregated crystals. From the similarity in which the metallic minerals are found in the aqueo-igneous and aqueo-organic magmas they are considered as minerals of first concentration, although metallic minerals of second concentration are found in connection with aqueo-organic magmas that have weathered.

3. *Aquea-Magma.*—This kind of magma includes sedimentary deposits such as salt and gypsum, sandstone and slate. The former two were formed from supersaturation of aqueous solutions. The latter are fragmentary, yet evidently laid down by water, consolidated by pressure, and cemented by colloidal substances that afterwards hardened. Rocks of the aqueo-magmatic class carry ore deposits of second concentration and sometimes of third concentration.

New University Mining Laboratory

It is stated by H. H. Stock, Professor of Mining Engineering, that the University of Illinois is just completing a mining laboratory 100 feet long by 42 feet wide, divided into two equal sections; one for the treatment of ores and one for the washing of coal. The building also includes sample crushers and screens and two steel sampling floors, one for ore, and one for coal.

The crushed material is elevated in a 15"×20" continuous carrier equipped to dump automatically along the upper run into any one of a row of steel bins, each holding 5 tons. Beneath these bins is an automatic traveling scale through which the material is delivered to any one of the screens or the washing or concentrating appliances. On the coal side there is a Holmes Brothers shaking screen and a Webster revolving screen, each fitted to separate four sizes and each about 13 feet long. On the ore side is a vibrating screen. Beneath each of these screens is a set of bins from which the screened material is taken in wheelbarrows to a dormant scale and then delivered to the lower run of the carrier which elevates it to the upper tier of bins. Through the automatic traveling scale the coal is delivered to an American Concentrator jig or to a Stewart jig. A Luhrig jig and a Jeffrey-Robinson cone washer will be added later. The washed coal is delivered into a 1,300-gallon settling tank, from which it is elevated by a Webster bucket elevator to an overhead bin and from thence by carrier delivered to a bin outside the building, from which it is carted away to the boiler plant. The coal side of the laboratory has a capacity of 5 tons per hour.

On the ore side the material may also be crushed in a stamp battery. The fine screened ore is mixed with water and delivered by a centrifugal sand pump to a three-compartment classifier, the products from which go to a 6-foot vanner, an 11-foot concentrating table, and a buddle. These three machines deliver to four pointed tanks, beneath which are drying tables.

In an adjoining room is a completely equipped chemical laboratory and assay room for carrying on such tests as are required in the concentration of ores and the washing of coal. The equipment also includes an assortment of hand jigs, classifiers, a spiral separator, a small Jeffrey-Robinson tub, and a small laboratory concentrating plant.

The Mining Department is also equipping a new blasting and explosives laboratory, a rock drilling and coal cutting laboratory, and is building a new rescue station for giving training with oxygen helmets and other rescue appliances.

The offices, drafting rooms, library, and recitation rooms of the Mining Department are located in the new Engineering Building, which will be ready for occupancy September 15. In this building there is also a completely equipped laboratory for the study of mine gases and safety lamps.

Beginning with the collegiate year the Mining Department of the University of Illinois will have a complete equipment for teaching all branches of mining engineering.

Society Meetings

The International Geological Congress, on the joint invitation of the Government of Canada, the Provincial Governments, the Department of Mines, and the Canadian Mining Institute, will hold its twelfth meeting in Canada during the summer of 1913. It is proposed to hold the meeting of the Congress in Toronto, beginning on or about August 21, and continuing the session 8 days. Prior to and after the session there will be excursions to various parts of Canada. For further information address W. Stanley Lecky, A. R. S. M., Victoria Memorial Museum, Ottawa, Can.

The opening meeting of the Eighth International Congress of Applied Chemistry will occur in Washington, D. C., September 4, the other meetings, business and scientific, in New York, beginning Friday, September 6, 1912, and ending September 13, 1912. Visiting members will register at Chemists' Club, 52 East Forty-first Street, New York City.

Canadian Mining Institute will hold a meeting in Victoria, B. C., on September 18 and 19. The main object of this meeting is to afford Western members the opportunity of expressing their views on a number of questions relating to the business affairs of the Institute, including proposed amendments to the by-laws and other questions of present importance. One or more sessions will be devoted to the reading and discussion of papers; and members proposing to contribute to the program are invited to communicate at once either with Mr. E. Jacobs, secretary of the Western Branch, Victoria, B. C., or with the secretary of the Institute. Arrangements are also being made for a meeting at Lethbridge, Alberta, of which further particulars will be issued later.

James F. Callbreath, Secretary of the American Mining Congress, has opened offices at 602-3 Munsey Building, Washington, D. C., where members of the Congress and mining men generally may always feel welcome. The headquarters of the Congress will remain, as heretofore, in Denver, Colo. Subsidiary organizations, known as Chapters, are now operating in Alaska, Arizona, Colorado, Oregon, Utah, and Washington, while there are also the Southwestern Lead and Zinc Chapter and the Wisconsin-Illinois Zinc Chapter.

SUBSCRIPTION RATES

Single Copies....25 cents
Yearly Subscription, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines.$2.00
To Canada....2.50
To all other countries....3.00

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us.

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

Our cover design shows one of the richest placer deposits ever found in Alaska, on Little Creek near Nome, on Seward Peninsula. The frozen ground was mined below the surface during the winter by the aid of steam, after which it was hoisted and stacked in the piles shown. When the sun commenced to thaw the piles in summer, and so furnish water, scrapers and horses were used to carry the gold-bearing dirt to the sluice boxes, in which dirt and gold were separated.

The price of silver, which has reached 62.5 cents per ounce, has created a revival of prospecting in the Cobalt district. Several prospects are being opened with a view to bringing them to the producing stage, among which are the John Black, Ophir, Columbus, Cochrane, Airgold, King Edward, and the 20th Century. The Cobalt-Central is now being worked under the name of the Penn-Canadian Mining Co., a number of Pennsylvania shareholders having purchased the old company and incorporated under a new name.

If the United States Bureau of Mines will close its "Press Agency," cease making spectacular exhibitions at Bruceton to prove what practical mining men know, and will make some effort to get at facts regarding waste in mining by other means than by relying on ancient history, and will be fair enough to concede that American mine managers and mining engineers are possessed of a modicum of sense which impels them to true conservation in both life and property, it may in the course of time live down the reputation it has earned during the past two years, and begin to be of some real value.

With a limited area from which to mine it, and a possible production that will be from 10,000,000 to 12,000,000 tons less than the probable demand for this year. plus higher wages paid the mine workers, and yearly increasing cost of production due to the gradual exhaustion of the most cheaply mined coal, prices of anthracite are bound to increase. Notwithstanding the opinions of editors who have never seen an anthracite mining plant and political demagogues who talk for effect, the price of anthracite coal as fixed by the producers is based on cost of production plus a fair profit. If based entirely on the law of supply and demand profits could be greatly increased this year. Years ago when the supply exceeded the demand and operators and mining corporations were bankrupted by the low prices at which coal was sold, uninformed and sometimes venal newspaper and magazine writers were just as persistent in their abuse of the mine operators as they are today. It would certainly be a sign of the near approach of the millenium if the truth regarding the commercial side of the anthracite industry was occasionally published in periodicals other than those specifically devoted to mining matters.

Car Shortage Likely

Mines and Minerals has been requested by officials of the Pennsylvania Railroad to state that railroad facilities are taxed to the utmost, and to request shippers of mineral products to cooperate with railroads to prevent car shortage and congestion of traffic. This can be accomplished if there is prompt loading and unloading of cars.

W. A. Garrett, Chairman of the Association of Western Railways, also requests cooperation from shippers.

The Cause and Prevention of Mine Accidents

There is always a cause for every mine accident, and competent mine officials continuously endeavor to remove such causes. They are unsuccessful when the cause does not become evident until immediately preceding the accident or after it has occurred. American coal mine officials are often unjustly blamed for permitting accidents to occur. There no doubt have been numerous accidents in American mines that could have been prevented by a little extra precaution that would have been an economy rather than an expense, but such instances are becoming fewer each year. That mine disasters cannot be entirely prevented, even by the use of the utmost care, is proved by the occasional large disasters in European countries, where the governmental control of mining operations is much more rigid than in America. In Germany, for instance, the government inspection of mines is most rigid, and the government has for years had able commissioners studying mining conditions and methods, reporting on causes of accidents, and suggesting remedial measures. The same may be said of France, Belgium, and Great Britain. Yet in all these countries large disasters occasionally occur, the recent German disaster being an example.

The occurrence of these disasters does not mean that the governmental work is ineffective, for such is not the case. The investigations and conclusions drawn therefrom have been of great value in lessening the dangers of coal mining. That great mining disasters will be entirely prevented is beyond the hope of the ablest practical mining men, but there will always be room for improvement, and from both a humanitarian and economic standpoint, rational investigation and study of the causes and prevention of accidents should be encouraged by every mining nation and state. Sometimes investigations are discouraged by mine managers, but in almost every instance the lack of cooperation on the part of mine managers is due to the foolish assumption of superior knowledge on the part of investigators, who, while highly educated in the technicalities of mining, are woefully lacking in the practical experience so essential in recognizing local details which often are of prime importance. If the work of the United States Bureau of Mines, in this respect, is to be of equal value to that of the commissions entrusted by other governments with similar work, the men employed in the Bureau must be good practical mining men, as well as men of superior technical education. In addition, to secure such men, the appropriation available for the support of the Bureau must be large enough to enable its director to pay for such talent fully as much as mining corporations pay for equal ability, and its continuance should be so certain as to enable the men engaged to be sure of their positions as long as they are efficient and active in the work.

Bulletin No. 47

During the past year the "Press Agent" of the United States Bureau of Mines has on numerous occasions made the Bureau ridiculous by certain claims of results achieved. In some cases the Bureau was given credit for establishing facts that were known to intelligent mining men for fifty or more years.

In a recent report, Mr. Charles L. Parsons, chief mineral chemist of the Bureau, says:

"In mining coal in this country, probably one-third of the bituminous coal and one-half of the anthracite is left behind in the mine. Fully 80,000,000 tons of anthracite is now being left behind in the mine each year, and it is estimated that since mining began in this country fully two billion tons of anthracite and three billion tons of bituminous coal have been left in the ground under conditions which make future recovery highly impossible."

If Mr. Parsons was writing of 30 years ago, his statement of proportionate waste in mining would be nearly correct, but it is absolutely at variance with facts today, and if it were not ridiculous it would be an unpardonable reflection on the ability of American mine officials.

As the annual production of anthracite in Pennsylvania is now approximately 90,000,000 tons, and the entire anthracite production of the United States is approximately 100,000,000 tons, Mr. Parsons' inference that the annual waste of anthracite is now 80,000,000 tons or 44.4 per cent. of the coal in the ground is absolutely incorrect.

Coke, Oil, and Patriotism

England is abundantly supplied with citizens who are ever forecasting what might happen in case of war. If her statesmen are doubtful of securing an appropriation for oil to lubricate her internal or external machinery they invent a war scare. There is no question but that this plan promotes patriotism and makes her people cling to each other for mutual protection; but it also has another good effect, it sharpens our cousins' wits and under the excitement of war produces results that are useful in times of peace. Gilbert R. Redgrave with other Englishmen views with alarm the fact that England is at present without a native oil supply, but must depend on foreigners for this commodity. Doctor Diesel greatly relieves his anxiety by stating that England has in her coal beds sufficient oil for all her requirements, because it is becoming generally recognized that the new era in dealing with coking coal about to arise will prove profitable alike to colliery owners and manufacturers of coking plants. The present method of manufacturing coke in by-product ovens yields a tar oil too much loaded with pitch for ordinary purposes and is correspondingly deficient in the lighter and more valuable oils. This can be remedied by the distillation of coal at a lower temperature than is usual with coke makers, and this also has the effect of reducing the output of gas by 50 per cent. If a high yield of gas is not desirable the volume of tar oils will be increased from 7 to 35 per cent. of the weight of the coal coked.

The oil produced in this way resembles petroleum rather than pitch tar oil, and after the removal of the more volatile constituents leaves a good fuel residuum.

While in the past the coke made by slow distillation of coal has been of poor quality, that difficulty has been overcome, and coke as good as ordinary gas-house coke is prepared. Thus England shall be free to lubricate with native oils, and run her internal combustion engines with gasoline.

Dust Explosions

At the Liverpool (England) section of the Society of Chemical Industry meeting on February 14, Dr. J. Harger read a paper on "Dust Explosions and Their Prevention," which exploited a new theory for the prevention of such explosions, worked out in the chemical laboratory of the Liverpool University. Briefly stated Doctor Harger's theory is to prevent the ignition of coal dust, and, in a measure, the ignition of firedamp, by reducing the amount of oxygen in the air-currents flowing through the mine. He stated that while a lamp would not burn in air in which the oxygen had been reduced to 17 per cent., a man could do continuous hard work in such an atmosphere and not notice that it differed from ordinary air containing 21 per cent. oxygen. He stated that a man would not notice or feel any bad effect until the oxygen was reduced to below 14 per cent. At 12 per cent. the shortage was noticeable, and a danger point was reached when the percentage of oxygen in the air was reduced to 7½ per cent. He drew attention to some work of Professor Haldane, F. R. S., Dr. Leonard Hill, and Prof. Benjamin Moore, F. R. S., all great English authorities on respiration, who agreed that air containing from 17 to 18 per cent. oxygen with a moderate amount of carbon dioxide, up to 1 per cent., was perfectly suitable for human requirements, and was in fact just as good as ordinary air. Dr. Leonard Hill had made this the subject of special research for 15 years, and his opinion therefore was worthy of credence. He quoted from Doctor Hill as follows:

"A reduction of oxygen to 17 or 18 per cent. of an atmosphere would have no influence on the work done. Mining operations are conducted, railways, etc., are built and big towns exist, at altitudes where the partial pressures of oxygen are much less than this. An increased percentage of carbon dioxide, say up to 1 per cent., will slightly increase the breathing; otherwise it will have no effect."

Doctor Harger stated as the result of his own experiments and the researches and experiments of others, that the reduction of oxygen necessary in the mine air varied with different coals, and with the method of working. In most mines a reduction of 1 per cent. in the oxygen, and the addition of ½ per cent. of carbon dioxide is sufficient. With others a reduction of nearly 2 per cent. in the oxygen, and an addition of ¾ per cent. of carbon dioxide, is necessary to render them safe. This diminution in the oxygen in the mine air is recommended in addition to the amount absorbed by the coal dust, loose coal, and coal faces and ribs. He further stated that absolute safety is secured if the reduction in oxygen is made to 17½ per cent. with ½ to 1 per cent. of carbon dioxide, not only from coal-dust explosions, but from firedamp explosions, also from fires of wood or coal in the roads, and from gob fires. For respiration such an atmosphere is as good as ordinary air, and for people predisposed to consumption it is better. This he stated has been proved by many investigators.

Doctor Harger suggested, as a means to reduce the oxygen in the air, that flue gases, purified from harmful gases and smoke, be mixed with the fresh air entering the mine—1 part to 30 of fresh air, or 1 part to 15 for the more dangerous mines. This he states can be done with very simple appliances.

The plan suggested does not appear feasible. In the first place lights do not burn brightly in air from hydraulic compressors carrying 18 per cent. oxygen. Flue gases even if purified from harmful gases will contain some feature that is not beneficial to the miner; besides, a small quantity additional of CO_2 due to lights absorbing the lessened quantity of the oxygen will create an atmosphere that will extinguish safety lamps. For instance in the Burrill experiments (see Vol. 32, Mines and Minerals, page 650) at the Pittsburg Testing Stations a candle went out when carbon dioxide reached 2.95 per cent. and oxygen 16.24 per cent.

As the United States Bureau of Mines is equipped for such air investigation, there is no reason why Doctor Harger's plan should not be proved either practical or impractical. If practical, even through modification, Doctor Harger will have been proved a benefactor to coal mine owners and workers. If impractical, the absolute knowledge that it is so will be of value.

Personals

Ivan De Lashmutt is superintendent for the Hobson Silver-Lead Co., at Ymir, B. C.

N. F. Drake has accepted the chair of geology at the University of Arkansas, Fayetteville, Ark.

C. M. Eye was recently appointed manager of the Corrigan-McKinney Co.'s operations in Chihuahua.

Albert L. Toenges, whose article on methods employed in the Homestake mine appeared in our August number, has moved to Hibbing, Minn., where he is on the engineering staff of the Oliver Mining Co.

Walter W. Barnett, of Golden, Colo., has returned to his work at the Wellington Mine, Breckenridge, Colo., after a year of recuperation from an accident sustained in this mine.

Rensallaer H. Toll has returned to Denver after spending several months starting up the once active Mineral Farm Mine at Ouray.

J. F. Callbreath, secretary of the American Mining Congress, has returned to his main office at Denver after his long stay in Washington during the recent session of Congress. He has issued a call for the fifteenth annual session, which will be held at Spokane, Wash., November 25 to 28.

Henry D. Milton is secretary-treasurer of the El Paso Gold Mining Co., in the company's new offices, 214 Equitable Building, Denver, Colo.

H. N. Herrick recently resigned his position as assistant professor of mining in the University of California and has gone into practical mining work.

Robert S. Lewis, of Stanford University, has been appointed assistant professor of mining in the University of Utah.

George McNaughton is now manager of the St. Anthony mine, at Sturgeon Lake, Ont.

Carl Scholz, manager mining department of the Rock Island Lines, issued a circular on September 2 stating that H. S. Mikesell has been appointed assistant to the manager.

Leroy A. Kling, who has been connected for some time past with two well-known crusher companies in Cedar Rapids, Iowa, has just accepted a position with the Wheeling Mold and Foundry Co., of Wheeling, W. Va., as sales manager of the road machinery department.

W. H. Cunningham, of the firm of Cunningham & Conner, consulting engineers, with offices in the Robson-Prichard Building, Huntington, W. Va., and the Blackstone Building, Ashland, Ky., has been appointed Assistant State Geologist of Kentucky. Mr. Cunningham is also secretary-treasurer of the Mine Owners' Association of Kentucky.

M. C. Reed, of Scranton, representative of the Sullivan Machinery Co., has persuaded the Hillside Coal and Iron Co., the Delaware, Lackawanna & Western Co., the Pennsylvania Coal Co., and some other anthracite companies to adopt coal cutters in their mines.

John E. McCarthy, recently of Denver, Colo., but now of Las Vegas, N. Mex., was recently married to Miss Hazel Shipman of Houghton, Mich.

W. H. Tangye has been appointed superintendent of the Calumet and Sonora properties, at Cananea, Sonora, Mex.

R. C. Glazier has been appointed manager of the Cambria Steel Co.'s blast furnaces at Johnstown, Pa.

Marshall G. Moore has been appointed mining engineer of the Cambria Steel Co. This position places Mr. Moore in general charge of mining operations.

L. F. Miller, Professor of Physics and Electrometallurgy at the Colorado School of Mines, recently visited many of the mining districts of his state, becoming familiar with their activities.

Dr. Karl Oestreich, of the University of Utrecht; Dr. Guster W. v. Zahn, of the University of Jena; Dr. Clinton Marinelli, of Florence, Italy; Dr. Joseph Partsch, of the University of Leipzig; Prof. Emile Chaix Du Bois, of Geneva University; with twenty other geographers of Europe visited Scranton recently. The visitors seemed to take great interest in everything shown them, which of course pleased those who escorted them to interesting places in Scranton. Colonel Phillips and Manager Tobey invited them to visit the Hampton power and water-hoisting plants of the D., L. & W.

A. P. Cameron, superintendent of the Penn Gas Coal Co., has been made superintendent of the Westmoreland Coal Co., succeeding E. G. Smith, who becomes consulting engineer of both companies.

John G. Hayes has resigned as general manager of the People's Coal Co., of Scranton. He will take charge of the Southern Sulphur Co.'s mines near Dallas, S. C. A. G. Bennett, a division superintendent of the mining department of the Delaware & Hudson Co., is Mr. Hayes' successor. Mr. Hayes has been superintendent of the People's Coal Co., for more than a decade, serving under the ownerships of J. L. Crawford and J. G. Shepherd, and was retained when the company passed into the control of New York interests about a year ago.

Lord Kelvin's Memorial

The Institution of Civil Engineers of Great Britain has invited the various British and American national engineering societies to cooperate with it in the erection of a memorial window in Westminster Abbey to the honor of the late distinguished scientist and engineer, Lord Kelvin. The American Institute of Mining Engineers' committee appointed to receive contributions for this fund consists of Prof. James F. Kemp, Samuel B. Christy, Dr. James Douglas, and Dr. Joseph Struthers, secretary of the Institute.

Kentucky Coal Mines, 1911

*By C. J. Norwood**

There was a decrease in the production of coal in Kentucky during 1911, amounting to 795,200 tons from 1910.

The production by districts was as follows:

District	Tons
Western, 11 counties	6,959,541
Southeastern, 7 counties	4,448,383
Northeastern, 9 counties	2,516,887
Total	13,924,811

The disposition of the coal mined was as follows:

	Tons
Sold locally	367,413
Used at mines	373,164
Coked	112,492
Shipped from mines	13,071,742
Total	13,924,811

The average value of the bituminous alone, at the mines, for the respective districts was as follows:

Western	$ .8632
Southeastern	1.1248
Northeastern	1.0584
Average for the state	$ .9816

The cannel (67,782 tons) was produced by three mines in Morgan County and one in Johnson. The average selling value at the mine was about $2.51 per ton.

The tonnage of coal mined by machine in each district, together with the percentage of the total product of the district represented by such tonnage, was as follows:

District	Machine Cut	Per Cent.
Western	5,490,274	78.86
Southeastern	1,437,718	32.32
Northeastern	1,870,375	74.31
Total	8,798,367	63.18

In 1910 the outward shipments amounted to 63.04 per cent. of the total production. The reported outbound shipments for 1911, together with the percentage of the total output represented by such shipments, for each district, were as follows:

District	Tons	Per Cent.
Western	4,337,736	62.23
Southeastern	1,867,253	41.97
Northeastern	1,753,979	69.68
Total	7,958,968	57.16

The average number of persons employed immediately at the coal mines in Kentucky was 23,018, of whom 18,161 were engaged underground.

The average number of employes and the average number of 10-hour days worked per operation, according to districts, were as follows:

District	Total Emps.	Inside	Days
Western	10,367	9,002	138
Southeastern	8,934	6,329	193
Northeastern	3,717	2,830	195
Total	23,018	18,161	

*Chief Inspector of Mines.

COAL MINING & PREPARATION

Buckner No. 2 Mine

Surface and Underground Arrangements, Showing Most Advanced Practice in the Illinois Coal Field

By Warren Roberts and Oscar Cartlidge

THE Franklin County, Illinois, coal field is attracting more attention at this particular time than any other in the United States. The operators going into this field erect the most modern and up-to-date surface plants that will care for a large tonnage of coal. Mr. Warren Roberts, of Roberts & Schaefer, of Chicago, has described the surface arrangements in this article, and Mr. Oscar Cartlidge, of Marion, Ill., State Inspector of the 12th Illinois District, the underground arrangements. The editor considers he is fortunate in obtaining one of the firm of engineers and contractors who designed the entire surface arrangements of the plant to describe it; and doubly fortunate to have Mr. Cartlidge, who followed the work from the breaking of ground at the surface to almost the present stage of the working.—EDITOR.]

SURFACE ARRANGEMENTS

The Buckner No. 2 mine of the United Coal Mining Co. is about 2 miles east and south of their No. 1 mine, which is 1 mile east of Christopher, Ill. This location was selected so the shafts would be in a central position on the property, and because railroad connections could be made with the Illinois Central and the Chicago, Burlington & Quincy railroads.

The railroad tracks forming the working yard extend east and west from the tipple, with the empty storage tracks to the west. The connection from the Illinois Central is made by a spur coming in from the north which forms into a Y connecting both to the empty and the loaded tracks. The C., B. & Q. comes in from the south and connects in the same manner, thus forming a double Y. The surface plant is within this double Y and therefore is arranged not only to receive empty cars but also to receive mine supplies.

Empty cars from the yard tracks pass over the railroad track scale and are weighed before being placed under the tipple. After being loaded, they are passed over another railroad track scale and are weighed before being delivered to the loaded track. The surface and underground arrangements were planned to produce, prepare for market, and load on to railroad cars 4,000 tons of coal daily.

The surface arrangements consist of a four-track steel tipple; combined power plant, hoisting engines, electrical equipment, boiler house with steel coal storage tanks; blacksmith, machine, and car-repair shop; supply house; an auxiliary hoisting engine; steel fan and concrete fan-engine house; a double compartment fireproof and weather-proof engine house; a complete water system; electric lighting system, and a small office for the mine superintendent. This entire surface plant, excepting the office, is of concrete, steel, and brick construction and is practically fireproof and permanent.

FIG. 1. BUCKNER NO. 2 MINE TIPPLE AND POWER PLANT

The head-frame and tipple, Fig. 1, are of steel, the latter being covered on sides and roof with corrugated galvanized-steel sheathing. It is also provided with stairs and walks to give access to all parts of the machinery. The only woodwork in this structure is the stair treads and the 2-inch plank floors and walk.

The agreement between the miners and operators is that all coal in a mine car shall be paid for by weight. Fortunately the coal at this mine is clean and there can be no friction between the miners and operators on the score of dirty coal as is frequently the case in other mining districts.

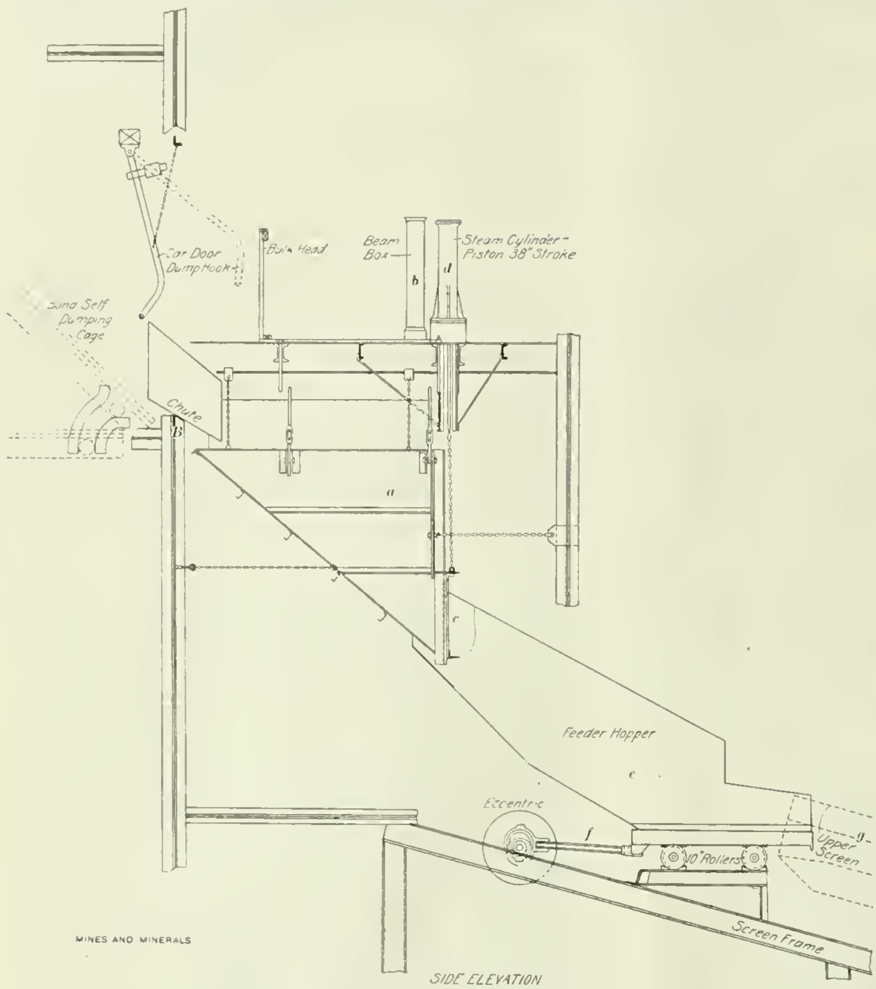

Fig. 2. Feeder and Weigh Hopper

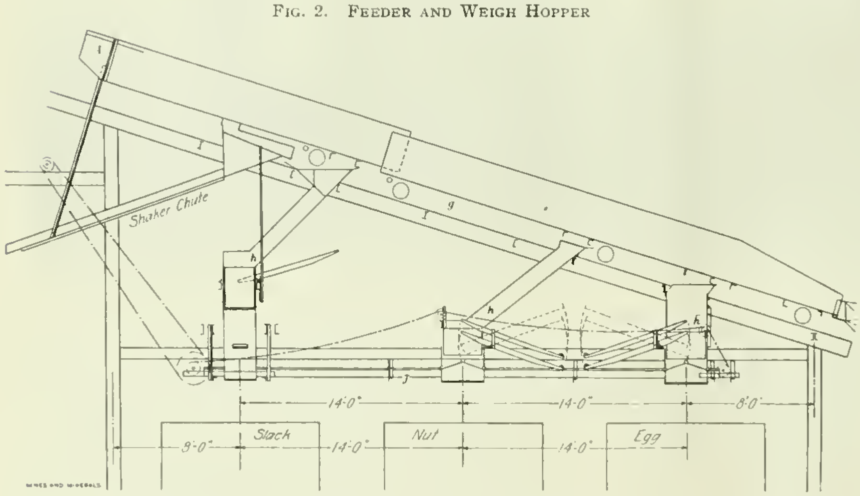

Fig. 3. Shaking Screens

Mine cars in this field are large and hold from 4 to 4½ tons of coal. They are raised to the top of the tipple on self-dumping cages and dumped into a weighing hopper *a*, shown in Fig. 2, attached to a suspended tipple scale *b*. The weighman operates the weigh hopper door *c*, by means of a steam cylinder *d*, which enables him to open and close the heavy steel door by simply turning a valve stem. The contents of the weighing hopper slide by gravity, as soon as the door is opened, into a receiving hopper *e* capable of holding the contents of two or three mine cars.

From this latter hopper the coal is fed gradually by the reciprocating feeder *f* on to the shaking screens *g*, Fig. 3. This arrangement was adopted to allow an even distribution of the coal on the screens and to prevent any hindrance in the hoisting and dumping when working to full capacity. The two counterbalanced shaker screens rest on rollers and are driven by an eccentric shaft connected by belt with a double engine placed on the ground underneath the tipple between the mine shaft mouth and the first loading track. These screens are 10 feet wide and of a length sufficient to span four railroad tracks. They are designed so that run-of-mine coal can be shipped from the lump-coal track without the use of cover plates. The upper screen has a double deck for making slack and nut coal and the lower screen has a single deck for taking the egg out of the lump coal. A small hopper *h* is placed beneath the screens over each track to receive a small amount of coal, which enables the railroad cars to be changed beneath the tipple without the necessity of interrupting hoisting.

The slack and screenings from the nut, egg, and lump coal are delivered by shaking chute to the slack car.

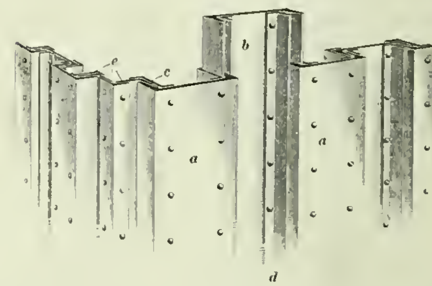

Fig. 4. Channel Bar Piling

The nut and egg sizes pass from the shaker screens into small pockets beneath the screen and above their respective loading tracks. The nut and egg coals pass from the hopper to the railroad cars by way of an end loading chute, which is of sufficient length to admit of considerable adjustment, that is, raising and lowering, to prevent breaking the coal with a high fall into an empty or partly loaded car. Each of these chutes is provided with a short lip screen for rescreening the coal just before it is loaded into the car. The slack from these lip screens is carried by a small conveyer *j* to the slack car, which is being loaded by the slack chute.

The lump coal passes off the end of the shaker screens and is loaded into a railroad car by means of a curved-end loading chute, which is also of a length to allow adjustment so as to raise and lower the outer end and deliver the coal into the car with the least breakage possible.

The loading chutes are raised and lowered by means of cables and windlasses. As this coal is practically free from impurities no further preparation is necessary, but it is evident from the description given that sizing and keeping the prepared sizes free from slack is of considerable importance.

Another interesting feature of these screens consists in an arrangement whereby different combinations of the various sizes can be made, or mine-run placed in the car on the lump track without use of cover plates on the screens. This is accomplished by making the screens double decked and by having a system of valves which, when closed for any particular size of coal, enables this coal to be carried forward and placed with coal of larger size.

The upper shaker screen is also provided with a small auxiliary screen which takes out a certain portion of the ¾-inch coal from the screenings and delivers it to a side chute to a boiler house conveyer, which in turn carries the coal to the bunkers above the boilers; and, from the bunkers, the coal is delivered by steel spouts into the automatic stokers.

The buildings in which boiler, hoisting engines, and electrical equipment are installed are to the right of the head-frame shown in Fig. 1. The boilers are in one room and the machinery in another. In the boiler room there are four water-tube boilers, arranged in batteries of two each, each battery having a steel smokestack, 54 inches in diameter and 150 feet high. The boilers are supplied with Murphy stokers and beneath the fireboxes there are small hoppers into which the ashes drop. Below the hopper there is a concrete tunnel in which an ash car travels, receives the ashes from the hopper, and carries them outside the tunnel to the yard. This ash car is moved by means of a small hoisting engine and rope placed in the corner of the boiler house and operated by the fireman as occasion demands.

Boiler feed-pumps made by the Platt Iron Works, of Dayton, Ohio, are installed in duplicate and cross-connected, each being of sufficient capacity to supply all four boilers with water. The engine room contains a Danville Foundry and Machine Co.'s duplex 28"×48" first-motion hoisting engine that operates two 8-foot diameter drums; a 250 kilowatt generator direct-connected to a four-valve engine; also a small direct-connected generator for use in lighting the mine and plant when the large generator is not running. One noteworthy feature is the auxiliary hoisting plant at the air-shaft. One of the three compartments of this shaft contains a steel stairway, and in another a small platform cage is operated on which materials are taken into the mine, and men hoisted and lowered during working hours. This arrangement avoids any interference with hoisting, which must be carried on at the rate of two cars per minute if a capacity of 4,000 tons in an 8-hour day is to be maintained. The auxiliary hoisting equipment consists of a pair of small first-motion engines operating a drum to which the cage and hoisting rope are attached. A small steel head-frame carries the customary rope sheave that is centered over the shaft compartment in which the cage plays.

Sinking and Underground Development

The work of sinking the No. 2 main and escapement shafts, known as the Buckner mine, was begun October 25, 1910, and coal was reached at a depth of 447 feet, May 28, 1911.

Unusual difficulty was experienced in sinking these shafts by reason of the fact that at a depth of 25 feet, 18 feet of very free running quicksand was encountered.

Previous drilling having shown the strata to be, surface, 25 feet; quicksand, 18 feet; with alternate layers of shale, sandstone, and limestone down to the coal, the shafts were laid off about 4 feet larger in each dimension than was required, and excavations made to within about 3 feet of the sand.

Interlocking steel sheet piling was then driven around the shaft through the sand; but when an attempt was made to remove the sand it was found that the piling would not turn the water and sand, and it was withdrawn and the Friested interlocking channel bar piling shown in Fig. 4, which is a combination of channel and Z bars, was used.

These bars were furnished by the Carnegie Steel Co. and were driven with a pile driver in the position shown in Fig. 4. The total depth to which the piling was driven was 40 feet, in two sections of 25 feet and 15 feet and 28 feet and 12 feet, and they were driven about 7 feet into the shale below the sand.

This type of piling proved to be perfectly water-tight, and the sand inside was easily shoveled out, the timbering with 12-inch yellow pine being carried down with the excavation. After getting down to the solid strata, forms were made to bring the main shaft to an inside clearance of 11 ft. × 19 ft. and it was

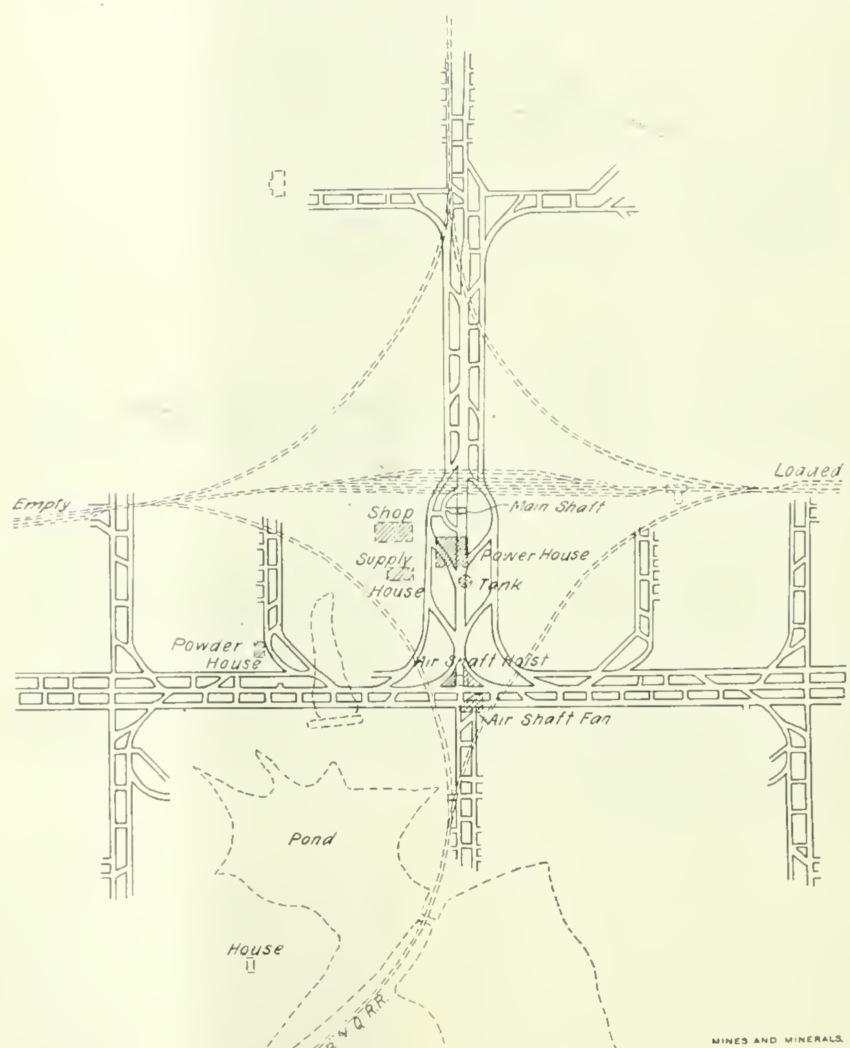

Fig. 5. Surface and Underground Plan, Surface Works Shown Dotted

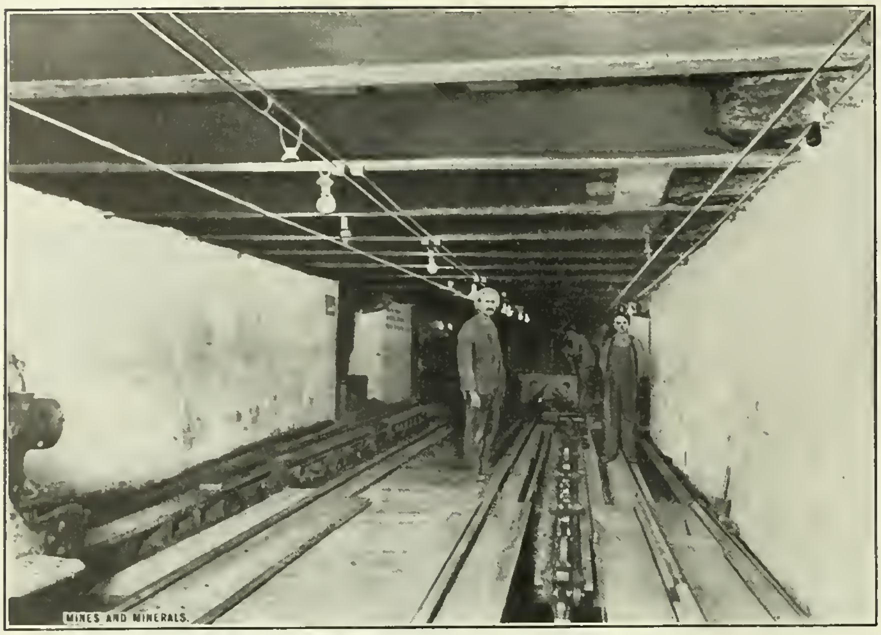

Fig. 6. Phillips Automatic Cager and Shaft Bottom

concreted. The remaining distance was timbered with 3-inch yellow pine, and the entire surface was then fireproofed with galvanized iron, which was nailed to the wood in overlapping sections. Steel buntons, 4 feet apart, divide the shaft into three compartments.

The escapement shaft was sunk in the same way, and is equipped with a man and material hoist, the cage being 4 ft. 6 in. × 4 ft. 2 in. There is also an air compartment 10 ft. 6 in. × 11 ft., and a stairway of solid steel so constructed that water cannot accumulate thereon.

The hoisting and stair compartments are separated from the air compartment by a solid reinforced-concrete dividing wall 6 inches thick.

The shaft bottom shown in Fig. 5 is laid out to cage the coal from one side as shown in Fig. 6, while the empty cars from the other are delivered to wings at either side, Fig. 8, by gravity after being elevated to a height of 7 feet by a Phillips drag shown in Fig. 9. Phillips mechanical cagers automatically place the loaded cars on the cage, releasing one car at a time as the cage touches the bottom. Recently, as an experiment, 136 tons were caged and hoisted in 12 minutes.

The coal, which is the Illinois No. 6 bed, is about 10 feet thick at this mine. It is of excellent quality, being very free from impurities of every kind, and lies comparatively level. The method of development is shown in Fig. 5. Three main entries are driven east and west, with cross-entries turned at right angles every 1,370 feet. From these cross-entries stub entries are turned in pairs every 350 feet. Pillars between main entries are 30 feet, with 150-foot barrier pillars on each side. The cross-entries have a dividing pillar of 20 feet with flanking pillars of 125 feet, while the stub or room entries have 20-foot pillars between them, with 32 rooms on each entry. Room necks are turned 10 feet wide, with 35-foot centers, and are widened out at an angle of 45 degrees to a width of 21 feet after the first 7-foot cut is taken out. The rooms are not advanced until one-half of the panel, or 16 rooms on each stub entry, are turned. when the 16 rooms are advanced concurrently a distance of 175 feet and the pillars are withdrawn retreating from No. 16 to No. 1. At the same time the stub entries are being driven for another 16 rooms, and after the stub entries hole into the next cross-entry this series of rooms is advanced and the pillars recovered retreating from No. 17 to No. 32, the coal being delivered to the cross-entry which has been holed.

Fig. 7. Fire-Fighting Station

When a panel of 64 rooms is worked out the stub entries will be sealed up at each end and abandoned. This method will be pursued with each succeeding panel; and as the company has tried this method to a limited extent in their No. 1 mine, they are assured of getting the maximum amount of coal with the least yardage cost.

The anticipated output of this mine is 4,000 tons in a day of 8 hours. Mine cars of 4 tons capacity will run on 50-pound steel in the main entries; 40-pound in the cross-entries, and 20-pound in the rooms. Electric haulage is used exclusively, no animals having ever been in the mine, and eventually there will be about 15 motors and 30 chain breast machines of the Goodman manufacture in operation. No hauling will be done on the middle main entry, so that it will be unobstructed for the free passage of air.

Fig. 8. Timbering and Concrete Walls at Track Intersection

All overcasts are of steel and concrete, while all stoppings between air-courses are of brick plastered over with cement; and at each intersection of a branch road concrete walls are constructed to support the roof. The walls at such an intersection are shown in Fig. 8, which also shows the substantial construction for supporting the roof.

Prominent above all other things is the precaution taken by this company to protect its employes from injury. Upon landing from the cage at the shaft bottom one is confronted by large signs of a warning nature, such as "Remember the Law"; "Danger"; "A little Caution on Your Part Will Avoid Many Accidents," etc., and at intervals along each entry similar signs call attention to the fact that the mine worker's occupation is a continual hazard.

Just off the shaft bottom is a combination office and emergency hospital of concrete, consisting of two rooms each 12 ft. x 12 ft. fitted up with desks, stretchers, first-aid outfits, etc., where the seriously injured can be given temporary aid. On the wall of the office room is a map of the workings which is extended monthly, and shows the actual development at a glance.

On the other side of the shaft is a concrete fire-fighting station, shown in Fig. 7, provided with hose, hand pump, buckets, chemical fire extinguishers, etc. In Fig. 7 Mr. F. J. Urbain is at the left; Edward Laughron, County Mine Inspector, is standing in the door; while Frank Rosbottom, 11th District State Mine Inspector, is sitting down.

A complete system of sprinkling pipes, having a 75-pound head from the water ring in the shaft, and which maintains a constant supply of 12,000 gallons, ramifies to every part of the mine, with hose connections every 100 feet; and the dust is kept thoroughly washed down. Permissible explosives are used exclusively; and it is the boast of the general manager that a pound of black powder has never been fired in the mine.

The writer wishes to acknowledge his indebtedness to President C. M. Moderwell and to General Manager F. J. Urbain for courtesies extended him while preparing this article.

Correction

On page 11 of MINES AND MINERALS for August appeared an interesting article by C. H. Thompson under the title which the author wrote as "Coal Cost and Coal Loading Machines." Through a typographical error this was incorrectly printed "Coal Dust and Coal Loading Machines." This will explain the evident lack of relation between the title and the article.

Clinkering of Coal Ash

By E. B. Wilson

Coal clinker is slag formed by the fusing together of the various ingredients composing the ash in coal. Ash derived from coal contains silica, SiO_2; lime, CaO; alumina, Al_2O_3; ferrous oxide, FeO; ferrous sulphide, FeS; magnesia, MgO; and small amounts of other chemical combinations.

If an analysis is made of the ash, it is possible to calculate whether a slag will form under the ordinary conditions that prevail in boiler furnaces.

In order to form slag there must be "acid silica" to unite with the "basic oxides," and although silica makes a number of combinations with bases, the heat required to bring about fusion to form the slags varies greatly, according to the relative proportions of the oxides and silica. with the silica, a fluid slag forms at comparatively low temperature. If there is a predominance of lime, the slag will be gray, but as the percentage of ferrous silicate increases it passes from bottle green to black. One of the most readily fusible combinations with silica is termed a "monosilicate"; that is, the ratio of oxygen in the base is to the ratio of oxygen in the acid (silica) as 1 : 1.

To show the method to be followed in determining whether an ash will form clinkers, the ash analyses from two coals are used, one being semibituminous and the other bituminous.

The semibituminous coal formed slag above and below the fire bed proper, thus causing considerable trouble. As the following analyses show, the coal is an excellent fuel aside from its slagging properties: Moisture, .496; volatile hydrocarbons,

FIG. 9. CAR HAUL HANDLING EMPTIES AT FOOT OF SHAFT

The oxides, when taken alone, are quite infusible, and are termed refractory materials; but when two or three are brought together with silica in indefinite proportions, a given heat will cause them to fuse and form a silicate, which is the slag called clinker. If there is a large proportion of the less fusible materials, lime, magnesia, and alumina, in the ash compared with the less fusible base, such as ferrous oxide, it will require an exceedingly high temperature to form slag, more in fact than the boiler furnace will produce. However, it requires less heat to fuse two oxides with silica than one, and three than two. In case there is a large excess of silica in the ash it will also require an exceedingly high heat to form slag, and if formed it will be pasty and probably give little if any trouble under a boiler. When there is a goodly proportion of ferrous oxide in ash and the proper proportions of other bases to unite

19.139; fixed carbon, 75.530; sulphur, .480; ash, 6.360. Analysis of the ash was as follows: Silica, 39.02; alumina, 23.52; ferrous oxide, 11.14; lime, 19.97; magnesia, 3.265; undetermined, 3.085.

For the benefit of those unfamiliar with slag calculations and the derivation of the factors used for determining the silica necessary to satisfy a given oxide and form a silicate, the following explanation is given:

The formula for calcium monosilicate is $2CaO{\cdot}SiO_2$ and results from the following chemical combination that requires 471,300 heat units:

$$\underset{\text{Lime}}{2\,CaO} + \underset{\text{Silica}}{SiO_2} = 2\,CaO{\cdot}Sio_2$$
$$111.16 \quad 55.96 = 171.12$$

From this equation it requires $\frac{59.96}{171.12}$ = .539 part of silica to combine with 1 part of lime to form a calcium monosilicate. The molecular weights of the lime and silica are used to obtain the factor .539, which is known as Ballinger's factor. Factors for other oxides are obtained in the same way. Using these factors and multiplying the percentages of the various bases in the slag by them, it will be found that there is enough silica and iron in the ash to form a monosilicate.

$$\begin{aligned} 23.52\ Al_2O_3 \times .886 &= 20.839 \\ 11.14\ FeO \times .419 &= 4.668 \\ 19.97\ CaO \times .539 &= 10.764 \\ 3.265\ MgO \times .758 &= 2.477 \\ \hline & \quad 38.748 \end{aligned}$$

It will be seen from this that the mixture was just right, there being sufficient silica to satisfy the bases and form a fluid slag.

It will be noticed also that the coal is low in sulphur and no sulphur is given in the ash analysis. The sulphur in coal is a very important feature in slag formation. Ordinarily it exists as pyrite, FeS_2, but while one molecule is driven off by heat, forming SO_2 gas, the other molecule is extremely difficult to oxidize even in an oxidizing furnace, which a boiler furnace, from a metallurgical standpoint, is not. When ferrous sulphide, FeS, is formed, silica will not combine with the iron, consequently no fusible slag is formed. The following illustration will show this, as well as the difficulty of forming fusible slag without an easily fusible base for flux. The bituminous coal under consideration contained 2.54 per cent. sulphur, but gave no trouble from clinker, the sulphur being in sufficient quantity to unite with the iron and prevent its slagging with the other ingredients of the ash. In this case the ash had the following analysis: Silica, 29.14; alumina, 15.56; lime, 20.73; magnesia, 1.91; ferrous oxide, 13.42; sulphur, 6.

The iron in the ash is reported as ferrous oxide, consequently there was $\frac{56 \times 100}{72}$ $= 78$ per cent. metallic iron in the oxide, or $13.42 \times .78 = 10.46$ per cent. iron in the ash. The formula for ferrous sulphide is FeS, and to satisfy the sulphur will require $\frac{56 \times 6}{32} = 10.5$ parts of iron; therefore, in this case there is no iron left to be converted into oxide to form a fusible slag. If 5 per cent. had been left, the amount would be so inconsequential in comparison with the other basic oxides that only a little slag would be formed, and that at extremely high temperature. In the first example, 19.2 per cent. of the total basic oxides was ferrous oxide, a matter which is called to the reader's attention to emphasize that unless more than 10 per cent. of the various oxides in ash is ferrous oxide available for slag, there will be little clinkering under boilers. Should a fuel have a tendency to slag, the formation temperature may be raised by spreading pieces of limestone or oyster shells, if convenient, on the fire, and thus making the ash material more refractory. When the silica in the ash is considerably lower than the bases, there will be little clinker formed, if any, since the effect is the converse of adding refractory oxides when sufficient silica is present.

The impression prevails that sulphur is a slag-forming material, which is not the case; on the contrary, it will prevent the formation of slag.

Early Dust Explosions

The Savanna, Indian Territory, mine explosion is of special interest because it brought on the first discussions of dust explosions in this country; was instrumental in introducing sprinkling to keep down dust; and did introduce shot firers in this country. Mr. E. W. Parker, of the United States Geological Survey, kindly furnished us with letters from Mr. William Cameron, of McAlester, Okla., giving authentic details of the Savanna and Krebs explosions in Indian Territory. His dates do not agree with those given on page 713, July, 1912, Mines and Minerals; however, the latter were given from memory and were slightly confused except in regard to the years in which the explosions occurred.

Mr. Cameron writes: "There were two explosions at Savanna, the first was in mine No. 1, February 2, 1885, whereby 33 men and boys were more or less injured, six of whom died from their injuries (four men and two boys). This explosion brought about the appointment of special shot firers to blast the coal after all miners and others had left the mine. These were the first shot firers appointed to fire shots in America, and I claim whatever credit, if any is due, for the initiation of shot firers into this country; I had to have the cooperation of Major McDowell, General Manager of the company, who gave it his hearty indorsement.

"The second explosion occurred in mine No. 2 on the night of April 4, 1887. There were four shot firers in the mine and two men sprinkling the slope when the explosion occurred, all of whom lost their lives. In the excitement and rush, 12 of the rescuers rushed ahead of the air and lost their lives, making a total of 18 lives lost in all. The explosion blew the timber out of the mouth of the slope for about 100 feet back from the portal, which allowed the entrance to cave for that distance, and made it impossible to enter the mine through original passage. The flame passed out of the slope and set fire to the tipple which was totally destroyed. The dust explosion at Krebs, Indian Territory, in which 67 men were killed, occurred at 5:03 p. m., January 7, 1892. Over 100 of the injured ultimately recovered, and some of those who died might have been saved had it not been for the lack of proper care and sanitation in their homes, and the unusual severity of the weather at the time of the accident."

Gas Ignition by Tungsten Filament Electric Lamp

The Bureau of Mines has been asked a number of times whether firedamp can be ignited by breaking the bulb of a miniature incandescent lamp in a body of it.

This question is of more importance now than at any previous time because of the increasing use of portable electric lamps for mine service. Portable electric lamps are often used where gas is known to be present, and some times, as in rescue work, such lamps must be used where gas (methane) may be present in dangerous amounts. Tests were made with miniature incandescent-lamp bulbs containing tungsten filaments. The bulbs were supplied to the bureau without cost by the General Electric Co., the Federal Miniature Lamp Co., and the National Electric Lamp Association. In all tests the filaments were glowing at the moment when the bulbs were broken. One hundred and thirty-one bulbs were broken in a mixture of natural gas (that used in Pittsburg) and air combined in the proportion of 8.6 per cent. gas to 91.4 per cent. air, the most explosive mixture.

Forty-five tests were made in gas-and-air mixtures other than the most explosive. These mixtures contained from 3 per cent. to 12.4 per cent. of gas. Mixtures containing as little as 5 per cent. of gas and others containing as much as 12.4 per cent. of gas were ignited by 1.5-candlepower, 3.5-volt, .3-ampere bulbs that were smashed while burning at rated voltage as follows:

Table 1. Bulbs Causing Ignition at or Below Rated Voltage

Manufacturer's Rating			No. of Tests	No. of Ignitions	Percentage of Rated Voltage Causing Ignition*
C. P.	Volts	Amprs.			
1.0	2.5	.3	11	7	100.0
1.5	3.5	.3	23	16	100.0
2.0	5.5	.3	9	6	98.7
1.0	2.0		9	7	100.0
1.0	2.5		10	3	100.0
2.0	4.0		10	7	82.2
2.0	4.5		10	7	85.3
	2.0	.73	5	3	94.5
	4.0	.53	5	5	94.9
	6.0	.30	5	5	88.2

Table 2. Bulbs Causing Ignition at More Than Rated Voltage

Manufacturer's Rating			No. of Tests	No. of Ignitions	Percentage of Rated Voltage Causing Ignition*
C. P.	Volts	Amprs.			
.5	1.5	.4	10	1	132.7
	2.0	.23	9	3	120.0
	2.0	.40	9	3	106.0
	2.0	.53	6	5	102.0

* The values given in this column are the average percentages of the voltages impressed upon such bulbs as caused ignition.

Lake Superior Mining Institute

An Account of the Proceedings and Excursions of the Meeting Held August 28, 29, and 30

Written for Mines and Minerals

On August 28, 29, and 30, about 300 out of the 600 members of the Lake Superior Mining Institute gathered at Houghton, Mich., to attend the seventeenth annual meeting. In addition to the attractive itinerary prepared by the committees, the weather was such that it harmonized with the good fellowship that prevailed. Politics was tabooed and none would signify his favorite animal, which permitted all hands to enjoy the outing.

On Wednesday afternoon the first excursion train conveyed the members to the Michigan smelter, at Coles Creek, where, on disembarking they entered the top of the sampling mill and descended to the furnace-charging floor. As it was casting time the visitors were able to see the molten copper flow from the furnace to the ladle and then see it poured into small ingot molds. The Walker machine, shown in Fig. 2, is a photograph of a machine in the works of the Electrolytic Refining and Smelting Co., Ltd., Port Kembla, N. S. W. The furnace spout and ladle are shown to the left; the molds, which are for 135-pound wire bars, dump into a water tank at the foot of the elevator shown to the right. Another furnace and casting machine is shown to the rear of Fig. 2. At the Michigan smelter the visitors saw the method followed for making copper-molds for the casting machines.

The party next embarked on the special Copper Range train and were conveyed to the Champion mine, which they reached in time to see the ore skip changed for a man-hoisting skip. This occupied about 10 minutes, after which a number waited to see the skip bring up the men from a depth of 2,420 feet. Fig. 1 shows the customary man-hoisting car used at inclined shafts in the Lake Superior region, with its load of human freight. The hoisting rope and car connections are carefully examined before the men are either hoisted or lowered in the shaft. On remarking that the miners were husky looking chaps, an iron miner said they were not as healthy looking as his men, in fact, lacked color in their faces, which would be natural now we come to think of hematite being a fairly good red mineral pigment.

From the Champion mine the members were conveyed by trains to the Baltic mine where the miners' wash and change house were examined and the concrete oil house was visited.

At the Baltic mine the lubricating oils received in tank cars flow by gravity to storage tanks in the basement of the oil house. From these tanks they are lifted by pumps and measured prior to consumption. To those unfamiliar with the conditions and the surface works at these mines, the time allotted for their inspection was inadequate; however, this could not be avoided and was in a great measure compensated by the pamphlet of information prepared especially for this meeting by Arthur L. Carnahan, in which there was also a poem by Allan Tyrrell, two verses of which slightly changed, appealed to those who are lovers of nature:

I stood on the hills of Houghton
As the sun sank slowly down
With a farewell glance of gladness
O'er the grim old northern town
And the *north* winds drifted softly
With perfume strangely sweet
And toyed with the *crimsoned maple*
Leaves that fluttered to my feet.

The ride back to Houghton just before dusk furnished an excellent view of Portage

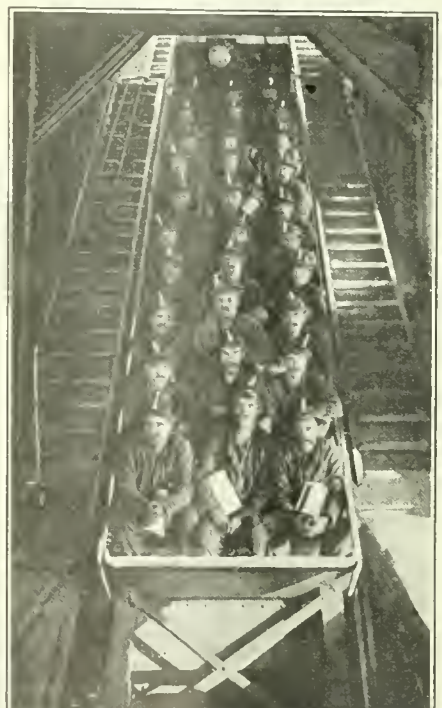

Fig. 1. Man Car, Lake Superior Copper Mine

Lake, flanked by hills, with Hancock and Quincy shaft houses looming high above the city of Hancock. Probably it was this sight that inspired Allan Tyrrell to paraphrase Longfellow, at any rate it recalls that peculiar state of mind which those who have camped by some lake deep in the woods are likely to have in the evening when there is nothing doing and it is too early to retire:

And out from Hancock city
As the deeper shadows fell
There rang o'er the murky waters
The tones of a silvery bell
And the echoes, oh! the echoes
Rolled gloriously and free
As over the lake to Houghton
They floated up to me.

At a Lake Superior Mining Institute meeting the tired feeling, due to an all-day excursion, is not allowed to interfere with the business end, consequently a session was held in the Masonic Building. President F. W. Denton opened with an address of welcome, after which several papers were read and discussed. Much interest is shown in the iron and copper regions relative to decrease in accidents, and William Conibear's paper on "System of Safety Inspection of the Cleveland-Cliffs Iron Co." was ably discussed by Messrs. Cole, Duncan, Sperr, Lawton, Grierson, Kelly, and Denton.

Early Thursday morning the members boarded a special Mineral Range train for points north of Houghton, where they inspected a small part of the largest mining machinery in the world. At Lake Linden there are two mills, one called the Calumet, with 17 steam stamps, and the other called the Hecla, with 11 steam stamps. The combination is capable of crushing about 10,000 tons of rock daily. The rock crushed at these mills carries an average of 25.47 pounds of copper per ton, and during the last fiscal year 2,909,972 tons were crushed. The latest wrinkle in ore dressing at these mills is the regrinding plant for the tailing coming from the mill tables. It has been the practice to use Chilian mills for this purpose; recently, however, one Hardinge and one cylindrical tube mill have been successfully used, and it is probable that others will be installed. In the electrical power house the five generating units with a combined capacity of 8,000 kilowatts were admired. This power drives 240 motors for various purposes about the company's works, ranging in capacity up to 700 electrical horsepower. The foundation for a new mixed-flow turbine generator, one unit of 10,000 kilowatts, is completed, and there already exists a demand throughout the various works of the Calumet & Hecla which will absorb all this power.

After leaving Lake Linden the Ahmeek mine was visited, where on one car were two masses of copper which comprised a car load. This kind of copper ore requires the roof to be taken from the reverberatory furnace in order to place it on the hearth. After this is accomplished the roof is repaired and the furnace heat raised. Owing to the large lumps of mass ore having some rock attached they are more infusible than copper concentrate, and because of their size they melt but slowly above the bath of molten metal and more slowly below.

On the surface at this plant there was a set of reinforced-concrete shaft lining for inspection. It is said to cost less than timber, lasts longer in these mines, which are practically free from acid water, and has the further advantage of being fireproof. The Ahmeek management was the first to adopt concrete timbering in the copper country.

After luncheon at Electric Park the party went by trolley cars to the Franklin mine, where a new and interesting duplex hoisting engine is coupled to air-compressing cylinders and the skip when going down the shaft is made to compress sufficient air to help hoist the next load one-third the way up the shaft. This is termed an air-balanced hoisting engine and was originated by General Manager R. M. Edwards. Mines and Minerals will, if permitted by the Institute, publish Mr. R. H. Corbett's paper on this hoister and compressor, in a future issue.

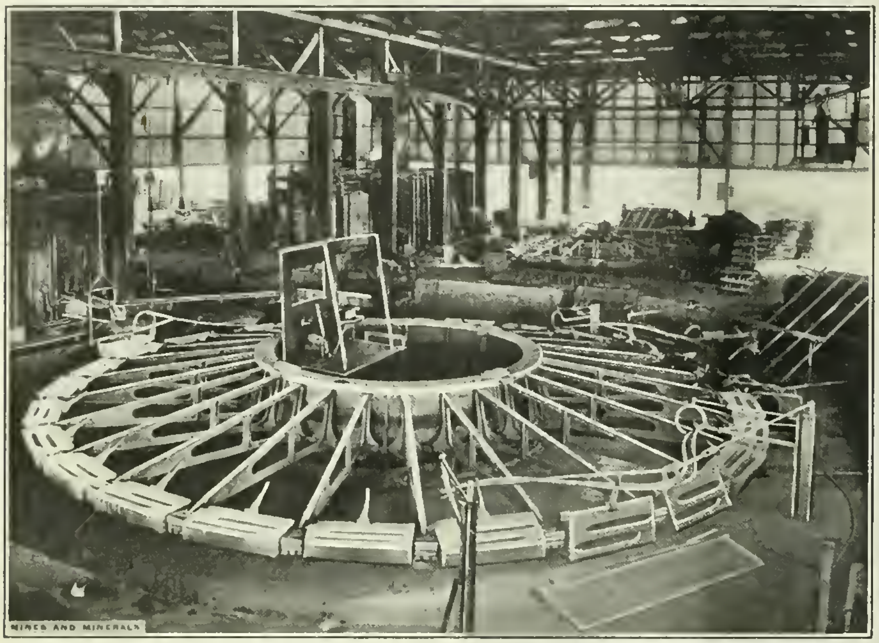

Fig. 2. Walker Casting Machine

From the Franklin mine the members returned by trolley cars to Houghton, where they got a "hoot" if they wanted one, after which they embarked on a barge and were towed down the lake to the Oniganing Yacht Club House. Here a dinner was served. Doctor Holmes explained the functions and aims of the United States Bureau of Mines, and then a concert was given by the Calumet & Hecla Band. Friday was devoted to reading papers and demonstrations at the Houghton School of Mines.

The following is a partial list of papers presented at the meeting: "Methods of Sampling at Lake Superior Iron Mines," by Benedict Crowell, Cleveland, Ohio; "System of Safety Inspection of the Cleveland-Cliffs Iron Co.," by William Conibear, Ishpeming, Mich.; "Raising Shaft at Rolling Mill Mine, Negaunee, Mich.," by Edwin N. Cory, Negaunee, Mich.; "Mine Sanitation," by E. B. Wilson, Scranton, Pa.; "Raising, Sinking, and Concreting, No. 3 Shaft, Negaunee Mine," by E. R. Elliott, Negaunee, Mich.; "The Unexplored Parts of the Copper Range of Keweenaw Point," by Alfred C. Lane, Tufts College, Mass.; "Foot-wall Shafts in Lake Superior Copper Mines," by Dr. L. L. Hubbard, Houghton, Mich.; "Some Applications of Concrete Underground," by H. T. Mercer; "Rock-House Practice of the Quincy Mining Co.," by T. C. DeSoller; "Construction of Intakes at the Mills of the Champion and Tri-Mountain Companies," by Edward Koepel, Beacon Hill, Mich.; "Balancing Rock Crushers," by O. P. Hood, Pittsburg, Pa.; "In the Lake Superior Area—What Influences if Any, Did the Ancient Topography of Foot-Wall Beds Have Upon the Subsequent Deposition and Distribution of Copper in Overlying Beds," by L. L. Hubbard, Houghton, Mich.; "The New Franklin Hoist," by R. H. Corbett, "Notes of Methods of Mining Iron Ore in the Lake Superior District," by F. W. Sperr, Houghton, Mich.; "Failures of the Rule of Following the Hanging in the Development of Lake Superior Copper Mines," by F. W. Sperr, Houghton, Mich.

To judge of the esteem in which a technical society is held by its members, it is only necessary to note the attendance at its meetings. Members of the Lake Superior Institute are widely scattered, yet 50 per cent. of its membership were probably present. The following list does not include all, for some came late after the list had been taken from the secretary's book.

Atlantic Mine, Mich., A. D. Edwards.

Ashland, Wis., W. F. Walker, G. J. Quickly.

Appleton, Wis., T. W. Orbison.

Boston, Mass., W. A. Paine, A. L. Carnahan, Thomas S. Dee, Alton L. Dickerman.

Bessemer, Mich., G. S. Barker, W. G. Trevarthen.

Beacon Hill, Mich., Charles Champion, C. L. Adams, Ed. Koepel.

Baraboo, Wis., A. W. Rahn.

Beaver Dam, Wis., J. R. Gish.

Crystal Falls, Mich., S. J. Goodney, W. J. Richards.

Cleveland, Ohio, S. L. Mather, M. T. Hearley, A. C. Bittchopsky, H. A. Raymond.

Calumet, Mich., John Knox, W. M. Gibson.

Crosby, Minn., T. H. Martin.

Commonwealth, Wis., E. W. Hopkins.

Chicago, Ill., W. A. Mitchell, H. C. Hampton, A. B. Conover, N. P. Mowatt, F. W. Mowatt, C. G. Strong, C. R. Silver, L. A. Sisley, J. W. Holman, H. M. Scott, B. W. Goodsell, M. W. Sherwood, R. D. Hunter, H. Cole Esteps, P. J. Woolf, L. B. Armstrong, W. D. Cantillon, C. Jackson, E. D. Brigham.

Rogers, R. I. Nilas, William Jory, Ed. N. Corey, J. T. Quinne, C. J. Stakel, H. G. Halt, C. D. Cole, M. M. Duncan, A. J. Youngbluth, H. L. Smythe, Howard Heyn, H. O. Young, C. T. Rice, J. P. Jopling, George A. Newett, W. G. Imhoff, W. C. Rowe, A. B. Miner.

Ironwood, Mich., B. W. Vallet, L. C. Brewer, George H. Abeel, D. Sutherland, F. B. Goodman, William Bond, O. W. Johnstone, Pearson Wills, C. E. Stevens, Carl Brewer, Dan Nolan, J. A. Rupp, J. M. Bush.

Iron Mountain, Mich., W. J. Davidson, Frank Carbis.

Iron River, Mich., D. H. Campbell.

Kearsarge, Mich., C. G. Smith.

Lansing, Mich., R. C. Allen.

Laurium, Mich., W. R. Jewett.

Lake Linden, Mich., C. H. Benedict.

La Crosse, Wis., L. I. Rehfuss.

Milwaukee, Wis., E. F. Fishwick, J. F. Letz, F. M. Prescott, E. C. Hingston, G. L. Tiffts, Irving Reynolds.

McKinley, Mich., W. P. Chinn, R. J. Chinn.

Menominee, Mich., C. W. Mott, L. L. Prescott.

Marquette, Mich., D. W. Powell, Joseph Fay, N. P. Fodin, F. L. Pearce, J. M. Longyear.

Mexico City, Mex., E. E. Ryan.

Mohawk, Mich., W. J. Smith.

Negaunee, Mich., J. H. Rough, W. H. Yates, Fred Ware.

New York, N. Y., J. R. Stanton, F. P. Bunall.

New Britain, Conn., Ferdinand Ritter.

Oshkosh, Wis., J. H. Whitney, A. B. Whitney.

Pittsburg, Pa., Doctor Holmes, F. F. Morris, O. P. Hood.

Palatka, Mich., W. H. Bengey.

Point Mills, Mich., R. L. Oliver.

Painesdale, Mich., W. J. Richards, W. A. Rankin, P. P. Daume, H. S. Goodell, F. W. Denton.

Republic, Mich., W. A. Siehenthal, P. W. Pascoe.

Rockland, Mich., Samuel Brady.

Redridge, Mich., A. H. Sawyer, O. D. Fellows, Jr.

Ramsey, Mich., T. S. Williams.

Scranton, Pa., E. B. Wilson.

St. Louis, Mo., W. B. Gotch.

San Antonio, Tex., J. C. McTyre.

Tuft's College, Mass., Prof. A. C. Lane.

Trimountain, Mich., B. D. Noetzel, Richard Bowden.

Virginia, Minn., John H. Burt.

Verona, Mich., W. J. Davis.

Vulcan, Mich., William Kelley, F. H. Armstrong, F. L. Burr.

Watertown, Mass., Prof. Henry L. Smyth..

The following officers were elected: President, Pentecost Mitchell, Duluth, Minn. Vice-Presidents, Geo. H. Abeel, Ironwood, Mich.; W. P. Chinn, McKinley, Minn.; W. H. Jobe, Palatka, Mich; Francis J. Webb, Duluth, Minn.; A. D. Edwards, Atlantic Mine, Mich. Treasurer, E. W. Hopkins, Commonwealth, Wis. Secretary, A. J. Yungbluth, Ishpeming, Mich. Representatives from five of the leading mining and metallurgical journals attended the meeting which shows the importance attached to the institute.

The various committees are to be congratulated for the systematic way in which every part of the program was carried to completion, and the reception committee for the generous treatment accorded the visitors.

Illinois State Inspectors of Mines

Reading from left to right—First row (sitting down)—Frank Rosbottom, Benton; Thomas Hndson, Galva; Walter Rutledge, Alton; Hector McAllister, Streator; W. W. Williams, Litchfield. Second row:—James Taylor, Peoria; Thomas Little, Murphyshoro; Oscar Cartlidge, Marion; John Dunlop, Peoria. Third row:—W. L. Morgan, East St. Louis, Thomas Back, Canton, W. S. Burris, Danville. Above:—Thomas Weeks (Deceased)

Fireproof Shaft, Vermillion Mine

Concrete Construction of Shaft Lining and Bottom—Description of Steel Sinking Shoe

*By A. F. Allard**

The Bunsen Coal Co., of Westville, Ill., a subsidiary of the United States Steel Corporation, broke ground on October 5, 1911, for the construction of a concrete-lined shaft combining an escapeway for the men and an upcast airway for ventilating purposes. The Vermilion mine has a daily output of 2,750 tons. The development at the present time comprises

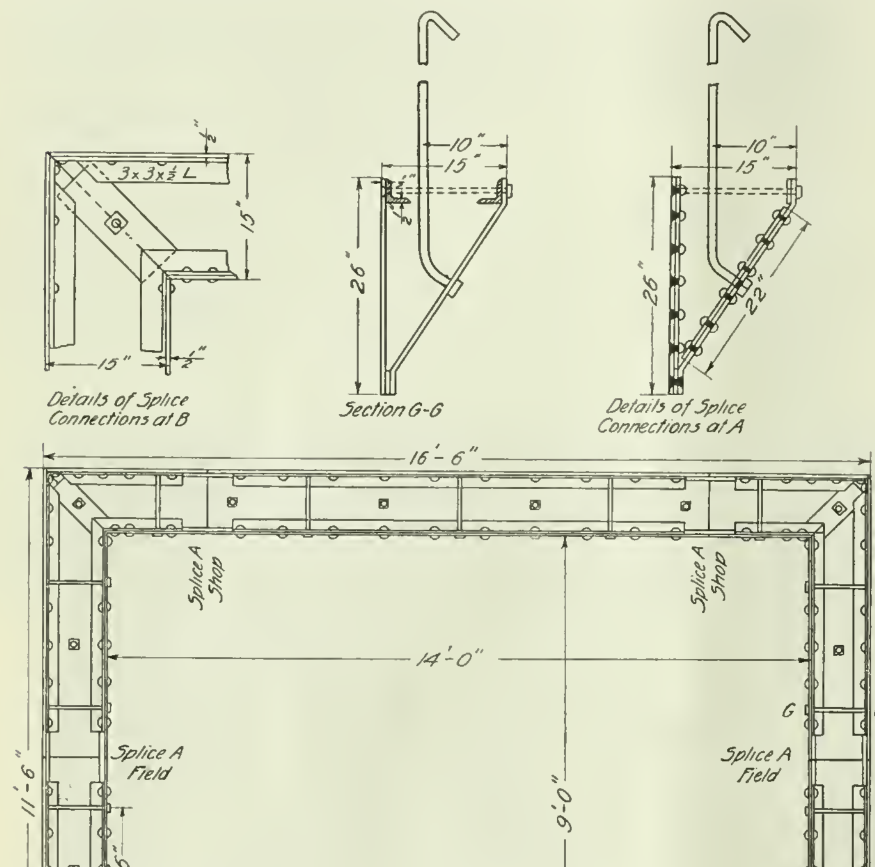

Fig. 1. Plan and Details of Steel Shoe

about 500 acres of the Grape Creek coal seam. The point chosen for the shaft location is 3,500 feet from the hoisting shaft. Departing from the ordinary procedure of contracting the work, and in order to obtain the experience during construction, the Bunsen Coal Co. purchased all equipment necessary and completed the work with their own forces. Work was stopped during the winter months and started again during April, 1912, the shaft lining walls being completed on June 1 of same year. The method of sinking and design adopted combined the new features of a rectangular designed shaft of concrete and the sinking of same through the soft strata by means of a steel shoe and the weight of the concrete lining walls.

The shaft is of rectangular design and measures 8 feet in width by 13 feet in length in the clear between the concrete lining walls. The concrete walls have a thickness of 21 inches from the top of coping to the steel shoe, a distance of 52 feet, from this point to the bottom of shaft the walls have an average thickness of 12 inches. The total depth of shaft is 205 feet to the archway landings at the bottom. A sump with a depth of 3 feet 6 inches is provided. The shaft has an opening area of 104 square feet. The steel stairway and landings occupy a width of 4 feet 10 inches and extends the length of the shaft; the pattern is of open design and only a small percentage of the space taken up would affect the ventilation and upcast of which a portion of the air goes through the stairway openings. Fig. 3 shows the plan and elevation of the shaft.

Two reinforced concrete archways are provided at the shaft bottom, one for the upcast air from the mine and the other from manway entrance to the stairway. Each arch has a span of 7 feet and a height of 9 feet from landing to the top of crown, both arches extend a distance of 6 feet from the shaft lining. The sump is floored over and supported on 3-inch I beams. Fig. 2 shows the arrangement at the bottom openings.

The steel shoe for the sinking of the shaft, from the surface of ground to the solid strata, was of rectangular design, forming an open caisson, and measured when set up ready for sinking 11 ft. 6 in. x 16 ft. 6 in. The side and end plates are ½ inch thick. Fig. 1 shows plan and section of shoe with details showing method of construction at the corners and splice connections.

The shoe before riveting together comprised six sections connected with ½" x 12" x 26" splice plates thoroughly riveted. The rivet heads were all countersunk on the back of the shoe to lessen the friction when sinking. The four rectangular corners were all stiffened with the same size plates. The shoe has a vertical depth on the back line of the lining of 26 inches and an angle of 45 degrees from the cutting edge to the inner side of the lining at top of shoe. The two side pieces between splice connections are each 10 feet long and the four corner sections measure each 5 feet 9 inches on the end, and 3 feet 3 inches on the side. The opening at top of the shoe provides for a concrete lining wall of 15 inches thickness. The side and end plates at the top between the splice connections are all stiffened with 3" x 3" x ½" angles. To prevent the top from buckling or spreading 1" x 15" bolts are placed every 3 feet around the entire shoe, these bolts have countersunk heads on the back of the shoe. Between the horizontal bolts and extending around the entire shoe, and spaced 3 feet apart, 1 inch diameter by 6 feet in length vertical rods were used to tie in the shoe to the first section of concrete lining, the top of these rods were bent in U form to receive similar rods which were placed as each section of lining wall was poured, and extended to the top of coping. The shoe when completed had a total weight of 7,000 pounds.

* Chief Engineer, Bunsen Coal Co.

Wooden forms were used for all of the concrete lining work and were made up of 2"×10" surfaced plank carefully put together and stiffened vertically with 4"×6" strips. The forms were 6 feet high, two side and two end pieces formed the units for the entire section. An inside and outside form was necessary for the placing of the concrete until the shoe was landed on solid strata. These forms remained in position at the top of the shaft until this portion of the work was completed. To readily release the concrete when set and remove the forms when necessary, all of the connecting joints had beveled edges and were brought into position by wedging. The sides and ends were well braced to hold in the correct position.

From the shoe to the shaft bottom an inside form only was necessary, the concrete filling into the sides of the rock excavation or against the 2-inch curbing timbers. No forms were removed from the concrete until it had set for at least two days.

Steel Stairway.—The steel stairway is of zigzag pattern and together with the landings occupies a space longitudinally in the shaft for a width of 4 feet 10 inches. Each flight rises on a 38-degree angle from the vertical, and is 11 feet long. The separate flights, including the landings, are supported on 8-inch channels weighing 11¼ pounds per foot placed crosswise in the shaft, and are secured in the concrete side walls by placing in pockets and grouting the ends, which have a bearing of 6 inches in the wall. These channels are placed 2 feet from the end walls and are spaced vertically 6 feet apart, alternating for each flight.

The stair stringers are ¼ in. × 7 in. deep. The treads are ¼ in. × 11 in. × 27 in. with checkered surfaces and are supported on 1½"×1½"×¼" angles riveted to the stringers. The rise between treads is 8 inches. The landing plates are ¼ in. × 25 in. × 58 in. and are also checkered on the surface. Three lugs of 3½"×5"×⅜" angle iron are riveted to the plate and fastened to the concrete wall by means of ⅝"×5" expansion bolts well drawn up. The hand railing is made up of two lines of 1½-inch pipe, the uprights are bolted to the stair stringers and connected to each line of railing. The total weight per vertical foot of stairway and landings, not including the channel supports, was 95 pounds.

Before placing any steel work, two coats of paint were applied on the surface and again another coat in the shaft upon completion of the work.

The cutting of the pocket holes in the concrete and the drilling of same for the bolt holes was all done by hand. The men erecting temporary scaffolds as each flight was placed, working from the bottom upwards. This stairway is easy for the men to walk on and is of economical design, making the shaft absolutely fireproof. Fig. 3 shows the plan and part elevation of the stairway.

Method of Sinking and Concreting. For sinking work, a steel shoe to penetrate the soft strata was used and carried the concrete caisson from the surface of ground to a point 52 feet below the top of the coping.

To give the shoe a good start, excavation was first made, giving ample clearance for a depth of 3 feet when the forms were placed in position at the surface and the first section of concrete lining wall poured to a depth of 6 feet.

Mucking was then started, and as the sides of the excavation were cleared the weight of the concrete started the cutting edge and penetration of the shoe, until sufficient depth was made for the placing of another 6-foot section of concrete wall. This same process was repeated until shoe and concrete walls were landed on the solid strata at a depth of 52 feet from top of coping. For this depth the walls were 21 inches thick, and the entire section sunk by the weight of the concrete through the surface soil, sand, gravel, and clay strata. To tie together each vertical 6-foot section of concrete lining wall, 1 inch diameter by 6 feet rods were placed around the entire section and spaced 3 feet apart. The concrete mix was composed of 1 part "Universal Portland Cement," 2 parts sand, and 5 parts gravel. For the closing-in sections an extra bag of cement was added to each batch. The concrete was mixed in a cubical mixer located near the top of the shaft, poured into a bucket, lowered, and the mix distributed in the several forms by means of a movable chute supported on a temporary platform at the top of each section in the shaft. No supporting buntons for the side walls were used in this shaft.

From shoe to the shaft bottom the usual method of sinking was employed; namely, drilling and shooting the sump holes and benches, carrying down the excavation as far as possible to permit the placing of from 20 to 60 feet of concrete lining wall, when the sinking and concreting process was repeated.

When soft strata and fireclay seams were encountered in the excavation, 2"×10" curbing timbers were placed to protect the sides from caving.

When the shoe was landed, several cracks appeared in the concrete walls mainly due to the pressures exerted because of the weight of the concrete not settling evenly; at times one end was much higher than the other, and mucking at the lower end had to be stopped and continued at the high end until both came to the same level. When the shoe was landed the shaft section for a depth of 52 feet was found to be about 9 inches out of plumb, this was equalized and the cracks grouted by placing a concrete veneer over the entire top section, the concrete was adhered to the original walls by the use of ¾-inch lag screws staggered every 3 feet and firmly placed

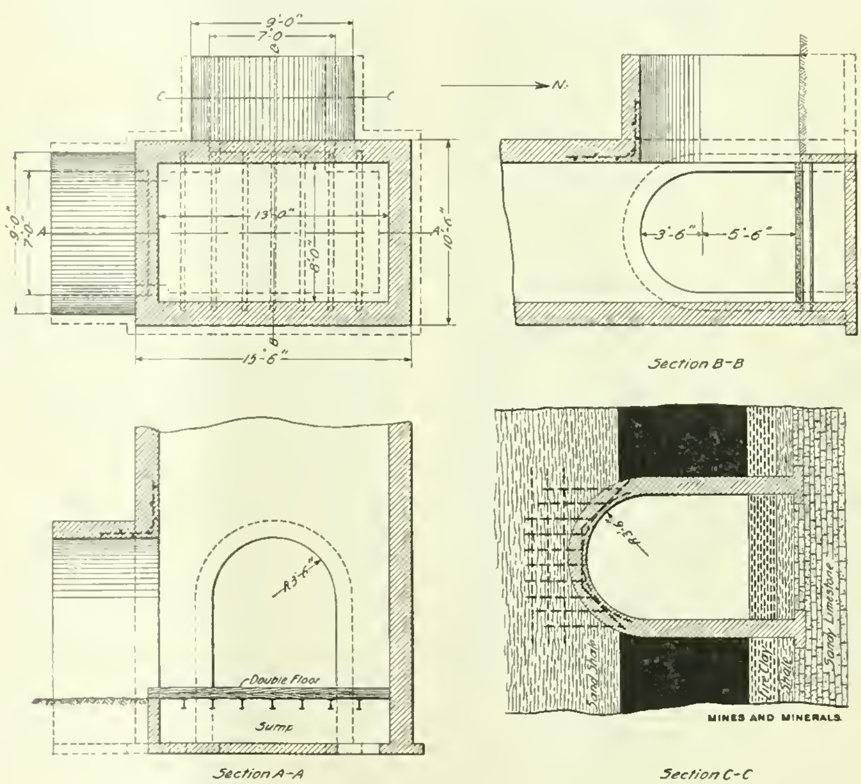

Fig. 2. Construction at Shaft Bottom

in the original concrete, making a good appearing and efficient job when the work was completed. The advantage of sinking by this method, through soft ground, over that of using curbing timber and jacking the shoe down by hand, was not only in progress, but also the saving in cost by eliminating any heavy timber that might be necessary, and by pouring the concrete for the heavier wall sections and erecting the forms on the surface. Very little water was met with during the work and little trouble was experienced taking care of it. During the sinking and con-

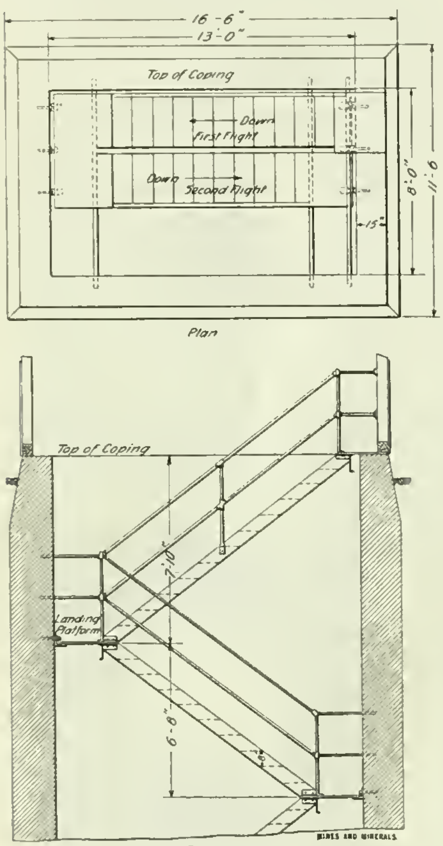

Fig. 3. Shaft and Stairway

creting work, two 8-hour shifts were employed consisting of 7 men on each shift. One shift only was used of 5 men when the stairway was erected.

The equipment consisted of a straight mast derrick with swinging gear attachment and a 50-foot boom handling all of the muck and conveying the concrete; one double-drum hoisting engine with 6½" x 10" cylinders, and attached to the engine was a 20-horsepower vertical boiler; one 50-horsepower portable fire-tube boiler; one duplex feedwater pump, size 6 in. x 4 in. x 6 in.; two side dump trucks; two dump buckets each of 1 cubic yard capacity; and one cubical concrete mixer with engine attached. The mixer had one-half cubic yard capacity. Electric lights for the work were furnished from the Vermilion mine, and water for boiler use was pumped from the same place.

Answers to Examination Questions

Answers to Questions Asked at the Examination for Mine Foremen, Held in Utah, 1911

(Continued from August)

Ques. 15.—What should a miner be made to know about a safety lamp?

Ans.—A miner should know that in the hands of ignorant, careless, or uninstructed men, the safety lamp instead of insuring freedom from gas explosions may be a positive source of danger through a false sense of security created by its presence and use. The miner should be able to know when the lamp has been properly cleaned and put together and when the gauze is in good condition; he should know that the lamp should not be opened under any circumstances except by those authorized to do so and in a place where such opening cannot ignite gas; that the flame should not be too high nor should the lamp be kept in a gaseous atmosphere too long; he should know that the lamp must be kept upright, must not be allowed to fall, must not be directly exposed to strong currents of air or, what is the same thing, must not be swung to and fro while being carried. He should be especially instructed that if anything goes wrong with his lamp, or if he even suspects that it is not working properly, to take the lamp carefully from his working place to the entry where gas is but rarely found and report to the fire boss or mine foreman.

Ques. 16.—Explain the difference, in method of producing an air-current, between a force and exhaust fan?

Ans.—As the power required to force a given amount of air through the same mine is the same with either an exhaust or blowing fan, the difference in the systems consists practically in the different arrangement of the fan casing. In exhaust fans the air is commonly discharged upward through a chimney-like extension which widens toward the outer end. In blowing fans the discharge is usually in a horizontal direction into the airway with only enough enlargement to accommodate it to the size of the mine heading.

However, the underground conditions produced by the use of the two systems are markedly different. With the exhaust fan the atmospheric pressure in the mine is always a little less than that outside, the result being that if the fan stops there is a tendency for any gas to be driven back into the coal or the gob, while with a blowing fan, the pressure in the mine being greater than that outside, a stoppage of the ventilating machinery has a tendency to permit the escape of gas from the coal and abandoned workings. In a mine making much gas the percentage of firedamp thus released from or forced back into the workings is insignificant, but the advantage, such as it is, is in favor of the exhaust fan. Under the exhaust system of ventilation, the hoisting shaft is the downcast and, if wet, much trouble may result in winter from water freezing on the guides, etc. With the blowing system the hoisting shaft is, of course, the return and the escaping air-current, being warm, there is rarely any danger from freezing. On the other hand, with a blowing fan the intake may freeze, and as the effect upon the ventilation is the same whichever shaft is clogged, from this standpoint it is immaterial which system is adopted, although it will be admitted that a hoisting shaft by reason of its greater accessibility is more easily kept clear of ice than an ordinary ventilating shaft. However, with modern methods of construction there is rarely any excuse for any great amount of water dropping in the shaft.

In regard to working conditions at the foot of the shaft; under the exhaust system the shaft parting is constantly supplied with fresh air and while relatively cool in summer is absolutely cold in winter. In the blowing system, the air on the shaft parting is always foul and is warm both winter and summer, as mine temperatures vary but little from season to season. With the exhaust system, the shaft parting is clear and free from fog or haze, except upon unusually warm and humid days in summer when there may be some slight condensation of moisture, whereas with the blowing system the shaft bottom is always more or less hazy from powder and lamp smoke and possibly some watery vapor. From the standpoint of health, proper working conditions, etc., at the shaft bottom, the exhaust system is to be preferred.

As regards conditions at the working face, the advantage is with the blowing system, because the haulage road being the return the foul air and dust are immediately conveyed away from the miners instead of toward them as is the case under the exhaust system when the haulage road is the intake. It should be remembered, however, if the seam is gaseous it may not be safe to make the haulage the return (blowing system) on account of danger from driver's lamps, sparks from the trolleys of electric locomotives and the like.

From the standpoint of humidification and dust treatment the advantage appears to be with the blowing system. If the air-shaft is the downcast, the incoming air may be heated at the entrance to any desired temperature and humidified to any degree of saturation so that it reaches the face in the best possible condition to keep the dust moist; and this may be done without the highly objectionable clouding of the haulage way with steam which is practically unavoidable under the exhaust system. As mine entrances are placed where there is least cover, it follows that there is a drop in the rock, or normal mine, temperature from the working face to the drift mouth or shaft bottom. Under the blowing system, this regular drop in temperature is favorable to a uniform deposition of moisture from the face outby, so that the haulage roads, where a large percentage of dangerous dust is made, are in a better and safer condition than under the exhaust system where the haulage roads are the intake, and where the entering air, except for a few months in summer, is below the normal mine temperature and hence tends to absorb moisture from the mine.

In general it may be stated that in non-gaseous mines, or in mines giving off but small amounts of explosive gas, but troubled with inflammable dust, the blowing system is to be preferred, because it permits of a very perfect handling of the dust. If the mine is very gaseous, unless compressed air or storage battery electric haulage is used, together with storage battery portable lamps, it would seem better to use the exhaust system because of danger of igniting the gas by open lights or sparks from a trolley. If the mine is both gaseous and dusty, hauling should be done on a separate heading and a 3-, 4-, or 5-entry system of mining be adopted.

Ques. 17.—Upon making your rounds of inspection in the morning, say in No. 3 entry and in Nos. 1, 2, 3, and 4 pillars, you found the gas down to the edge of the roof on the caves, these pillars being worked with safety lamps while other rooms and entries on the same split were worked with open lights, (*a*) What would you do? (*b*) Do you think that the above method can be made a safe practice?

Ans.—(*a*) While attention should be paid to the situation of the pillars and rooms with respect to the direction of the air-current, safety would demand the immediate withdrawing of the men until such a time, at least, as all have been provided with safety lamps. (*b*) Whether working the pillars with safeties and rooms and entries with open lights can be made a safe practice will, as stated, depend in some measure upon the direction of the air-current. If, in the line of motion of the air, the pillars are outside the rooms, most superintendents would work the rooms, or all except the one or two nearest the pillars with open lights, as the gas is being pulled away from the rooms. On the other hand, if the rooms were inside the pillars, that is, if the air entered the pillars first, ordinary prudence would indicate the use of safety lamps in the rooms beyond. It would seem better practice to use safeties in both rooms and pillars under any circumstances, as a heavy fall might force the gas in any direction back upon the open lights. A higher degree of safety would be obtained by using electric storage battery lamps in place of open lights as they are absolutely safe unless the bulb be broken in a mixture of air containing a quite large proportion of explosive gas.

Ques. 18.—What are the principal things to be looked after in haulage ways in mines to insure safety to men and animals and economical haulage?

Ans.—The headings should be driven "on points," or sights set by the mining engineer with a transit, or if an engineer and a transit are not available sights may be set by the foreman with a compass. It is advisable to so place the line of sight with respect to the ribs of the entry that one rail may be laid on this line. This will insure, due care being taken by the tracklayer to bring the other rail to gauge, that the track is absolutely straight, and no one thing does more to prevent derailments and consequent loss of time and possibly of life and property, than having a straight track. Grades should be made as uniform as possible by taking up the bottom on the rises and filling in the swags. Also the track should be properly lined so that there are no vertical kinks in the rails, and surfaced to prevent local low places or "low joints." The rails should be of good size, 45 pounds per yard or larger where high-speed electric haulage is employed, some mines employing 60- and 65-pound rails on main headings. Ties should be large, sound, and evenly spaced on 2-foot centers or sufficient in number to prevent the rails bending between them upon the passage of a heavy trip. Track should be well ballasted to insure proper drainage to the ditch, which should be carried on one side of the entry in all wet mines, and which ditch should be kept clean so that water may not back up under the road bed. The regular split switch of the surface railroad type should be used in preference to the old style stub, or blunt, switch. There should be at least 2 feet clearance between the widest part of the body of the mine car and the rib, which distance should be maintained on one side of the entry so that men using the haulage way as a traveling road instinctively turn in the proper direction to pass an approaching trip. This is easily possible, if the heading is straight and the rails laid on points, but difficult of accomplishment otherwise. It is also advisable to have refuge, safety, or man, holes cut in the rib at regular intervals on the same side of the heading as the widening used as a traveling way or path. These places of refuge should be whitewashed or painted to indicate their location, and it is advisable to have an electric light burning in front of each. Unquestionably many of our readers have at one time or another dropped their lamps and been in the dark and thus in serious danger when traveling on the main road. An electric lamp every 60 or 100 feet affords sufficient light for one to reach a place of safety where he can wait until some one with a lamp comes or even may proceed with perfect safety to the parting. The above applies to permanent main haulage ways which are to be used throughout the life of the mine; and large operators now realize that the increased investment for first-class track and rolling stock is returned many times over in less cost of haulage and maintenance. On cross-entries such precautions are not needed, as the life of the entry is relatively short and the speed of haulage not so great. In any case, however, the track should be straight, or good weight of rail, properly surfaced, etc. The amount of money spent upon cross-entry tracks should be proportioned to the amount of coal to "come off" them. Poor room switches probably cause more trouble on cross-entries than anything else. It is by no means unusual to see a fine piece of entry track disfigured on the room side with a series of cheap cast-iron frogs. It is almost impossible to set these frogs properly, or if set properly, they soon get out of line and are a continual source of derailment, with its attendant loss of time and labor, both of which mean money. Room frogs should be of the same general type as those used for entry turnouts from the main haulage road, only smaller. If properly cared for they may be taken up and relaid until the mine is exhausted. In pitching seams the entries generally follow the water level or are driven with a slightly rising gradient to insure proper drainage. The curves should be as regular as possible and the rails should be bent by machine to the shape of the curve and not sprung into place. An elevation dependent upon the degree of curvature and the speed of the trip should be given to the outer rail. In other particulars the handling of track and haulage roads is the same in pitching as in flat seams.

Ques. 19.—How much more resistance does an air-current encounter when traveling 600 feet per minute than at 500 feet per minute? If the water gauge is .8 inch at the lower speed what would it be at the higher?

Ans.—If P and V are the pressure and velocity at a speed of 600 feet a minute and p and v those at 500 feet per minute, the formula for the resistance (pressure) is in the first case, $P = \frac{k\,s\,V^2}{a}$ and in the second, $p = \frac{k\,s\,v^2}{a}$. The ratio between them is $\frac{P}{p} = \frac{\frac{k\,s\,V^2}{a}}{\frac{k\,s\,v^2}{a}} = \frac{k\,s\,V^2}{k\,s\,v^2} = \frac{V^2}{v^2}$, since k, s, and a are the same in either case; or the resistance, which is measured by the pressure, p, is proportional to the square of the respective velocities. If the pressure at the lower velocity is called l, we have by substituting the values of V and v, $\frac{P}{l}=\frac{600^2}{500^2}$ $=\frac{360,000}{250,000}=\frac{36}{25}=1.44$. That is, the resistance at 600 feet per minute is 1.44 times as much or 44 per cent. greater than at 500 feet per minute.

If I equals the water gauge at the greater velocity and i the water gauge at the lower velocity, we have the two formulas, $I=\frac{P}{5.2}$ and $i=\frac{p}{5.2}$ and the water gauge ratio is $\frac{I}{i}=\frac{P}{p}$. But, since $\frac{P}{p}=\frac{V^2}{v^2}$, we have by substitution, $\frac{I}{i}=\frac{V^2}{v^2}$, that is, the water gauge ratio and the pressure ratio are the same, which is to be expected, since the water gauge is used to measure directly the drag, or resistance. Since we have found the ratio $\frac{P}{p}=1.44$, the ratio $\frac{I}{i}=1.44$ as well, Since the water gauge, i, at the lower velocity is equal to .8 inch, we have by substitution, $\frac{I}{.8}=1.44$. From this $I=.8\times1.44$ $=1.152$ inches.

Ques. 20.—(*a*) What precautions would you take to prevent a squeeze in a coal mine? (*b*) What are the main dangers attendant on a squeeze?

Ans.—As a squeeze is due to too great a weight being thrown upon the pillars the best means of prevention is, naturally, to proportion the width of the pillars and rooms to the thickness of the overlying rock; the thicker the superincumbent rocks, the wider the pillars and the narrower the rooms and entries. For the proportioning of pillars according to the depth of the workings beneath the surface, various more or less satisfactory formulas are given. It is obvious that a single room even of unusual width, say as much as 50 feet, when driven in a solid block of coal will not bring about a squeeze, whereas the working of a 20-acre tract with rooms of this width separated by 20-foot pillars will result in one. From this it follows that too large an area of coal should not be opened and left standing. The use of almost any retreating system of mining lends itself to the prevention of squeezes because the headings are driven narrow to the boundary, the rooms turned at the far end of the workings, and the pillars drawn as soon as the rooms reach the limit of their length. Squeezes are apt to occur in mines where the pillars and rooms are not of uniform width or where the pillars are improperly drawn. Spacing the rooms a regular distance apart and driving them on sights will eliminate danger from pillars of variable width, and systematic pillaring carefully watched should prevent squeezes during robbing.

A squeeze once started is a very difficult thing to control and no set rules can be laid down for the purpose. In handling a squeeze the object is to remove the weight from the pillars of coal as rapidly as possible. In the early stages this may sometimes be done, in part, by shooting down the roof to a height as great as it is possible to drill a round of holes. In some cases it is possible to flush slack through bore holes drilled from the surface into the openings made by the entries and rooms. Usually, however, an attempt is made to secure a break of the overlying rocks to the surface. Sometimes this may be done by a rapid drawing of the pillars, but usually it is attempted by building a series of masonry or timber cribs in a line across a number of rooms. If the squeeze is found to be beyond control and it is seen that the district in which it occurs is destined to be closed, efforts should at once be made to recover all the timber, rails, and other property within its boundaries. A district in which a squeeze has developed should be surrounded by ample barrier pillars or solid coal, so that the crushing action may not "ride over" into what would otherwise be good ground.

(*b*) Squeezes generally begin and extend slowly, giving ample warning for the retreat of the workers. Should the action be violent, men may be caught by falls of roof or imprisoned by the closing of a portion of the workings; gas may be forced out upon open lights, resulting in an explosion; or the sudden closing of a large area may force out a volume of air with the velocity and violence of an explosion, tearing down timbers, destroying brattices and doors and even propelling cars up the hoisting slope.

Ques. 21.—If you are operating a mine in which firedamp was generated freely, using a locked safety lamp, the coal in the gaseous zone becoming exhausted, and you decided to develop another portion of the mine in which no gas had been discovered, what restriction would you enforce to prevent naked lights being taken into the fire zone?

Ans.—The question is not quite clear, in that it fails to state the situation of the proposed new and non-gaseous working with reference to the about to be abandoned and gaseous workings. If, as is not infrequently the case, the gaseous workings consist of a pair of cross-entries with the accompanying rooms, the entries being connected with the main haulage road and intake, respectively, it would be advisable to seal off the mouths of the entries and air-course with masonry stoppings provided with a small man door which should be kept locked. This will prevent any but those in authority from entering the dangerous workings.

However, if it is necessary to use the entries in the fiery zone to reach the new workings, the above course cannot be followed. If the pillars therein have not been drawn it would be advisable to brattice off the room necks as close to the entry as possible. This will prevent any one entering the old workings; and if these old workings be ventilated by a separate split and the brattices be properly built, there should be no danger of leakage of explosive gas into the entries. If bratticing is not possible, an ordinary lamp station should be established at the entrance to the gaseous workings and no one allowed to enter and pass through them unless provided with a locked safety lamp in good condition obtained from some one in authority at the station. The customary rules and regulations prevailing in gaseous mines should be posted and enforced.

Notwithstanding that gas has not been discovered in the advanced workings, it would seem good policy to work them with safety lamps. The fact that the old workings have developed large quantities of gas is strong indication that the new ones will do so at some time, and perhaps unexpectedly. It is by many considered the best practice to use safety lamps exclusively in all parts of a mine when the existence of gas compels their use in one part thereof; that is, either use all open or all safety lamps. Whatever objections may be raised to this view, it will be admitted that it tends to insure safety.

State Coal Mine

In Victoria, Australia, there is a state coal mine in the control of the Railway Commissioners. Prospecting with drills has proved that there are 22 million tons of coal in a bed 2 feet 6 inches thick covering 3,500 acres.

Eleven shafts have been sunk ranging in depth from 177 to 283 feet, but all are not producers, only 3, 5, and 11 being used for that purpose at the time of writing.

In 1911, 710,058 tons of coal were mined, but with the exception of slack coal, which averages 42 per cent. of the output, no coal was sold to the public. Evidently public utilities are run by the Government or else they have to buy this coal from the Government, for the prices given at the mine are \$2.75 for screened coal, \$2.50 for second grade, \$2.12 for run-of-mine, and \$1.62 for slack. The total number of men employed at the mines near Wonthaggi are 1,200; these averaged \$3.47 per shift during 1911 when working on contract.

Adiabatic differs from isothermal compression in not having the air cooled during compression. Most compressors, if not all, are constructed on isothermal lines.

Waste Heat Coke Ovens

At Marianna, Pa.—A Plant Using Heat from 75 Ovens at a Large Saving Over Coal Firing

*By Sim Reynolds**

THE Marianna waste-heat system consists of four Stirling boilers of 500 horsepower each, fired by the gases given off from a block of 75 beehive coke ovens; and it has been demonstrated that these boilers are delivering 90 per cent. efficiency. The four boilers were originally installed with automatic chain-grate stokers, and it is interesting to note that with the present waste-heat system in use there is an actual saving of over $60 per day, as shown by the following:

COST OF OPERATING AUTOMATIC STOKERS		
2 firemen (also tending water)	$2.25 per day	$ 4.50
4 ashmen	2.00 per day	8.00
68 tons coal at 75 cents per ton		51.00
Total		$63.50

The cost of getting coal to stokers has not been included in the above, yet with these same boilers fired with the waste heat the cost of operation does not exceed $2.50 per 24 hours, or a daily saving of $61 in the operation of a batch of 75 coke ovens.

To those who are more or less familiar with waste-heat systems, as applied to coke making in the United States, it is a generally understood fact that one of the most annoying features of the ordinary, or earlier systems, was the burning out of the connecting flues which carry the gases from the individual ovens to the main conduit. These flues are of course subjected to a great heat, that burns them out more or less completely, in the ordinary waste-heat apparatus. In the ordinary construction this destruction occurs 4 or 5 feet below the top of the oven, or in a line with the top of the coke, and considerable time must elapse before workmen can enter the oven to repair the damage.

In the Kearns waste-heat system, used at the Marianna mine, the oven gases pass to the main conduit by means of a flue set on a line with the top of the oven as shown in Fig. 1. This flue, placed as it is, can be opened in a few minutes after the coke is drawn, and any repairs necessary made. It will also be noted that the flues of this system are built with an air cooling arrangement under and around them, cold air entering at an opening in front of the oven, and out by the way of a small brick stack at the rear. With this method the burning out of a flue is of rare occurrence, and, should the flue need attention at any time in the process of making coke, it is readily accessible, a point not to be overlooked during a busy season. Another of the advantages of having the waste-heat flue connected at or near the top of the oven is that the gases rise naturally from the burning coal, thus giving a uniform draft throughout the oven, and, consequently, a more uniform combustion and quality of coke. This is a decided advantage over having the gas flue lower down in the oven, from the fact that the coal near the entrance to the waste-heat flue as ordinarily constructed, gets a draft out of proportion with the balance of the charge, which has a decided effect on the quality and structure of the product.

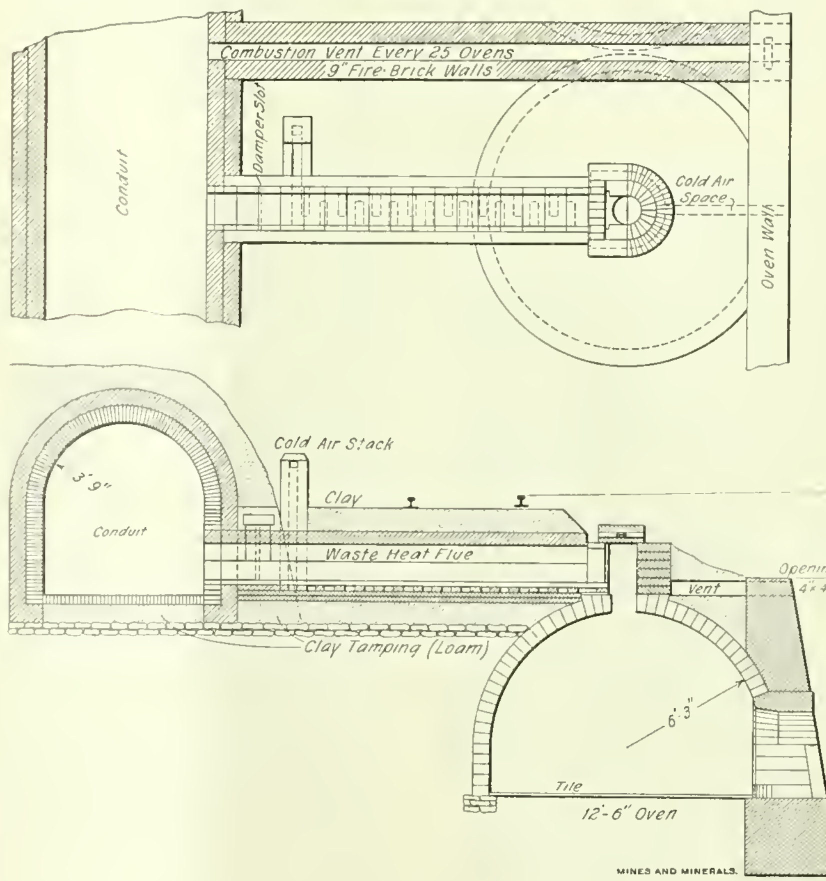

FIG. 1. PLAN AND ELEVATION OF WASTE HEAT COKE OVENS

The results obtained at the Marianna plant have certainly been gratifying, both to the inventor and the Pittsburg-Buffalo Co. Over 90 per cent. of the fullest possible efficiency is obtained (something the reader will readily agree is far from common in heating or power departments of our industrial plants), and a block of 75 ovens requires only the services of one man to watch the water in the boilers, etc., and who has ample time to give to other duties besides.

The system at Marianna has been in operation over 2 years, certainly a sufficient time to give it a thorough test, and so far the cost of upkeep has been hardly worth mentioning; in fact, the only expense in the whole system has been that of slight repairs to the connecting flues from ovens to main conduit. When this is necessary a small sheet-iron damper is placed in position to shut off the oven from the main conduit, and so isolate the faulty oven from the rest of the block, when the repairs can then be accomplished without further interference.

The coke manufactured in these ovens is unusually free from black butts, which is due to the uniform rate of coking, a constant draft being maintained direct from the ovens to the boilers. The percentage of sulphur is also lower than the ordinary beehive coke, being below the 1 per cent. mark. Wind storms and other climatic conditions have no effect whatever on the coking process, which cannot be said of the old beehive ovens. Draft is regulated at the boiler room for the entire system. Each boiler can be disconnected when necessary from the main conduit by means of a damper through which water circulates. The matter of cleaning boilers is more simple and convenient than with any other style of firing, to say nothing of the absence of dirt under the boilers.

The cost of a waste-heat plant, such as is installed at Marianna, varies according to local conditions, but for a plant say of 50 to 75 ovens, the cost will be approximately $250 per oven over and above the

* Inspector for W. J. Rainey Co., Uniontown, Pa.

beehive oven, or say an initial cost of $20,000 for a block of 75 ovens, which should supply something like 2,000 boiler horsepower. It is safe to say that the Marianna waste-heat plant on this block of coke ovens paid for itself during the first year of its operation. The construction of 300 additional ovens is under consideration by the Pittsburg-Buffalo Co., and enough of these will be put on waste heat to furnish power for the entire plant.

Another point worth considering in regard to waste-heat ovens is the fact that it has been found by actual test that it is possible to burn from 10 to 15 bushels more coal per oven in the waste-heat than in any other style of oven operation.

At the Marianna plant 48-hour and 72-hour coke are the principal grades made, and the demand for the furnace coke has been greater than could be supplied.

Coal is fed to the ovens by electrically-driven larries over a 90-pound track laid on I beams.

Air-Compressor Cylinder Lubrication

Influence of Heat Upon Oils—Dangers Resulting From Caking and Carbonizing of Improper Lubricants

By L. A. Christian

The following is an abstract from the paper entitled: "Lubrication," read before the West Virginia Mining Institute:

In the last 15 years the use of compressed air has become so general that a knowledge concerning the lubrication of air compressing cylinders is of importance.

The compression of air results in the conversion of energy into heat, and the temperature of the air increases with the pressure to which it is subjected. From time to time trouble arises with the discharge and intake valves of air-compressor cylinders, much of which is caused by the use of heavy and gummy oil.

Experience has shown that the occasional non-seating of valves in air compressing cylinders and the occurrence of fire in discharge pipes and air receivers, is due to the oil used. These difficulties cannot be laid to the oil alone, although it is a well-known fact that an inferior oil, which contains a large amount of easily volatilized carbon, can readily cause an explosion, because structural features of a machine may facilitate the volatilization of the oil and the ignition of the vapors.

The fact that an air compressor frequently pollutes the air in a mine indicates that some foreign substance is in the atmosphere. For instance, at those mines where there is an unusual amount of dusty substances in the atmosphere, which can be drawn in the air cylinder and mixed with the oil, there is formed a substance which, on heating, cakes and may take fire.

Experience has shown that the greatest heating takes place at the point where the air passes from the cylinder into the discharge pipes. At this place the mixed oil and dust gathers and decreases the size of the aperture into the discharge pipe, and more air is compressed in the cylinders than can pass through the valves. This results in recompressing the air and increasing friction, also an abnormal heat. If the discharge valves be incrusted with carbon scale deposited from oil, a portion of the compressed air passes back through the valves and decreases the air pressure in the cylinder, but does not decrease the temperature.

It is important that the temperature of the compressed air be kept as low as possible, and to that end all the standard makes of air-compressor cylinders are provided with jackets through which cold water is kept circulating. The flash point of oil used in air compressing cylinders should be as high as good lubricating qualities will permit. By flash point is meant that degree of heat at which some part of the oil passes off as vapor, which being inflammable, will ignite if brought into contact with fire. The mere raising of the temperature of an oil to the flash point will not produce ignition of the vapors; indeed ignition may occur before the flash point is reached, as in the case of sawdust saturated with linseed oil. Combustion is the rapid chemical combination, of a substance with oxygen. This combination called rapid oxidation generates sufficient heat to set the substance on fire. If a considerable quantity of inflammable vapor be present, an explosion follows. In the air cylinder of a compressor an oil should be used which will resist the relatively large quantity of highly heated oxygen.

Ignition in the compressor air cylinders, discharge pipes, and passages, is not uncommon, and at times is in the nature of an explosion. Two air receivers were blown up during the construction of the New York aqueduct. In one case the engine room was destroyed by fire resulting from the explosion. Other instances have occurred where ignition has taken place near the air compressor, the pipes becoming red hot at the joint. The ignition has been known to extend into the air receivers, and the flames to be carried down into the mines by the compressed air.

A lubricant which is of a high flash point, 625° F., and comparatively free from unnecessary volatile carbon, is best suited for air compressing cylinders. One explosion took place where the flash point of the oil was 554° F. and the ignition point 606° F. In another case an explosion occurred with oil which had a flash point of 575° F. and an ignition point of 625° F. Conditions were similar, the air was compressed to about 60 pounds per square inch. If the temperature of the air before its admission to the compressors is 60° F. and it is compressed to 58.8 pounds absolute pressure the final temperature where no cooling is used during the compression will be *317.4 degrees. If the air which is admitted at 60° F. is compressed without cooling to 73.5 pounds absolute pressure, the final temperature will be 369.4° F. These figures are also based on dry air, which increases in temperature during compression to a greater degree than moist air, and it is known that the compressed air is never very dry. The additional frictional resistance may raise the temperature of the compressed air to the ignition point of the oil.

Too small a discharge pipe or too many angles in a discharge pipe might also tend to produce an explosion, although they occur in well-designed systems. An explosion occurred about 6 years ago, where the temperature of the incoming air was normal, the discharge passages and pipes were free and of ample area, hence the only possible explanation that could be advanced was that the temperature of the compressed air was made excessive by the sticking of the discharge valves, thus letting some of the compressed air back into the cylinder to influence the temperature before compression.

When the piston of an air compressor has forced a cylinder volume of air through the discharge valves, and when this piston has its direction of movement reversed, there will immediately be a tendency of the compressed air to return to the cylinder. In this it is checked by the valves; but the discharge valves are liable to become incrusted with carbon scale and not seat properly.

At the Mammoth mine in the Tintic district, Utah, an explosion occurred in the air-compressor cylinder of a duplex Corliss air compressor which resulted in the death of an assistant engineer and injury to the chief engineer. The cause of the explosion has been attributed to the oil used in the cylinders. The explosion shattered the back head; the back

*Peele, "Compressed Air Plants for Mines," p. 46.

flange of the cylinder was torn off at several points, particularly at the top, where a portion of the cylinder was blown away. Such explosions, while rare, serve to emphasize the importance of using only the best grades of oil for air-cylinder lubricant.

Cheap oil is not advisable in air cylinders, for with the best of oil explosions occur if too much oil is used, or if the valves and ports are not kept clean and free from deposits. If the oil is of low flash test, on reaching the interior of the heated cylinder it will vaporize and pass out with the air without affording any lubrication to the wearing surfaces.

If the oil be too dense, or is compounded with animal or vegetable oils, as is the case with many steam cylinder oils, it will have a tendency to adhere to the discharge valves and passages, and, being subjected to the dry heat of the compressed air, will gradually change to a hard, brittle crust, which in time will completely choke up the air passages or prevent the valves seating.

It has been found by numerous experiments that petroleum oil of a high flash test is the best lubricant for air compressing cylinders. Some engineers presume that an air cylinder requires the same amount of oil as a steam cylinder. This is a mistake.

In lubricating the interior of an air-compressor cylinder the conditions are different from those found in a steam engine cylinder. In the air cylinder the heat is a dry heat and the oil has a tendency to stick to the surface, consequently less is needed than in a steam cylinder where moisture is always present and has a tendency to wash the oil away from the surface.

The amount of oil to be fed into the air cylinder should be, if the machine makes less than 120 revolutions per minute, about 1 drop every 3 minutes.

Some engineers find that a carbon deposit is easily cut away by kerosene oil, and in their anxiety to remedy the difficulty throw kerosene oil into the inlet valves. Kerosene should never be used in air cylinders. It has a flash point of 120° F., and it is not difficult to understand that there will be an explosion under circumstances when the temperature in the air cylinder may be from 300 degrees to 450 degrees.

A high-grade non-carbonizing lubricant will cost a few cents more per gallon, but when the time it takes to clean the intake and discharge valves is taken into consideration, the high-grade oil will be found the cheaper.

To clean the air cylinders or air passage, use soapsuds, made of 1 part soft soap to 15 parts water. Feed this into the cylinder and let the machine work with a liberal solution instead of oil for a few hours or a day; then open the blow-off valve of the receiver and drain off the accumulation of oil and water. This cleaning process if repeated about once in 2 months where a good lubricant is used will be sufficient; but bear in mind that oil is to be fed into the cylinder for an hour or so before shutting the machine down, in order that the valves and the parts connected with the cylinder may be coated with oil; for if this is not done the inside of the cylinder will rust.

At a plant in W. Va. there was an air compressor with one cylinder 24" x 26½" x 40", guaranteed to compress 1,444 cubic feet of free air per minute with 90 revolutions per minute. This machine worked satisfactorily for about 11 months, then the capacity fell to about 900 cubic feet of free air per minute. On examination it was found that 11 out of 28 discharge valves were incrusted with carbon scale, and that they were stuck and partly open. When the valve caps were taken off the valves were found stuck so fast it was necessary to take off the cylinder head. Then by taking a round piece of hard wood large enough to cover the face of the valve they were driven out of the valve seats. It took four men over four days to get this machine in proper working order.

The manager was anxious to know what caused the valves to stick and where the carbon scale came from. When asked what kind of air-cylinder lubricant was being used, his answer was that he was using an 18 cents per gallon engine oil. To get a proper lubrication, that oil was fed through a sight-feed lubricator at the rate of from 5 to 10 drops per minute. It was thought any kind of oil would do. If this company had used a good non-carbonizing oil from the time the machine was put in operation it would have saved nearly a hundred dollars.

Receivers of Air Compressors

The purpose of a compressed-air receiver is to reduce the pulsations of the air from the compressor, to collect water and grease carried by the air in the pipes. The receiver is not intended as an air reservoir of power, though to a limited extent it may be employed for this purpose, as in the event of sudden stoppage of the compressor for any cause the air in the receiver may have sufficient volume and pressure to accomplish some work, such as hoisting a skip that has already been started by the engines which are run by compressed air. The extent to which the receiver may be used for this purpose depends upon the volume of air and its pressure. The principle is exemplified in the compressed-air motors.

Publications on Mine Accidents and Tests of Explosives

The following Bureau of Mines publications may be obtained free by applying to the Director, Bureau of Mines, Washington, D. C.:

Bulletin 10. The use of permissible explosives, by J. J. Rutledge and Clarence Hall. 34 pages, 5 plates.

Bulletin 15. Investigations of explosives used in coal mines, by Clarence Hall, W. O. Snelling, and S. P. Howell, with a chapter on the natural gas used at Pittsburg, by G. A. Burrell, and an introduction by C. E. Munroe. 1911. 197 pages, 7 plates.

Bulletin 17. A primer on explosives for coal miners, by C. E. Munroe and Clarence Hall. 61 pages, 10 plates. Reprint of United States Geological Survey Bulletin 423.

Bulletin 20. The explosibility of coal dust, by G. S. Rice, with chapters by J. C. W. Frazer, Axel Larsen, Frank Haas, and Carl Scholz. 204 pages, 14 plates. Reprint of United States Geological Survey Bulletin 425.

Bulletin 26. Notes on explosive mine gases and dusts, by R. T. Chamberlin. 67 pages. Reprint of United States Geological Survey Bulletin 383.

Technical Paper 4. The electrical section of the Bureau of Mines, its purpose and equipment, by H. H. Clark. 1911. 12 pages.

Technical Paper 6. The rate of burning of fuse as influenced by temperature and pressure, by W. O. Snelling and W. C. Cope. 1912. 28 pages.

Technical Paper 7. Investigations of fuse and miners' squibs, by Clarence Hall and S. P. Howell. 1912. 19 pages.

Technical Paper 11. The use of mice and birds for detecting carbon monoxide after mine fires and explosions, by G. A. Burrell. 1912. 15 pages.

Technical Paper 12. The behavior of nitroglycerin when heated, by W. O. Snelling and C. G. Storm. 1912. 14 pages, 1 plate.

Technical Paper 13. Gas analysis as an aid in fighting mine fires, by G. A. Burrell and F. M. Seibert. 1912. 16 pages.

Miners' Circular 2. Permissible explosives tested prior to January 1, 1911, and precautions to be taken in their use, by Clarence Hall. 1911. 12 pages.

Miners' Circular 3. Coal-dust explosions, by G. S. Rice. 1911. 22 pages.

Miners' Circular 4. The use and care of mine-rescue breathing apparatus, by J. W. Paul. 1911. 24 pages.

Miners' Circular 5. Electrical accidents in mines, their causes and prevention, by H. H. Clark. 1911. 10 pages, 3 plates.

Miners' Circular 6. Permissible explosives tested prior to January 1, 1912, and precautions to be observed in their use, by Clarence Hall. 1912. 20 pages.

Automatic Blocks for Inclines

*By Simon H. Ash**

Most of the coal mines in the Roslyn district of the state of Washington are worked at a considerable distance above the railroads along which the tipples must be located. This necessitates the haulage of the coal being carried on in two distinct stages, namely: the gathering of the trips at the mouth of the mine or at a parting inside; and the conveying of the coal from the top of the plane, incline, or parting to the tipple. This requires the trips to be blocked between the two stages.

At the No. 1 mine of the Roslyn Cascade Coal Co., William Mackay, general manager, the trips are gathered at the mine mouth and then lowered over a gravity plane to the tipple by means of a set of gravity-plane sheaves. The cars are handled in trips of 10. The weight of the average empty car is 850 pounds; the weight of the average loaded car is 2,400 pounds; the size of the rope is ⅞ inch. The gravity plane, which is 3,400 feet long, has an average grade of 14½ per cent., and crosses three ravines on timber trestles. As shown in Fig. 1, the plane has three rails from the knuckle at the mine mouth to the midway point. The by-pass is here, and below this point a single track runs to the tipple. The rails are of 25-pound steel. The track gauge is 30 inches.

To hold the cars at the head of the plane, a pair of automatic blocks have been installed and these are working perfectly. The blocks which are operated automatically by the ropes on the gravity plane are made of 4"×6" timbers, and can be raised or lowered to any height desired above or below the level of the tracks. At all times except when the ropes are in tension and in contact with the pulleys *a* and *b*, the blocks *c* and *d* are up and will block any cars above them. They are held in this position by means of the balance weights *e* attached as shown to the levers *f* and *g*; the balance weight counterbalances the weight of the pulley and truck, and the weight of the rope not in tension which rests on either pulley when the trips are not in motion, one standing on the tipple the other in the yard.

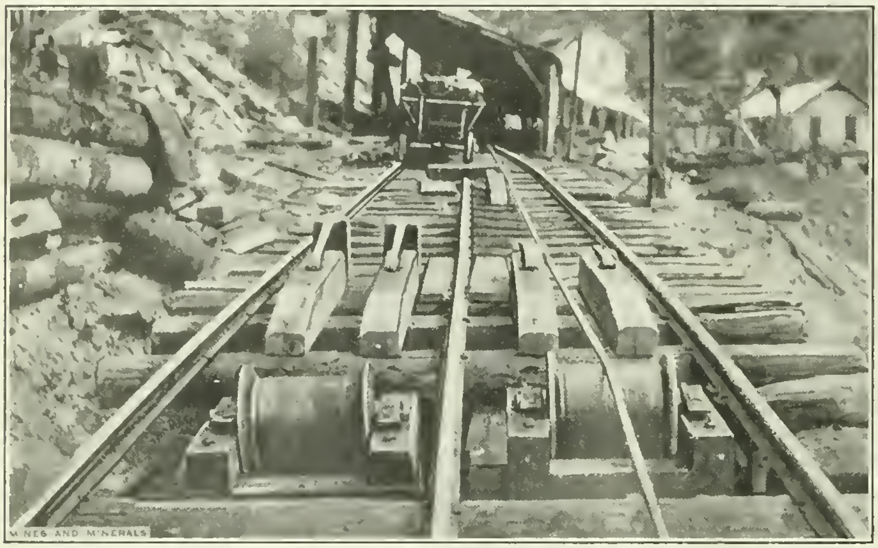

Fig. 1. Automatic Safety Blocks at Head of Plane

As soon as a loaded trip is run out of the mine it is spragged in the yard and the mine rope disconnected. The rope of the gravity plane is then connected to the rear of the loaded trip. At a signal from the tipple that an empty trip is ready, the sprags are withdrawn and the loaded trip moves toward the tipple. Up to this point the blocks are both up, but as soon as the tension of the rope on the empty-car track takes place the rope pushes down on the pulley on which it rests at *a*. As this end of the lever *f* moves downwards the other end moves upwards. This lever in turn is connected with the lever *h*, as shown, by means of a pointed strap passing through the hole *i*; this causes this end of the lever *h* to move upwards while the other end which is connected to the block *c* moves downwards, thus moving the block *c* downwards level with the tops of the rope guide *j* and allows the loaded trip to pass. As soon as the loaded trip reaches the knuckle, the rope resting on the pulley *b*, the tension of the loaded trip rope causes *b* to move downwards, which in the same manner as described above causes the block *d* to move downwards allowing the empty trip to pass as it comes up the plane into the yard. As soon as the empty-trip rope passes *a* the block *c* goes up. As soon as the trips are landed the tension in the loaded trip rope on the pulley *b* is released and the block *d* goes up, thus blocking the empty trip above the knuckle. When both ropes are below the knuckle both blocks are down. If for any reason whatsoever when the trips are in motion below the knuckle the block on the empty-car track should fail to go down, instead of the empty cars running into the block and being wrecked, the front car of the trip would ride on the 1"×1" irons *k*, which are hinged as shown, and push the blocks down to their necessary position.

The time that accidents are most likely to occur, and which has frequently been the case is when the cars are being transferred to or from the gravity-plane ropes at the top of the plane. The device described is simple, easy to keep in working order, costs little to construct, and has proven itself practical.

The Classification of Coal

A Study of the Classifications Proposed by Different Investigators—British Thermal Units

By Leonard V. Newton

A CLASSIFICATION of a natural object is usually based on some fundamental and permanent attribute of the thing itself.

The earliest classification of which there is available authentic records is Uray's Dictionary of Chemistry, published in 1845. Uray classified coal according to physical properties, and his classification was as follows:

1. Cubical coal.
2. Splint or slate coal.
3. Cannel coal.
4. Glance coal.

This classification, it is readily seen, is very rudimentary and crude. No coal could even be approximately classified, because in the determination of physical properties, personal equation plays a very great part.

Uray's classification was followed by Watt's. Watt's method was still physical in its character, but was good in that he grouped the coal under more substantial headings, as may be seen from the following:

1. Lignite, or lean coal, 30 to 40 per cent. H_2O.
2. Bituminous, or caking coal:
   - (a) Caking coal.
   - (b) Cherry coal.
   - (c) Splint coal.
   - (d) Cannel coal.
3. Anthracite coal.

Prof. H. D. Rogers was the next man to take the step that Watt started, and he offered a classification in which coal was classified according to diminishing carbon and augmenting hydrogen. His classification was as follows:

Anthracite, volatile matter below 6 per cent.; semianthracite, volatile matter below 10 per cent.; semibituminous, volatile matter, 12 to 18 per cent.; bituminous, volatile matter above 18 per cent.

Commercially, Professor Rogers' classification may be all right, but from a theoretical standpoint, no coal can be classified according to volatile matter, as it is a variable too great to be considered alone. Furthermore, volatile matter includes both combustible and non-combustible matter; hence, one coal might be high in CO_2, due to a piece of calcium carbonate in the sample, and it could not possibly fall in the same place in the classification with a piece of the same coal without the calcite.

In 1844, Prof. W. R. Johnson, in his report to the United States Government on American coals, advanced the following classification: "Coal shall be classified according to the ratio of the volatile matter to the fixed combustible matter." Thus, we have $C : V H C : W$ = fixed carbon : Vol. Hydrocarbons : Water.

Coal classified thus would vary between proportions as follows:

Between Proportions

Anthracite coal: $99\,C : 1\,V\,H\,C$ and $89\,C : 11\,V\,H\,C$.
Semianthracite: $93\,C : 7\,V\,H\,C$ and $84\,C : 16\,V\,H\,C$.
Semibituminous: $84\,C : 16\,V\,H\,C$ and $81\,C : 19\,V\,H\,C$.
Bituminous: $80\,C : 20\,V\,H\,C$ and $47\,C : 53\,V\,H\,C$.

Mr. P. Frazer proposed his first classification while engaged in work as assistant geologist of the Second Geological Survey of Pennsylvania. His classification is based on the fuel ratio, which was described as the quotient of the fixed carbon divided by the volatile combustible matter. Coals classified thus would be as follows:

Classes of Coal	$\frac{C}{V\,H\,C}$
Hard dry anthracite from	67 02 to 8.64
Semianthracite from	12.75 to 5.41
Semibituminous from	11.41 to 4.52
Bituminous from	3.93 to .68

This classification is poor because of overlapping of values, which makes the classification of coals not only difficult, but incorrect.

Campbell said this classification was poor because of the uneven values, and because of overlapping. He suggested that coal be classified as follows:

Classes of Coal	$\frac{C}{V\,H\,C}$
Anthracite from	100 to 12
Semianthracite from	12 to 8
Semibituminous from	8 to 5
Bituminous from	5 to 0

This classification failed because in grouping all the coals under a ratio of 5, for instance, as in the case of bituminous coals, the range is too wide; furthermore, no provision is made for lignite, which is one of the most important coals of the West.

Collier, in the "Coal Resources of Yukon," proposed a classification to care for lignite coal, by making all coals with a moisture content of 10 per cent. or over, lignite coal. This is incorrect, because by analysis many bituminous coals have a moisture content of over 10 per cent.; for instance, samples taken from laboratory tests run as in Table 1.

Table 1

Laboratory No.	Date	County	Proximate Analysis					B. T. U.	Unit Coal B. T. U.
			Total H_2O	Fixed C	Volume Matter	Ash	Sulphur		
1786	8-08	Sangamon	14.18	37.84	35.39	12.59	4.29	10,396	14,574
1790	9-08	Sangamon	16.41	40.85	33.80	8.94	3.05	10,603	14,477
2622	7-09	Bureau	17.31	39.11	34.81	8.77	3.38	10,502	14,480
1843	9-08	Vermilion	13.23	39.41	37.44	9.92	2.75	11,143	14,761
1129	2-08	St. Clair	15.91	37.43	37.33	9.33	3.95	10.685	14,593

The proximate analyses just given clearly show that Collier's classification is radically wrong.

Thus we see that the full ratio is unsatisfactory; the classification by carbon content is wrong. Where combustible matter is small, this is all right, otherwise it is not. The calorific value of the coal is unsatisfactory, as many bituminous coals are higher in British thermal units than anthracite, due probably to higher percentage of H, or much sulphur. The hydrogen of the coal does not classify it, as low-grade coals sometimes have as large a hydrogen content as high-grade coals.

Mr. Campbell, in 1905, proposed a classification by means of a carbon-hydrogen ratio, which he claimed was very satisfactory. His data are based upon the works of Prof. N. W. Lord, in charge of the chemical laboratory of the United States Geological Survey of the Louisiana Exposition.

His classification is as follows:

		$C\,H$ Ratio
Group A	(Graphite)	D to ?
Group B	Anthracite	? to 30?
Group C	Anthracite	30? to 26?
Group D	Semianthracite	26? to 23?
Group E	Semianthracite	23? to 20
Group F	Bituminous	20 to 17
Group G	Bituminous	17 to 14.4
Group H	Bituminous	14.4 to 12.5
Group I	Bituminous	12.5 to 11.2
Group J	Lignite	11.2 to 9.3?
Group K	Peat	9.3? to ?
Group L	Wood	7.2

The trouble with this classification is, first, an ultimate analysis is necessary to determine the carbon and hydrogen; second, the determination of the hydrogen is very difficult, and therefore the classification is made worthless for commercial purposes. It may be said, however, that Campbell's ranges are limited.

If Mr. Campbell had excluded both H_2O and ash, in his arrangement based on total carbon, he would have had an excellent separation of coal, and would have also separated the lignites and peats.

Prof. S. W. Parr, in his paper of July 3, 1906, says: "A good classification must have correct analytical facts, and scientific data." He claimed that Campbell's classification is poor because hydrogen is a variable, and Campbell failed to use the ratio of the volatile hydrocarbons to total carbonaceous matter. The constituent lost sight of in differentiating the lignites and bituminous coals is the water of hydration, which, according to Dulong $= H - \frac{O}{S}$.

The ratio employed by Professor Parr is the ratio existing between the forms of carbon; namely, $V\,C \times \frac{100}{C}$.

VC = volatile carbon unassociated with H.
C = total carbon by analysis.

In classifying coals, the *anthracites* are those in which the carbon ratio is not greater than 15 per cent.

In bituminous coals, the ratio is not below 20 per cent.

The chemical nature of coal is becoming better known, and Mr. Grout, seeing how well Mr. Iddings represented the composition of coal by graphic methods, decided to do likewise with coal. In this work, the works of the United States Geological Survey and Professor Parr have been used; also the work of Prof. C. N. Gould.

The value of a diagram depends on clearness and readiness with which its meaning can be grasped, and, second, its purpose. No arrangement can be found in which distances being made proportional to analysis, the areas will be intelligible.

Equilateral triangles, Fig. 1 (a), are used such that the areas are proportional to the four constituents of the coal, as shown by proximate analysis.

Fixed carbon: Central white triangle.
Volatile matter: Black triangle placed just above.
Ash: Black triangle below to left.
Moisture: Black triangle below to the right.

To further show the chemical composition of coal, it is instructive to arrange them in a multiple diagram, Fig. 1 (b), based on the ultimate analysis. Essential parts are C, H, and O. N and S are subordinate and not considered.

According to the diagram, coals may be classified according to their position in the coal series, and by their British thermal unit values, Fig. 2. However, I believe that the classification according to the position in the series is poor, because of the fact that the semianthracites have a higher British thermal unit value than anthracite; furthermore, the series is very confusing.

Dowling used

$$\frac{FC + \frac{1}{2}\text{ vol. combustible}}{\text{Moisture} + \frac{1}{2}\text{ vol. combustible}}$$

for air-dried coal analysis. He suggested that it would be well to start with the weathered coal and trace it back into the seam until the maximum is found, and so determine the depths at which coal is subject to the loss from air exposure, as well as finding the maximum loss to which the coal is liable. He says that were it not for weathering effects, a curve could be platted, and the calorific efficiency of any coal found directly by reference to the curve. Dowling's ratio arranges coals much the same as the old fuel ratio does for the eastern coals, but a better arrangement is given for the western lower-grade coals.

The phrase unit coal is used to represent the organic material which is involved in combustion, as apart from the mineral constituents which are the extraneous and variable accompaniments of the actual or unit coal. A number of men have worked

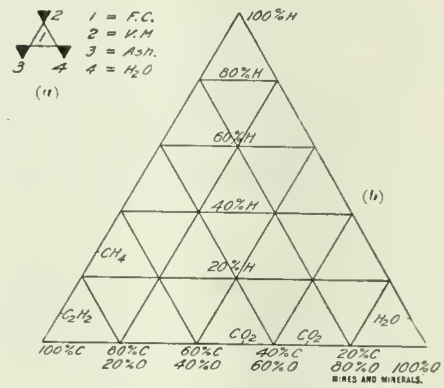

Fig. 1. Hydrocarbon Compounds

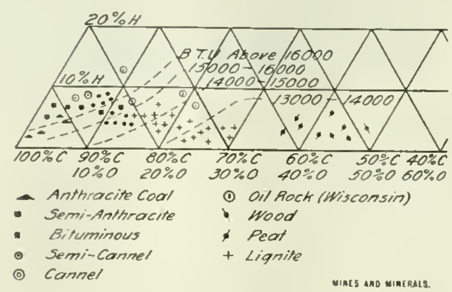

Fig. 2

Professor Parr's Classification of Coal

Coals	Anthracite	Anthracite:	$VC \times \frac{100}{C}$ below 4 per cent.
		Semianthracite:	$VC \times \frac{100}{C}$ between 4 and 8 per cent.
		Semibituminous:	$VC \times \frac{100}{C}$ from 10 to 15 per cent.
	Bituminous	Bituminous proper, A	$VC \times \frac{100}{C}$ from 20 to 32 per cent. Inert volatile 5 to 10 per cent.
		Bituminous proper, B	$VC \times \frac{100}{C}$ from 20 to 27 per cent. Inert volatile 10 to 15 per cent.
		Bituminous proper, C	$VC \times \frac{100}{C}$ from 32 to 44 per cent. Inert volatile 5 to 10 per cent.
		Bituminous proper, D	$VC \times \frac{100}{C}$ from 27 to 44 per cent. Inert volatile 10 to 15 per cent.
		Black lignite	$VC \times \frac{100}{C}$ from 27 per cent. up. Inert volatile 16 to 20 per cent.
		Brown lignite	$VC \times \frac{100}{C}$ from 27 per cent. up. Inert volatile 20 to 30 per cent.

along these lines; namely, Lord and Haas, Noyes, Parr, and Wheeler.

The various statements made are:

(a) According to Bement:

$$\frac{\text{British thermal unit as indicated}}{1.00 - (\text{moisture} + \text{ash as weighed})}$$

(b) According to Lord and Haas:

$$\frac{\text{British thermal units} - 4050\,S}{1.00 - (\text{moisture} + \text{ash as weighed} + S}$$

(c) According to Noyes:

$$\frac{\text{British thermal units as indicated}}{1.00 - (\text{moisture} + \text{ash as weighed} + \frac{1}{2}\,S)}$$

(d) According to Parr and Wheeler:

$$\frac{\text{British thermal units} - 5000\,S}{1.00 - [\text{moist. and ash} + \frac{5}{8}\,S + .08\,(\text{ash} - \frac{10}{8}\,S)]}$$

The idea in getting the British thermal unit value of the coal is to find the actual heat produced by the coal, disregarding the heat produced by S, H, etc.

By means of this British thermal unit value coal may be classified. The classification of fuel types by heat values for unit or actual organic substances is as follows:

	British Thermal Units
Cellulose and wood	6,500– 7,800
Peat	7,800–11,500
Lignite, brown	11,500–12,500
Lignite, black	12,500–13,500
Subbituminous	13,500–14,200
Bituminous coal—(Mid-continental)	14,200–15,000
Bituminous coal—(Eastern field)	15,000–16,000
Semianthracite, Semibituminous	15,500–16,000
Anthracite	15,000–15,500

Regarding the various classifications, I consider that the classification of coal according to British thermal units, said British thermal units being determined by unit coal, is best. It is fit for a commercial usage, and being easily handled, when approximate analysis is given, it is theoretically and commercially good.

Michigan Coal Statistics, 1911

Andrew Stevenson, Inspector, Saginaw, Mich., reports the following for the mines of Michigan in 1911:

Number mines	27
Average employed monthly	2,550
Average daily wages	\$3.39
Tons pick mined	758,626
Tons machine mined	636,737
Total tons mined	1,395,363
Cost per ton	\$1.80
Number days worked	220.8
Tons per man	546
Pounds powder per ton	.827
Number fatal accidents	7
Fatal accidents per 1,000 men	2.73

American Red Cross

The First-Aid Department of The American Red Cross has issued a catalog of first-aid books and supplies.

With a view to conserving human life by rendering immediate aid to the injured in mines, the Red Cross has established a First-Aid Department. In this work the Red Cross is assisted by Mayor Charles Lynch, Medical Corps, United States Army, and Dr. M. J. Shields, one of the pioneer teachers of first aid among miners in this country.

Moistening Mine Ventilating Currents

Use of Steam Jets and Water Sprays—Methods of Avoiding Fog and Undue Dampness

*By A. A. Steel**

EXPERIMENTS have shown that only dry fine dust explodes and that plenty of water furnishes the simplest method of preventing the spread of a dust explosion. But it is necessary to wet the dust thoroughly in all parts of the mine. After the dust has been thoroughly dried, it cannot be quickly moistened. Therefore, the water should be applied continuously and the air-current of the mine prevented from drying it. These results are most readily obtained by keeping the air-current so moist that it will not absorb the natural water of the mine.

When air is cooled, the amount of invisible water vapor it can carry is diminished. If therefore the outside air in summer time is sufficiently supplied with moisture, some of this moisture is deposited in drops upon all parts of the walls of the mine with which warm air comes in contact, because the temperature of the coal and rocks in the mine does not change much during the year and so cools this air. In the winter time, the cold outside air contains very little moisture and it rapidly dries out the mine dust as it warms up on entering the mine. These facts explain why the mines sweat in summer and are so dry in winter.

Whenever the outside air does not contain substantially as much water as it will hold at the mine temperature, water should be added to it. In order that the air can carry enough water, it must be at least as warm as the rocks of the mine. It may be raised to the mine temperature and at the same time moistened by a sufficient number of sprays of warm water. In severe weather, there will be trouble from the freezing of the pipes and the spray, and a great deal of water will be needed. A few jets will not be sufficient, and the fact that a certain mine has suffered from a dust explosion, even though there were a few water sprays in the intake, cannot be taken as proof that wet dust is explosive. Rather it proves that water sprays do not immediately warm the air to mine temperatures.

The fact that the new mines in Kansas are more likely to explode is not due to the fact that more air is supplied but to the fact that the air reaches the actual working places in less time and dries them out more completely than it does the actual working places of the more extensive mines.

Steam Jets.—It is cheaper and easier to use jets of exhaust steam, which will both warm and moisten the air. No more steam will be used than that needed to raise the air to a little above mine temperature and the steam jets will cause no uncomfortable heat if they are small and not pointed directly at a passer-by. If a number of small jets are used, the air will mix with the steam before it has a chance to heat the roof unduly. If the steam is turned toward the roof or wall, this can be protected by light lagging.

It should be noted that the drying effect of the current will extend throughout a mine as rapidly as the moisture nearer the intake is absorbed. On the other hand, air deposits moisture only while cooling and as soon as the warm air of summer reaches the temperature of the mine, it ceases to deposit water. The sweating only extends into the mine as the dripping coal near the intake gets warmer, and this change is slight. Therefore, to quickly dampen the mine by means of the air-current, steam jets must be placed at more than one place in the path of a long ventilating current. The writer has noticed, however, that coal dust gets very wet if

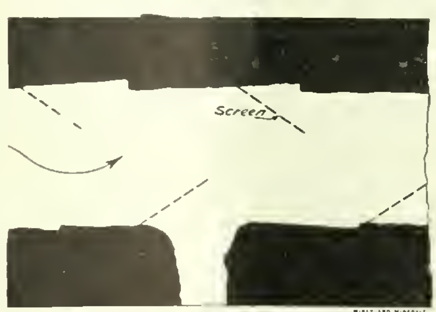

FIG. 1

stored in cellars, the bottom of piles of coal, abandoned mine workings, or other damp places free from a current of drying air; therefore, jets near the face will not be necessary unless the dust is made very rapidly as by heavy shooting in a dry mine. This point can be determined by experience at each mine.

The heating effect of steam is not great unless it is condensed to water, consequently except under exceptional conditions, more steam will be needed to heat the air than is required to moisten it. The condensed steam remains as a thick mist until it settles upon the walls of the mine workings. This will make the hauling of the coal past the steam jets both disagreeable and dangerous, if, as in some states, the law requires the haulage road to carry the intake air, and some means must then be taken to prevent the mist from interfering with the hauling of coal.

Mr. Rice suggests using water jets to slightly moisten the air during the day time, and steam jets at night, in case the coal must be hauled past the jets. Warm water will make some mist as well as steam, and at best as much water will be taken up by the air as it will hold at that temperature. Since even a little steam will warm the air slightly, more water can be introduced by steam jets without a fog than by water. In very cold weather, water jets would freeze unless far from the mouth of the mine with expensive pipes. For these reasons, it seems better to omit water sprays in winter, and merely cut down the amount of steam in the day time when necessary until the mist is not objectionable.

Where there are steam pipes in one compartment of the downcast shaft, they warm the air considerably and quite a little steam can be added at the top of the shaft without causing a mist at the bottom. During the night, an excess of steam can be used to make up for the shortage during the day. This can be obtained from the exhaust of the fan engine supplemented by some steam direct from the boilers if necessary. A sufficient quantity of steam will of course melt all accumulations of ice and make it unnecessary to reverse the fan at night. The mine will not dry out too much in a single day.

The mist may be eliminated by the plan of first warming the air by passing it over steam pipes until the steam jets will just saturate the air and finish warming it without condensation. At a large mine, however, this will require several thousand dollars worth of radiators. This mist can also be avoided by superheating the steam, until the steam needed to supply moisture to the air will bring in enough heat to warm the air to mine temperature. For outside air at 10° F. with a humidity of 80 per cent. this would require 1,200 degrees of superheat which is also impracticable.

The suspended drops of water can be thrown out by centrifugal force, by driving the air at high velocity through a spiral passage. This is done in some forms of steam separators, but the velocity there used is 6,000 feet per minute or more, and it is quite impracticable to give the entire ventilating current of the mine this velocity. Other steam separators cause the drops of water to cling to metal surfaces by causing the steam to pass projecting points. B. N. Wilson, Professor of Mechanical Engineering, University of Arkansas, has suggested that this principle might be used in the mine by stretching wire screens from the roof to the floor on alternate sides of the air-course as shown in Fig. 1. The air-current will be sufficiently stirred so that all parts of it will soon come into contact with the screens, and pass through them without much extra resistance. As the mist passes through the screen, some drops of water cling to the metal, other drops unite with each other and so become heavy enough to quickly settle. Light galvan-

* Professor of Mining, University of Arkansas, Fayetteville.

ized wire screen (hardware cloth) of about four mesh is recommended. It is regretted that no funds are available for the purpose of determining the efficiency of this apparatus and affording data as to the number of screens necessary. They are cheap and screens can easily be added in the mine until the air is cleared. This is the most feasible method for quickly settling the mist.

Objection to the mist can be avoided by placing the steam jets where the fog will not be objectionable. If the air is to be moistened at the main intake, some intake may be provided in addition to the main outlet for coal If the mine is large, additional intakes will be necessary anyway and the problem presents little difficulty. If the mine is ventilated by a separate split for each entry, the air generally first passes through the old working of the entry. A few steam jets could then be placed at the entrance to the old rooms of each entry. By the time the air-current of such a mine reaches those entries having no old workings, it would be so warm that the air could be moistened sufficiently with little or no condensation of the steam to a mist. Piping for such steam jets will be expensive, but this system is much cheaper as well as more effective than that of piping all parts of the mine for sprinkling with a hose. This is required by law in Oklahoma. The pipes could also be left bare to partly warm the air by radiation and so reduce the mist. The small slope mines ventilated by coursing can be moistened by the exhaust from the steam pump. This can be distributed along the air-courses leading to the two lower entries and so throughout the mine. It is thus seen that objectionable mist can be avoided at little expense.

As yet none of the American coal mines are so deep that they are uncomfortably warm. Therefore, the miners will not be inconvenienced by the humidity of sprayed air. At the worst, the conditions will be the same as they now are in the summer time. Some of the recently published lurid rhetoric about saving the miners from the dire disaster of working in a moist mine is no argument against steam jets. As the mines get warmer, stone dust will have to be substituted for water to check dust explosions.

The most common objection to spraying the air is that it causes the roof to fall. This is unquestionably true if the roof is such a pure clay that it will absorb water indefinitely. Even then, it is doubtful if the number of accidents will be increased, because in any case the rooms will become moist in the summer time and the same amount of rock will fall. All of this is likely to fall on the miners except that in the few working places finished before the roof becomes wet.

Most of the falls of rock in old entries and traveling ways are caused by the wetting of roof that has dried out from its naturally moist condition and so cracked open to let moisture get behind the slabs. These falls, which are the heavy and dangerous ones, will be largely reduced by keeping the mine constantly moist. It is believed that falls are also caused by the changes in temperature of the mine workings. The fact that a uniformly moist air-current does not injure the mine roof was demonstrated by the experiments of Frank Haas, Consulting Engineer for the Consolidation Coal Co., of West Virginia, and this argument against sprays has little weight.

It seems, therefore, that steam jets should be installed in most of our mines. If experience proves that they do not injure the roof, their universal adoption should be required by a law in each state, requiring that the ventilating current of the mine shall be so warmed and moistened that it is within 5 degrees of the temperature of the return air and shall have a humidity of over 90 per cent. of saturation before it reaches the first active working place upon each split of the air.

On warm and very dry days, the air of a mine should be moistened only, and the extra heating caused by steam will be objectionable. For this purpose, a few sprays of water will be sufficient. They can be used to rapidly cool the air even when it is wet. The same apparatus can be used for the steam jets in winter. As a preliminary arrangement, a line of pipe may be installed along each side of the main intake slope or shaft bottom about opposite the center of the coal seam. To prevent spoiling the pipe for other use, two or three holes for the jets, say one-sixteenth inch in diameter, can be drilled in each coupling of the pipe. These may be placed as far apart as the ordinary length of pipe, and the sprays received upon bits of sheet iron fastened to the coal. Valves should be placed at intervals to cut off as much of the end of the pipe as may be necessary when using water. A valve at the exhaust of the pump or fan will regulate the amount of steam to be used. Experience will show how much the pipe must be extended or how many holes should be plugged with wood. Special nozzles for mine sprays are now on the market.

To illustrate the amount of water and steam needed to warm and moisten the incoming air to saturated air at mine temperature, consider the case of a medium-sized mine with an output of 1,400 tons of coal in 8 hours and requiring 50,000 cubic feet of air per minute. Assume the mine temperature to be 60° F. which is about the Arkansas mine temperature.

If the moisture is supplied in the form of a water spray, a good deal of heat will be required to evaporate the water so that it can enter the air as vapor. If the incoming air is warm, it can supply this heat in cooling to 60° F. provided that it is not so dry that too much water will be required. If the warm incoming air at any given temperature has just the right humidity, it can be both cooled and moistened to saturated air at 60° F. by the evaporation of a certain amount of water. Table I gives in round numbers this humidity and the weight of water required for several temperatures.

Table 1.—Humidity of Outside Air at Given Temperature and Pounds of Water at 60° F. Needed to Produce 50,000 Cubic Feet of Saturated Air at 60°

Outside Temperature	Per Cent. of Humidity	Water Needed Pounds	Water Needed Gallons
65	79.2	2.3	.239
70	63.8	4.2	5.13
80	39.8	8.5	1.019
90	24.6	12.6	1.510
100	15.2	16.5	1.978
110	9.5	20.5	2.458

The humidity of this air at the higher temperature is so low that this condition will seldom if ever occur except in the Far West. The table shows however, that the amount of water required to saturate the air is in the extreme case only 2.5 gallons per minute. This can be supplied by a 1-inch pipe with a fall of 3 feet in 100 feet. Under a 50-foot head, this will require only nine jets one-sixteenth inch in diameter.

If the air contains more water than the amounts given in this table, it will become saturated before it is cooled to mine temperature by the evaporation of the water of the jets. It can only be cooled further by warming the water of the jets. In practice,

Table 2.—Pounds of Water at 60° F. Required to Cool 50,000 Cubic Feet of Air (Measured at 65° F.) to 65° F.

Outside Air Temperature Degrees	Outside Air Humidity Per Cent.	Cooling Water Required If Heated to 65° F.	Each Spray Heated to Temperature of Passing Air	Each Spray Heated to Temperature of Incoming Air
70	85	830	700	450
	90	1,450	1,225	750
	100	2,750	1,950	1,375
80	70	4,450	2,200	1,125
	80	6,250	3,150	1,575
	90	8,000	3,850	2,025
	100	9,800	4,350	2,475
90	70	11,400	4,650	1,900
	80	13,900	5,200	2,325
	90	16,450	5,725	2,750
	100	18,950	6,200	3,150
100	70	20,000	6,300	2,525
	80	23,550	6,900	2,950
	90	27,050	7,400	3,375
	100	30,500	7,850	3,800

it can therefore not be cooled quite to mine temperature; assume, therefore, that it is to be cooled to 65° F. and that sufficient air will be used to make 50,000 cubic feet when saturated with moisture and at a temperature of 65° F. If the water is introduced as a fine spray, it can be assumed that the water is warmed and the air cooled until both reach the same temperature. If enough water is sprayed into the air to cool it at once, no part of the water will remain heated above 65° F. The quantity of water at 60° F. required by this plan to cool the air entering the mine at various temperatures and humidities is given in column 3 of Table 2

If the particles of water could be made to travel against the air-current, they would continue to cool the air and warm themselves until they all reached the temperature of the incoming air. The amount of cooling water so required is given in column 5 of Table 2

It is quite impracticable to apply cooling water in this way, but by applying it slowly to the incoming air by a number of jets some distance apart, the water of the first spray can be raised to nearly the tempcrture of the incoming air and that of only the last to the temperature of the cooled air. The minimum quantities of water required by this method are given in column 4 of Table 2. Actually a little more than this amount of water will be needed even if the jets are small and far apart, and directed against the air-current.

The outside conditions will be seldom worse than 70 per cent. humidity at a temperature of 100 degrees. This may be assumed to take about 7,500 pounds of water per minute. This will require about 750 jets one-eighth inch in diameter under a 50-foot head, and will require about a 5-inch pipe. It seems therefore commercially impossible to so cool the air that there will be no sweating in the mine at all. Even a small amount of water will be beneficial and at least the amount given in Table 1 should be used to start the sweating immediately.

The difference in the amount of water required to cool wet air and dry air arises from the fact that the evaporation of a pound of water spray has a greater cooling effect than 200 pounds of water heated 5 degrees, and because the moisture of warm air has such a large proportion of its total heat.

If the outside air at any given temperature is dryer than the figures given in Table 1, heat in addition to the water spray will have to be added to bring it to the condition of saturated air at 60° F. If heat is furnished by dry steam, the amount needed is given in Table 3. The third column gives the pounds of steam needed to saturate the air with moisture. This is merely cooled from the boiling point to 60° F. The next column gives the additional steam which will be condensed to mist at 60° F. For any given temperature, the steam required increases as the humidity decreases, and the amount for any other humidity can be readily figured by noticing the rate of change for the humidities given. For low temperatures the amount of moisture in saturated air is so small that the influence of humidity is almost negligible.

Dry air at 60° F. or warmer can be brought to the condition of saturated air by adding warm water or a mixture of mine water and steam. There will then be no mist. The last column of the table gives the negligible amount of water required in connection with steam for dry air at 60° F. Dry air at higher temperatures will need very little steam in addition to the water given in Table 2.

Table 3.—Pounds of Dry Steam Needed to Warm 50,000 Cubic Feet of Air to 60 Degrees and Saturate it With Moisture

Temperature	Humidity	Steam as Vapor	Steam as Mist	Total Steam	Water
60	100				
60	90	4.0		4.0	.2
60	80	7.5		7.5	.3
60	70	12.0		12.0	.5
60	60	16.0		16.0	.7
60	50	19.5		19.5	.8
50	100	12.2	8.0	19.7	
50	90	15.1	7.5	22.6	
50	80	17.9	7.0	24.9	
50	60	23.7	7.0	30.7	
50	40	29.5	6.5	36.0	
40	100	21.5	15.0	36.5	
40	90	23.5	15.0	38.5	
40	80	25.5	14.5	40.0	
40	60	29.5	14.5	44.0	
40	40	33.5	14.0	47.5	
30	100	28.0	22.0	50.0	
30	80	30.5	22.0	52.5	
30	60	33.0	22.0	55.0	
20	100	32.5	30.0	62.5	
20	80	34.0	30.0	64.0	
20	60	35.5	30.0	65.5	
10	100	35.0	38.0	73.0	
10	80	36.0	38.0	74.0	
10	60	37.0	38.0	75.0	
0	100	37.0	46.0	83.0	
0	80	38.0	46.0	84.0	
0	60	39.0	46.0	85.0	
−10	100	39.0	54.0	93.0	
−10	80	39.5	54.0	93.5	
−10	60	40.0	54.0	94.0	
−20	100	39.5	62.0	101.5	
−20	80	40.0	62.0	102.0	
−20	60	40.6	62.0	102.5	

At the low temperatures, the amount of mist is not exact. This is due to the fact that no information could be obtained as to the heat required to evaporate water at temperatures below freezing. It was necessary to assume that it increased with lower temperatures at the same rate below freezing, as it did above, although this is not the case. The error is trifling because at these temperatures, the amount of moisture in air is very small.

All computations are for mines at sea level. The temperature alone determines the amount of vapor in a cubic foot of air. As a result, column 3 of Table 3 does not vary with the altitude of the mine. The weight of dry air in a cubic foot decreases at higher elevations. As a result, less steam will be required to warm it.

The exhaust of a common slide-valve engine may be assumed to contain 25 pounds of dry steam for each horsepower for each hour it runs. A temperature of 10° F. above zero with a humidity of 60 per cent. is as severe as may be expected for more than a day or two at a time. This would then require all the exhaust steam of 180 horsepower of engines. This is available at any mine of this size which in addition to the fan should have a good plant for power haulage and mining machines. If exhaust steam is used, a good steam separator must be placed just before the first jet to take out the water condensed in the engine, otherwise it will increase the amount of mist. This water can be drawn off continuously into the air along with a little steam, if the pipe is large so it will not be sprayed. It will then heat the air slightly.

Assuming 30 pounds of steam per hour as a boiler horsepower, the same air would require at night 150 boiler horsepower if all engines were stopped. One pound of good slack coal should evaporate 6.5 pounds of water. This would then require, in an extreme case, the burning of about 700 pounds of coal per hour. At large mines, a fireman is now employed each shift anyway and the coal would cost about $4.50 a day, 16 hours a day. The night temperature will seldom average below 40 degrees any month. This will require only 40 to 45 pounds of steam per minute which should be largely supplied by a fan engine. If made especially, it will cost about $2.50 per winter night at the larger mines, or $150 a year. This is a small price to pay for freedom from dust explosions.

Production of Coke in Kentucky

The output of coke in Kentucky for 1911 shows a gain of 15,534 tons over that for 1910, but the total production is still comparatively small. The increase was due to the output of ovens in Pike County, together with a small tonnage made at the close of the year in Harlan County. Following are the tonnages of coke reported:

Company	County	Coke	Ovens
St. Bernard Mg......	Hopkins	35,336	155
Ohio Valley C. & M..	Union	1,555	20
Wisconsin Steel	Harlan	120	60
Elkhorn Con. C. & C.	Pike	10,252	50
Marrowbone C. & C..	Pike	12,814	32
Totals..........		60,077	317

The Wisconsin Steel Co., which is expected to become a large producer, was still constructing ovens at the close of the year; it is expected to have 300 ovens burning by the end of 1912. The Marrowbone Coal and Coke Co. reported only 463 tons for 1910. This company will finish 68 ovens in 1912, making a total of 100. The Elkhorn Consolidated Coal and Coke Co. reported no coke for 1910. The Straight Creek ovens (now owned by the Continental Coal Corporation), in Bell County, which produced 215 tons in 1910, were idle in 1911, and are expected to so remain during 1912.

Correspondence

Rock Dump Wanted

Editor Mines and Minerals:

Sir:—I noticed in Mines and Minerals sometime ago a description of an apparatus for tipping rock that comes out of a coal mine. The mine that I have charge of is a slope (not a shaft), and I have a large quantity of rock coming out of the mine. Now I would like more information of this apparatus, or even the maker's address or any hint from your readers who have had to handle quantities of dirt or rock from a mine. A wooden apparatus is no use, because the rock heap is on fire, and to unload the rock cars with shovels takes too many men and ties up the cars too long.

Anxious

Conveyor System for Mining Coal

Editor Mines and Minerals:

Sir:—I know of a coal mine 4 feet in height, with a very bad roof (some call it soapstone roof), that must be machine cut. Would it be practical to introduce the Blacketts conveyer system to work the blocks out by the retreating method? How long are the Blacketts conveyers, or what is the most economical length to work it. Which is recommended, to work by electricity, or compressed air? How many men or boys does it generally take to handle this conveyer system to give satisfactory result? I may say that I prefer to cut, with electric longwall chain cutter, such as the Jeffrey or Sullivan chain cutters. An answer will greatly oblige

Blackett

British Electric Mining Lamp Contest

Editor Mines and Minerals:

Sir:—As readers of Mines and Minerals are aware, a British mine owner, something over a year ago offered a prize £1,000 or $5,000 for the most practical and best portable electric mine lamp.

The judges of the contest were Mr. Charles Rhodes, former president of the Institute of Mining Engineers, and Chas. H. Merz, member of the British home department committee on the use of electricity in mines. The conditions of the competition were:

1. The competition open to persons of any nationality.
2. The judges empowered to award the whole of the prize, to divide it, or to make no award if no lamp appeared to them to be of sufficient merit.
3. The competition was open for 6 months, closing on December 31, 1911.

The requirements which all the lamps submitted in competition were asked to fulfil were as follows:

1. Each lamp to be of sound mechanical construction so as to withstand rough usage.
2. It was to be of simple construction and easy to maintain in good order and repair.
3. It was to be so constructed as to render impossible the ignition of inflammable gas, either within or without the lamp.
4. The lamp battery was to be so constructed that any liquid it might contain could not be spilled with the lamp in use.
5. The lamp was to be so constructed as not to be liable to deterioration by corrosion as a result of the action of the electrolyte.
6. It was to be effectively locked.
7. It was to be capable of giving an amount of light not less than 2 candlepower continuously for 10 hours.
8. The light was to be well distributed outside the lamp.

In addition to the above, regard was directed to be paid to: (*a*) The first cost of the lamp; (*b*) the cost of maintenance; (*c*) convenience in handling; and (*d*) the weight of the lamp when charged and ready for use.

In issuing their award the judges said: "We have had submitted to us 195 lamps, varying very considerably in design and construction.

"We have awarded the first prize to the C. E. A. G. lamp, sent in by F. Farber, Beurhausstrasse 3, Dortmund, Germany. Inasmuch as a number of other lamps possess considerable merits, we have apportioned the amount offered for the competition as follows:

Farber, F., Beurhausstrasse 3, Dortmund, Germany	£600
Attwater, Thomas, 22, Pelham square, Brighton	50
Bohres, Adolf, Zietenstrasse 12, Hanover, Germany	50
Bristol Electric Safety Lamp Works, 40, Gt. Smith St., Westminster	50
Electrical Company, Ltd, The, 122-124, Charing Cross road, London, W. C.	50
Gray, W. E., 19, Archer St., Camden Town, London, N. W.	50
Joel, H. F., 134B, Kingsland road, London, N. E.	50
Oldham & Son, Denton, Manchester.	50
Tudor Accumulator Company, 119 Victoria St., Westminster, S. W.	50

Of all the different lamps submitted I know from good authority that there was but one outfit that not only met the necessary requirements, but had the advantage of having the lamp attached to the cap (adjustable to all angles), while all the others were hand lanterns. The disadvantage of a hand lantern as compared with a light on the cap is so obvious that it seems incredible that prizes should have been awarded to so many lamps of that type, even if, in construction and principle they may have been most excellent.

This award carries with it an implied indorsement of the British Government, which seems to me to be at variance with that government's usual conservatism and traditional practicability in commending mechanical appliances. I am most heartily in favor of competition among the world's inventions, and of course commend the spirit and generosity of the colliery owner who gave the prize, but I think that a practical and economical electric light outfit embracing the feature of the lamp worn on the cap, with a small battery carried on the belt, more nearly meets the requirement of the working miner than a hand lamp, since the lamp worn on the cap gives the miner the use of both hands, and furthermore throws the light in whichever direction he turns his face. I cannot understand why awards should be made to lamps built on an old principle and of inconvenient type.

Electrician

Personal Views Re Affairs American Institute Mining Engineers

Editor Mines and Minerals:

Sir:—The Institute has labored for some years under three separate difficulties:

1. Ill-defined division of responsibility, in the dual control of its activities, between the Board of Directors and the Council.
2. The independence of the Secretary of the Council, because of his election by the Institute at large, of the body he is supposed to serve: an illogical situation.
3. The possibility afforded, by the present form of Constitution and By-Laws of placing the management of the entire affairs of the Institute in the hands of a single individual.

The Directors are made solely responsible for the funds and property of the Institute by the incorporation laws of the State of New York. The Constitution places the management of all its professional and social affairs in the hands of the Council who may, and who have in the past, in arranging them incurred indebtedness for which the Directors are responsible; but in which they have frequently had no voice. This should be changed so that no expenditures can be incurred except on previous appropriation by the Board of Directors.

The Secretary has been the executive officer and has the power, under the Constitution, of incurring debts in the name of the Institute, auditing the bills and paying them without consulting either of the governing bodies.

As shown in the report of the Committee of Five, the Institute has for some years been short of funds. Its annual income has not sufficed to meet all of its financial obligations.

The main reasons for this are:

1. The expense incurred by the interest in the United Engineering Society building.

2. High salaries and inefficiency in the office work.

3. The large proportion of life members whose commutation of dues has been spent for current expenses as fast as received, while the obligations of the Institute to them are continuous.

4. The large number of delinquent members carried on the books and supplied with publications.

Together the life members and delinquents are about one-fourth of the total, so that the entire expenses are paid by about three-fourths of the membership.

It is generally admitted the Constitution should be amended, and in so doing we believe the difficulties mentioned above should be borne in mind and every effort made to remove them.

It is hardly possible to do away with the dual control of Directors and Council without putting the control entirely in the hands of the New York members, which they do not desire, and which would not be for the good of the Institute. The incorporation laws place the responsibility so entirely in the hands of the Directors that in order to have meetings most of them must be residents of New York or vicinity, or the power be delegated to an Executive Committee of such residents, which amounts to the same thing. For this reason the dual control will have to be continued.

The undue influence of the Secretary of the Council should, and can be, obviated by abolishing his election by the membership at the annual meeting and by letting the Council elect their own Secretary subject to their own pleasure. A one-man management can be prevented by changes in the Constitution and By-Laws precluding the occupancy of certain offices by the same individual.

Two policies have been in mind for the future management of the Institute. One is a contiuance of the present predominating influence on the part of a single individual; the other a practical divorce of the business management and the professional activities so that they will not come in contact except at a single point.

In the past the Institute has had an especially versatile and energetic Secretary; but even in this case the number of those who have not agreed with his policy has increased until they now probably constitute a considerable majority of the Institute. Even if it were desired to continue what is practically a one-man management, and if an individual combining all of the necessary qualifications could be found it is doubtful whether the Institute, with its present obligations and comparatively small membership could afford to pay sufficient to obtain him.

We believe it would be better, at least for the moment, to have a Business Manager selected by and responsible to the Directors and have the editorial work, so far at least as the selection of material goes, performed by a Committee on Papers and Publications, as is done by most similar societies who attempt to manage their affairs economically; the papers so selected to be turned over to an Editor and the Business Manager, who would attend to the details of publication and distribution.

The expenses of the United Engineering Society building have been incurred and must be provided for. It is therefore either necessary to increase the income of the Institute, decrease its expenditures, or both. The former result can be obtained by making the Institute of greater value to its members which would probably result in increasing the membership, the latter result by more efficient management at the head office and by eliminating various subsidiary activities not strictly a part of the Institute's business.

We believe that the membership can be largely increased, as other societies of similar aims and scope have grown largely in the past few years, while the Institute has stood still. An increase in the membership beyond the present number will increase the income much more rapidly than the expense, so that a comparatively small number of additional members would place the Institute in an easy financial position.

We believe this to be a better and surer way of providing the needed funds than to increase the dues, which would undoubtedly cause enough resignations to make the financial result uncertain. When a large proportion of the members are dissatisfied and are asking themselves whether they are getting a proper return for their money it is a bad time to ask them to pay more unless they can be clearly shown that they are to receive an adequate return.

We believe that by lopping off some unnecessary expenditures, by still closer supervision on the part of the Board of Directors considerable economies can be effected without in any way curtailing the work which the Institute was called into existence to do.

Geo. C. Stone
C. R. Corning

New York, N. Y.

The DuPont Powder Co. state that the permissible explosives now made by them were first put on the market late in 1907. Before that there were two others, one made by the Dupont Company and the other by the Masurite Explosive Co., which were introduced late in 1904 or early in 1905.

Increasing the Efficiency of the Fire Boss

By Bert Lloyd

When Joseph Smith became general superintendent of the Stag Cañon Fuel Co., at Dawson, N. Mex., the slogan "Safety First" was immediately adopted, and many new systems of inspection, looking to the prevention of accidents were inaugurated, the most important of which is the one that governs the fire bosses.

Each fire boss is provided with a small, detachable-leaf notebook, in which he records all faulty or dangerous conditions that he discovers on his morning tour of inspection, and upon his return to his station these notes are amplified in a larger book, on the inside of the front cover of which the following notice is pasted:

NOTICE

The object of this book is to prevent accidents as much as possible and if the proper attention is given to the different conditions as reported, no doubt some accidents will be avoided.

There are few accidents that could not have been prevented had proper precautions been taken in time; however, it is the duty of every one who is employed by this company, such as fire bosses, shot inspectors, foremen, capmen, etc., to report any bad conditions that come under their notice, so that accidents can be prevented.

Fire bosses and shot inspectors are employed principally on account of the safety of the men and mines, and have greater responsibility than most people realize. Pit bosses should give them all the support they can, and also the fire bosses should and can greatly assist the pit bosses. If places are reported in dangerous condition and are too numerous for the pit boss to get around to in any reasonable time, he can authorize the fire boss to revisit such places and see that they are being properly fixed up and men prevented from working in dangerous places or under dangerous conditions.

If any places are without sufficient timber, either in place or loose, it should be noted and men not allowed to work or go in the place until they secure sufficient timber.

If stumps have been left behind in pillars, the fire bosses should stop the men from taking too much of the pillars back from such stumps, and report on the book anything they consider dangerous.

The information referred to in this book is considered the private property of this company for the benefit of the officials concerned in the safety of the mines and is not for public inspection, and should be treated as such.

When men refuse to properly timber their places or take down loose and dangerous rock or coal, this should be reported, and it is the duty of the pit bosses to see that they are not allowed to work until the place is put in a safe condition.

The original sheet from this book will be returned to the General Office with the time of day that bad conditions have been remedied stated thereon.

(Signed) Stag Cañon Fuel Co.

The original report is written on a leaf that is perforated, a carbon copy being made on a duplicate leaf that remains in the book. The fire boss then signs the original and duplicate, and upon the arrival of the pit boss the original is detached and given to him. This official now becomes responsible for the remedying of the conditions as noted by his subordinate, so taking this report with him, he proceeds, according to his convenience or the exigencies, to personally investigate the extent of each unfavorable condition reported, giving necessary orders for their correction, at the same time noting in a proper column of the report the time he made the inspection. After each item has been checked he signs the report and submits it to the superintendent, who checks it and forwards it in turn to the desk of the general superintendent.

The accompanying is the copy of a report as it is received by the last-named official. This is an ideal report made up to show some of the various matters that are to be noted, consequently, the time given is not for any one day, and this brings up the old subject of how many places can the fire boss visit in a given time.

The many great advantages of this system are obvious. In the first place nothing is left to memory. The transcript of the fire boss' report is a constant reminder to the pit boss, and the pit boss is enabled to systematically check the observations of the fire boss.

Should a dangerous condition be overlooked and an accident occur in consequence, the pit boss is responsible if the fire boss reported the danger; and the fire boss is held responsible if he failed to include it in his report. The fire boss soon learns to omit nothing from the report regarding conditions that the pit boss should know.

A tremendous advantage is gained through the knowledge the fire boss has that the general superintendent is in close touch with him; that his reports are criterions of his energy, interest, and intelligence. His main effort, therefore, is to discover and report all the existing adverse conditions, knowing that he will be commended for his diligence. The pit boss in turn is speeded up, as he must either provide remedies for the troubles as reported or answer the "whys" that come from the man above. Again, the man above speedily gauges the value of his subordinates by noting what the fire bosses report, and the interest shown by the pit boss as denoted by the time it takes him to get around.

Should there be a lack of cooperation on the part of the pit boss and the fire bosses, due to personal differences, this dangerous condition may be quickly detected from the spirit of the reports.

It is possible that the value of the system would be increased by requiring a notation regarding the condition of every working place in the mine. A fire boss would absolutely satisfy himself that no dangerous conditions existed before he would write the word "good" after the number of a room if he knew that his comment would hold against him if it were incorrect. To not mention a place at all and to report it as being in a good condition are two very different things.

Stag Cañon Fuel Co.

Fire Bosses' Daily Report of Conditions, Mine No. 3

Date

Time	Entry	Room No.	Remarks
	3rd North	Entry	Small cap of gas at face.
8:40 A. M.	4th North	Entry	Lagging on timbers near face loose.
9:05 A. M.	4th North	14	Shots not fired. Not mined deep enough.
9:15 A. M.	5th Cross	Entry	Door won't close. Damaged by car.
9:20 A. M.	6th Cross	Entry	Canvas down near face.
10:15 A. M.	5th North	2	Bad piece of rock at face.
10:30 A. M.	5th North	14	Timber near face loosened by shot.
10:35 A. M.	5th North	19	Standing shot. Not enough powder.
11:10 A. M.	6th North	3	Blown-out shot.
11:25 A. M.	6th North	24	Not enough props placed in room.
11:30 A. M.	6th North	27	Roof at cross-cut very loose.
11:35 A. M.	6th North	28	Small quantity of gas, right hand. Face.
1:10 P. M.	9th West	Entry	Cross-cut blocked with timbers.
1:15 P. M.	10th West	Entry	Shots not fired. No dobe dummies.
1:40 P. M.	10th West	7	Roof in cross-cut very bad.
2:05 P. M.	10th West	19	Three sets of timber at mouth of room are broken. Mule can't pass under.
2:10 P. M.	10th West	24	Pillar working. Hold men out.
2:15 P. M.	10th West	30	Not enough props in place.
7:50 A. M.	12th West	Entry	Stopping in 2nd X cut from face is in bad order.
8:00 A. M.	11th West	Entry	Board off top.
8:10 A. M.	11th West	Entry	Small fall of rock at mouth of 25 room. 1 set timbers broken.
7:10 A. M.	Main Motor Road		Trolley wire loosened from hangers near 9 West overcast.
	Main Motor Road		Timbers near 5 West too close to track.

J. G. T., Supt. O. K., Rich. Harris, Pit Boss Johnny Franks, Fire Boss

Red tape and system are synonymous terms to a great many people. In this case there is just enough red tape used to enable the general officers to be in continual close touch with the underground conditions of all their mines.

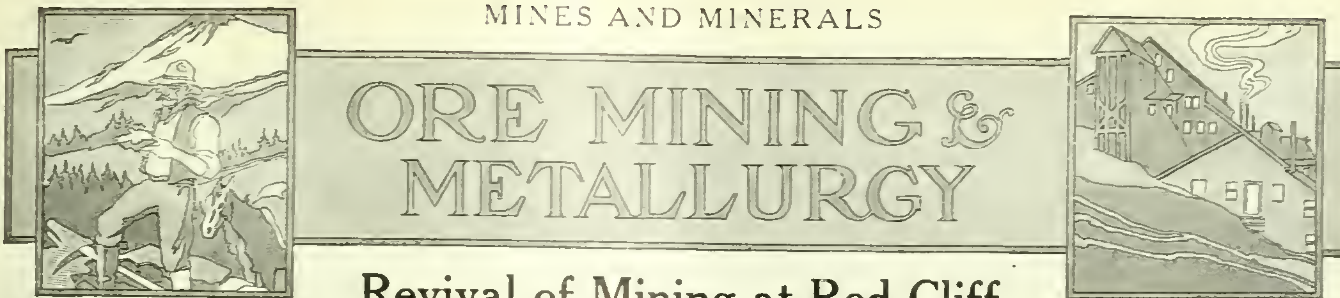
Coal-Mine Accidents in Pennsylvania

James E. Roderick, chief of the Department of Mines of Pennsylvania, in commenting on accidents states: "Much is written on the subject, and the people have their imaginations and sympathies worked upon to such an extent by the ofttimes thrilling and exaggerated accounts of accidents, the suffering of the victims and their families and the many attendant horrors natural to such catastrophes, that they form erroneous opinions not only regarding the number of accidents and the suffering they entail but also regarding the physical and social conditions that surround the miner, his compensation, and his welfare generally." He then quotes a statement which had been circulated as follows: "The most important problem before the Bureau of Mines (Federal) is an attempt to reduce the number of deaths in the mines, and it is gratifying to note that in the last 3 years for which statistics are obtainable there has been a decrease in the number of fatalities amounting to 25 per cent."

Frederick L. Hoffman, in refutation, said: "The fatality rate for 1910 was 4.18 per 1,000 persons against 3.39 for 1909. This comparison of the record for 1910 and 1909 is upon the basis of the official returns furnished by the mine inspectors of the different states. The facts derived from trustworthy sources, therefore contradict the statement made in the program of the National Mine Safety Demonstration under the auspices of the United States Department of Mines....."

Mr. Roderick in commenting on this controversy says: "It may be said here that it is not surprising that there should be a decrease in accidents since 1907 as that was the most disastrous year in the history of the coal industry in this state, the fatalities numbering 4.40 for every 1,000 persons employed. There is unfortunately no evidence to show that there has been any material decrease from the years immediately preceding 1907. In fact the 4 years since that date and the 4 years immediately preceding show about an equal number of fatalities. It is gratifying of course to know that the number of accidents during the latter period has decreased even slightly, but the percentage is so small that there is little cause for congratulation over the results of the widely heralded preventive measures that have been introduced in recent years. In the former period 1903-1906 for every 1,000 persons employed 2.93 lives were lost; during the latter period 1908-1911, 2.87 lives were lost, a decrease of .06 per cent. The average number of lives lost per 1,000 persons employed for the entire period of 9 years was 3.07. During the 9 years the great catastrophes at the Harwick, Naomi, Darr, and Marianna mines occurred by which 604 lives were lost. The Harwick explosion occurred in January, 1904; the Naomi and Darr in December, 1907, and the Marianna in December, 1908. The total lives lost inside all the mines during that time by explosions of gas and dust was 792, deducting 604, there are left 188, an average of about 20 a year from these causes or only 4 per cent.

"The total number of all the fatal accidents in the bituminous mines during the 9 years was 4,832. The number of lives lost by falls was 2,552, or 52.82 per cent.; by cars 709, or 14.67 per cent.; by gas and dust, 792, or 16.39 per cent.; by electricity, 191, or 3.95 per cent.; by explosions and blasts 88, or 1.82 per cent.; by miscellaneous causes 500, or 10.35 per cent. The general average loss from gas and dust omitting the four explosions referred to was less than 4 per cent., while the average loss from falls was about 60 per cent., or 15 times as great."



Revival of Mining at Red Cliff

Old Colorado Mines Formerly Abandoned on Reaching Sulphide Ores, Now Successfully Operated

By A. J. Hoskin

THERE is a small mining district in Colorado that is almost unobserved as such by the persons who compose an almost constant tide of overland travel through this area. Eagle River heads in the Continental Divide at Tennessee Pass, on the Denver & Rio Grande Railroad, a few miles north of Leadville, and starting on its way down the Pacific Slope, quickly assumes a volume that, in a less precipitous country, would spread out into a very pretentious river. Here, however, it is admired only as a beautiful mountain torrent of clear snow water and is a haunt of trout fishermen. Within a very short distance from its head, this stream swirls through one of the most picturesque spots in the world and it is right here that one may find the very interesting mining district that forms the topic of this article.

FIG. 1. EAGLE CAÑON, ROCK CREEK

The geology of this district is comparatively simple. In Fig. I. one may discern the characteristic weathering surfaces of the three principal kinds of rocks that occur in this region. Extending up some distance from the bed of the river, we find Archean granite with its surfaces exposed in large, irregular blocks and its detached portions in large, angular boulders. The railroad tunnel shown in the view penetrates this granite. Upon this fundamental formation, we find Cambrian quartzite beds whose aggregate thickness varies between 200 and 300 feet. In the picture, these rocks comprise the cliff in the middle distance. These strata can be seen to dip away from the observer into the distant mountain. This quartzite presents very beautiful cliffs all along this cañon and such surfaces are always beautifully marked with the striæ corresponding to the planes of sedimentation. Upon the quartz beds, are, conformably laid, the white limestone beds of Silurian age. The limestone, in places, appears as cliffs somewhat similar to those of the quartzite; but as this series is much higher on the mountain and comprises their tops, the disintegration has usually produced a fine "wash" and soil that sustains the major part of the flora of this area. This is shown on the distant peak, Battle Mountain. Here the foliage is principally spruce and aspen. The planes of sedimentation are dimly visible.

The sedimentary rocks have all been quite uniformly tilted from their original position so that they now dip about 10 degrees to 15 degrees northeasterly. In portions of this district, sheets of porphyry lie between the strata of limestone and it is probable that these intrusive magmas were the ultimate sources of the metallic minerals that compose the ores. All these formations are considered as extensions of the corresponding series at Leadville.

The district does not appear to have been as much disturbed by faulting as are most of the Rocky Mountain mining districts. Faults are present, to be sure, but they are of small displacement. In the Bleak House mine, whose buildings appear in Fig. 1, a vertical fault fracture became a richly mineralized silver-lead vein. But the relative movement of the two walls did not exceed 3 feet. In other properties, similar veins have been, and are, worked. These faults extend through all the formations and hence the resulting veins may be classified as true. Such veins present very attractive outcrops in the several formations, but their exploitation has proved their best contents to lie between walls of quartzite. These fissures, in general, strike northeasterly or in the direction of the dip of the sedimentaries.

Years ago, Eagle County, Colo., was famous through the production from its many small gold, silver and lead mines.

FIG. 2. ROCKY POINT MINE

The region is usually spoken of as the Battle Mountain mining district from the name of the mountain upon which most of the mines are located. At one time, a little camp known as Gilman, situated high up on the ridge of the mountain (Fig. 3) did a flourishing business; but this town, handicapped by its location, could not compete in permanency with Red Cliff, which is on the main line of the Denver & Rio Grande Railroad. Just now, however, Gilman is enjoying a slight renewal of life through the resumption of mining in the Iron Mask and Rocky Point mines.

The discoveries of mineral wealth were made here contemporaneously with, or shortly after, those of the neighboring districts of Leadville, Alma, Kokomo, Robinson, Aspen, and Breckenridge. Many remarkably rich bodies were excavated by the pioneers. The first finds were of the rich gold and silver ore bodies filling what appeared to be peculiar irregular caves in the quartzite, the metals occurring in their metallic or free state, frequently in the forms of beautiful nuggets. It is believed that these bodies were replacements of the country rock rather than the filling of preexisting cavities. The outcrops of these masses were indicated on the cliffs by rusty iron stains that resulted from the oxidation of pyrite, an original component of these ores. The miners generally found that their ore shoots were thus oxidized for not more than 200 feet from the outcrops and that their bonanzas gave out when the unaltered or sulphide ground was encountered. At such points, the ore was always found to be so low grade and refractory to existing methods of treatment that profitable operations ceased.

These shoots of ore were limited to particular strata, so that both the roofs and floors of the stopes were unusually smooth, firm, and readily followed. The Ground Hog mine was one of the early-day producers from this type of ore body. In this mine, most beautiful nuggets and crystals of gold were found cemented or united with both native silver and horn silver (cerargyrite). The crystalline gold probably resulted through a secondary deposition, the metal being originally in minute particles disseminated through the ore and associated with pyrite. The oxidation of pyrite produced the persulphate of iron (one of the few solvents of gold), and the gold, after being brought into solution was redeposited in its typical crystal forms.

In the pioneer days, much mining was conducted in the limestone beds high up on Battle Mountain, but here the operations were short lived, just as were those in the quartzite, for the operators soon reached the obnoxious sulphide zone that always terminated their bodies of lead, copper, gold, and silver ores.

The metallurgy of precious metals was then in its fundamentals and only the simplest or least complex ores could be treated at profit. Prospectors, therefore, sought only the rich oxidized ores. They were heartily disgusted whenever their developments led them into the unaltered or sulphide zone. The miners of this district were obliged to acknowledge the fact that their treasures occupied only a comparatively shallow zone along the outcrops and accordingly, when they had skimmed off this cream, as it were, they moved on to other fields. And yet, as is always true of any old mining camp of the West, a few men have retained their faith in this district to such an extent that they have steadfastly remained with it through all its period of desuetude and they are now "on the ground" to participate in what promises to be a notable revival of activity.

Fig. 3. Iron Mask Mine and Town of Gilman

About the time that the Red Cliff miners were exhausting their bonanzas, the entire mining industry of the state received a staggering blow through a sudden and pronounced decline in the market price of silver. This particular district, being in a weakened condition, naturally succumbed along with numerous other pioneer mining districts. A very common inquiry made by visitors to the Colorado mining districts is why so many gold camps suffered along with the typical silver camps during the depression of the early nineties. To explain this seeming paradox, one must reflect upon the status of metallurgy in those days. As already suggested, it was of a primitive sort and there was a striking similarity in the treatments applied to both sorts of ore. The ores of the two metals were usually subjected to practically the very same treatments; they were classified as either "free milling" or "smelting." Very often, the ore bodies were valuable for both the precious metals, and success in their exploitation and excavation depended upon good market prices for each. At one time, a small copper smelting plant operated at Red Cliff, but the producers of the copper ore soon learned that it was economy to ship their output over the range to Leadville, and the Red Cliff plant was obliged to discontinue operations.

For the moment disregarding the unjust dishonest practices charged against the smelting companies of those days, and assuming that the smelting of custom ores was done at fair rates, we must admit that the closing down of many silver mines had the indirect effect of curtailing the output of lead ores which were depended upon by most smelteries to effect the separation of the silver and gold from the gangue of the ores. This flux being thus hard to obtain, smelting rates were raised at the most inopportune time, and none but the very high-grade mines could endure the adverse costs thus imposed.

However, when operations in this district closed, nearly a score of years ago, probably the main cause was the one already suggested; viz., the encountering of low grades of silver and gold ore in which so-called refractory sulphides existed in abundance. In this instance, the trouble was accentuated in the fact that the sulphide stuff was principally sphalerite. Zinc was then despised by the Western miner, for a very heavy penalty was imposed—with more or less fairness—by smelting companies in their charges for treating ores carrying appreciable percentages of this metal.

The intervening years have wrought changes in the worth of zinciferous ores and science has been evolving methods whereby the base metal in such ores may be recovered at much less cost than formerly. Pronounced economies in mining methods have also been developed and, as a sequel to all these changes, miners now entertain new opinions relative to such ores and, in place of mining primarily for the gold and silver that may be contained in the low grades of these complex ores, they are actually seduously seeking and mining crude materials that were formerly thoroughly obnoxious to them. Further than this, they now consider any recovery of the precious metals from such ores as but adventitious, or "velvet."

Typical Red Cliff veins are being worked now in a number of properties, among them being the Star of the West and the Bleak House mines.

Bleak House Mine.—This property comprises a group of claims lying on Battle Mountain. It is developed and operated through an adit whose portal is along the bed of Rock Creek (Fig. 1) so that it is probably not more than 10 to 12 feet above the granite. This tunnel was driven as a cross-cut for 300 feet and, at that distance, intercepted the Bleak House vein. As the bore advanced, it reached continually higher geological zones. Upon reaching the vein, the adit was deflected and became a drift northeasterly along this vein. This work was done years ago, and we are told that the operators removed very rich silver-lead ore from the stopes above this level. The vein is far from uniform in thickness, but it will be fair to assume its average as about 4 inches. As already mentioned, this is a fault plane. The ore in this vein is argentiferous galena and is very easily distinguished from the quartz gangue. This galena varies in silver from 50 ounces to 700 ounces per ton. Minor cross-faults have been encountered, and while the vein has been somewhat displaced by them, the disturbances have never seriously interrupted ordinary procedure of mining.

During the drifting and stoping in this vein, there was disclosed a large so-called "contact" of zinc ore, which, of course, proved objectionable in those days. Some desultory exploitation of this ground was performed, but it remained practically virgin until recently. The ore shoots of zinc have been attacked, within the past couple of years, and a very notable tonnage has been removed, if one may judge from the sizes of the resulting chambers. These stopes have smooth roofs and floors that conform absolutely with the bedding planes of the quartzite and hence have a slope that is not at all troublesome in mining.

The surface plant at the Bleak House is very primitive in its layout and equipment. Its site is a precarious one in times of Rock Creek's heavy flow. Ore coming from the tunnel is trammed into the small ore house where it undergoes washing with water from a hose, and hand sorting. Two grades of ore are thus selected. A small gasoline engine drives a correspondingly small compressor that supplies air enough to operate one hammer drill; most of the drilling underground is by hand. About twenty men are employed in the mine and on top. The property is leased to R. V. and J. M. Dismant, brothers, who have undertaken to make it succeed despite the numerous failures of predecessors. The mine could be operated to produce two distinct types of ore; viz., the silver-lead, from the vein; and the zinciferous, from the masses. The property appears to possess mineralogical and geological features that warrant the installation of a much better mining plant. There can never be a large, systematic production of the mine's zinc ore until such an improvement is made, and this suggested plant should include a mill adequate to effect a local concentration of the ore. The zinc is found here as two minerals, sphalerite and smithsonite. With an up-to-date equipment, the costs, instead of being necessarily excessive as they now are, could be reduced so materially that the mine would enter upon an entirely new lease of life.

Eagle Mining and Milling Co.—Interest has lately centered in the operations of the Eagle Mining and Milling Co., for it is conducting its work on the greatest scale and according to strictly modern ideas. Some 3 or 4 years ago, this company acquired title to two groups of mining property which, though contiguous and actually conflicting, had theretofore been owned by distinct interests.

Rocky Point Mine.—One of these groups 2 miles from Red Cliff was known as the Rocky Point mine. Its ore was confined to a zone in the quartzite outcropping about half-way up the steep side of the mountain.

Fig. 2 shows that this mine was well named, and it also exhibits the contrast in the appearance of the granite and the quartzite. The writer endeavored to secure a picture of this property that would show all the details, but the restricted width of the gorge together with the precipitous height of the walls prevented. This view is from a high point on the opposite wall of the cañon but it does not show either the foot or the top of the cliffs. There is a light aerial tramway extending from the building at the mouth of the Rocky Point slope (near top of Fig. 2), down to the railroad at the foot of the cliff. This is now used to handle the ore being mined. Near the middle of the picture may be seen the portal of an adit driven in the granite, years ago, to develop the same formation as the slope.

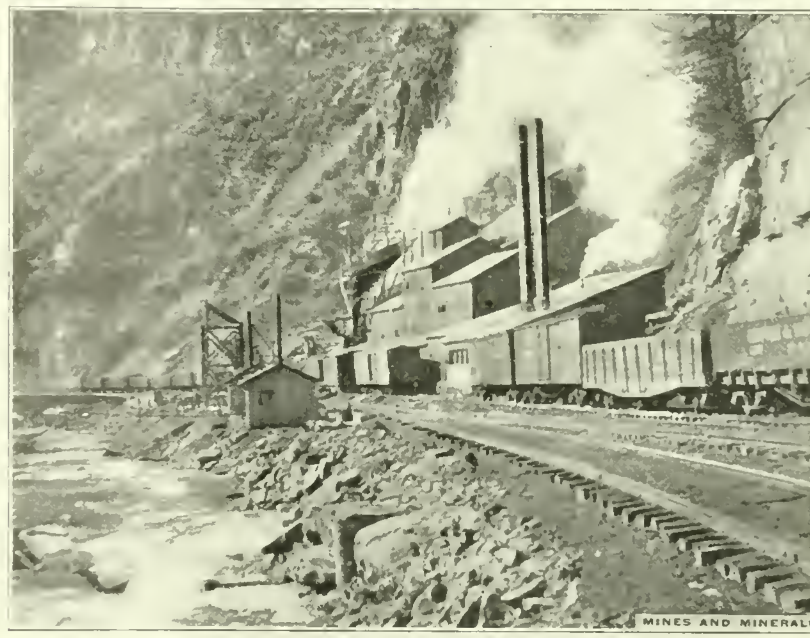


Fig. 4. Iron Mask Mill, Eagle Cañon

Production from this mine is limited to sulphide ore averaging 8½ per cent. copper and which is shipped in its crude form to the Arkansas Valley smeltery at Leadville. This ore will eventually come through the Newhouse adit.

Iron Mask Mine.—The other mining group mentioned as having been purchased by the Eagle company is the Iron Mask mine that, during the early nineties, produced a large tonnage of ore from the limestone beds. This mine is shown in Fig. 3 and lies above the Rocky Point mine. The aerial tramway is shown leading down from this mine to the mill in the bottom of the gulch and better shown in Fig. 2. This mine, too, is developed through a slope practically parallel to the Rocky Point slope, but in a different geological series. The workings of both the original mining companies followed the stratification; they were both mining the replacement bodies. When the companies reached such a stage that they were both extracting ore from ground bounded by the same surface lines, litigation was inevitable. The controversy was but one of the very many that have arisen through the application of the American doctrine of extra-lateral rights. The

Rocky Point mine owners, having an unquestioned outcrop, claimed the right to follow their ore bodies on their dip; but the Iron Mask owners resented this and instituted legal obstruction that resulted in the cessation of operations. About the time of this legal entanglement, the ore bodies in both mines had changed from bonanzas of gold and silver into shoots rich in zinc. In a way, therefore, the shutting down of these mines was not solely attributable to litigation; but the prolonged inactivity of these properties may be justly ascribed to the failure of the principals to reach a compromise or to arbitrate.

Recognizing the new value that changing metallurgical, mining, and industrial conditions had meanwhile set upon ground such as was owned by the two litigants, Mr. S. N. Hicks, of Denver, bought both pieces of property and thus silenced the controversy. With the able assistance of Mr. R. M. Henderson and Mr. Charles H. Hanington, also of Denver, exhaustive experimentation in the milling of the ore was performed, numerous natural obstacles were overcome, and a very complete plant both for mining and for concentration was finally completed. This company, a close corporation, is now operating its property with the smoothness of an old, time-worn concern and the adventurers mentioned are enjoying the merited success that their perseverance made possible.

Zinc Deposits.—The Iron Mask mine is being worked now exclusively for zinc ore. The masses of sphalerite within the limestone beds are really marvelous in both size and richness. Drifts lead away from the slope, the main artery of the mine, into these ore bodies which are practically solid "mineral." The ore carries a fair percentage of pyrite but practically no quartz. The sphalerite, which accounts for about 17 per cent. zinc in the crude ore, is of the black variety and is generally in small crystals. Galena occurs pretty uniformly associated with the sphalerite, but is so much less abundant that the crude ore will average not over 1½ per cent. lead. One component of this ore is siderite which occurs frequently in most beautiful forms, among them being the botryoidal. However, even this material occurs in limited amounts. A person visiting these stopes wonders how Nature could have produced such a concentration of zinc sulphide. Gold and silver occur in very small amounts in the crude ore, but their value is appreciable in the subsequent concentration products.

Stoping.—Great chambers of irregular shapes spread out and crook about, branching and reuniting around pillars, with numerous instances of stoping being conducted by men working upon shelves of ore, and for hundreds of feet, in all directions, there is no country rock to be found. A very interesting feature of the excavation of this stuff is the fact that it drills easily, but the blasting of it cannot be depended upon to break down large blocks, because of the peculiar, fine, loose, crystalline structure. Absolutely no sorting is required either in the stopes or on the surface. Every pound of material shot down is ore and is elevated to the surface, in ordinary ore cars through the slope, by a duplex, self-contained steam hoisting engine. Here the only treatment before loading into the buckets of the aerial tram is crushing of this crude ore so that it will pass ⅞-inch apertures.

The ground stands up wonderfully. Whereas these mine chambers are very wide and often quite high, no timbers are used to support the roofs. Indeed, it seems that natural conditions have been multiplied for rendering the mining cheap. The early-day operations produced many passages connecting with the surface, and these now accomplish the natural ventilation of the mine.

The attention of the writer was called to a very peculiar odor that may be noted in freshly broken specimens of the sphalerite. When the miners are shoveling this material, the same odor is noticeable. It is not at all unpleasant, it being comparable both in kind and in strength to that of fresh, warm, cow's milk. This may not be a novelty to some readers of this article who have worked similar deposits, but the author has wondered how many persons will accuse him of nature faking.

Steam, generated in coal-fired boilers, propels the hoisting engine and the air compressor that sends air to the drills. The only other use of power at this mine is for running the crushers in the head-house and these are driven by electricity generated in the mill at the foot of the mountain, Fig. 4.

The mine is worked but one shift per day, for with such tremendous ore reserves if is an extremely easy matter to produce, in a single shift, many times the mill's capacity per 24 hours. As fast as hoisted, the ore is trammed to the head-house, put through a 9″ × 15″ Blake crusher, thence through a ¾-inch trommel into a 9″ × 16″ Samson crusher, and thence to the storage bin.

From this bin, the crushed ore is loaded directly into the buckets of the tram. This tramway is a Bleichert, two-bucket affair in which a descending bucket loaded with 1,200 pounds of ore serves to pull up the empty one on the opposite cable. The standing cables are of the locked-coil type, 1⅛-inch diameter. The running rope is ½ inch and is wrapped but once around the brake drum in the head-house. One man attends to loading the buckets and operating the brake. No attention is required in dumping the buckets at the lower terminals, this step being performed automatically, the ore dropping into a commodious bin, vaguely discernible behind the clouds of sulphur and coal smoke.

The receiving bin at the mill will hold a 24-hour supply. From this bin, automatic feeders pass the ore to stationary, slotted, inclined screens (of the Edison type), the apertures being 16 mesh and ⅛ inch. The particles of the ore over ⅛ inch go directly to a set of coarse rolls, while the stuff of intermediate size is delivered to fine rolls. The feed to both these sets of rolls is by means of shaking chutes hung at a very small inclination, these chutes being really conveyers. All the rolled products are returned to the slotted screens.

The screen products drop into a hopper-shaped bin from which they are continuously delivered to a belt conveyer that discharges into another bin from which, in turn, the ore is discharged by two plunger-type feeders to two six-hearth Dewey roasters whose combined capacity is rated at 70 tons per 24 hours, but which are easily taking care of about 85 tons. In these roasters, which are performing exactly duplicate duty, the ore is not given a dead roast, but the temperatures and speed of ore travel are so closely regulated that but a part of the sulphur is removed from each molecule of pyrite, while the siderite is converted into magnetic iron oxide. All the iron is thus put into such forms that it is subsequently removable by magnetism. From the discharge of these roasters, the product, while still hot, is elevated through a revolving, inclined, cylindrical, steel cooler having spirally set interior riffles for tumbling the ore. Upon emerging from this, the ore is quite cool and goes directly to a second storage bin.

The roasted and cooled material is next fed automatically to the belt of a remodeled Ball-Norton magnetic separator, the alternating polarity magnets of which were constructed especially for this installation. The two products of this treatment are, (*a*) silica and the sulphides of lead and zinc; (*b*) magnetic oxide of iron, carrying some structurally entangled galena and sphalerite.

The (*a*) product is elevated and passed into a Bunker Hill screen, where it is, for the first time, brought into contact with water. The oversize and undersize go to different Card tables, where a separation is made into concentrates of galena and blende. The (*b*) product from the Ball-Norton separator is passed through a grinder of the coffee-mill style, and then is elevated and delivered to a Cleveland-Knowles magnetic machine which effects the separation of an iron product and a lead-zinc-silica product. The iron material is discharged into a launder to waste, while the preserved material is delivered to the same Bunker Hill screen and put through the same treatment as product (*a*).

With ordinary attention to feed and operation, the millman is now able to keep his respective products practically uniform. It is his aim to make a zinc concentrate running about 48 per cent. metal. His galena concentrate runs about 75 per cent. lead.

The proportion of lead to zinc is small, the comparative tonnages of shipped concentrates being about 10 to 1. The mill being on the right of way of the railroad, the shipping products are loaded directly into box cars. The lead concentrates are sold to the American Smelting and Refining Co., while the zinc concentrates are shipped to the American Metals Co.'s plants in Oklahoma.

A very important part of the installation has thus far been overlooked. High upon the opposite mountain, the company impounded a small mountain stream and directed this into a 10-inch, sheet-steel pipe that conveys the water down the mountainside and across the river into the mill. In a total length of 3,200 feet, this pipe gives a head to the water of nearly 600 feet, or a pressure in the mill of practically 250 pounds per square inch. This water, passing a ¾-inch nozzle, drives a 24-inch Pelton wheel that ordinarily delivers about 120 horsepower, and this power is conveyed by belting to various generators and the mill's line shafts. It is from one of these generators that the current to operate the crusher up at the Iron Mask mine is taken. The mill contains a set of coal-fired boilers and an engine for use whenever a shortage of water may occur through drought or freezing. The photos show the boilers in use, the exhaust steam issuing from a Norwalk compressor furnishing air to the mines. The power plant occupies a very limited space in the right end of the mill building and is so planned that steam and water-power may be utilized separately or together.

There has been nothing to conceal, but the owners have been opposed to any public announcements of their operations; indeed, during the days of tribulation in equipping and adjusting their plant, they did not care for the attention of outsiders. There has been no ulterior motive back of this reticence, for the property was purchased and equipped as a permanent investment, there being no notion of promotion or of selling out. The writer recently accepted an invitation to visit this property and he was more than elated, later, when he was granted the privilege of writing it up. He, therefore, desires to express his appreciation of the assistance and courtesies of both Mr. Hicks and Mr. Hanington.

Economical Shaft Sinking

*By Mark B. Kerr**

The mines of the Grass Valley and Nevada City district, in California, have long been noted as among the permanent and paying in that state. One pay zone after another is encountered on the strike and dip, connected along the fracture planes in the diabase by what are locally known as crossings. As a rule, this crossing or fault merely throws the vein from the foot-wall to the hanging wall, or vice versa

In the Pittsburg mine, near Nevada City, a very strong, well-defined crossing threw the vein about 40 feet and was the principal cause for closing down this promising property some 12 or 15 years ago.

When the present holders recently took hold of this mine, they found the shaft down 1,000 feet and the vein flattened off in the hanging wall, even beyond where the south segment of the vein should be by projection. The problem was then to sink the shaft through the crossing and pick up the south segment of the vein and sink on it.

In sinking to the 1,100 level, and then driving on the vein and picking up the south segment of it, it was found that the main shaft had been flattened so much that both segments, north and south, were back of the shaft, or in other words, in the foot-wall (see Fig. 1).

A gradual curve below the 1,100 level was made, increasing the dip of the shaft from 25 degrees to 53 degrees. At the 1,300 level a station was cut and the vein developed both sides. The country rock is a close-grained diabase, so it was decided to sink a winze 200 feet on the vein, then drift back north to a point under the shaft and raise up with stoping drills to connect with the bottom of the shaft.

The result of the survey for this work (the last distance up the raise to point of beginning being calculated) was as follows:

Station	North	South	East	West
0–1	15.56	10.47		
1–2			42.76	22.41
2–3	55.16	32.68		
3–4			56.94	15.64
4–5	18.48	18.21		
5–6			51.55	65.50
6–7	23.68	47.89		
7–8			27.72	15.25
8–9	9.89	65.65		
9–10			24.98	14.72
10–0	47.40			70.55
	170.17	174.90	203.95	204.07

Eastings and westings checked within .12 foot and a possible error of 4.73 feet was found in the northings and southings. Distributing this error, the upraise was made on this line, the dip calculating between 52 degrees and 53 degrees, to correspond with the shaft above.

* Mining Engineer, San Francisco, Cal.

The vein at the 1,500 level was found to dip 52 degrees, but, after going up 20 feet, it flattened, so the raise, the rest of the way, was made in the wall, thus saving time and expense; for sinking in this hard ground is very tedious. The slope distance up this raise was 153 feet, and 30 feet per week was made with two shifts, performing the work in 5 weeks. The work was delayed a week in order to trim the sides and corners. From now on the shaft can be sunk deeper on the vein, with only a slight divergence now and then from the theoretical dip adopted from the course in the shaft below the 1,100 level.

The drills used were the Ingersoll and the Shaw stoping. The total cost of this work, including all hoisting, supplies, labor, and supervising, and electric power throughout, was $3,950, or $20.57 per foot. When it is realized that to sink this shaft the same distance would have taken just twice as long and would have doubled the

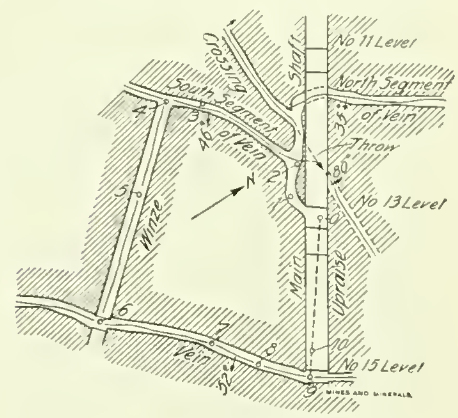

Fig. 1

cost, the justification for the engineering work is obvious; and again, the company had the advantage of exploring the vein and knowing its peculiarities in advance.

Such a piece of work, although novel, is not difficult to lay out; but the greatest care should be taken in the surveys, especially to obtain the proper alinement. If any other superintendent cares to follow this up, it is best to do as was done in this case; that is, explore ahead sufficiently to be sure that the practical conditions are favorable when the work is complete, for the saving accomplished is a tremendous factor in favor of its adoption.

In Bessemer pig iron the greatest allowable quantity of phosphorus is 1 per cent. To obtain allowable percentage of *P* in ore divide its per cent. in iron by 1,000, thus: $\frac{62\%\ Fe}{1,000} = .062$ per cent. *P*, allowable. If over this amount the ore is classed as non-Bessemer. Some insist that limit is .05 per cent. *P*. The ore must be so low in *P* as to allow for the *P* in fuel and flux and yield pig iron not over 1 per cent. *P*. Phosphorus is wanted for white iron and in iron that is to be machined.

Tennessee Phosphate Practice

Kinds of Rock Mined—Prospecting, Sampling, Handling, and Mining—Organization and Management

*By James Allen Barr**

Phosphate rock is tricalcium phosphate, $Ca_3P_2O_8$, combined with various impurities, both mechanically and chemically, the former being represented by silica, some free iron and clay, and the latter by alumina in the form of aluminum phosphate $Al_2(PO_4)_2$, iron phosphate $Fe_2(PO_4)_2$, calcium carbonate, flourine as CaF, and traces of arsenic.

Brown phosphate rock varies from shale rock resembling half-burnt clay to the more common cellular brown rock occurring in irregular plates, and the gray rock, much harder, and presenting a vitreous-looking fracture, though still somewhat cellular. The percentage of iron and alumina is largest in the first variety and lowest in the last. The mechanically combined impurities, chiefly clay, are removed by washing. Silica, which is of very nearly the same specific gravity, has not as yet been eliminated successfully except when it occurs in a very fine state and floats off with the wash water.

The brown rock occurs in the Lower Silurian, more commonly known as the Ordovician horizon, resting on the Bigby limestone.

Blue phosphate rock resembles blue limestone, into which it sometimes grades by imperceptible stages. It occurs in the Devonian series, and ordinarily below the Chattanooga shale, unless the latter is missing by reason of erosion. The grade runs from 50 per cent. to 75 per cent. bone phosphate of lime, with occasional analyses showing 80 per cent. The lowest commercial limit is about 65 per cent.

The color of the blue rock also indicates its grade, ordinarily the gray rock being the highest and the darker color indicating a lower grade.

Above the blue rock occurs a thin stratum of Kidney, which is of still lower grade, though there is an exception to this.

White phosphate rock is the highest grade occurring in Tennessee, and has been known to run over 90 per cent. bone phosphate of lime. The known deposits are so far from transportation that they are not being mined to any extent at present.

Brown rock prospecting should be conducted in a systematic manner, as unless the person in charge of the work has had a very large experience in the occurrence of the phosphate he is more than liable to so place the prospect holes or pits as to obtain results which are not the average. To be on the safe side, the ground should be laid off in from 100-foot to 200-foot squares, according to the uniformity of the deposits, and holes sunk with post-hole diggers and augers. In this way the outcrops are determined and barren spots traced. When the rock runs out between two holes, it can be, if necessary, more exactly determined by additional boring. Each hole should be numbered, and a sample of the rock taken, placed in a cloth bag, marked with the number of the hole, and sent immediately to the testing place. It is said that a man selling land at one time switched good samples for bad ones; another lined the prospect holes with high-grade rock. In the West this is commonly called "salting." It might be well to observe precautions to prevent anything like this.

The depth of the overburden and rock should be taken from each hole and the proper record made of the same, so that it can be transferred to a prospect map. When the deposit occurs in the ribbon or hat-band formation, the holes should run across the deposit.

About in every acre a pit should be dug to verify the results of the auger holes and obtain a proper sample for washing tests. The fine-cut samples from the auger holes would not fairly represent the rock coming from the mine. The samples are also liable to be contaminated by flint and dirt, scraped down from the overburden.

In case of very irregular deposits, where there are many cutters in the limestone, it would be well to use the pit method in prospecting entirely, it being almost impossible to gain even an idea of the rock between cutters by auger holes alone. This latter amount will run from one-fourth to one-half of the total volume as represented by the average depth of the rock below the top of the lime.

In blue rock prospecting, ordinarily the outcrop may be uncovered easily on a hillside. If possible, this should be done at intervals of 100 to 200 feet, the thickness of the rock determined, and samples taken for analysis. The outcrop will run lower in bone phosphate of lime than farther in, and the joints will have a brown-colored border, due to oxidation. Back in the hill a diamond or core drill will have to be employed or shafts sunk to determine the thickness of the rock, its grade, and continuity.

The blue rock is by no means a uniform deposit. It will be broken by low-grade "horses," and will very often "pinch out" farther in the hill, or at least be uniform only in one direction as to thickness and grade.

In Tennessee the grade of blue rock is practically the only consideration, and hence analysis is the ultimate test.

The impurities in brown rock, which are removed by washing, are principally clay with an inappreciable amount of fine silica. The object of all the washing tests is to determine to what grade the sample will wash under actual conditions of operation and how much will be recovered. In general, hand washing will be slightly more thorough—say, to the extent of ½ per cent. to 1 per cent. bone phosphate of lime, and the recovery 10 per cent. to 20 per cent. higher. This is true in any testing on a small scale, as has been demonstrated in western practice, where some disastrous failures have resulted in erecting reduction plants and purchasing properties on the results of laboratory tests.

The sample to be tested is soaked in a tub of water until fairly soft. The tub is then dumped into the top screen of a washing apparatus, which is easily described as two superimposed screens, set in some watertight basin, such as an iron wheelbarrow. The top screen should have about 1-inch holes, and the other slightly smaller than 16-mesh holes. The sample is then washed by a stream of water, with a piece of ⅜-inch pipe bent in an angle for a nozzle. About 20 pounds pressure is sufficient. The operation is continued until all of the rock is cleaned of the clay. The lumps of muck should be broken by stirring with the hand paddle, using a motion similar to the action of a log washer. The screens are now removed, the muddy water decanted from the sand, and fresh water added until it runs off almost clear.

The resulting products are separately dried, weighed, and sampled for analysis. The ratio of the original to the final weights will give the recovery, which may be either figured on a wet or dry recovery; or if moisture samples are taken of the original, the recovery on a dry basis may be calculated. The weight of the rock occurring in the field, per cubic foot, should also be determined at intervals for computing the recovery of the rock in tons from an area represented by the sample. The specific gravity of the rock in Mount Pleasant field varies from 10 per cent. to 20 per cent.

The results of these recovery tests should show the total tonnage of sand, rock, and screenings from each acre of ground as selected, the average analysis of each size, and thus give the all-important information as to the commercial value of the rock.

Careful account should be kept by an experienced person of the behavior of the sample in washing, for it is by observing the action of the rock in a test that valuable data can be gathered for the design of the prospective plant. The percentages of the rock screenings and sand also bear an important part in the plant design, so that the sand washer may bear the proper ratio to the total capacity of the plant.

It is evident that the more difficult the

*Engineering Association of th South.

washing of the sample and the greater the amount of impurities to be removed, the more thorough must be the washing in the plant designed to handle this material.

The commercial value of the prospecting data for blue rock is as follows: The grades should run on an average of 68 per cent. with some 70 per cent. to 72 per cent. bone phosphate of lime, $Ca_3(PO_4)_2$. Below 60 per cent. it is practically impossible to handle at the present market quotations. The 60 per cent. to 67 per cent. grade is largely ground for the raw-rock trade.

The thickness of the deposit should not be less than 28 inches in order that mining can be done economically. Providing the mine is developed systematically, the cost of mining should not be over $1.25 per ton.

The roof should be of good, firm shale, unless the overburden is light—that is, not over 20 feet—so that it can be removed economically.

From the results of the prospecting for brown rock the tonnages are computed, and thus knowing the market price for the respective grades, and also the cost of handling the rock, the commercial value per acre of ground is obtained.

The overburden is an important item, and is charged against the washed rock at so much per ton. This is obtained by figuring the removal of the overburden at 14 cents per yard.

In the valuation of the property there are on the credit side so many tons of the various grades, with a given value at the present market quotations, and, if the land is also owned, its value after the mining operations have been completed, together with any rents which may accrue during the life of the operations. Any other sources of revenue should also be included, of which timber is the chief.

On the debit side are the following costs, figured from the total price of the land and other purchases, such as right of way, all figured to a tonnage basis, plus the estimated working costs.

The following figures are representative of the present-day practice and show the effects of grades on the valuation of property, viz.:

Price of property	$400,000.00
Brokerage and prospecting	25,000.00
Erection of plant and mining equipment	125,000.00
Total	$550,000.00
Tons of rock on property	1,250,000
Cost per ton initial expenditure	$ .44
Removing overburden	.50
Mining	.40
Washing	.35
Drying	.16
Screening, stocking, and loading	.15
Overhead expense	.50
Total	$2.50

At the rate of 60,000 tons per year, the property will have a life of 21 years.

	73%	75%
Average selling price of rock	$ 3.50	$ 4.00
Net profit	1.00	1.50
Profit per year	60,000.00	90,000.00
Per cent. profit per year	12%	18%

Considering the risks of the business, not less than 20 per cent. per year should be considered justifiable. The above procedure should be carefully studied to arrive at the proper value of the rock.

From the experience gained in washing the samples, a very good idea may be formed as to the elaborateness of the washing plant necessary. Comparatively clean material may be obtained by the use of a single set of logs; but if much clay be present, a tandem set is much better, especially when capacity is a figure. The log washer consists of a box about 25 feet long, 7 feet wide, and 4 feet deep, in which are made to revolve, in the case of a double log, two shafts constructed of angle irons, in which are fastened chilled cast-iron paddles. The rock is dumped in the lower or tail-end and pushed forward by the paddles, which are set at an angle to form a screw when revolving. At the same time the water and material are agitated so as to put the clay in mechanical suspension. The tail-end of the logs being the lowest, an overflow gate is provided through which the muddy water and considerable phosphate sand flow, the coarser sand and rock being pushed to the higher or discharge end, where it should issue from the logs with very little water. The log washers should work with as little water as possible, and the contents of the box should be of creamy consistency to give the best results. The function of the second set of logs is to receive the material from the first, and with the addition of fresh water, again elutriate the clay in a more thorough manner than could be done in one set in the presence of so much of the contaminating substance.

It is the general procedure of the present-day practice to prepare the material for the logs by crushing much finer than formerly, the last three plants being built to reduce the phosphate rock to 1 inch and smaller. This not only permits a thorough washing of the rock, but reduces the power necessary to operate the logs compared with what is required when working lump rock. However, fine crushing is productive of a larger percentage of sand. By employing fine crushing, 150 to 400 tons, figured on a washed basis, may be put through a set of logs, providing the grade will permit, in 1 day's time.

Following the log washers, a revolving screen, with an internal spray, eliminates the remaining clay and the smaller sand from the rock. The screens have jackets ranging from ⅛-inch to $\frac{1}{16}$-inch mesh. In former days the screen holes were anywhere between ½-inch to 2 inches in diameter, the resulting undersize often being wasted

Following the rock department comes the sand washer, which is the most important part of the entire plant, but which is today the least perfected. The system known as the "tank process," was introduced by Mr. Granbery Jackson. In this system the sand is run into large square or round tanks, where it settles out as much as is permitted by the overflow velocity and eddy current. The surplus water flows to a discharge launder. This system has two methods of transferring the sand to the next washing tank. In one it is continuously removed by a jet of water operating in a pipe and pumping into a second tank, where the operation is again repeated until the sand has received five washings. From the last tank it is run into a bin, where it is drained and discharged on to a conveyer from the bottom dump door.

In the second-mentioned system of transferring, the sand is washed by hand hose from the tank to a steam pump, where it is elevated to a second washing system, and so on.

While these tanks wash the sand perfectly, the inherent defect is that the fine material is still wasted and the water used is unnecessarily large in volume. The perfect sand washer should embody the following principles:

1. The velocity of the water in the final overflow should not be greater than .4 of a foot per second, which will just carry off 150- to 200-mesh phosphate sand and all the elutriated clay. Any greater velocity will carry off a correspondingly larger grain of sand, viz., .17 of a foot per second will float 100-mesh material.

2. The clay must be elutriated and caused to rise and travel in one direction by reason of its fineness and properties of suspension in a collodial solution, and the sand to settle out or travel in an opposite direction by reason of its greater settling power. The clayey water must be thoroughly eliminated from the sand by the addition of fresh water, as in the operation of decanting. It must also be remembered that in some steps of the process, either in the logs or sand washer, the sticky clay must be scoured from the sand particles.

3. The sand must be dewatered and placed in condition for handling or drying.

The coarse and fine sand should be treated separately. In western cyanide plants the slime is effectively separated from the coarse sand in various forms of classifiers. The practice of dewatering, or eliminating the large volume of water coming from the washer might be well improved upon by noting the use of the Dorr mechanical dewaterer in the majority of the modern cyaniding plants, which operates under very similar conditions to those required in this field.

In designing equipment to handle the sand from the washers, valuable information can be obtained in Mexico and the West, where the Blaisdell excavating system automatically handles thousands of tons daily.

The rock and sand issuing from the washer should be stored in piles where it will drain and eliminate the excess moisture before drying. The storage piles should be large enough to supply the dryers during stoppages of the washer and bad weather, which prohibits mining. Probably the best machine adapted for storage purposes is a modification of a traveling crane equipped with a 54-cubic-foot clam-shell bucket.

The two systems of drying in use in the Mount Pleasant field are feeding at the cold end and discharging at the hot end; and reversing the above operation.

It is evident that the fuel economy in the first system will be higher on account of the low-stack temperatures possible. The importance of this item will be clearly seen upon studying the percentage of heat lost from this source in a furnace test.

In the first system one can put his hand on the cold end of the dryer, which ranges between 150° F. and 200° F. In the second system the temperature of the flue gases will range between 400° F. and 600° F. The first system was formerly operated entirely with natural draft, with the exception of a steam jet, which furnished the necessary volume of air by induction through the grate and forced the gases through the shells, at the same time insuring complete combustion, but, at a considerable loss of steam. With this method of firing, wood is also used with coal to obtain the necessary openness of fire, the ratio being about 2 cords of wood to 1 ton of coal. Later the system was changed to coal entirely by using the following modifications: To burn the coal, a slight air pressure was introduced in the ash pit, the latter being preferably kept filled with water to keep down the formation of clinkers and cool off the grates. Only sufficient air is forced through the grates to balance the vacuum due to the stack draft. This not only lengthened the life of the furnace, but eliminated any objectionable feature of smoke being forced out of the fire-door and dryer opening. The combustion in this case is almost perfect, only a white feather of steam appearing at the stack.

The second system relies entirely upon the forced draft to obtain its results, and, in general, uses a much smaller furnace and grate area than the first system. The combustion is not complete, and a very high percentage of the fines is carried through the cylinder by the high velocity of air, which is unnecessary waste and requires additional handling to save. In roasting fine ores metallurgists aim to keep down the velocity of air through the ore bed to 200 feet per minute. Adequate dust chambers should be provided to reduce the velocity of the flue gases and to precipitate the fine dust.

The rock from the dryer is elevated to a storage tower, preferably of steel construction on account of the hot rock issuing from the dryers occasionally at almost a red heat. Probably the best form of elevator for this service is a malleable bucket, continuous pattern, single-strand type, with plain idlers and traction head and tail-sprockets, operating at a speed of 60 to 100 feet per minute. The use of sprockets in the elevator greatly increases the wear and jar, especially on the chain. The most commonly used chain is a combination malleable and steel link. The dry rock may be either screened or run directly to the storage bin. By using a separate wet storage pile there is no use for this screening, as the rock and sand may be kept apart all through the operation.

The distribution of the dry rock is best effected by man-operated motor car. A belt conveyer might be used, but an occasional rush of red-hot rock would preclude the use of any ordinary-priced belt and also tend to increase the cost of maintenance. One attendant would be necessary to look after it, which is enough for the operation of a motor car handling 400 tons per day.

The dry rock may be stored the same as the wet rock. If the life of the property and the magnitude of the operations warrant, a more elaborate system of storage bins of reinforced concrete or steel might be installed; but it is doubtful whether the present condition of phosphate mining industry in this state would warrant such an expenditure for the slight reduction in cost obtained.

The rock from the elevator may be spouted direct to a car and conveyed back from the doors to the end either by hand or a short belt conveyer. Care should be taken to prevent burning up the car from an occasional rush of red-hot rock or cinder.

MINING AND STRIPPING

The overburden to be removed is generally clay, with occasional flint boulders. The ground works very well during dry weather, but in rainy weather becomes too miry for a scraper outfit.

At present the majority of stripping is done by wheel scraper outfits under contract price of 14 cents per yard. One company pays 15 cents, but does not advance any money ahead of the engineer's estimate.

Steam shovels have been little used. The drawback to their use is the manner in which the scraping has been done in scattered pits with long hauls for dirt. The pockety nature of the deposits partly accounts for this, but mostly the lack of system in mining.

A long-boom revolving shovel, equipped with either drag-line bucket or extra long dipper stick, makes about the best outfit for removing dirt by mechanical means. The radius of this operation enables a pit 50 feet wide to be stripped and the overburden piled up in a previously made cut which has been mined out. There are offers to do this work for 10 cents per yard where sufficiently large area for scraping warrants continuous operation for the shovel without moving.

Grab buckets have been tried, but it is a common experience that they will not handle anything economically that a man cannot dig with a shovel.

The work of the wheel scraper is too well known to warrant description. Scraping by this method is usually done in pits 40 to 60 feet wide and 150 to 300 feet long.

The depth of the overburden removed in this field will average about 9 feet.

At the Ward mines, near Centerville, the overburden is being taken off by a hydraulic giant, water under 150-pound pressure being used through a $1\frac{1}{2}$-inch nozzle. The flow back is ditched to a sump with the aid of a ditching hose, where it is pumped out by an 8-inch centrifugal pump to the waste. In some cases this is done entirely by gravity.

Whenever stiff yellow clay is encountered, the progress is slow and costly, it being possible to remove about 100 yards in 1 day, costing 17 cents to 20 cents. However, this material is so hard and stiff that it is difficult to handle with pick and shovel. While working in the best of conditions, removing loose sand with little clay and boulders, it is possible to move at least 1,000 yards of material in 1 day at a cost of 5 cents per yard. It will be safer to figure the average cost at 8 cents to 10 cents.

The flow back from the working face will not handle any material larger than ordinary gravel, about 3 inches in diameter; the larger size must be washed back with the ditching hose and the hydraulic giant. The centrifugal pump will handle pieces 2 inches smaller in size than the diameter of the suction, though, of course, this is very hard on the pump linings and impeller.

Around the outcrop of a blue-rock deposit, where the overburden and slate roof is light, this may be removed, and the rock quarried. The underground mining is ordinarily done on the room-and-pillar system, the pillars being recovered by drawing back. With a good roof, the only timbering necessary is a few posts near the working face, the gob being thrown behind and to one side to provide additional support.

The following precautions should always be observed in laying out and operating underground workings of this kind:

1. The room should be so directed as to run parallel with the joints of the rock in order to fire the shots to the best advantage. If a miner can locate two joints, he can then place his hole so as to obtain the maximum effect of the powder; but if the room runs at right angles with the joints, he cannot then tell where the next one occurs, and is liable to lose a part of his shot.

2. The entries should be so located as to block out the maximum amount of rock with the minimum of drifting in the direction in which the phosphate rock pinches out.

3. The mine must be worked according to a system and kept to this by a competent surveyor.

4. Drainage must be provided and kept open.

5. Main line tracks should be laid with not less than 30-pound rail, properly lined and surfaced.

6. The entries should be driven and kept in shape by a competent foreman.

7. Rooms should not be over 200 feet long and 40 feet apart, being staggered on each side of the main drift to facilitate trackage.

In brown-rock mining the prospect map should be carefully studied, a plan laid down and thereafter followed as closely as practical. Before beginning operations formulate a plan and decide how to obtain the rock cheaply, not only in one particular pit, but on a general average. Always keep the mine in condition so that it will not have to be cleaned up with attendant high cost.

Material which only brings on an average of $4 per ton f. o. b. the cars requires large tonnages and strictly economical methods to produce profits, especially when the prices are based on a 50-per-cent. recovery, bringing down the price to about $2 in the field.

In laying out the future plans of mining operations, the following points must be considered:

1. How can the overburden be disposed of without covering up rock and without long hauls or rehandling? This may be done by starting in on the outcrop and working in; or if no outcrop is available, then the first cut must be hauled away to a barren spot or rehandled. As soon as the first cut is available and mined out, it may be used for dirt room.

2. Open the mines so that the track may be thrown continually without tearing up and so that the entire deposit may be reached with a minimum amount of trackage.

3. Sufficient rock must be opened to permit placing of enough cars to supply the plant. It will take from 100 to 150 cars per day to take care of a 200-ton plant.

4. Always provide for drainage. This must be done, or every rain will mean a shut-down of the mines.

5. Provide a good main-line track from mines to plant, laid with not less than 40-pound rails on a good road bed, laid out by an engineer who knows his business. This will enable one locomotive to haul twice as much as it could on a poor road bed. A 12-ton locomotive makes a good size for the main-line service, while a 7-ton locomotive is large enough for switching around the mines and plant.

Hydraulic mining is to be tried shortly in this field. Judging from its work in Florida and the operation at the Ward mines, it will prove successful as far as the mining is concerned The only objection to this method is that it will send so much water to the washer as to make the problem of sand handling a difficult one. In getting around this objection, valuable information might be obtained by observing the operations of the Washoe smelter at Anaconda, Mont., for saving the very fine slime from their concentrating plant. The material is run into one of three large ponds—one for filling, one for draining, one for excavating. The latter is done by grab bucket, operated on the Lidgerwood cableway system. The excavated and dewatered material can then be handled by ordinary methods.

There are not many deposits of rock in the Mount Pleasant field which will permit other than hand mining. This is because the rock often runs in deep cutters between the limestone. Flint and other waste material also occurs in irregular deposits, and at times even a whole stratum of low-grade flinty material will separate two good layers of phosphate rock, all of which makes a close selection by hand mining imperative to maintain the proper grade.

Where it is possible to obtain a good block of rock free from flint and clay seams and unobstructed by lime boulders, then a steam shovel will remove the rock economically and be cheaper than hand mining. It has often occurred to the writer that a locomotive crane adapted to a narrow-gauge track could be used to advantage for mining rock in the deep cutters by dropping buckets down to the working face, where they would be filled by hand, raised and unloaded into the cars. It costs 20 cents per mine car to load from the face of the rock up to 40 cents and 50 cents from deep cutters.

There should be one superintendent over all the field work, mines, and plants: all orders for the operations to go through him. Do not pay him superintendent's wages and make a foreman out of him by having the higher officials issue orders direct to the men, with its attendant demoralizing effect on the system. The plants and mines should each have a foreman, responsible to the superintendent only. The master mechanic should be in charge of all mechanical operations, being in full authority in his department and over his assistants, but under order of the superintendent or plant superintendent in the same manner as a locomotive engineer is governed by the conductor. Above all, there must be harmony in the working quarters and a loyal spirit among the men.

All requisitions for supplies should come from the heads of the respective departments, O. K.'d by the superintendent, and, if necessary, passed by the engineer. Spare parts should be kept in stock along with supplies, which requires that a storehouse be kept and regulated by a stores and supplies account, showing each day the balance of any item on hand. The supplies as taken out should be charged to the proper account, with allowance for freight and handling.

Repairs are not charged directly against the separate accounts on the cost sheet, but are provided for by a set charge against each ton of output. At the beginning of the year the master mechanic or engineer should prepare an estimate of the amount required for the maintenance of each machine and building. These charges are then prorated among the proper accounts to obtain the above-mentioned fixed charge. The object of this is to eliminate the violent fluctuations of the cost sheet due to a breakdown, which may occur only once a year. Of course the charges per ton for repairs and maintenance may require changing if the output does not come up to expectations.

Time cards should be turned into the office each morning by the head of the department. On the back of each card should be a distribution of the time to the proper accounts, this to be used in making up the cost sheet.

The cost sheet is the vital part and chief consideration of the elaborate system of accounting. It enables the superintendent to keep an accurate check on the work and shows him each day how to improve the next one. The cost sheet should by all means be a daily one. The older an event is, the less interest it holds and the less meaning it has. The actual operating cost should be separately shown in an itemized statement, giving for mining, washing, drying, etc., the cost today, amounts forward, and totals to date, of labor, supplies, fuel, and maintenance, all of which are totaled and the average cost for each item figured. A separate part of the sheet may in like manner contain a statement of other costs charged against the production, but not included in the actual working cost. The above two items are then recapitulated to show the total cost today and the average cost to date from the first of the month. This sheet should also show the mine cars dumped, tons washed and recovered, percentage of recovery, and tons dried. A separate account should be kept of the number of tons in wet and dry storage, with the probable grades.

Normal Volumetric Solutions

In wet assaying a normal solution is one which contains in 1 liter, in any stated reaction, the chemical equivalent of 1 gram of hydrogen. If the molecule of the reagent be univalent 1 liter will contain the weight in grams equal to the molecular weight of the reagent; if bivalent, a weight in grams equal to one-half its molecular weight: if trivalent, a weight in grams equal to one-third its molecular weight, etc.

Antimony Ores

The following shows the percentage of antimony in various minerals:

		Per Cent. Sb			Per Cent. Sb
	Stibnite	71.80	(3)	Senarmontite	83.56
	Chalcostibnite	48.90	(4)	Valentinite	83.56
	Berthierite	57.00	(5)	Cervantite	79.20
	Zinkinite	42.60		Kermesite	75.30
(1)	Stilconite	74.90	(6)	Volgerite	58.91
	Durfeldite	30.52		Livingstonite	53.12
(2)	Burunite	50.11		Guejarite	58.50

Those numbered are oxides. The others contain sulphur.

Brakpan Mines, Limited

Description of a Large Modern Electrically Operated Cyanide Plant on the Rand, South Africa

*By H. S. Gilser**

The property of the Brakpan Mines, Ltd., is situated on the far East Rand, 21 miles from Johannesburg. It consists of 1,150½ (=1,691 acres) deep level claims and is opened by two seven-compartment shafts, 4,400 feet apart. No. 1, or the north shaft, is 3,100 feet deep vertically. Shaft No. 2, or the south shaft, is 3,700 feet deep, at which point the reef was intersected. An incline with an average grade of 7½ degrees connects the two shafts underground, and from this six levels are driven off in both directions. Underground haulage in the incline is effected by means of an endless rope.

Fig. 1. Surface Plant, Brakpan Mines, Showing Shaft No. 2

Electric power purchased from the Victoria Falls and Transvaal Power Co. is used throughout the plant, the 10,000 horsepower taken being distributed in part as follows: Main hoisting engines, 4,500 horsepower; mine pumps, 1,500 horsepower; battery and tube mills, 1,950 horsepower; reduction works, 1,000 horsepower.

The balance is used on the surface and for underground ventilation and haulage. All transmitting cables are paper insulated, lead covered, and armored, upwards of 30,000 feet having been placed underground. To a large extent, they are laid on the ring system, thus preventing serious stoppage due to cable failure, or damage. Power is metered to show the consumption for pumping, hoisting, milling, etc., and also each pair of feeders is separately metered, enabling the supply to different departments to be closely checked.

No. 2 shaft has seven compartments, measuring 42 ft. × 9 ft. over all. It is provided with a steel head-frame and is served by two electric hoists. One has parallel drums 11 feet diameter by 8 feet long, grooved for ropes 1½ inches in diameter. Tooth clutches are provided for adjustment and also the standard type of liquid starter and automatic overwinding-prevention devices. The post brakes are applied by dead weight, relieved by air-operated cylinders with the ordinary cataract-cylinder attachments. The hoist is direct-connected to a three-phase alternating-current motor. The second hoist, the main dimensions of which are the same as the others, uses direct current, the motor-generator set being located in a subdivision of the hoist room. No. 1 shaft has seven compartments, is equipped with a steel head-frame and a hoist similar to that erected at No. 2 shaft. All three hoists are 1,500 horsepower each and have a capacity of 100 tons per hour from a vertical depth of 3,800 feet. The maximum hoisting speed is 3,500 feet per minute, and the average time for a complete trip is about 2 minutes.

The reduction plant started up toward the end of May, 1911, and up to the first of the year 241,204 tons of ore had been treated, yielding a working profit of £110,977, or 9s. 2.42d. per ton crushed. The ore reserves at the time of starting up the plant were 2,035,108 mine tons, carrying 6.62 pennyweights of gold, with a stoping width of 52.5 inches. According to the annual report, the development accomplished during the year amounted to 10,675 feet, of which 9,701 linear feet were in reef, with an average value of 10.07 pennyweights of gold, in a stoping width of 32.89 inches. The ore reserves were recalculated on the first of the year 1912 and gave 1,925,346 tons of ore carrying 6.73 pennyweights over a stoping width of 58 inches. The reduced tonnage is partly due to the elimination of certain low-grade blocks of material about which more information has been gained since the beginning of milling. Recent reports show the lowest level carries 12 pennyweights of gold over a width of 60 inches of reef.

It is interesting to note in the cost of developing and equipping the property an item of £38,644 spent on bore holes, also the original estimated total cost was to be £1,135,700, whilst the cash provided by the issue of shares, interest received, and sundry revenue totaled £1,078,734, or a shortage of £56,956. But the complete equipment cost £1,185,283, or an original underestimation of £49,583. Therefore, it cost to equip the mine £106,548 more than the total sum provided, which is more than balanced by the profits gained up to the end of the year.

The reduction works are situated near No. 2 shaft, as are the machine shops, offices, and staff quarters. The ore leaving the mine is dumped from 5-ton skips on to a 1½-inch grizzly, the undersize going to a fine bin of 1,300 tons capacity, and the oversize to a coarse bin of 1,250 tons capacity. The coarse ore from No. 1 shaft is hauled by a locomotive in 40-ton hopper-bottom cars to a coarse bin, and the fine to a separate fine bin. Five belts convey the coarse ore to the five trommels shown in Fig. 2, where further fine ore is separated and the remainder sprayed with water. It passes to five sorting belts 32 inches wide and 72 feet long, where 16 per cent. waste is picked out and placed on waste belts on either side and sent to the waste dump. Tube-mill pebbles are picked off the discharge end of the sorting belts and thrown into small bins from whence they are trammed to the tube mills. Each sorting belt, together with its waste belt, is driven by a 5-horsepower motor. The trommels and five belts feeding them are driven by a 50-horsepower motor. The remaining ore on the belts is delivered to five Blake-type crushers, each driven by a 50-horsepower motor and having a capacity of 40 tons per hour. At the base of each crusher is the intake of a dust flue connected to an exhaust fan which delivers to a dust chamber outside the building. Space is provided for a sixth unit, consisting of a trommel, sorting belt, and crusher. The crushed ore and fines are conveyed by cross-belts to a main-incline belt 32 inches wide,

*Johannesburg, South Africa.

which ascends at an angle of 18 degrees and delivers at right angles on to a shuttle belt which discharges the ore where wanted in the battery bin, holding 6,000 tons.

The battery comprises 160 stamps, 2,000 pounds each, 94 drops per minute, with a 9-inch drop. The following are the details of the stamp parts:

	Diameter Inches	Length Feet.	Length Inches	Weight Pounds
Heads ...	$9\frac{1}{8}$		42	770
Stems....	$4\frac{1}{4}$	14	6	696
Tappets..				232
Shoes....	$9\frac{1}{4}$		14	288
Dies.....	$9\frac{1}{4}$		8	163
Cam-shaft	$7\frac{1}{2}$	16	3	.

The cam-shaft pulleys are 7 feet in diameter by 22 inches wide, with 21-inch belts.

The mortar boxes are of the open-front type, placed on concrete foundations with anchor bolts accessible for inspection and replacement. Ordinary rubber sheeting is placed between the foundation and mortar box. The foundation also carries cast-iron shoes for the timber kingposts, timber cushions being provided between the shoes and the concrete. Of the 160 stamps, 140 are driven in sets of 10 by 50 horsepower motors placed on the screen floor, and the remaining 20 stamps, 10 at each end of the mill, are driven in sets of five with the idea of enabling broken camshafts to be utilized. Tighteners of the rigid type are provided for the battery belts. Twin Challenge feeders serve 140 stamps, the remaining 20 being fed by those of the New Comet type. The mill-water service pipe is 8 inches in diameter and the back of each box is served by two branches, discharging between stamps 1 and 2 and 4 and 5. Four storage tanks 30 feet in diameter by 10 feet and 16 feet deep, mounted on steel lattice framework, having a total capacity of 240,000 gallons, are provided. Each stamp is at present crushing 14 tons per 24 hours through an eight-mesh screen, but 20 tons per 24 hours through a three-mesh screen have been crushed. The pulp leaving the mortar boxes passes direct to launders leading to one of two 10-inch coarse-sand pumps driven by a 75-horsepower motor. They have a lift of 45 feet, and when running at 440 revolutions per minute either one can handle 14 tons of pulp per minute. An overflow pit having a capacity of 150 tons is provided.

The elevated pulp is distributed by launders to six Caldecott diaphragm tube-mill cones 6 feet in diameter by 8 feet deep. The underflow from the cones, with added clear water, is fed to six tube mills, each 22 feet long by 5 feet 6 inches in diameter, fitted with patent spiral feeders and lined with rib-type lining made of bar iron set in cement. Tube pebbles are fed by hand, an ammeter indicating when there are enough present, and the tube is driven by a 125-horsepower motor. A portion of the overflow from the cones joins the product from the tube mills and flows over the amalgamating tables shown in Fig. 3, a group of five being provided for each mill. The 30 tables are stationary, set at an angle of 18 degrees, and are 5 ft. × 12 ft. Each table and the tail-launders are provided with amalgam traps.

The pulp from the tables is elevated by one of two 10-inch fine-sand pumps, driven by a 75-horsepower motor, to a launder placed at an angle of 9 degrees, which delivers it to four primary diaphragm cones 8 feet in diameter by 8 feet deep, which are kept filled with sand. The underflow from the cones is returned with clear water to the two center tube-mill cones by a 10-degree launder. The overflow goes to four secondary diaphragm cones 8 feet in diameter by 10 feet deep; these are kept filled to within 3 feet of the top with sand. The underflow from the cones with clear water goes to four sand-collecting tanks 60 feet in diameter by 10 feet deep, the pulp discharging to the center by launder and overflow gates at periphery. The overflow from the collecting tanks, together with the overflow from the secondary cones goes to four small cones 5 feet in diameter by 5 feet deep, the underflow of which is returned to the fine-sand pump. Lime is added to the overflow from a ball mill, and it passes to the slime-collecting tanks.

The collected sand is shoveled on to belts and then delivered from a double balanced distributor to eight sand-treatment tanks 60 feet in diameter by 11 feet 3 inches deep, holding 1,180 tons. A 6-day treatment is allowed, the tanks being pumped dry several times by vacuum. The treated sand is discharged by hand into buckets underneath the tank of 22 cubic feet capacity, holding about 1 ton and automatically dumped by the Bleichert system of aerial sand haulage from the top of a cantilever 210 feet high, rising at an angle of 32 degrees, and driven by a 75-horsepower motor. Ad. Bleichert & Co. installed this system, shown in Fig. 4, under a guarantee to dump sand at a cost not to exceed 3 cents per ton. The buckets run on a monorail automatically attached to an endless rope and can be dumped at any point on the circuit. The cantilever can be extended when the dump reaches the present top.

In the slime plant there are four cone-bottom slime collectors 65 feet in diameter by 12 feet to 17 feet deep, with a column to start pumping and a hose for cleaning. Three are collecting while the fourth is being decanted and transferred. The clear-water overflow goes to two cone-bottom water tanks 65 feet in diameter by 6 feet to 11 feet deep, and is pumped to the battery, the excess rising in the mill-water tanks. The slime is transferred with weak solution to six Pachuca tanks, 15 feet in diameter by 45 feet deep, by one of two 12-inch sludge pumps driven by a 100-horsepower motor. The charged pulp contains about 1.25 parts solution to 1 of pulp, and cyanide is added to make the strength of solution equal .02 *KCN*. It is agitated 4 hours and then transferred to the stock-pulp tank from which it gravitates to the vacuum filter boxes. Thirty to 40 minutes is taken to make a slime cake $1\frac{1}{2}$ inches thick, after which it is washed 30 minutes with barren solution, dropped into a V-shaped concrete sump, agitated with compressed air, and pumped to the dam. The vacuum slime plant consists of two boxes 70 feet long each, having six hoppers. There are 168 filter leaves in each box,

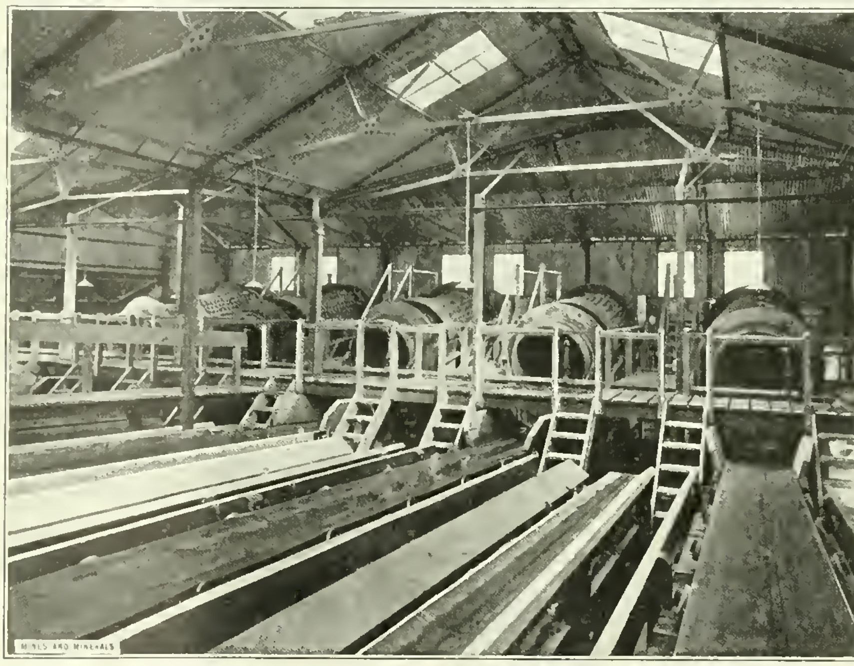

Fig. 2. Trommels and Sorting Belts

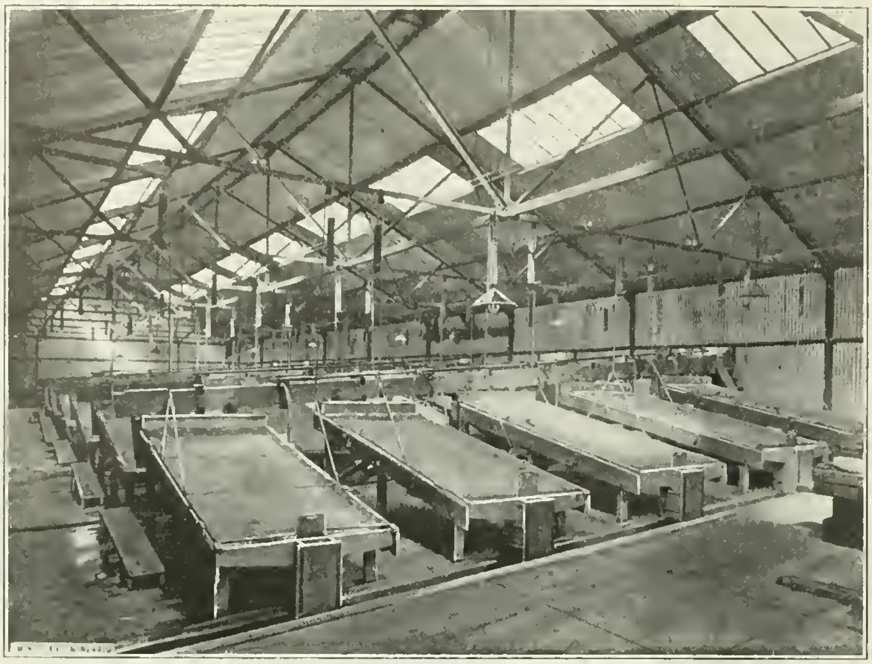

Fig. 3. Amalgamating Tables

each leaf having a filtering area of 80 square feet, or a total area of about 27,000 square feet. The stock-pulp tank is provided with a paddle agitator and is 60 feet in diameter by 10 feet deep. The stock-solution tank has the same dimensions and holds 1,000 tons. There are cone bottom excess-pulp and excess-solution tanks each 65 feet in diameter by 6 feet to 11 feet deep, also a weak-solution tank of the same dimensions, and two sand-bottom classifiers, 50 feet in diameter by 8 feet deep taking the solution from the filter leaves. The sump tanks are as follows: One slime gold-solution tank, 65 feet in diameter by 6 feet deep; three sand gold-solution tanks, 50 feet in diameter by 6 feet deep; one slime barren-solution tank, 20 feet in diameter by 8 feet deep; two sand barren-solution tanks, 60 feet in diameter by 10 feet deep; and another one 65 feet in diameter by 6 feet deep.

For precipitation, weighed amounts of zinc in proportion to the amount of solution to be precipitated are fed by three belts, with barren solution, to the suction of three triplex pumps driven by 10-horsepower motors and then to three 52-inch Merrill presses, capacity 1,000 tons of solution per day each, the precipitated solution passing to the barren solution sumps. The Merrill presses are situated in the extractor house, along with the amalgamating plates and refining furnaces, enabling all the gold-recovery processes to take place under one roof under the supervision of one operating staff.

A small elevator is provided to raise the gold slime to the acid tank, which, after being acid treated is collected in a small filter press. There is a reverberatory furnace holding 20 No. 100 pots, a drying oven for eight 3'×2'×6" pans, a ball mill for grinding slag, etc., three amalgamating barrels for black sand, with batea, amalgamating plates, and settling tanks, two 4½-inch amalgam presses, and two amalgam retorts.

Space has been provided for the addition of 40 stamps, four tube mills, the necessary amalgamating plates, and cyanide tanks. The plant was designed for 60,000 tons a month, but recent experience has shown that the capacity of the battery was underestimated.

The returns for the month of May, 1912, show that 130 stamps and six tube mills crushed 53,650 tons of ore, yielding 20,821 ounces of gold valued at £88,442, giving a working profit of £40,317, at a cost of 17s. 11d. per ton treated.

The Smoke Problem

In the fall of 1911 the Department of Industrial Research of the University of Pittsburg was provided by a Pittsburg business man with funds for a thorough investigation of the smoke nuisance. At the present time the investigation is being conducted by a staff of 25 specialists, of which seven are giving their entire attention to this task. Some of these men are studying the effect of smoke and soot on the atmosphere, on the weather, on plant life, on buildings, on the public health; some are investigating the economic damage done by smoke and soot; others are making a detailed study of the mechanical devices for preventing or abating smoke; and still others are inquiring into the chemistry and physics of smoke and soot, into the laws concerning the smoke nuisance, and into the history of the subject as a whole.

Recognizing the interest in the smoke problem manifested by a large number of American cities, and in response to inquiries that have been made, the Department announces that the members of its staff are prepared to lecture on the following phases of this problem:

1. The Smoke Nuisance (A general presentation of the subject.)
2. Smoke and the Public Health.
3. Smoke and the Cost of Living.
4. Smoke and Plant Life.
5. Methods and Means of Smoke Abatement.
6. The Effect of Smoke on Buildings and Building Materials.
7. The Psychology of Smoke.
8. The Smoke Nuisance and the Housekeeper.

For further particulars apply to Dr. R. C. Benner, Department of Industrial Research, University of Pittsburg, Pittsburg.

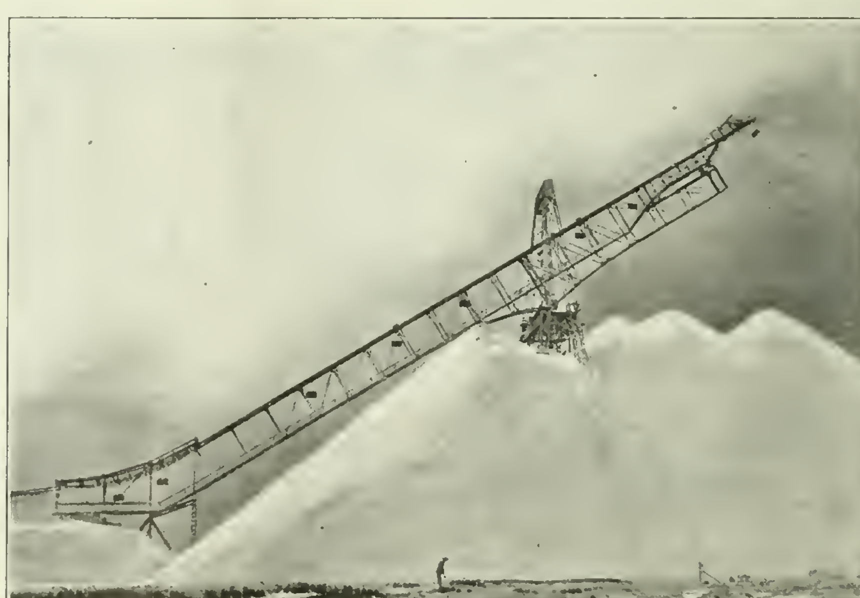

Fig. 4 Aerial Sand Dump

Shaft Upraising Profitable

Driving a Raise to Surface by Use of a Swinging Platform Hanging from a Cable Through a Bore Hole

By *Lucius L. Wittich*

Both in point of time and money a great saving was accomplished at the property of the Nowata Lead and Zinc Co., at Duenweg, Mo., when a new shaft was made by driving an upraise to the surface. H. Correll, manager of the company, undertook the work of upraising on his own responsibility after having received bids for sinking the shaft by contract. The lowest contract bid received was $15.50 per foot, for a shaft 5 ft. x 7 ft. in the clear, put down to a depth of 210 feet. This would have meant an expenditure of $3,255, to say nothing of the greater time required. Although the upraising was purely an experiment, the first instance of the kind in the Missouri-Kansas-Oklahoma district, and although many unforseen difficulties arose which can be remedied in subsequent operations of a similar nature, the aggregate cost of upraising the shaft was only $1,273.58, or $6.06 per foot. This saving of $1,981.42 has convinced the company that where it is possible to start at the bottom, that is the wise course to pursue. The company has started a second upraise for a shaft, and it is safe to prophesy that the cost figures will show a still greater saving.

The existence of a 6-inch drill hole at a point where his company desired to sink a new shaft caused Mr. Correll to consider the advisability of using the hole as a medium through which a cable could be passed, to support a working platform at the lower end. Fig. 1 shows the plan adopted in upraising for the shaft. At the top, near the drill hole opening, was stationed a hoister, which was operated so little of the time that an expenditure of 50 cents a day for natural gas for fuel defrayed the cost. As this was a minimum flat rate it was in excess of what would have been charged had only the gas really used been paid for. The drill hole extended into the drifts of the mine, the distance from the surface to the roof of the drift where the drill broke through being 210 feet. Through the drill hole was lowered a ⅝-inch cable, which passed over a pulley in a derrick and thence to the hoister.

At the lower end, the cable was attached to a specially constructed platform, built of 2"×4" and 4"×4" oak lumber, the size of the platform being 4 ft. 8 in. x 6 ft. 8 in., thus leaving 2 inches in the clear, all around, when the platform was hoisted into the upraise. The aggregate weight of the platform, operators, and equipment was 800 pounds, divided as follows: stoping drill, 110 pounds; steel, 50 pounds; two operators, 300 pounds; platform, 340 pounds.

Starting the shaft in the roof of the drift was much the same as starting it in solid ground at the surface. The 5'×7' space was marked out, with the drill hole as its center, and the work of shooting

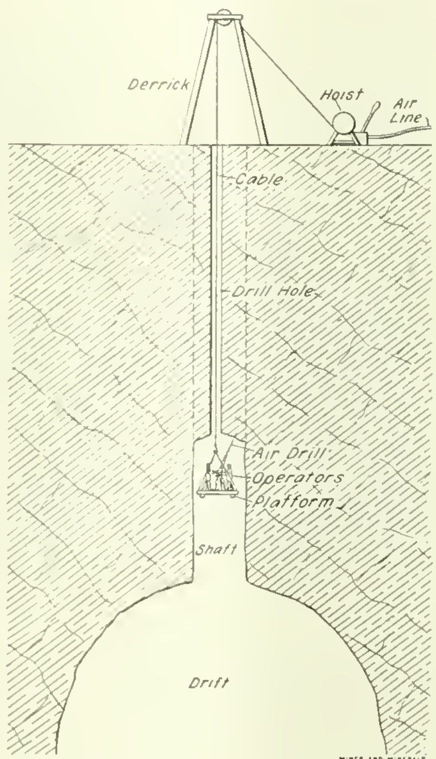

Fig. 1. Method of Upraising

down the rock started. The platform was supported by four iron bars, fastened at the corners of the platform, and meeting at a point above the center, high enough

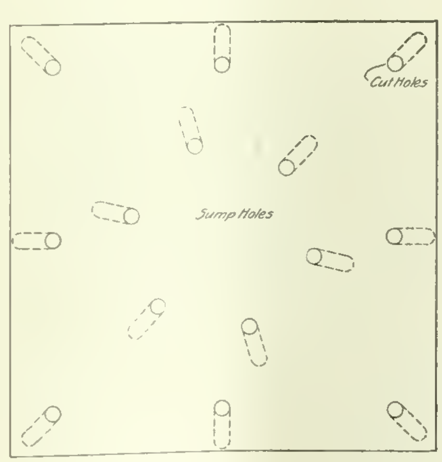

Fig. 2

to permit the operators to work freely. A hook permitted the cable to be detached from the platform; thus when shots were fired the platform was lowered to the floor of the drift and pulled to a point of safety to be out of the way of falling rock, while the detachable cable was hoisted up the drill hole in order that it might not be damaged by the blast.

From the time the first round of shots was placed in the roof of the upraise until the shaft was completed, cribbing being included, fifty-two 8-hour shifts were required. This was about a third of the time usually required for sinking a shaft of similar dimensions. The cribbing was installed from the bottom up.

In upraising, 14 holes were driven to a depth of 5 feet in the roof, as shown in Fig. 2. Six of these corresponded to the ordinary sump holes used in sinking a shaft from the top down, while eight corresponded to the cut holes, four of these being driven near the corners and four along the edges, midway between the corner holes. Each hole was loaded with four sticks of dynamite, a total of 56 sticks for one charge. Forty-per-cent. dynamite was used. During the upraising of the first 100 feet the shots were fired from below, the electrical shot firer being stationed in a drift. During the remainder of the work, the shots were fired from the surface. A signal cord down the drill hole enabled the operators to signal to the hoisting engineer.

The 18 feet of surface soil was shot down at a single blast, the drill hole being plugged at the bottom and loaded with dynamite. The result of the blast was an opening more than large enough to accommodate an ordinary mine bucket, and in this bucket workmen were lowered and the edges blasted out and trimmed. It was this final step that Mr. Correll considers his one big mistake. He believes matters could have been expedited by first sinking from the surface down to the hard limestone, then beginning the upraise. As it was, an enormous mass of surface dirt was shot into the drifts when the surface was blasted down, and this became a sticky mass following a heavy rain. It was almost impossible to remove it, and as a result much valuable time was lost. The surface caved, also, to some extent, but heavy concrete walls were built down to the limestone, thus making it secure.

The upraising method has many advantages over the former methods of shaft excavating employed in the district. Ordinarily in shaft sinking the necessity of removing the pumps before each blast, or the necessity of at least covering them with heavy timbers, is of greatest importance. Repairs are constantly being made to the pumps as the result of damage from the shots. Water is invariably rising in the sump and the workmen have an unsanitary place in which to toil. As virtually all of the larger mines of the district frequently used from one to half a dozen extra shafts, exclusive of the mill shaft, and as the underground workings usually connect, the possibility of making an upraise is found on every hand.

The cost item of $1,273.58 includes the fuel, wages, powder, timbering, every feature in fact of the work; it even includes the purchase price of the stope drill, $135. However, it does not include the cost of sinking the 6-inch drill hole, which was already at hand. If it had been necessary to sink such a hole, the added cost would have been 80 cents per foot, including the casing, meaning a total of $168 to be added to the figures already given. Many mines, however, have their drill holes already sunk, that can be used as was the one at the Nowata company.

At all times the ventilation was good, as the fumes quickly lifted through the drill hole. In this respect the method is even better than the methods of upraising employed in many of the western mines, where pens are built to hold the working platforms. In such cases, the air may become foul at the highest point of operation.

Concentration at the Butte and Superior Mill

The following description of the very interesting practice being conducted in the new mill at the Black Rock mine, north of Butte, Mont., was written by Prof. George W. Schneider, of the Colorado School of Mines, after a recent visit to this plant, and was published in the *Rocky Mountain News*, Denver, Colo.

What may be considered the last word in zinc concentration is the new Butte and Superior mill, at Butte, built for the treatment of the zinc ores which are the principal product of the Butte and Superior Co. operating the Black Rock property in North Butte. The ore is practically a clear zinc sulphide, with little or no iron sulphide, a little galena, and some rhodochrosite (carbonate of manganese), occurring in the Butte granite. A simple problem presents itself so far as a separation is concerned, as the usually troublesome iron sulphides are conspicuous by their absence. But the point to be desired, and which has been obtained, is the recovery of a large percentage of the zinc from the gangue material. The ore fed carries about 23.3 per cent. of zinc, the concentrate, 51.4 per cent., and the tailing 3.2 per cent., indicating a 91-per-cent. recovery, which is expected to be increased.

The following is a brief description of the treatment: The ore is hoisted and dumped from mine cars (to be replaced later by skips) to ore bins, thence to 18″ × 30″ Blake crusher for preliminary crushing—thence by belt conveyer to 500-ton circular steel bin, thence to two apron feeders over Berthlett screens, 1½-inch mesh, to two gyratory crushers. Thence over Berthlett screens to two sets of 20″ × 54″ rolls set to one-half inch, and thence on belt conveyer to 1,500-ton bin at head of mill. The preliminary crushing is done in a building at the shaft, and the gyratory and roll crushing is done in a separate building located between the shaft and mill building and connected with same by belt conveyer.

The main mill bin discharges to apron feeders thence to 10-millimeter impact screens—thence to No. 1 elevator, the oversize going to 16″ × 42″ rolls, to No. 1 elevator to 5-millimeter impact screen, after which water is added and the product sent to first set of Janney classifiers, the oversize going to second set of rolls, thence back to No. 1 elevator. The products from the Janney classifiers go to the coarse jigs, the side draw from the same going direct to mineral bin, hutch product to cleaner jigs, and the tail to 6-foot Akron Chilian mill reducing to one-half millimeter, then to second set Janney classifiers, the product from which goes to sand jigs giving a hutch product which goes to No. 5 elevator to No. 3 Janney classifiers to the cleaner jig, and the tail which goes to 4½′ × 20′ tube mill. The cleaner jigs make a first hutch product going to 16″ × 30″ rolls to No. 4 Janney classifier, to Wilfley table, making a lead product which goes to lead bin and a zinc product which goes to zinc bin. No tail is made by the Wilfley. Nos. 2 and 3 hutch products from the cleaner jigs go direct to mineral bin. Tailing from cleaner jig goes to 5-foot Huntington mill, screen 4.5 millimeters, thence to No. 5 elevator and returns to cleaner jigs, making a closed circuit for this product.

The tube mill product goes to mill sump, from which it is raised by two pumps to Dorr classifiers, and the slime going to settling tanks, together with slimes from all the Janney classifiers. Sands are returned to tube mill for further grinding, the fineness required being 150 mesh.

To the settling tanks is added about 8 ounces of copper for each 1,000 gallons of pulp, which, when made slightly acid with sulphuric acid (one-quarter to one-half pound per ton of ore) gives a crystal water and a four to one pulp in about 2 hours. It is this last pulp which is given the oil-flotation treatment, and consists in running same to a chamber where it is heated to 40 degrees centigrade with live steam. Oil commonly known as "candle maker's red oil" is then added in the proportion of about 1 pound per ton of ore. The steam in heating the sulphide expands the gas bubbles, and facilitates the coating of the sulphide particles with the oil. The rhodochrosite in the ore is sufficient to supply the necessary carbon dioxide needed for its flotation. After emulsifying, the product is pumped to the first treatment tank where the entire mass is agitated. A float concentrate is then taken off from the top of the tank and the remaining pulp goes to the second treatment tank where the process is repeated, and thence to the third tank where the pulp is again agitated and the third concentrate taken off. From the third tank the pulp discharge is a final tailing. There is considerable silica mixed with the first concentrates, so they are all cleaned in a second set of tanks, the concentrates from which are the final product, while the tailing is sent back to the first treatment tank for further treatment. The zinc concentrate is shipped to the zinc smelters of Oklahoma and Ohio.

The above treatment was determined upon only after a long series of experiments, starting on a small scale and finally resulting in the renting of the plant of the United Copper Co. at Basin, some 30 miles distant, which was fitted up for the commercial treatment of several thousand tons of ore along the lines here considered. The oil-flotation end of the plant, which is a slime treatment for sulphides, largely employed at the present time in Australia, was worked out by James M. Hyde after experience in that locality.

The new mill has a capacity of 1,000 tons for 24 hours, the size of the main building being 94 ft. × 332 ft. Electric power is used, 1,000 horsepower being required. A new departure is afforded in the operation of all the large shaft clutches which are controlled by compressed air, and 250 gallons of water are required for each ton of ore.

All of the primary concentration is effected by well-known methods, the best standard machinery being employed. The oil flotation, as stated above, is not new, so that no new or radical departures have been adopted, but a sound conservative employment of the best and most recent successful methods to the solution of the problem at hand.

Antimony

Antimonial ores carrying gold and silver are difficult to treat, for the reason that roasting is usually required, and the fact that antimony fuses at a comparatively low temperature renders this difficult. Successful roasting of antimonial ores can be accomplished by treating the ore several times at moderate heat between 400° and 700° F. This gradually volatilizes the antimony and sulphur.

Churn Drill Examination of Placers

Forms of Keeping Records—Cost of Drilling—Remedies for Drilling Troubles—Sources of Error

By James E. Dick, E. M.*
(Concluded from September)

The object of recording is to keep a section of each hole so that, later, when the series of holes is completed, the strata—gold bearing, cemented, clayey, or otherwise—of each hole may be correlated with those strata of the other holes. Things which may not appear to be of importance in the record of an individual hole, may, when read from the accumulated records of all the holes, have considerable bearing.

Fig. 5. Hoisting the Tools

The vertical distribution of the gold (i. e., the horizons of the pay streak or pay streaks); the zones of cemented gravel (false bed rock) or of clays; or the thicknesses of beds of coarse and fine gravel, are all determined from the records. From these same rocks, the contour of the bed rock and the course of the channel may be plotted into comprehensive maps and sections.

In addition to the records of the holes, it is often desirable to keep time records in order to determine the amount of time consumed in each operation, and thus assist in working out cost sheets.

The record of a hole usually consists of a set of sheets—often two and sometimes three. The drill man always keeps a record. In the case of a two-sheet record, the panner also keeps one; and when three sheets are used, one is prepared by the rocker. The accompanying are different types of records that have been used. The type for each individual case will depend upon the nature of the ground and the desire of the operator.

Set No. 1 is the usual type of record. One sheet is kept by the drill man, and the other by the panner. The drill man records the time consumed in each operation, while the panner records the results of his panning, together with the formations encountered and the depths. This kind of record has its main advantage in that the superintendent is not required to be continually about the machine. The time record tells whether or not the work is moving along at a proper rate. But, aside from this advantage, the time record has very little in its favor.

Sometimes a single sheet, like the "Panner's Record," Sheet 2, is used. The drill man records the depths and formations, and the panner fills in the heading under "gold." The third sheet of the set is merely a summing up of the results of all the holes. In this set, the drill man's sheet and the right-hand side of the panner's sheet are kept by using lines as indicated.

Set No. 2 shows a very thorough and convenient type of record. Like Set No. 1, the time sheet is kept by the drill man, and the formations and the gold by the panner. It will be noticed that the sizes of the gold "colors" are recorded by numbers. This is a method used considerably in California, where the meaning of the sizes is generally known. However, it is not advisable to use it generally, as it means nothing to those who are not familiar with the ground or to those for whom the information may be obtained. By using "nuggets," "colors," "dust," and "flour," the records will be better understood, and more easily explained.

Under the heading "formations," are seen such symbols as *L*, *C*, *St*, etc. These are abbreviations and, properly, a key should be printed on the bottom of the record blanks as follows: *C* = coarse; *S* = sand; *Md* = medium; *G* = gravel; *St* = sticky; *M* = much; *Cl* = clay; *F* = fine; *Li* = little; *L* = loose; *V* = very; *Sm* = some.

It is also advisable to use a key at the bottom of the drill man's record as follows: *P* = pipe; *Pul* = pulling; *Pmp* = pumping; *T* = times; *Be* = began; *Stp* = stopped; *drv* = drive; *D* = drilled.

The third sheet in Set 2 is a summing up in condensed form of the calculated results and all other information obtained from each hole. It constitutes a report on the hole.

Set No. 3 contains no record of the time consumed in the various operations, and when such time record is not desired, this makes an ideal set. The manner of keeping the core permits an accurate record of the amount of material taken out. In the case of running ground, the actual length of core and not the depth of hole is used in calculating the value for the hole.

Sometimes it may be better to have the panner keep the record of the formations, and, if so, the headings may be shifted from the drill man's to the panner's sheet. It is best, however, to have this record kept by

Fig. 6. Straightening the Casing

* Akron, Ohio

both men for, in this way, each will act as a check on the other.

Cost of Drilling.—The cost of churn drilling naturally varies between wide limits, and will depend on the following factors: Price of labor—skilled and unskilled; price of fuel; accessibility to a base of supplies: coarseness of gravel; compactness of gravel; depth of gravel; climate—arid or wet; ease or difficulty of moving machine.

Perhaps the most suitable conditions for this drilling are in California, while the most difficult conditions are probably in Alaska and South America. In California, all of the above conditions are favorable; but in Alaska they are all unfavorable, except, perhaps, the items of coarseness, compactness, and depth, which are liable to vary even within a single locality. In southern countries, where the rainfall is heavy, great difficulty may be experienced in moving a machine because of the soft and swampy soil. This adversity applies also in many sections of Alaska, where the drill must be moved over the "tundra," or soft swampy overburden of decomposed moss and vegetable matter. In some cases, the time consumed in moving a machine is twice or thrice as long as that required in sinking a hole, and consequently, such a condition materially increases the cost of drilling.

If the country is arid, water for drilling may have to be hauled long distances. If the country is wet, high water may interfere with the work If a deposit is coarse and compact, the speed of drilling is slow with the cost correspondingly great. If a base of supplies is not within reasonable distance, or if the cost of fuel is excessive, the cost of drilling is high.

The following are actual costs of drilling per day in different states:

California

Machine man	$3.00
Panner	3.00
Fireman	2.50
Roustabout and team	$ 4.00 to 5.00
Superintendent	3.00 to 7.00
Wood	3.00 to 5.00
Repairs	3.00
Rental of machine	5.00
Total	$27.00 to $33.00

Colorado

Machine man	$ 5.00
Panner	3.00
Helper	3 00
Team	$ 2.50 to $ 5.00
Superintendent	3.00 to 7.00
Fuel	1.25 to 5.25
Repairs	1.00 to 2.00
Rental of machine	5 00
Total	$23.75 to $35.25

Alaska

Machine man	$ 5.00
Panner	$ 3.00 to 4.00
Fireman	3.00 to 4.00
Helper	3.00 to 4.00
Team	7.00 to 10.00
Superintendent	7.00
Wood	4.00 to 5.00
Repairs	3.00
Rental	7.00
Total	$42.00 to $49.00

These figures are the operating costs per day rather than the cost of drilling (as usually expressed) per foot drilled; and they may vary greatly even within a given district. It is evident that, if a drill is making but 10 feet per day, the cost per foot will be three times as much as when it is making 30 feet each day. However, in California, the deposits are pretty uniform, and the average cost of drilling per foot is about $2.50. This means that the rate of drilling is 11 to 14 feet per day. The cost in the Breckenridge district of Colorado will average about as in California. In the interior of Alaska, the costs are about $3.50 or $4 per foot, while along the coast, the costs vary between $4 and $8 per foot. This difference between costs in Alaskan districts is explained in the fact that the streams of the coast regions are rapid and consequently have coarse deposits; whereas, the streams of the interior districts have opposite characteristics.

Also, the coast placers are often more isolated and actually more difficult of access.

The division of labor has considerable bearing on the cost of drilling. The most ideal conditions exist when the superintendent does the panning and the helper does the firing. This is impracticable in some cases on account of the extra amount of work caused during the drilling of hard ground. In many districts, it is hard to get men who are willing to work in this fashion.

DRILLING TROUBLES AND THEIR REMEDIES

The difficulties encountered in drilling vary in number and magnitude with the character of the ground. Coarse and deep gravels present the greatest troubles, which arise from the difficulty in driving casing and in keeping the casing straight.

When the casing becomes crooked before the hole reaches a depth of 15 to 20 feet, it is usually an easy matter to straighten it, either by driving wedges alongside of it or by bringing slight pressure against it in some other way. But when greater depths are reached, it is not an easy matter to get the casing back into alinement. The following method will often prove a remedy: Have a long, straight pole, and a sling made of a 6-foot piece of manila rope, doubled. By the use of these, leverage may be had against the casing in any desired direction. Figs. 1 and 6 show the method of using the lever without the sling. This is done while driving, and the helper operates the pole, throwing his weight against it. If the drive head is near the ground, the method shown in Fig. 6 is best. The leverage is obtained

with crowbars. The sling is used when a pressure is desired in such a direction as cannot be obtained with the pole alone. It is fastened to the machine frame and over the end of the pole. The direction of pressure can be adjusted and the length of the rope may be changed by looping it over the end of the pole as many times as necessary.

Occasionally, the casing may be straightened when crooked by turning it half-way around with the heavy chain tongs. When this is done, care should be taken to turn in the direction of screw-threading on the casing. This method seems to be most successful when the entire string of casing is bent throughout; that is, not merely at one or two of the joints, but a little at each joint. The exact condition of the casing can be seen by throwing a light down into it with a mirror, after the water has been pumped out, and by noticing just where the bend is. The cause of the trouble itself can often be discovered in this way. For instance, if the last one or two joints are the only ones at which the bending occurs, this might indicate that the casing has been deflected by the sloping side of a large boulder. In such a case, it will be well to pull up until the casing is again straight and to then drill ahead of the casing.

If the casing has a tendency to dip directly away from the front of the machine, this can be remedied by the simple method of placing a 2"×6" piece of wood of proper length between the casing and the blocks upon which the jack-screws set.

When the casing cannot be driven, it is usually because the shoe is on a boulder or perhaps is wedged between boulders. In either case, it will be necessary to drill with the rock bit ahead of the casing, and clear the way for it. If the boulder is of extreme thickness or toughness, blasting is resorted to. The casing must be pulled up a couple of feet and all the water pumped out before shooting. When the cause of hard driving is tight ground rather than boulders, the speed of the work will be increased by turning the casing around a few times with the chain tongs. This also applies to hard pulling.

Sources of Error.—The sources of error in sampling by this method are numerous and difficult to determine. However, with a thorough knowledge of them and their causes, they can usually be avoided.

The greatest source of error is getting too large or too small a sample. Evidently if the sample is too large the content will be high, while if it is too small, the content will be correspondingly low. The length of core left in the casing after pumping should be such as to prevent an inrush of water. If the water does rush in from hydrostatic pressure on the outside, some gold may be carried from the surrounding ground and the sample will show a value in excess of the truth. Therefore, when possible, the level of water in the casing should be kept the same as the level of ground water, and less core will be required to prevent this error. After pumping, water is poured into the casing until the level remains constant and the core is drilled a little before driving. If the core is not loosened in this way, it may become so solidly packed that, on driving, a part of the gravel (carrying gold) is forced to one side and lost.

A flat rock struck squarely by the shoe and forced ahead will also force the gravel to one side. If a rock is struck by one side of the shoe, it may be forced down and to one side and the gold immediately above and to each side will follow down and be lost. Assume that a long, narrow boulder is struck by one side of the shoe. The other end of the boulder acts as a hinge and the end under the shoe will be swung down, to one side, and all the material underneath it will be carried outside of the path of the casing. All of these cases should be detected by the drill man.

It is essential that the bit be kept sharp. If it is dull and a 4- or 5-inch round boulder gets into the casing, the stone will be driven down and all the core beneath it forced ahead. If, however, the bit be sharp, the boulder will be split and broken and ground up with the rest of the core. The rock bit is the most liable to cause this error, and for this reason this bit should never be used except when absolutely necessary.

The bit should never be below the shoe and the core should always be a few inches in length before driving. If the core is too long, gravel will be forced out of the end of the casing; while if the drilling takes place below the shoe, the gravel will be either forced to one side by the bit or it will be carried into the casing when there is a water pressure on the outside.

Drill results have been shown to vary as much as 200 per cent. above and below the actual results obtained by subsequent operation. In other instances, properties have been "turned down" after testing by drills, whereas later tests by shafts proved the deposits valuable. If the drilling had been carefully and intelligently conducted, such mistakes never would have occurred. When so done, estimates can be made with reasonable certainty and exactness

A Field Inkstand

By E. J. Henkhe

Some time ago there appeared in the columns of Mines and Minerals a suggestion for an ink-bottle holder. Though

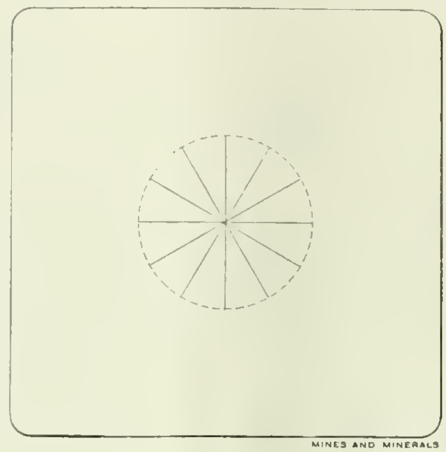

Fig. 1

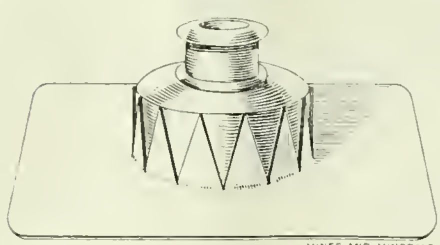

Fig. 2

the scheme was good, yet it is troublesome and cannot be fulfilled without premeditation, as it requires glue, which is not always available in the field or 1,000 feet below the surface. The writer has been using for quite a long time the following holder, which is much simpler, as it can be made in any place where a piece of cardboard and a penknife are available. Take a piece of cardboard and, holding the bottle against it, mark the outline of the bottom, as shown in dotted lines in Fig. 1. With a penknife cut through the cardboard a number of radial lines, as indicated by the full lines in Fig. 1. A number of triangular tongues are thus obtained. Squeeze the bottle through the cardboard, as shown in Fig. 2, and the inkstand is ready. It may now be nailed to any log, or put in an inclined position without fear of being overturned.

Obituary

THOMAS LANE CARTER

Thomas Lane Carter, mining engineer, member of the firm of Osgood, Carter, & Co., of Chicago, lost his life recently in the shaft of the Polaris mine near Dillon, Beaverhead County, Mont.

Mr. Carter was connected in various capacities with South African mines, from 1896 to 1904, being sampler, assayer, and surveyor for the Crown Deep and Robinson Central Deep mines. Later he was employed in engineering investigations in Central Africa. From 1905 to 1908 he was manager of the French G. mine on the Witwatersrand, controlled by H. Eckstein & Co., Johannesburg. Mr. Carter was a frequent contributor to mining publications

GEORGE W. MCCLURE

George W. McClure, one of the first to engage in the construction of blast furnaces about Pittsburg, died on September 4, at the age of 76.

W. W. TWEEDALE

W. W. Tweedale, Superintendent of the Rocky Mountain Fuel Co.'s Frisco mines at Piedmont, Colo., was killed, with his assistant Nathan Rubin, by the explosion of a pocket of gas on August 29. It is presumed that the two men were inspecting the workings to permit Mr. Tweedale to become familiar with them, he being comparatively new to the mine.

First Test of Gatun Lock Gate

The miter gate moving machinery for the first leaf of the Gatun lock gate completed in the construction of the Canal was tested in operation of the leaf on May 13. The west leaf of the upper guard gate in the east chamber of Gatun locks was swung from half-way position to closure, opened fully, closed, and drawn back to half-way position. The complete revolution of the bull wheel, a strut from which moves the gate, occupied 1 minute and 48 seconds, which is 12 seconds less than the time required in the specifications. The machinery worked perfectly, swinging the 448 tons of steel in the gate proper, which is 54 feet high, 65 feet long and 7 feet thick, under perfect control, and without noise or vibration.

Practical Cyaniding—Part 3

Mill Solutions and Leaching—Standardizing Solutions—Electric Current—Mill Treatment of Ores

*By John Randall**

The Solution Man.—The solutions as well as the leaching vats and zinc boxes are in charge of the solution man who acts under the general direction of the mill superintendent or chemist. His shift is either 8 or 12 hours, according to the custom of the camp, and he is not permitted to leave the mill until relieved by the next shift. As soon as practicable after coming on shift he should go over the whole department to ascertain the exact conditions of affairs, particularly noting whether valves have been left open or otherwise misplaced. At the end of the shift he should report to the man relieving him any unusual circumstances or conditions. A card is usually kept showing the stage of progress of each leaching vat and where leaching to, but he should check the correctness of these records by actual observation. He makes titrations of such solutions as are required for his guidance in performing his duties and is expected to keep the standard solution to the proper strength by the addition of cyanide. Should he find any abnormal change in the amount of protective alkali in the solution at any part of the mill he will at once report his discovery to the proper authority. He will keep his solution pumps in order except when needing extraordinary repairs, carefully avoid overflows of solution, see that the vats are properly filled and discharged, and in a mill of moderate capacity is expected to do all the work in the leaching and precipitation departments. The work of packing the zinc boxes is generally done only during the day shift. He assists with the clean-up which generally occurs at the first and middle of each month. If he be active, faithful, and intelligent he he earns better wages than the average workman about a mill. The position is a good post-graduate school for a man having the necessary theoretical knowledge and desirous of fitting himself to take charge of a mill. While there is plenty of hard labor for the solution man to do, he should not always be required to "keep busy" as is the rule with laborers The superintendent in making his rounds of the mill should be well satisfied if he finds everything in good order, even though he should find his solution man sitting down and calmly surveying the flow of the solutions. But when a good solution man begins any task he moves as if he meant to "do it now."

Standardizing the Solution.—The telltale boards of the solution tanks are graduated in tons. If not, a properly graduated board should be put up either at the side or in place of the old one. Table 1 gives the depth of 1 ton of water in tanks of even sizes from 8 to 32 feet in diameter.

Observe by the telltale board the number of tons of solution to be standardized, and by a titration of the solution observe how many tenths of a pound the solution is below the standard. As this amount is required to be added to each ton, the total amount of cyanide required is found by multiplying this amount by the number of tons.

Table 1.—Depth of 1 Ton of Water in Circular Tanks, the Volume of 1 Ton of Water Being Taken at 32 Cubic Feet

Diameter in Feet	Area in Square Feet	Depth of Water in Feet
8	50.27	.636
10	78.54	.408
12	113.10	.282
14	153.94	.208
16	201.06	.159
18	254.47	.126
20	314.16	.102
22	380.13	.084
24	452.39	.071
26	530.93	.060
28	615.75	.052
30	706.86	.045
32	804.25	.040

Example.—There are 80 tons of solution to be standardized and the solution is found to be .2 of a pound below standard. $80 \times .2 = 16$, the number of pounds of cyanide required

As the cyanide is very poisonous it should be handled in a manner involving as little risk as possible. Convenience is also a prime requisite, as the solution man generally has plenty to do. The dissolving box, a wooden box with holes in its bottom, is located over the sump and just below the floor of the precipitating room. The stream of solution continually entering the sump passes through this box. A case of cyanide is brought around and laid on its side. The boards are ripped from the side uppermost and the tin cut around three sides. Lumps of cyanide too large to handle with a miner's shovel are broken with an ax or pick. The amount of cyanide that the dissolving box will hold is known. If it will hold 30 pounds the 16 pounds required in the example is shoveled in, filling it to about half full. The shovel is put back in the opened case of cyanide and never used for any other purpose. The solution man then starts the pump and goes about other work. As in the example noted it would require 8 pounds of cyanide to change the titre of the solution a single point, it will be seen that weighing the cyanide is a needless refinement.

Introducing Oxygen Into Cyanide Solutions.—Air or even pure oxygen in the form of bubbles mixed with a solution has no effect upon it unless actually absorbed (i. e., dissolved) by the solution. High temperature and the presence of dissolved solids reduce the amount of gases a liquid will absorb. Agitation under pressure promotes such absorption.

A theoretically correct method of introducing atmospheric oxygen would require the absorption of all the air admitted to the solution. In this case the amount of air admitted need not be large.

A reciprocating solution pump running sufficiently fast to cause a little water hammer in the pipes is extremely efficient, provided a little air is admitted at some point in the tail-pipe. If the opening in the tail-pipe for drawing in the air is small it will not interfere with the pump in picking up its load on starting. The small quantity of finely divided air thus admitted to the solution and the enormous rise in pressure caused by the stroke at the instant of impact promotes the absorption of the air. Aerating solutions by means of a centrifugal pump with a small inlet at the intake is efficient, and less objectionable than the foregoing from a mechanical standpoint. Raising solutions by means of the air lift is efficient, but would convert caustic lime into carbonate of lime on account of the comparatively large amount of air used and the carbon dioxide it contains.

Showering the solution into the storage tank in the form of a spray, particularly if allowed to fall from a considerable height, is helpful but is open to the same objection as the air lift.

Chemical oxidizers are little used as they are expensive and consume cyanide to some extent. Litharge, PbO, is used with good commercial results in treating some ores which give rise to large amounts of alkaline sulphides in the solution. The lead parts with its oxygen and locks up sulphur by forming the practically insoluble sulphate.

Electric Current.—A method of destroying some reducing agents in a cyanide solution is by passing through it an alternating electric current. The 60-cycle current supplied to many mills as a source of power is said to answer the purpose, but its cost might place it at a disadvantage unless the mining company has its own hydroelectric plant with current to spare. This method is used in a few special cases, but its success depends upon the nature of the reducing agents in the solution. Its efficiency should be determined by laboratory experiment on the mill solution before the apparatus is installed. The alternating current has no effect upon alkaline sulphides, hydrogen sulphide, or ferrocyanides, when added to a laboratory solution. The operator desiring to use this method could suspend in the barren sump

*Boulder, Colo. Article began in August, 1912, number.

two or more ½-inch lead pipes with the bottom ends closed to serve as electrodes, their distance apart to be somewhat greater than half the diameter of the sump. If the sump tank is of wood the electrodes might be placed quite close to opposite sides. The electrodes should be attached to the 110-volt lighting circuit by means of insulated wires controlled by a switch. The resistance of the circuit should be approximately determined before the current is turned on and the probable amperage of the current thus estimated. The current will be found to pervade the entire volume of solution in the tank. A better plan than using the current direct from the lighting circuit would probably be to step the current down to about 10 volts by means of a transformer and correspondingly increase the size of the electrodes, making them of heavy sheet lead.

The cyanide chemist should use every means at his disposal to keep reducing agents in his mill solution down to a reasonably low limit

Mill Treatment of Ore.—The treatment as well as the kind of mill required for a given ore depends upon the facts brought out in the laboratory tests. If there is much ground for doubt, these tests should be verified by sending a quantity of the ore to a custom mill before the construction of a mill is decided.

While varying widely in detail, all ore treatment by the cyanide process must of necessity consist of the following steps:

(*a*) Crushing or grinding.

(*b*) Leaching or agitating with cyanide solution, in order to dissolve the precious metals.

(*c*) Washing the solution and the dissolved metals from the ore.

(*d*) Precipitating the metals from the solution, usually by means of finely divided zinc.

(*e*) Refining the precipitate and melting it into bullion

In detail the principal methods of treatment are as follows:

Coarse, Dry Crushing.—If in order to secure a fair extraction the ore is only required to be crushed to ¼-inch or ½-inch size, it may be treated at a low cost, which sometimes more than compensates for the lower extraction obtained. Presuming that the ore does not require a preliminary water wash to remove soluble acidity, a supply of unslacked lime is provided at the place where the ore is dumped at the top of the mill. With a shovel of the proper size the dumpsman places one shovelful of lime on each car before dumping. An ore breaker and two sets of crushing rolls with their usual accompaniment of screens and elevators will be found sufficient. After passing these the ore falls into the bin, from which it is ready to be charged into the leaching vats. The finish bin should be large enough to hold a comfortable surplus of ore so that a temporary stoppage of the crushing machinery will not interfere with the regular routine of work in the leaching department. Ore of this kind is best sent to the vats by means of a belt conveyer combined with an automatic tripper that can be placed at any vat desired. It is best to have the ore distributed evenly in the vat by some automatic device, as the Blaisdell distributor. If allowed to fall into the vat in conical piles the ore is liable to classify, the coarser particles rolling to the bottom of the pile. This may in part be prevented by spraying cyanide solution upon the stream of ore as it leaves the tripper It is always best to arrange the work of filling and discharging vats as well as other intermittent operations so that they will come at a specified time of the day.

Preliminary Treatment.—When ore contains a considerable quantity of soluble sulphates a preliminary wash may be advisable before percolating with a cyanide solution. This more generally applies to the treatment of old tailing. The wash may consist of water only or a solution of sodium hydrate. In any event alkali should be added toward the end of this preliminary treatment. Whenever pyritic ore is kiln dried previous to dry crushing, soluble sulphates that are destructive to cyanide are formed. The proper remedy for this is wet crushing, preferably in cyanide solution, thus avoiding the cost of drying, as well as the large mechanical loss of cyanide in displacing the preliminary wash with solution. Cases are quite rare in which an ore contains sufficient soluble sulphates to make a preliminary wash advisable with its attendant loss of cyanide that must occur by the dilution of the solution in displacing the moisture left by the wash. If a preliminary wash is used it should not be introduced below the filter, but be put on from the top. If introduced at the bottom, a little cyanide solution left under the filter will be brought up into the ore and occasion a loss of gold.

Putting on the Solution.—Some mills have facilities for circulating two solutions, a standard and a weak solution, but in any event the ore should be first treated with solution of standard strength, the weak solution, if used, serving as a preliminary wash near the end of the leaching period and before the wash water is put on. Sometimes a weak solution is very serviceable in washing out dissolved gold that barren solution of standard strength fails to dislodge from the ore particles. The first solution is put on from the bottom of the vat through a pipe communicating with the space below the filter cloth, and allowed to run on so slowly as not to make channels in the ore charge. The best way to accomplish this is to bush the pipe down to the proper sized opening at some convenient point so that the valve may be opened to its full extent without danger. As soon as the solution has risen to within 18 inches of the top it may be started on from the top also in order to expedite the operation. After the ore is covered to a depth of 6 inches the solution is shut off and the vat allowed to stand 1 or 2 hours before leaching begins. Generally speaking, leaching with standard solution should be continued during the time required for extraction, regulating the flow of the solution at the valve so that about 5 tons of solution shall be used per ton of ore during the treatment. More solution than this would require a needless amount to be passed through the zinc boxes. This rule is of a general character only, and might in special cases be exceeded.

Special Method of Treating Coarsely Crushed Ore.—In treating the ore under present consideration it is generally found best to repeatedly drain the charge, all the applications, of solutions after the first being put on from top, the leaching valve being closed for, say 2 hours, after the application of each quantity of solution, after which the vat may be allowed to slowly percolate, the ore being in the meantime kept covered with solution slowly added at the top. When it is desired to drain the charge, the leaching valve is opened wider and the solution rapidly run off, a sufficient interval of draining being allowed to filter off all the solution that will readily come away, bearing in mind that the ore is under treatment and gold is being dissolved during this draining process, with access of air to the charge. Assays of the solution at the end of the draining process are instructive in this regard, but in order to assign a practical value to these high assays the smaller flow of solution must be taken into consideration. The process applied to this coarse ore becomes one of maceration rather than percolation and its success is more marked in cases where the charge is not entirely homogeneous on account of poor distribution while filling. After a number of applications of the standard solution one or at the most two applications of the weak solution may be made in the same manner, the first weak solution being sent to the strong gold solution tank. At last the wash water is applied in the same manner, but no time for slow percolation need be allowed, the wash being rapidly run off to the weak gold tank. The rate at which the solutions are run off has some influence on the amount which can be taken off, which should be as great as possible within a reasonable time. Under some conditions too rapid draining causes solution to be entrapped in the ore by air coming in below it, thus making a much less complete draining possible. The operator will ascertain the proper rate at which the charge should be drained by careful and intelligent observation, sparing no pains in arriving at the best obtainable result. This maceration method is of doubtful advantage in the treatment of finely crushed and less permeable ore charges.

Discharging the Tailing.—If sufficient water is available and the tailing can be allowed to run into an adjacent stream or to a flat piece of ground of considerable extent, sluicing by means of water delivered at a hose nozzle under considerable pressure is by far the cheapest method of emptying the vat. The vat should be full of water, the hose made ready, then the bottom discharge gates dropped. In the case of the coarsely crushed ore, the tailing will rush out as soon as a gate is opened. In discharging finely crushed tailing the charge should be first saturated with water but the ore not covered. The pipeman walks out to a point above the open discharge gate, directs the stream down into the sand and pushes the hose pipe straight down until the sand begins to cave and run through the gate. The sand is then broken down by the stream as rapidly as possible. The greater part of the sand can be removed by undercutting the bank with the stream and allowing it to fall toward the discharge gate. The bottom is cleaned up with a smaller stream of water at a lower pressure in order to avoid damage to the filter cloth. The filter is then examined and if necessary holes are patched, bits of canvas, sail needles and waxed thread being on hand for that purpose. The practice of nailing patches to the filter rack should not be countenanced. Sand will work through between the nails while sluicing, and if it is necessary to afterwards take up the filter the cloth is ruined. When the discharge gates are closed they should be tested with a little water to see that they are tight. This may be the duty of the solution man, but after the next charge of ore is in and the solution has been put on, the mill superintendent should go under the vat to see that the gate is not leaking.

In case water cannot be used for discharging the tailing, a belt-conveyer system may be installed. This in connection with the Blaisdell excavator leaves nothing to be desired, provided the enterprise warrants a considerable expenditure for equipment. Where the Blaisdell system is used, good distribution of the charge is secured at a low cost. In a small plant the tailing may be shoveled into cars running on tracks under the vats. When vats are discharged by shoveling, cocoa matting should be laid on the filter to protect the canvas.

Leaching Finely Crushed Ore.—If the ore has been roasted it can generally be leached without separating the dust. The heat used in roasting dehydrates the clayey matter that would otherwise form slime and impede or prevent leaching. The first solution is put on as directed for coarsely crushed ore. Then leaching is begun and continued throughout the time allotted for treatment. The charge is in some cases drained once or twice to admit air, but draining generally has the effect of packing the charge. It is not generally considered best to drain between the application of different solutions as the following solution will mix less with the preceding one if put on as soon as the first has disappeared from the surface. The percolation then proceeds continuously.

A vat charge of finely crushed ore, after draining, contains a large amount of moisture held by capillary attraction. The next solution put on runs down into the charge at once and is mixed with this moisture. Air is also entrapped which for a time impedes percolation.

Weak Solution.—After putting on weak solution the vat is left leaching to the strong gold tank for a specified period or until a titration shows the effluent to be sufficiently weak. This point is determined by the necessity of keeping a convenient amount of each solution in circulation.

Wash Water.—No definite rule can be laid down for applying the wash water. The practice will vary according to the kind of the ore. Sometimes good results are obtained by using the same method for the wash water as has been recommended for the weak solution. In other cases it has been found quite beneficial to first drain the vat and then run on the water in small amounts, not more than 3 inches in depth at a time, with an interval allowed for draining between each application of water. The amount of water used is of necessity determined by the question of keeping a convenient quantity of mill solution in circulation.

Shortage or excess of solution. If the mill is short of solution the leaching vats may be more thoroughly washed with water. On no account should any fresh solution be made up to supply such deficiency. In a carefully operated mill there is little or no necessity of ever running solution to waste in order to reduce the stock. If sufficient time is allowed for extraction in the vats, the last solutions are in reality a wash, and the very large amount of moisture unavoidably discharged with the tailing keeps the quantity of solution within convenient limits.

Two solutions vs. one. With the increasing use of weaker standard solutions the necessity for a second solution is much less apparent than formerly. It is often not regarded worth while to run the extra set of zinc boxes required by the second solution.

Fine Crushing.—Millmen in most cyanide plants try to crush the ore only sufficiently fine to liberate the gold, knowing that in so doing a large percentage of the crushed material will be much finer. When crushing to a 40-mesh screen, it may be that 86 per cent. of the product will pass through a 100-mesh screen and 46 per cent. of the remainder will pass through a 150-mesh screen. In fact when crushing to a 30-mesh screen, over 50 per cent. may pass through a 200-mesh screen and be considered slime. The quantity of material finer than the screen crushed through depends on the kind of ore and the machine used in crushing. If the stamp mill, Huntington mill, or Chilian mill is used, the fineness of the material will be influenced by the height of the discharge above the die. The quantity of water used in crushing also has considerable bearing on the amount of fine ore made. In one instance, when the ratio of ore to water was $\frac{1}{6.39}$, 43.57 per cent. of the ore passed through a 100-mesh screen, while, when the ratio was $\frac{1}{4.2}$, 56.15 per cent. of the ore passed the same screen. When dry crushing was attempted, 22.6 per cent. of the ore passed the screen in the same period of time, but 45 per cent. of the ore in the mortar box was finer than 120 mesh. In Table 2 are shown the results of tests made with ore after flowing over an amalgamating plate. These tests show that the coarser ore contains the greatest values, and that while 54.6 per cent. of the ore was finer than 150 mesh it contained but $1.24 to the ton; under such circumstances, the coarser ore must be crushed finer if cyaniding is to be effective. The signs + and − indicate the ore remaining on or passing through the screens. Thus −60 +90 means passing through 60 and remaining on 90.

Table 2.—Pulp Sized and Assayed After Amalgamation

Mesh	Per Cent.	Assay Value	Total
+ 60	14.6	$9.09	$1.327
− 60+ 90	16.5	8.16	1.346
− 90+100	5.8	4.65	.270
−100+150	8.5	3.00	.255
−150	54.6	1.24	.677
	100.0		$3.875

Wet fine crushing for cyanide treatment is almost invariably done in solution. The solution circulated through the grinding or crushing machinery is called the battery or mill solution to distinguish it from the barren and wash solutions. Unless the ore is all ground to slime it is necessary to classify the product of the grinding or crushing machinery into sand and slime.

Before wet crushed ore can be made leachable, the slime, which for convenience is classed as all material finer than 150 or 200 mesh, must be removed. Hydraulic sizers and classifiers such as are used in concentrating mills have not been found satisfactory when operated by cyanide solution, and the Dorr classifier is almost exclusively used for this purpose. These machines separate the sand by dragging or scraping it up an inclined plane while washing it with a spray of solution. It is best to have the sand clean, as a little coating of slime over the grains of sand materially hinders extraction. Experiments have demonstrated that each per cent. of slime contained in a sand charge lowers the extraction about 1 per cent. This applies to the colloidal slime formed during the wet crushing of an ore.

Manner of Filling.—When sand is washed into a vat by means of water or solution it tends to classify, the coarser and finer grains becoming separated, also a little motion of the pulp in the solution causes the sand to pack, the smaller grains filling the voids between the larger, thus hindering leaching. No matter how free from slime the sand is when it starts on its journey to the leaching vat, if the ore is somewhat soft the grinding of its particles in the launders and distributing pipes will produce some slime. Under the constant movement of the solution this slime will classify in the vat to some extent. On examining a charge filled by means of a Butters distributor the trace of the distributor jets can often be discerned in the annular rings of partly classified material. The fault is not in the distributor but in distributing with solution. For these reasons wet filling is not so much in vogue as formerly.

A better method is to take the dewatered sand as it comes from the Dorr classifier and transport it directly to the leaching vat by a belt conveyer. The charge may be automatically leveled as the filling proceeds, by the Blaisdell system, or in a smaller plant, where the cost of distributing machinery is not warranted, the conveyer system may be placed sufficiently high to admit of leveling by hand labor. If the leaching valve is kept open during the filling and leveling, there will be no danger of packing the charge. In some mills the sand is run into receiving vats by means of Butters distributors, and after draining is transferred to the leaching vats. This secures equally good results, but has no advantages over direct filling provided the filling is properly done. The dewatering of the sand is beneficial in case it is necessary to give the charge more air than can be carried by the solution.

A method of filling to keep up protective alkalinity is to feed a small quantity of crushed lime to the sand as it travels in the launder or on the belt conveyer. Some ores consume alkali during the entire time of treatment and if the charge is deep or the percolation slow the free alkali is liable to become exhausted from the solution before it reaches the filter. Small granules of unslacked lime distributed through the charge dissolve slowly and give out alkali to the solution during the entire leaching period. The lime should be crushed to an 8-mesh screen and may be fed to the belt conveyer by means of a mechanical feeder. The feeder should be belt driven. The hopper may be of the same size as used for stamp mill feeders but the shaking tray should be only about 3 inches wide. The tray is pulled backward by means of a cam and a spring throws it forward striking a stop which jars down a small portion of lime at each stroke. The position of the stop is adjusted by means of a screw which regulates the length of the stroke. One filling of the hopper may answer for several hundred tons of ore, but in some cases it is extremely important to have this small portion of lime fed into the vat in this way.

All-Sliming.—Whenever it is necessary to reduce all of the ore to slime, it is most economical to put a coarse screen (3 or 4 mesh) on the stamp batteries and send the battery product to a tube mill. It is necessary to dewater and classify the material between the stamps and tube mill, as either slime or an excess of water in the tube mill will greatly reduce capacity. A Dorr classifier is used to fill both these requirements. The tube mill discharge contains some coarse sand and this discharge is therefore returned to the classifier, the oversize passing through the mill a second time. In mills of low capacity, a slowly running Chilian mill with a high discharge is sometimes placed below the stamps for sliming, but this plan is not recommended where low milling cost is of first importance.

In mills of considerable size, three-stage grinding is practiced with a considerable saving in cost of equipment as it very greatly increases the capacity of the different machines. Four-mesh screens are put on the stamp batteries, this product is sent to Chilian mills crushing to an 8-mesh screen, and the Chilian mill product sent to tube mills, the slime being separated after leaving the Chilian mills. By this arrangement it would be quite easy to slime 150 tons of ore per day with twenty 1,000-pound stamps, one 6-foot Chilian mill and two $5' \times 22'$ tube mills. This allows for a stamp duty of $7\frac{1}{2}$ tons per stamp, which is rather low when crushing to a 4-mesh screen. A considerable portion of the ore would be slimed in the Chilian mill, thus relieving the tube mills. In any arrangement for stage crushing the sizes of screen openings are adjusted to balance up the work done at the different stages, regard being had to the hardness of the ore and the efficiency of each machine.

Experiments in tube milling show that, with possibly slight variations for different ores and makes of mills, the moisture in the feed should be kept at 38 to 40 per cent., and in any event regulated within very narrow limits. A little variation from this "critical point" causes a serious falling off in efficiency. In one series of experiments it was found that with a feed containing 39-per-cent. moisture three 5-foot tube mills would do the same work as four of the same mills working on a feed containing either 36 or 48 per-cent. moisture.

(To be Continued)

Zinc mixes with lead when heated but separates when cooled. The amount that will remain permanently alloyed depends upon the temperature of lead.

Domestic Camp Science

Oregon Agricultural College, Corvallis, Ore., has issued a bulletin on "Camp Cookery." It contains 31 pages of practical and useful information for those who spread their table under the greenwood bough. It was prepared by the school of domestic science and art for the special use of forest rangers, campers, mining prospectors, and sportsmen. It follows somewhat the lines of instruction in the course in camp cookery given at the college for the forestry, mining, and surveying students.

Believing that they could relieve some of the "blue days" in camp consequent upon "sad" biscuits, half-cooked "spuds," and monotonously greasy fried things, the domestic science teachers obtained from the forestry department of the college and the Forest Service a ration list and camp equipment selected by men of many years field experience, and prepared a list of 65 carefully selected recipes. These are so simply explained that it takes no initial culinary skill to use them. They are also conveniently indexed at the back of the book.

The ration list, sufficient for one man for 100 days, or 100 men for 1 day, as given, may be used as a basis for making up supplies for camping parties. It includes the following: 100 pounds fresh meat, including fish and poultry; 50 pounds of cured meat, canned meat or cheese; 15 pounds lard; 80 pounds flour, bread, or crackers; 15 pounds corn meal, cereals, macaroni, sago, or corn starch; 5 pounds baking powder or yeast cakes; 40 pounds sugar; 1 gallon molasses; 12 pounds coffee; 2 pounds tea, chocolate or cocoa; 2 cans condensed milk; 10 pounds butter; 20 pounds dried fruit; 20 pounds rice or beans; 100 pounds potatoes or other fresh vegetables; 30 cans canned vegetables or fruit; 4 ounces spices; 4 ounces flavoring extracts; 8 ounces pepper or mustard; 3 quarts pickles; 1 quart vinegar; and 4 pounds salt.

Eggs may be substituted for fresh meat at the rate of 8 eggs to a pound of meat. Fresh and cured meats may be interchanged at the rate of 5 pounds of the fresh or 2 pounds of cured. A substitution of fresh milk may also be made for condensed, at the rate of 5 quarts of fresh to a can of the other. Likewise fresh fruit may take the place of the dried in the ratio of 5 pounds of fresh to 1 pound of dried. A ration, as the word is commonly used, is the food estimated to be necessary for one man for one day. The amount in this list is designed to be sufficiently liberal and varied for all circumstances, and is the maximum which should not be exceeded.

On the basis of this list a party of six may be comfortably fed for 17 days. The cost will vary, necessarily, with the location, being from 45 to 55 cents a man for a day if near large markets and convenient to railways. Where pack horses must be used, or transportation is otherwise difficult, the omission of the heavier provisions, such as canned goods containing much water, and the substitution of more flour, beans, and dried fruits is advised. Where fresh meat cannot be obtained additional bacon and corned beef must be included. Where the campers pack their own food on their backs a still further cut must be made in the heavy things. Under favorable conditions plenty of flour, bacon, rice, beans, oatmeal, cornmeal, tea, sugar, dried fruit, and salt must be taken. As much soap and matches as seems necessary must also be carried.

The pamphlet also explains how to build camp fires, and what should be included in the camp equipment. Among the interesting recipes are those for "army bread," "emergency biscuits," "dough boys," "pulled fire bread," ranchman's bread, flap-jacks, "fried quoits," "Mulligan," "hunter's pudding," and Johnnie cake. This information has long been needed and little has been written before.

Notes on Mine Surveying

Devices for Identifying Stations Underground—Method of Correcting Traverse that Fails to Tie

By H. G. Henderson

The practice of mine surveying from time to time reveals practical points, not only worthy of record by the mine surveyor for his own use on future occasions, but also possessing a larger interest as affecting the general practice in connection with this branch of the industry. Many of these are simple, but if neglected, the surveyor probably will adopt some roundabout method that will possibly tend toward mistakes. For this reason it is thought advisable to put on record one or two brief notes concerning metal mine surveying, which may be of interest to surveyors and engineers engaged in this work. Nothing new or original is claimed in connection with these points, but as they do not appear to have been specifically recorded and made available for public use, they have value.

It is important in mine surveying that the surface and underground measurements tally with each other. To a large extent the accuracy of the plans depends upon the accuracy of the instrument used, and the proverb that "No chain is stronger than its weakest link" holds good in surveying work. There is a temptation in mine practice to reserve the newest and most up-to-date instruments for the surface work, while the older and inferior instruments are used for the underground work. Probably this arises from the mistaken idea that the chief thing to remember is to keep the good instruments from injury as much as possible, and the reluctance to subject them to rough work underground. It is far better, as a practical matter, to use the inferior instruments both at the surface and underground; as any errors inherent in the instrument would manifest themselves in both cases, and on the principle that sometimes two wrongs may make a right, the surface errors would tend to cut out the errors underground, and vice versa. If necessary, the better instrument can then

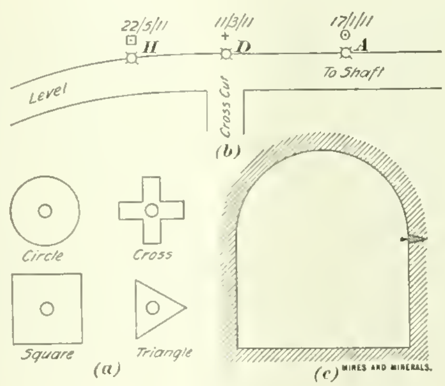

Fig. 1

be used on the surface work to check the readings of the inferior one. As an illustration in point, there was a dispute between two mining companies regarding a question of encroachment. The whole matter turned on the question of the reliability of the plans, and one party as evidence produced a most costly theodolite, and argued that with the use of such an instrument a mistake was practically impossible. This argument, would of course, only hold good if the same instruments were used both on the surface and underground.

One of the greatest difficulties which a surveyor encounters in work carried on underground is the location and identification of the pegs put in at the finish of the last survey in order to form a basis for the commencement of further work. It is often found that these pegs become in course of time covered with slime and dirt and generally must be searched for in order to commence a fresh piece of survey work. The surveyor could easily mistake some other peg put in by the machine drillers or by a miner to hang his jacket on, for the peg which he himself put in at the last survey. The miners who are attendant on the surveyor are generally ready in order to save themselves trouble in the search to assert that the first peg they come across in the neighborhood, is the very one that they put in at his previous visit. Hence it sometimes occurs that the unfortunate surveyor starts his work underground from the wrong peg and then plots it on the mine plan as from the correct peg, with dire results. It is therefore necessary that the surveyor should have distinguishing marks for his own pegs; and a convenient system is for the surveyor to keep in his pockets what may be called "tokens" of different shapes cut out of sheet lead, as illustrated in Fig. 1 (*a*). It will be observed that the names of these tokens, "circles," "crosses," "squares," "triangles," run in what may be termed "dictionary" or alphabetical sequence, and hence the order in which they occur is easily remembered. In order to illustrate their practical use it may be supposed that Fig. 1 (*b*) represents, in plan, a level which is in process of survey. On July 14, 1911, the surveyor went underground with the intention of starting from the peg *D* put in on March 11, 1911, in order to survey a new cross-cut which had been driven. The attendant miners, having scraped away the dirt discovered the peg *A* and are prepared to swear that it is the very peg that they put in on March 11, and the one that the surveyor wants. The distinguishing mark, however, proclaims to the surveyor that this is not the right peg, and he tells them that the proper one is ahead of them, further to the west. The miners next unearth peg *H*, and are confident that now they have the right one. The surveyor, however, sees by the distinguishing mark that they are again wrong, and that since the word "cross" in dictionary sequence lies between the words "circle" and "square," the real peg must be between the two already discovered, and after further search this peg is found.

In practice these tokens are placed as shown in Fig. 1 (*c*). After the necessary hole has been bored, the wooden peg is driven into the wall of the level and the usual nail is hammered into the peg, the token having been strung on to the nail before use. It will, of course, be remembered that in the majority of mines two pegs are left as a base for a further start, and a careful measurement of the distance between these will settle any doubt which might exist. There are, however, many mines where the levels are so narrow and tortuous that only one peg can be left as a base, and therefore the system previously described has been found to be of immense practical benefit and the means of saving much time.

It occasionally happens that, in spite of every care taken by the surveyor to secure accurate results, the measurements taken in the field, when plotted in the office fail to "tie." This may be due either to inaccuracies in the instruments and means of measurement used, or to the unavoidable errors of observation that occasionally fall to the lot of even the most careful operator. It will, of course, be a harassing and sometimes expensive and time-wasting thing to have to go back and resurvey the whole area or that portion which is affected by inaccuracies, and therefore it will be interesting to give a simple method of making the necessary corrections for a closed traverse that on plotting fails to "tie." The method may be followed by reference to Fig. 2 (*a*). Assume that *A B*, *B C*, *C D*, and *D E* are the lines of the survey as plotted and which fail to tie by the distance *E A*. The error may be corrected by assuming that the discrepancy is divided equally over the whole of the series of operations, and in order to make the necessary corrections, a drawing such as is shown in Fig. 2 (*b*), is made.

On a sheet of paper then a straight line is drawn, on which is marked off the successive lengths *A B*, *B C*, *C D*, and *D E* corresponding to the same lines shown in Fig. 2 (*a*). They should, of course, be marked off on the same scale as plotted on the mine map. A perpendicular should then be set at *A* on the line *A E* and the distance *A F* should be marked off on it representing on a magnified scale the length *A E* on the plant. The points *E F* should then be joined by a straight line. At points *B*, *C*, and *D* perpendiculars are

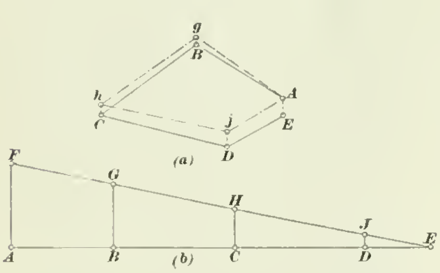

Fig. 2

drawn from *A E* to the line *E F*. Comparing these perpendicular heights with the distance *A F* the length, by scale on the plan, of *B G*, *C H*, and *D J* should be marked upon them.

With a parallel ruler, lines should then be marked off parallel to line *A E*, Fig. 2 (*a*) running through the points *B*, *C*, and *D*, respectively. On these lines the lengths of the respective perpendiculars should be marked off to scale from the perpendiculars in the triangle *A E F*, Fig. 2 (*b*), and when the points *g*, *h*, *j*, have been obtained, lines should be drawn to join the points *A g*, *g h*, *h i* and *j A*. These will represent the closed traverse corrected so as to "tie," distributing the error over the various points in a proportional manner. It will usually be found that this method of correction leads to results which are accurate within any practical limit of error, providing that no gross mistake has been made in one or more of the measurements.

It will be seen from the foregoing that nothing very new has been enunciated and that all of the points raised can be solved by a little common sense. As, however, there is no advantage in each surveyor having to rediscover the best methods of going to work in any particular instance, it is possibly the case that the above notes may serve their turn in facilitating the work of other mining engineers and for this reason they have been written.

Recent Jig Design

Form of Jig Containing Some Improvements that Give Increased Efficiency and Capacity

By Roy Reddie

The jig equipment illustrated in Fig. 2 was designed to replace six "Hartz" jigs of the following dimensions: Four 3-cell 18 in. × 40 in., and two 4-cell 18 in. × 30 in. These jigs were working on a carbonate of zinc ore (Smithsonite) in a decomposed dolomite gangue, which was crushed, sized, and fed to the jigs as follows: $-\frac{1}{2}$ in. + $\frac{3}{8}$ in. to two 3-cell 18 in. × 40 in. jigs; $-\frac{3}{8}$ in. + $\frac{3}{16}$ in. to two 4-cell, 18 in. × 30 in. jigs; $-\frac{3}{16}$ in. + $\frac{3}{32}$ in. to one 3-cell, 18 in. × 40 in. jig; and, $-\frac{3}{32}$ and through the spigot of classifier to one 3-cell, 18 in. × 40 in. jig.

The four jigs handling material over $\frac{3}{16}$ inch in size made screen and hutch concentrate, sending the tailing to a set of rolls for finer crushing, the crushed material being returned to the system. The jigs treating material through $\frac{3}{16}$-inch screen, made screen and hutch concentrate; tailing from these jigs went to the dump.

The concentrate was drawn intermittently from the "bed" through the usual side-draw Heberle gate, Fig. 1. A fairly good grade of shipping concentrate was produced, but to do so required considerable reworking of the hutch concentrate.

The problem was to increase capacity, improve the grade of concentrate, and to decrease working costs.

A simplification of the screening system seemed desirable, so it was decided to adopt one limiting size of trommel screen for admission of jig feed to the system; a $\frac{3}{8}$-inch round hole was fixed upon as the maximum size, and the concentration of this practically unsized feed is effected by jig adjustment rather than by a refinement of sizing.

The equipment designed to meet these conditions consists of a 5-cell rougher jig and a 6-cell cleaner jig, the salient points in the construction of which are shown in the accompanying illustrations. The framing consists of 6″ × 6″ scantling; the posts are gained into, and bolted to the sills by brackets and lag screws, and the bridge trees are gained to receive the posts and bolted to them by means of $1\frac{1}{8}$-inch holding-down bolts. The rigidity of the bridge trees is still further insured by bolting them down to the center partition by an expansion bolt, the center partition having been built up to the bridge trees for this purpose.

The jig tank is built up inside the framing, by spiking together 2″ × 4″ sized timber, the compartments being then lined with 1-inch tongued-and-grooved flooring. A strip of soft cotton wicking should be placed between the 2 × 4's to make them water-tight.

The design seeks to reduce the risk of

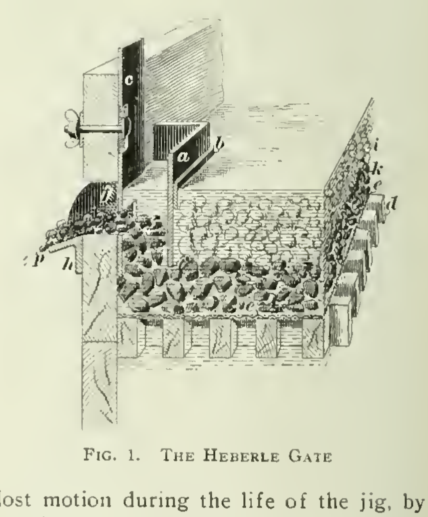

Fig. 1. The Heberle Gate

lost motion during the life of the jig, by providing heavy transmission gear. The $3\frac{7}{16}$-inch shafting runs in heavy plain pillow boxes. The eccentrics are of the readily removable "Clark patent" type. These are massive, readily adjusted, and work without any differential motion. The cleaner-jig shaft is cut on the middle bridge tree to allow a variation of plunger speed between the first three and the last three plungers. Cast-iron grates are used, the openings of the bars running at right angles to the flow of jig feed. These grates are easily "spudded," or cleaned, while the jig is working.

The bottom of the plunger compartment was designed with several ends in view. It will be noted that it is a body of solid concrete, faced with sheet iron, in the form of a paraboloid. This mass of concrete, and the form of it, fulfils the following functions: it increases the rigidity of the structure as a whole; reduces the volume of water to be moved at each stroke of the plunger; reduces the frictional resistance to the flow of water through the throat of the jig; so changes the direction of flow of the jigging water, passing through the throat of the jig, that a comparatively uniform impulse passes upward through the whole screen area; it provides a comparatively still well below the jigging currents, which is favorable to the settlement of fines. It will be noted that the form as well as the depth of the center board influences the pulsion and suction strokes.

The use of a gate and dam at the center of the tail-board will be found to insure a more even bed than the old side-draw gate and dam of the Heberle type can maintain, and the tailings will also discharge more evenly over the tail-board. This tail-board gate will be found equally serviceable for drawing off concentrates or "chats" and it can be worked automatically or intermittently, as desired.

These jigs have met the conditions for which they were designed. Working on a feed which varies from − 3/8 inch to 60 mesh, they are doing much better work than the jigs which they replaced, despite the fact that they are handling a large proportion of fine feed, from 20 mesh to 60 mesh, that was formerly concentrated on tables.

California Oil in Peru

In the mining section of *Peru To-Day*, it is stated that "Peruvian producers of petroleum, after distilling out the gasoline and kerosene, find a ready market for the residuum in the nitrate fields of Chili. In several places it has displaced coal, but California fuel oil is used in greater quantities, because the Peruvian producers cannot supply the demand. It has been found in the nitrate fields that oil is cheaper, easier to transport, load and unload, requiring no labor or lighterage, and it reduces the cost in the fireroom.

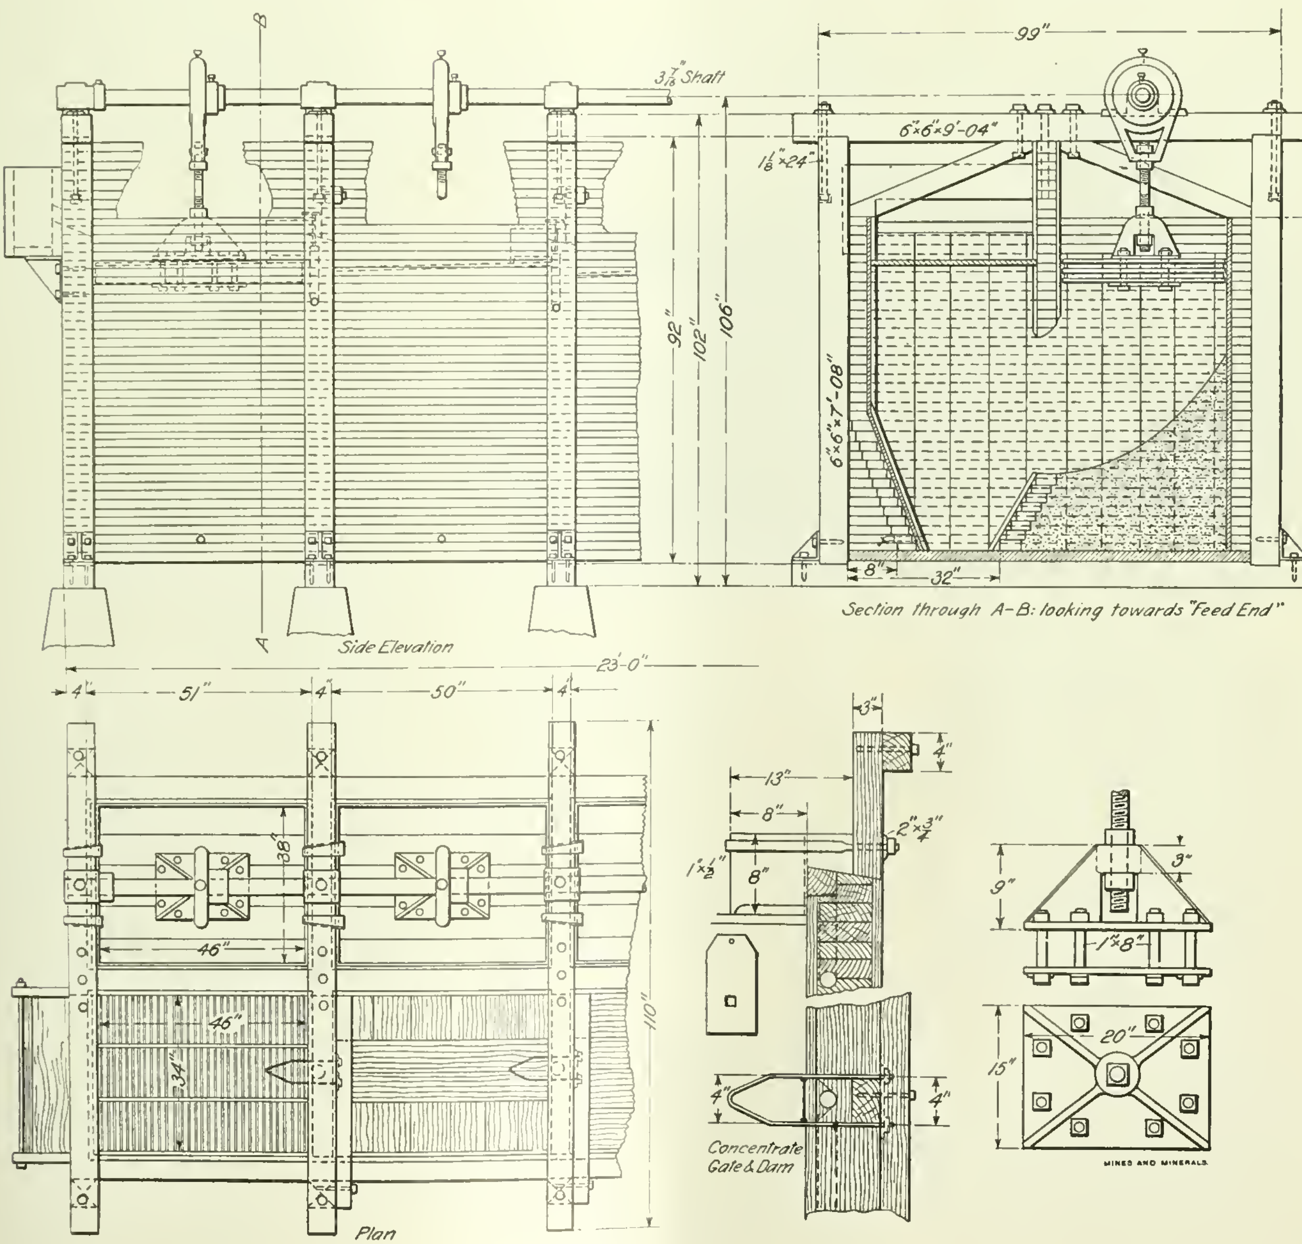

Fig. 2. Rougher Jig

NEW MINING MACHINERY

Direct-Current Turbogenerators

*By J. C. McQuiston**

Turbogenerators are being so generally introduced in mining it is believed the following information will be of interest to readers of Mines and Minerals.

Many are used for exciter sets in alternating-current generating stations, for lighting, pumping, and for storage battery charging. They are particularly applicable for exciter service in modern generating stations where the steam pressure exceeds 125 pounds per square inch, because small reciprocating engines ordinarily used for driving exciters are usually designed for pressures not greater than 125 pounds per square inch. Where the boiler pressure exceeds 125 pounds per square inch, a reducing valve must be used with such engines. Turbines operate directly on pressures up to 200 pounds and with steam superheated to 150° F.

As compared with reciprocating engine sets the features in favor of the turbogenerator set are: Simplicity; reliability; few-moving hence wearing parts; few bearings to oil; compactness and less floor space; less cost for installation; and less oil used.

The line of turbogenerator sets now being manufactured includes machines of the capacities most in demand of from 10 kilowatts to 200 kilowatts. Standard voltages are 125 and 250. Three-wire generators—125 and 250 volts—can be supplied. The steam pressure range is from 75 to 200 pounds per square inch. Either shunt- or compound-wound generators can be furnished. Standard compounding is 118 volts, no load, and 125 volts, full load, or 235 no load, and 250 full load. Compounding can be varied by adjusting the shunt.

*East Pittsburg, Pa.

The Westinghouse Electrical and Mfg. Co., East Pittsburg, Pa., manufacture machines of this type. Fig. 1 shows a turbine of the single wheel impulse type with the upper half of the cylinder and casing removed. The rotor is mounted directly on the end of the generator shaft. Although only one impulse wheel is used, an unusually high efficiency is obtained by using the steam two or more times on the one wheel. The governor is of the flyball kind. In case of overspeeding, the automatic, safety-stop, throttle valve is tripped, thereby immediately shutting off the steam supply.

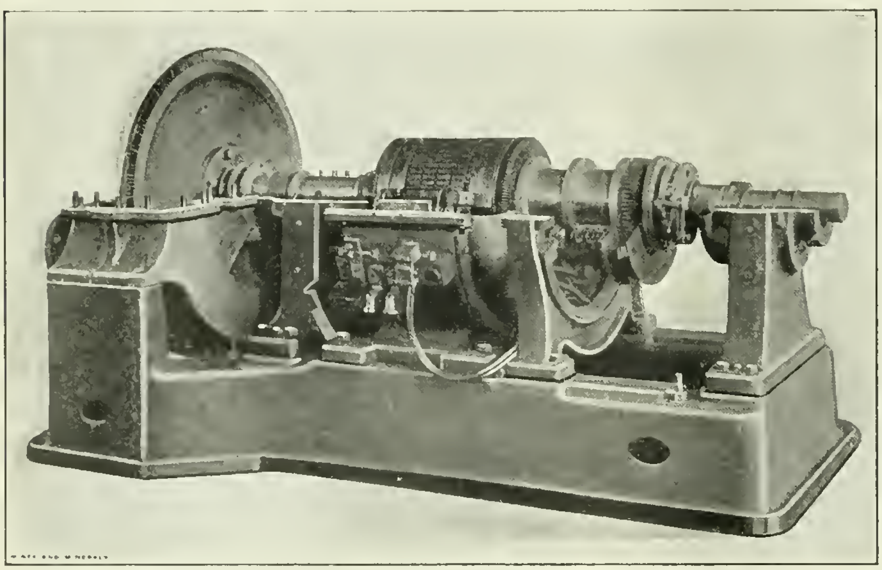

Fig. 1. Direct-Current Turbo Generator With Casing Removed

All parts of the turbine are readily accessible for inspection or repair. The upper half of the cylinder and casing may be removed as shown in Fig. 1, without interfering with the valve or governor mechanism, and, if necessary, the whirl or rotor may be entirely removed from the casing.

Generally speaking, the steam consumption of turbines of small powers compares favorably with the performance of automatic high-speed engines of similar capacity. As the turbines are carefully tested in the shop before shipment, there can be no uncertainty as to their performance. The guarantees of steam consumption are based on an average of actual test results plus a comfortable margin.

Trade Notices

Pipe Line Pumping Equipment.—William Schwashauser, chief engineer of the International Steam Pump Co., has returned from a 3 months trip to Europe, visiting England, Germany, and Russia. While in London he closed a contract with S. Pierson & Son for the entire pumping equipment required for a new oil pipe line now under construction in Mexico. The pumping engines will be furnished by the Fred. N. Prescott Steam Pump Co., of Milwaukee, Wis., and the condensers and auxiliaries by Henry R. Worthington.

New Catalog.—An especially fine catalog (No. 45) has been recently issued by the Ludlow-Saylor Wire Co., of St. Louis, showing the various lines of products made by the company. They report that business is extremely good in all lines, with an exceptionally heavy demand for mining cloth, cement cloth, and other weaving products.

Notice.—John Davis & Son (Derby), Limited, of All Saints' Works, Derby, England, announce that on and after August 29, their house at 110 West Fayette Street, Baltimore, Md., will be closed. All orders for new instruments and for repairs should be addressed to All Saints' Works, Derby, England, where they will be promptly executed.

Covering Steam Pipes.—A neat booklet issued by the Armstrong Cork Co., of Pittsburg, Pa., describes the Nonpareil high-pressure pipe coverings, the methods of applying, together with tests of this and other coverings. It also describes Nonpareil cork covering for use in refrigeration work. The book will be sent free on application.

New Buildings.—Plans have been made by the Western Electric Co. for new buildings to be erected at Hawthorne, Ill., near Chicago, which will cost approximately $750,000, to take care of increases in business in the future. This construction follows out the company's general policy of concentration of the manufacturing part of the business at Hawthorne, where upwards of 11,000 people are now employed. Business during the summer has been increasing rapidly and the conditions are exceedingly satisfactory.

Prospectors' Supplies.—On account of increasing sales and the probable big resumption of prospecting and development this fall and early winter, the Way's Pocket Smelter Co. has found it advisable to separate the manufacturing and selling organizations. In the future, the Way's Pocket Smelter Co. will devote its entire time to making smelters and to experimental work along new lines. The selling organization will be J. W. Swaren & Co., 112 Market Street, San Francisco, Cal., to whom all orders for Way's Smelters and supplies should be addressed. This new company will also handle a complete line of machinery and supplies ordinarily used by prospectors and new properties. Mr. Swaren has been a prospector himself, and appreciates the difficulties met in getting equipment and supplies while out on the hills or on the desert, and his personal attention will be given to securing for customers the best materials on the market.

Coaling Stations.—A contract has recently been awarded the Roberts & Schaefer Co., of Chicago, by the Queen & Crescent Route, for a 500-ton reinforced-concrete Holmen counterbalanced-bucket locomotive coaling station for installation at Ludlow, Ky., near Cincinnati. Contract price is $17,500. The Louisville & Nashville Railroad have also awarded a contract for a 400-ton frame-constructed, counterbalanced-bucket coaling station for installation on their line at Livingston, Ky. The Roberts & Shaefer Co. have also recently secured a contract for a large complete coal-mining plant for the Calgary Coal Syndicate, to be installed at Mitford, Alberta, Can.

Technical Advertisers.—An evidence of the increasing attention being given to the most efficient methods of advertising engineering and technical products appears in the announcement of Wightman & Richards, forming the Technical Department of Jos. A. Richards & Staff, general advertising agents, Tribune Building, New York City, representing the association of Joseph A. Richards, Lucius I. Wightman and Paul Morse Richards. Joseph A. Richards is the head of the agency founded by Joseph H. Richards in 1872, and since identified with conspicuous national successes in advertising salesmanship. Mr. Wightman is an engineer who has for many years specialized in the advertising and marketing of machinery and engineering products. Paul Morse Richards is a publisher, sales manager and advertising man of wide experience. Messrs. Wightman and Richards bring to the field served by the technical press a much needed combination of agency facilities with specialized technical and engineering skill. The new organization guarantees, through specialized service, a judicious administration of any account, combining, as it does, an experienced advertising manager, an engineer, and a sales manager, with a complete corps of trained assistants.

New Calendar

The British Parliment has been weighing the importance of a bill providing for the establishment of a simple and symmetrical business calendar. This bill, as at present prepared, does not propose to alter the ordinary succession of the days of the week. The chief objects to be attained in the enactment are as follows: Each business year will be of four quarters of exactly 91 days, or 13 weeks, each. Any period of 3 successive months will contain this same number of days or of weeks. There must be some plan devised for the absorption of the one extra day in the year, but this can be readily done by the declaration of a holiday. In the event of a leap year, the plan must provide for two such extra days. The adoption of this as a law will effect great simplification of commercial accounting in every line. Americans will be interested in following up this plan in its actual practice.

Book Review

The Examination of Prospects, by C. Godfrey Gunther, E. M., 222 pages, illustrated. McGraw Book Co. Price $2 net. This little volume, in its limp leather binding, fits one's coat pocket, so, no doubt, the author's intention will be fulfilled in the practical use to which the book is put during the field work of examining engineers. As explained in the preface, the book aims to concisely present economic geology in a practical manner and to emphasize the applications of accepted modern views. The writer dwells on the difficulties presented in the valuation of undeveloped mining properties. He devotes the first chapter to a discussion of examinations by going into the very practical methods employed by leading engineers and covering a number of precautions to be exercised. The balance of the book is pure science, as the following chapter headings will indicate: Structural Geology; Structural Features of Ore Deposits; Primary Ores and Their Distribution; Types of Primary Ore Deposits; Primary Ore Shoots; Primary Alteration of Wall Rocks; Alterations by Surface Agencies; Residual Ores and Their Distribution; Secondary Ores and Ore Shoots; Outcrops. The book is profusely illustrated by reproductions of figures that appear classical to readers of the United States Geological Survey publications. Throughout the book, the reader notes the brevity with which each topic is handled, but realizing that he receives the meat of the nut, he experiences a satisfaction that is ofttimes lacking in the persual of books along similar lines.

Hendricks' Commercial Register. S. E. Hendricks Co., publishers, 74 Lafayette Street, New York. 1,574 pages; price $10. The twenty-fifth annual revised edition of Hendricks' Commercial Register of the United States for Buyers and Sellers has just been issued. Its aim is to furnish complete classified lists of manufacturers for the benefit of those who want to buy as well as for those who have something to sell. It covers very completely the architectural, engineering, electrical, mechanical, railroad, mining, manufacturing and kindred trades and professions. The present is by far the most complete edition of this work so far published. The total number of classifications in this book is over 50,000, each representing the manufacturers or dealers of some machine, tool, specialty, or material required in the architectural, engineering, mechanical, electrical, railroad, mine, and kindred industries, representing upwards of 385,000 names and addresses. An important feature of Commercial Register is the simplicity of its classifications. They are so arranged that the book can be used for either purchasing or mailing purposes. It gives much information following the names of thousands of firms that is of great assistance to the buyer. It also includes the trade names of all articles classified in the book as far as they can be secured. The book is revised, improved, and issued annually.

The National Forests

Secretary Wilson, of the United States Department of Agriculture, has decided to establish an experiment station on the Manti National Forest near Ephraim, Utah, for the study of grazing and water protection problems. Already the gathering of observations on the relations of erosion and run-off to the forest cover have begun.

It has already been proved conclusively that the overgrazed condition of areas on which the natural vegetative cover has been seriously altered is responsible for the formation of torrents and the rapid discharge of debris-laden flood waters. In a recent destructive storm the water ran clear from a part of the watershed which was within the National Forest, and in good condition as a result of well-regulated grazing, while from other areas it swept down sand and boulders.

The National Forests provide range during a part or all of the year for a considerable part of the stock produced in the Western States. Approximately one and one-half million head of cattle and horses and seven and one-half million head of sheep and goats occupy the forest lands each year. These figures do not include nearly three hundred thousand calves and over four million lambs and kids for which permits are not required.

The experts of the Department believe that when the ranges which were denuded by many years of improper use are restored to a normal condition of productivity it will be possible to provide feed for a much larger number of stock without injury to forest growths or watersheds, and both the stock grower and the consumer of meat products will thus be benefited.

Sapphire Mines of Northern Kashmir

Valuable Gems Discovered by Wandering Natives in a Wild and Desolate Country

*By J. Godwin**

THE sapphire mines of Northern Kashmir, India, are at about longitude 76° 55′ E and latitude 33° 30′ N. They were discovered through a landslip which brought down the precious stones from the face of a precipitous cliff to the narrow valley below. The beautiful blue color of the crystals and their adamantine luster attracted the curiosity of some Bhootian

A Bombay Rekla

shepherds who frequent these solitary hills during the summer months of July, August, and September. Although these people were ignorant of the value of the stones scattered about the place, they had the common sense to pick up some of the best crystals, which were perfect in color and without flaws, with the hope of exchanging them for salt and sugar. These commodities are very scarce in the hills and can only be procured at a very high price from the traders of Pangi, Chamba, Kulu, and the Simla hills. Finding that the traders eagerly gave them salt, sugar, iron, and other necessaries of life for the stones, the shepherds began a regular exchange with them. The traders reaped a good harvest through the ignorance of these uncivilized people and the Kashmir State lost much wealth.

His Highness the late Maharajah of Jammu and Kashmir, on hearing of the discovery of sapphire mines in his territory, immediately deputed some of his trusted officers to proceed to the mines and collect all the stones procurable and to put guards on the mines to stop further plunder. The sapphires which were brought down from the mines by the officers were worth several thousands of pounds. The journey from the scene of the sapphire mines to Jammu, a distance of over 160 miles, has to be made over dangerous mountain paths and over difficult mountain passes. During the journey some of the sapphires changed hands, but the majority were brought down safely and deposited in the state treasury of Jammu. Thus after many years the illicit trade was stopped.

Some years after the death of the Maharajah the mines were leased to a company for a couple of years. More sapphires worth several thousands of pounds were recovered from the alluvial workings. The company to which the mines were given had a short lease and the difficulties they encountered in carrying out the work were great. The working period was but three months out of the twelve, for the mines were situated at an altitude of 15,000 feet and were in the region of perpetual glaciers and snow. There is small wonder that the company was obliged to retire and abandon the mines.

On my visit to the mines in 1909 to demarcate the boundary, I first turned my attention to the washing of the alluvium to find whether there were any sapphires left from previous washings, but found that not a speck of sapphire worth washing for had been overlooked.

My attention was next drawn to the original mines, 14,500 feet above sea level, but before I traveled up the narrow zigzag path leading to the mines I examined the local geological formation of the hills, and this I found to be mostly plutonic rocks of aqueo-igneous origin, and in some places small laccolites were also observed. In going higher up the slope by the narrow path I looked very closely in order to see whether any veins or even streaks could be found traversing the rocks. I was successful in finding a good many small white streaks of decomposed feldspar running through the rocks. These contained minute specks of sapphires and the most prominent among them were found to be on the face of the cliff some distance below the original mines. This vein had been worked by the company to whom the lease was given, but unfortunately it was unable to follow the vein more than 6 or 8 feet during the working season of 6 months in 2 years. The sapphires which were obtained, although small and not of good color, were encouraging. I examined the veins closely, and it seemed as if these small veins were mere branches emanating from a central source or pocket. It is not improbable that my inference is correct, because those laccolites which were observed distinctly show that the rocks underwent great disturbance at the time when they were intruded by molten magma which not only caused large fissures and fractured the overlying strata, but many small fissures and minute cracks in the surrounding rocks. These fissures were subsequently filled by mineral solutions and crystallized into the valuable gems found. To prove that the inference is correct and that pockets of sapphire still exist in these rocks requires money, patience, and courage.

The original sapphire mines were first discovered through the landslip some 32 years ago. I found the place, but the adjoining rocks had been blasted so that no trace of the original pocket was left for further exploitation. After the landslip some of the most valuable of the sapphires had been picked up by the Bhootian shepherds, but subsequently gems to the value of more than a million pounds were discovered by washing.

From this mine I climbed 500 feet higher and there found a natural pit covered with ice, from which according to the natives many valuable stones were extracted and taken away by robbers from Kulu and the Bashar Hills. Unfortunately I had not been authorized by the Kashmir Government to dig trenches or to examine the mines; hence, after placing a landmark on the spot, I left reluctantly.

During this trip I traced other valuable minerals such as galena, blende, chalcopyrite, extensive beds of sulphur, magnetite, hematite, bauxite, coal, and recently some quartz veins containing gold and silver, but in small quantities. From this it must not be surmised that gold in paying quantities cannot be found in the Jammu and Kashmir Himalayas.

Exploration and prospecting require wealth, courage, and patience. There are few in India who will risk even a mite out of their millions unless they can see

Camel Coach, Bhopal, India

a ready and sure return. As a consequence, industries which are the true source of wealth are neglected. In spite of her great natural resources and aspirations, India will not rise to the level of the other enterprising nations unless the Indians learn to be active and intelligent and to enrich themselves by hard work, perseverance, and definite training.

*Mining and Exploring Officer, Jammu and Kashmir State.

Mines and Minerals

Vol. XXXIII.—No. 4. NOVEMBER, 1912—SCRANTON, PA. Price, 25 Cents

PUBLISHED MONTHLY AT SCRANTON, PA.
ESTABLISHED 1881
INTERNATIONAL TEXTBOOK CO., PUBLISHERS
T. J. FOSTER, President S. P. ALLEN, Secretary E. H. LAWALL, Treasurer
RUFUS J. FOSTER, Vice-President and Manager
EUGENE B. WILSON, Editor HUGH ARCHBALD, E. M., Asst. Editor
CHICAGO OFFICE: 1006 Michigan Ave.
Entered at the Post Office at Scranton, Pa., as second-class matter
Address all business communications to MINES AND MINERALS, Scranton, Pa.
CABLE ADDRESS, "RETSOF, SCRANTON"
LONDON OFFICE: INTERNATIONAL BUILDINGS, KINGSWAY, LONDON, W. C.
SOUTH AFRICAN OFFICE: MANSION HOUSE CHAMBERS, ALDERLEY STREET, CAPE TOWN.
NEW ZEALAND OFFICE: 63 DIXON STREET, WELLINGTON.
AUSTRALIAN OFFICE: 83 PITT STREET, SIDNEY.

SUBSCRIPTION RATES

Single Copies........ 25 cents
Yearly Subscription, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines... $2.00
To Canada........ 2.50
To all other countries........ 3.00

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us.
Notice to discontinue or change of address should be sent to the Scranton office.
When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

IN selecting a mine manager, or a mine foreman, it is just as essential to know under what conditions he made his record as to know the record. An inferior man in charge of a mine where all natural conditions are favorable to economical and safe mining may acquire a better reputation than a superior man in charge of a mine where the natural conditions are not nearly so favorable.

ON another page, Malachi Hogan, an old Irish coal miner and philosopher, discusses with his friend Reilly the work of the Federal Bureau of Mines, from the standpoint of the mine worker. Mr. Hogan expresses himself emphatically on some of the vagaries of the Bureau, and the truths so quaintly expressed in his native brogue will be appreciated by all practical coal-mining men, from miners to general managers.

IN September many of the numerous First-aid corps held competitive contests; and in this issue of MINES AND MINERALS, will be found an account of several. The Wadesville No. 3 First-aid team, one of the 72 which took part in the Philadelphia & Reading Coal and Iron Co.'s contest is shown on the front cover. The subject has left eye bandaged because of an injury and the right arm in splints, because the hand has been crushed. This shows the neat work which first-aid teams perform.

Correction

IN our October issue we entitled the article descriptive of the Christopher No. 2 Mine of the United Coal Mining Co. "Buckner No. 2 Mine" instead of "Christopher No. 2 Mine." The name we used is a local designation, and is not the correct name by which the mine and its product are so favorably known.

Notice

THE Denver editorial office of MINES AND MINERALS was closed on November 1, and all business heretofore transacted there has been transferred to the main offices at Scranton. The editorial force at Scranton has been augmented so that plans for the constant improvement of the journal may be more conveniently and quickly carried out. All mail heretofore sent to Denver should from this date be addressed to Scranton, Pa.

In this connection the management desires to emphatically state that the change and consequent retirement of Prof. A. J. Hoskin as Western Editor is not due in any way to lack of ability or loyalty on his part. On the contrary, if Professor Hoskin's personal affairs permitted his locating in the East, we would have been pleased to retain his services. As it is, he will be an occasional contributor and from time to time will very probably be called on for special service in line with the plans decided on.

Statement

Mines and Minerals, and similar publications are now required, by the Post Office Department, to file, with the Postmaster General, a sworn statement giving the names of the publishers, owners, editors, business managers and, if owned by a corporation, the names of the holders of at least 1 per cent. of the stock, twice each year, and to publish the same in its reading columns. In just what way this information will be of service to the Government we are at loss to understand, but the statement required will be found in this column.

Our readers probably know that Mines and Minerals is one of the properties of the International Textbook Co., whose stock is very widely held, so that while we would gladly do so were it practical, it would be impossible to give a complete list of the stockholders without crowding out of our reading columns, matter of vastly more interest to our subscribers. We have, therefore, taken advantage of the clause which permits us to give only the names of those whose holdings amount to more than 1 per cent. of the stock of the corporation.

Statement of the Ownership, Management, Circulation, etc., of MINES AND MINERALS, published monthly at Scranton, Pa., required by the Act of August 24, 1912.

NAME OF	POST-OFFICE ADDRESS
Editor, E. B. Wilson	Scranton, Pa.
Managing Editor, Rufus J. Foster	Scranton, Pa.
Business Manager Rufus J. Foster	Scranton, Pa.
Publisher, International Textbook Co.	Scranton, Pa.

Owners: (If a corporation, give names and addresses of stockholders holding 1 per cent. or more of total amount of stock.)

T. J. Foster	Scranton, Pa.
Rufus J. Foster	Scranton, Pa.
J. K. Griffith	Pittston, Pa.
Elmer H. Lawall	Wilkes-Barre, Pa.

Known bondholders, mortgagees, and other security holders, holding 1 per cent. or more of total amount of bonds, mortgages, or other securities:

NONE.

Rufus J. Foster,
Business Manager

Sworn to and subscribed before me this 30th day of September, 1912.

Frank Lambader,
[Seal] Notary Public

(My commission expires February 8, 1913.)

Proper Mining Terms

Mining Engineers who are editors have persistently advocated the proper use of mining terms. So early as 1880 Dr. Rossiter W. Raymond compiled a "Glossary of Mining and Metallurgical Terms," which was printed in Vol. IX of the Transactions of American Institute of Mining Engineers, and he has frequently urged engineers to carefully consider their expressions when writing.

The erroneous impression prevails that if a judge, ignorant of a technical meaning, constructs a definition to suit his case, that he has forever defined the word. Mr. D. W. Kuhn, of Pittsburg, Pa., in his remarks on the Sherman anti-trust law said: "A judge in Tennessee held in an elaborate opinion that a mule was a horse, and the court has ever since stuck to that decision." He also commits "lese majeste" and says "the Supreme Court has sometimes as much as said that a mule was a horse and at other times that a mule was not a horse"; but in the face of this the Attorney General "believes every horse is a mule."

The legal fraternity are not the only sinners; young mining engineers and many older ones use colloquialisms, which amount to the use of slang to those not intimately acquainted with the district, and usually leave a doubt in the reader's mind as to the writer's meaning. Take for instance the word "killas," a Cornish term which is used to express a series of more or less fissile sedimentary rocks in the West of England mining region, but not elsewhere. As another example, take the word "elvans," a term which has been applied to almost every kind of rock which occurs in dikes or distinct beds, other than granite, limestone, slate, or shale, and consequently has to be defined to mean anything. This term is also local and confined to Cornwall unless a Cornishman gets away from his native land. While the use of colloquialisms in technical writing tends to spread illiteracy, the misuse of words by those who pose as mining experts is inexcusable. Frequently they will write on anthracite coal, zinc-blende, veins of coal, butt-headings, cross-cuts in coal veins, and numerous other monstrosities. Doctor Chance defined the word heading as "the face where work is being done in driving a horizontal passage."

Miller's definition of heading is "the breast or face of a working."

W. S. Gresley states a "heading is any subterraneous passage driven for the purpose of proving or working the mine." The Standard Dictionary gives the following definition of heading: "A driftway in the line of a tunnel or adit in which men work; also any place where work is being done in driving a horizontal passage."

Coal and Metal Miners' Pocketbook: (1) A continuous passage for air or for use as a manway; a gangway or entry. (2) A connecting passage between two rooms or other working places. The word "heading" is derived from the word "head," meaning a leader. Doctor Chance is right for coal, and Mr. Miller is right for ore; the other definitions are wrong or partly so. An expert must have written the Standard definition to make use of the term *driftway*, and then getting mixed used the Doctor Chance definition.

Many of the so-called "butt entries" are "face entries" in which case the main entry is a butt entry, and some one is going to become mixed. If there is any necessity for using the word "butt," which signifies the short cleat in coal, it should be used correctly. The term "cross-entry" should be given the preference, as it means an entry turned at right angles to the "main entries."

The Institute of Mining and Metallurgy, England, is now trying to standardize mining terms; they should consult our friend T. A. Rickard if in doubt on the proper word to use.

Putting Money into the Ground

ONE hears many caustic remarks about the money that has been wasted—actually thrown away—in mining. There is a very common statement, taken by most people as fact, to the effect that more money has been put into, than has ever been taken out of, the ground. Many people accept this in the same way that they assent to many other popular remarks, giving no considerable amount of thought to the matter but assuming that this epigram must have been coined by somebody who had authority to speak.

It cannot be denied that vast sums of money have been actually thrown away in men's aspirations for mineral wealth. But can anybody deny that just as great sums have been wasted in the pursuit of other forms of wealth? Why has nobody coined the remark that more money has been lost in mercantile lines than has been won from them?

Acknowledging that money has really been lost "in mining," let us consider the manner of its losing. There are certain ways in which this money could be lost that would appeal to us as strictly legitimate; but there are more numerous and unqualifiedly illegitimate ways of unprofitably dispersing capital.

People, as we all know, possess an innate gambling tendency. This has often induced people of small as well as large means to undertake ventures, pure and simple, in mining. Without perhaps a single worthy indication, they have spent good money in the exploitation of ground, in driving long cross-cuts, or in sinking deep shafts or inclines. Is it any wonder that the majority of such undertakings have proved failures? Not at all; nor is it fair to charge such pure speculations against mining proper.

Other people are prone to be induced by the most unwarrantable excuses to prosecute operations in unproved ground. Many persons have spent large amounts in ground exploitation merely in pursuance of dreams, or because thay have been advised by spirits, or the more tangible, but no more reliable, fortune tellers, who are always ready to pervert this industry to their illegitimate ends. Such losses of money should not be placed on the debit side of mining.

Then, too, we must award the wild-catters and mine sharks their just credit for the ill repute into which the mining industry has fallen among their many dupes. Such victims are made to feel that they have really had a taste of mining, but the fact remains that they were never directly concerned with any actual mining. They were no more associated with the business of mining than if they had bought "green goods" or "gold bricks." Consequently, it is only justice to exclude such money losses from the account books of the mining industry.

We can now pass to slightly different sorts of capital expenditure that have almost invariably proved losses. We recognize numerous ways in which persons have unwisely placed money that was presumed to develop mining property.

One very familiar method of parting with money upon the assumption that it is going into mining is to listen to, then believe, and finally to follow, the advice of "practical miners," prospectors, and other persons who lack technical knowledge along geological or mineralogical lines. When anybody has lived in mining communities long enough, he will understand the force of this argument against heeding the advice of all such individuals. This is not meant to imply that all such persons are actually deceitful. It is perhaps true that there is not another class of individuals more absolutely honest at heart than prospectors. Genuine prospectors always expect to win their fortunes from Mother Earth and they have no thought of cheating. They finally become imbued with the idea that they have succeeded in finding their coveted bonanzas; but they usually fail in the culmination of their quests only because they have exhausted their resources. Hence they must find persons of means who will assist them financially to their goals. Their stories are beguiling and they ring with sincerity: sometimes they may prove just as true as they sound; but, more often, these men are so misled by their hopes that realities are unintentionally distorted. Persons who yield to the lure of such tales and eventually regret their steps have no logical reason for placing any censure upon the industry of mining. On the other hand, they should blame themselves roundly and learn the lesson that such a mistake presents.

A certain class of imposters, omnipresent in every new (if not in every old) mining district or camp, stands responsible for a large percentage of the losses incurred by inexperienced mining investors. These men are pretenders pure and simple. They pose as either mining engineers or "practical miners." They are sometimes known among the legitimate engineers as "sidewalk experts." They frequent hotel lobbies and ingratiate themselves with the new arrivals in camp until they overcome their deficiency by a superabundance of cleverly contrived conversation that quite disarms the victims. Whether or not such fakers have any mining propositions worthy of consideration, the chance of success in mining under their guidance is, indeed, precarious. Assuming that such a person really has the right to promote and to develop a given piece of worthy mining property, how much chance does the capitalist have of getting value received for his money if such investment be administered by one ignorant of mining economics? Quite often, these self-styled mining engineers believe themselves to be sincere in their promotions, but they finally come to the miserable terminations of their efforts with absolutely no benefit to their clients and with very little permanent benefit to themselves. Of course, they always see to it that they receive commissions or salaries so long as the funds last.

Personals

John T. Fuller, E. M., formerly with the DeBeers company, South Africa, is now Superintendent of Mines for the Canadian Copper Co., Copper Cliff, Ontario.

Charles L. Fay, mining secretary of the Y. M. C. A., resigned his position October 1, to enter the manufacturing and sale of oils and oil products at Wilkes-Barre, Pa. Mr. Fay will continue as Secretary-Treasurer of the Coal Mining Institute of America.

John P. Reese has been appointed general superintendent of the coal mining operations of the Chicago & Northwestern road. The operations are the Superior Coal Co., of Illinois, and the Consolidation Coal Co., of Iowa.

W. R. Brasher, of St. Charles, Ky., has been appointed assistant mine inspector by Prof. C. J. Norwood, chief inspector of Kentucky, to succeed T. O. Long, whose time has expired.

Old Freibergers in America are arranging for a dinner in New York City around the Christmas holidays. Secretary, C. L. Bryden, 1015 Myrtle St., Scranton, Pa.

Archibald A. C. Dickson, Metallurgist and Mining Engineer, announces the removal of his office from Rejauli P. O., India, to Kodarma, E. I. R., India, where facilities exist for conducting his professional work economically and efficiently.

Robert S. Lewis, Salt Lake City, has been appointed Associate Professor of Mining, State University, Salt Lake City, Utah.

V. H. Hughes, E. M., has been appointed Assistant State Geologist of Missouri.

F. L. Sizer has taken the position of general superintendent of the Mascot Copper Co., at Dos Cabezos, Arizona.

James H. Gardner, formerly Assistant Geologist on the U. S. Geological Survey and recently doing work on the clays, coals, and oil fields for the State Geological Survey of Kentucky, has been engaged by the Topographic and Geologic Survey of Pennsylvania and given charge of the mapping and general study of the Broad Top coal field, with field headquarters at Hopewell, Pa.

Samuel M. McMahon, has been promoted to the position of Superintendent of the La Belle mine, of Wellsburg, West Virginia, belonging to the West Virginia-Pittsburg Coal Co., of Pittsburg.

William O'Conner, F. G. S., Mining Engineer, Argoed, Monmouthshire, England, attended the first-aid contest for the "Muckle Cup" at Inkerman, Pa.

John J. Tierney, Vice-President and General Sales Manager of the Coozer-Pocahontas Sales Co., sailed for Europe October 8, for a well-earned rest. He expects to return in November.

W. E. Fohl, J. Aarons, and R. N. Hosler, Membership Committee of the Coal Mining Institute of America, hereby serve notice that each member is to secure one new member before December 10, 1912.

George Watkin Evans, Mining Engineer, of Seattle, Washington, who has been examining the Ground Hog Coal Field, Hazleton District, British Columbia, was injured while in the field, but is now recovering. He had planned to return but has decided to remain in Seattle for the winter.

Dr. Henry M. Payne, has returned from the Yukon Gold Fields in Alaska, where he spent the summer in consultation work. He is associated with S. T. Williams and staff, 346 Broadway, New York City.

Robert M. Black, formerly engineer with mining companies in Oklahoma, Illinois, and West Virginia, has been chosen for the assistant professorship of mining in the University of Pittsburg, succeeding E. N. Zern, now of the West Virginia University.

Prof. Arthur J. Hoskins, late western editor of Mines and Minerals, has established an office in Room 1221, First National Bank Building, Denver, Colo., to resume the practice of his profession as a mining and metallurgical engineer, giving special attention to examinations, equipment, operation, management, and consultation. Professor Hoskins is eminently qualified to succeed in such work through a diversified experience of nearly 20 years, in which he has combined practical work with close study of the methods applied in successful operations throughout the Rocky Mountain region.

Frank Koester, Consulting Engineer, has removed his office from 115 Broadway to larger quarters at 50 Church Street (Hudson Terminal Bldg.), New York. Mr. Koester is principally engaged in steam and hydroelectric power plant work and electric transmission.

Rush T. Sill, Mining Engineer, and Harley A. Sill, Metallurgist, have opened an office in Los Angeles, California, to carry on work in their specialties. They were formerly located at Culiacan, Mexico.

Prof. J. F. Kemp, of New York, has returned from an inspection of geological conditions in Panama.

C. E. Coolidge and C. S. Johnson, have been appointed assistant professors in mechanical engineering at the Colorado School of Mines.

Dr. F. H. Newell, director of the U. S. Reclamation Service, on September 20, addressed the Colorado Scientific Society, Denver, on "Reclamation."

Chester T. Kennan, Eagle, Colorado, is active in a movement on the part of prospectors and miners to have mineral lands above timber line withdrawn from national forest reserves.

Thomas Thomas, of Dorranceton, Pa., was recently promoted to be General Superintendent of the Lehigh Valley Coal Co., with headquarters at Wilkes-Barre, Pa. Mr. Thomas is a man who has successfully devoted himself to one company. He started to work in 1877, when he was 9 years old, for the same company of which he is now general superintendent, and except for the years when he was attending school and college, he has always worked for the Lehigh Valley Coal Co. His first work in the mines was tending door, an occupation at which a good many of the competent men of the anthracite region started. With that beginning, he has done every kind of work around the mines. Mr. Thomas is also a college man, having been a member of the class of 1886 at Lehigh. Shortly after leaving college, in 1891, he was made outside foreman at the Exeter colliery and then inside foreman in 1894. In 1901 he was made superintendent of the Lackawanna Division of the Lehigh Valley Coal Co., which comprised several collieries near Pittston, Pa., among them being the one in which he had started to work as a boy. Then, successively, Mr. Thomas was put in charge of the Hazleton district in 1905, and the Wyoming district in 1907, until he is now General Superintendent.

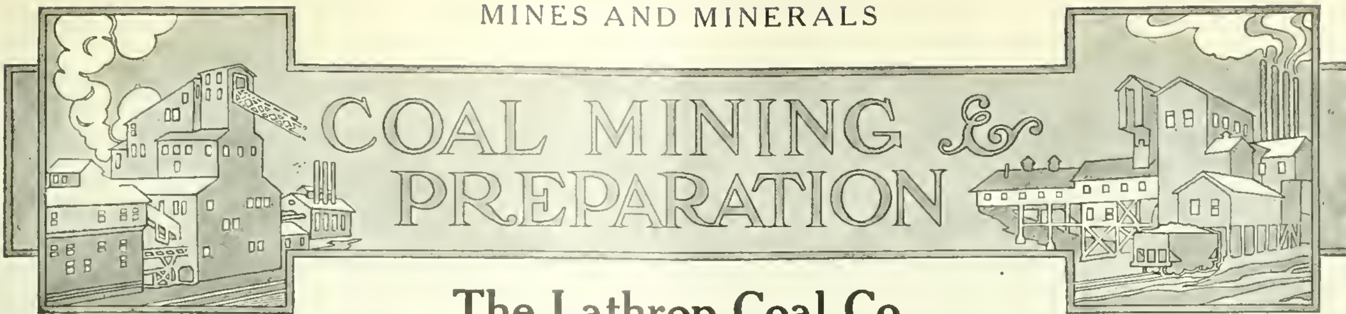
J. H. Hearter, of Wilkes-Barre, has been appointed to the position which Mr. Thomas formerly held.

The Denver & Rio Grande Railroad has provided J. C. Roberts, of the United States Bureau of Mines, a coach for use in traveling throughout the portions of Colorado traversed only by narrow-gauge roads. This car has been fitted up with the apparatus from the regular standard-gauge rescue car, and on September 5 started on its first trip. Professor Roberts, K. H. Chisholm, foreman miner, and W. D. Scofield, first-aid miner, will have charge of the work and will give instruction in both first-aid and rescue work in all of the metal mining camps of southwestern Colorado.

At the examination for Managers of Mine Rescue Stations, held by the State Civil Service Commission of Illinois on October 3, 1912, the following candidates successfully passed: Oscar Cartlidge, Marion, Ill.; Evan D. John, Carbondale, Ill.; John Dunlop, Peoria, Ill.

Correction

The flow sheet, which appeared on page 96 of the September issue of Mines and Minerals, shows a recovery of the barite from the tables and no galena, whereas it should show a recovery of galena and no barite at this point. The middling is returned to the table feed and the barite rejected with the tailing, as the recovery of this fine material is unprofitable.



The Lathrop Coal Co.

A Description of the New Plant at Panther, W. Va., and the Method Employed in Mining

*By J. Harvey Williams, E. M.**

A FEW years ago, Panther (a small town situated on Tug Fork of the Big Sandy, in McDowell County, W. Va., and about midway between Welch and Williamson) was known as a lumber manufacturing town, but the stately poplar and the brave old oak could not stand the mighty onslaught of the axman, so the lumber mills are no more.

Fifteen months ago, however, the town took on a new life, and its inhabitants together with those of the surrounding community were glad to see the hillside being leveled off for storage tracks and work in general going on toward installing a large coal operation. Today many of them find employment with the Lathrop Coal Co., while others till the soil and find a ready market and a good price for their products.

There are several veins of coal underlying the hills around Panther, but the one nearest the hilltop is being operated by the Lathrop Coal Co. and is 700 feet vertical height above the railroad. The vein is from $6\frac{1}{2}$ to 7 feet thick and the coal is of excellent quality, being high in carbon and low in ash. The dip of the strata at this point is approximately 45 degrees north of west on a grade of about $1\frac{1}{2}$ per cent.; the roof is of solid sandstone and is prominent all around the outcrop, thereby preserving the quality of the outcrop coal.

The present projection for the developing of this mine was made with the view of securing a maximum efficiency of the ventilating current, safety to the employes inside of the mine, and the total extraction of the coal, together with a minimum cost to the operators.

Owing to the fact that there is a long line of outcrop and necessarily will be many breaks to the outside, the management favored a force fan, therefore a 5'×7' Jeffrey electric force fan was installed in the center entry or airway, the entries on either side forming the return airways as well as being the haulage ways, thus forming a three-entry system. All cut-throughs are built up with stone stoppings as fast as the work advances, in order to force the intake air directly to the face of the main entries and allowing it to return along the rooms, cross-entries, etc. Where cross-entries have sufficient territory to warrant so doing, overcasts will be constructed in order to furnish a separate split of air for these sections, regulators being installed at proper places to govern the flow of air to various parts of the mine.

The method as adopted for mining the coal, which is shown in Fig. 2, is to drive the cross-entries out, then drive out the four rooms nearest the outcrop and start retreating with these four pillars as soon as the rooms are finished. While the pillars are being drawn the next four rooms are driven up and so on until the cross-entry is finished.

The writer is of the opinion that this method of mining will obtain a minimum cost for track work and from falls of roof and eliminate all possibilities of a squeeze.

All entries are driven 70 feet on centers and 14 feet wide. Rooms are 70 feet on centers and 30 feet wide, with two tracks in each room; the motor delivers an empty on one track and takes the load from the other, thus giving the miner a chance to keep busy loading and saves labor for him by reducing the distance from the coal to the car.

The coal is all cut with electric machines of the Goodman short-wall type, and is

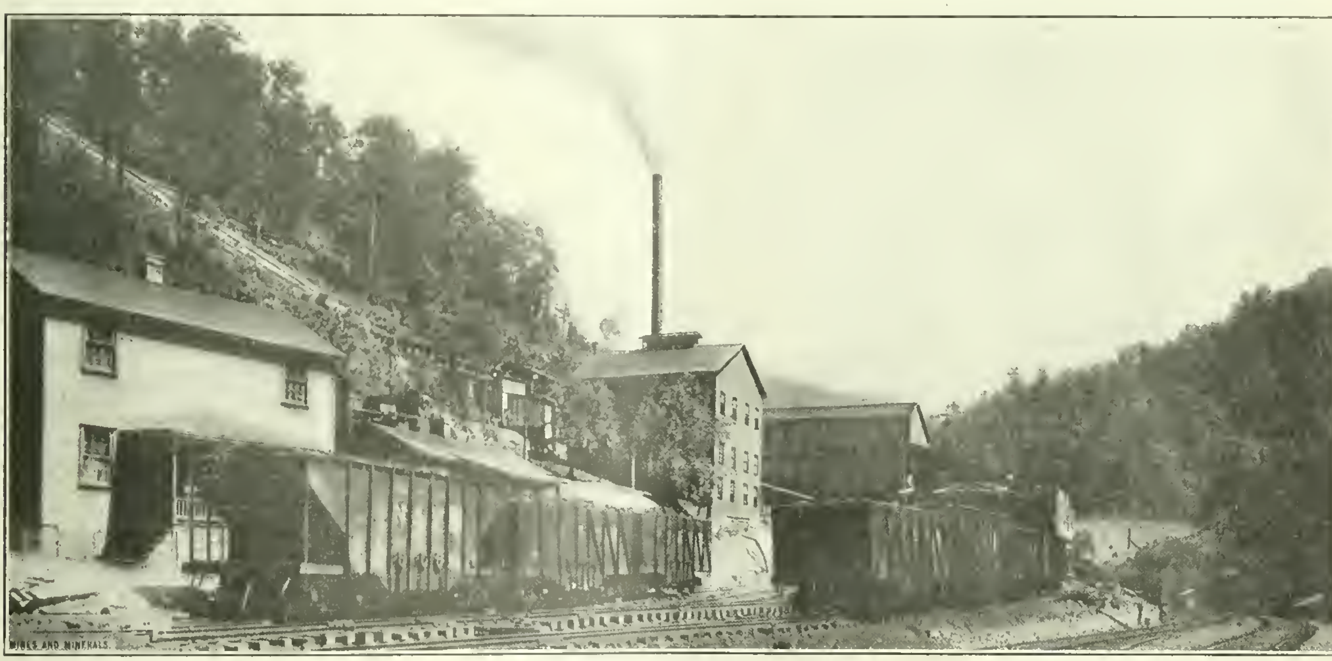


Fig. 1. Plant of the Lathrop Coal Co.

*Welch, W. Va.

hauled to the top of the plane with Goodman motors, where it is dumped into a receiving bin; from this bin it is conveyed to the lower tipple by 10-ton monitors and a 14-foot diameter drum, over a plane 1,450 feet long. This is without exception the best plane of its character that I have ever seen, being laid of 60-pound steel on well hewn and sawed ties. When the coal reaches the foot of the plane, it is dumped into a receiving bin, which is equipped with an oscillating feeder that delivers the coal on to a shaker with $\frac{7}{8}$-inch spaces between bars, which takes out all of the slack and delivers the over sizes on to a picking table where the coal is cleaned; and when making run of mine, the slack and over sizes are reassembled after cleaning. When making prepared coal, it is delivered from the picking table on to a second slack screen with $\frac{7}{8}$-inch openings and from this to a screen with $1\frac{1}{2}$-inch openings which makes nut coal, the over sizes going on to a screen with $3\frac{1}{2}$-inch openings making egg coal. All of the coal that passes over this latter screen is conveyed to the lump car by an electric traveling table which can be raised or lowered, thereby saving the breakage of the coal. The screens are all of shaker type and the tipple in every respect is up to date. Slack and all other sizes can be loaded together; or nut and egg, or egg and lump, together, all of the machinery being run by electric motors. There are five loading tracks, one for mine run and slack, one for nut, one for egg, one for lump, and one for boxcar loading. The blacksmith and machine shop are conveniently arranged.

The power plant consists of one 275-horsepower upright boiler, with a water heater, and one 150-kilowatt, 250-volt, Ridgway generator. The coal is delivered to the power house from the tipple by a conveyer, and the ashes are flushed from the power plant through a 12-inch pipe; this enables one man to easily take care of the power plant and the deep-well pump, which pumps water into a 30,000-gallon tank for the town supply, and a 40,000-gallon tank for the power plant.

An electric hoist and a separate plane, laid with 40-pound rails conveys the men to and from the mine, and hauls supplies.

All houses are built single, with two, three, and four rooms, as the miners like these much better than double houses. The houses are plastered inside and are neatly furnished, giving a good appearance to the town in general. The company store has ample room for offices outside the store department. There are two churches, one for white and one for colored, and Mr. Leckie who is president and general manager of the company has constructed a building for the different secret orders at this place. He is very much concerned as to the welfare of his employes and is always ready to encourage them along social and educational lines, and one can safely say that he will spare no pains to keep the operation and the town up to date.

Fig. 2. Method of Mining, Lathrop Coal Co.

Testing Texas Lump Lignite

By D. C. Earnest

On page 3 of the August edition of Mines and Minerals there is an article entitled "The Status of the Gas Producer," and we take exception to the statement that for steaming purposes lignite is practically valueless. This statement has been made by the United States Bureau of Mines many times, and up to this time it has not been challenged by this company because we had an idea that the investigations made by the Bureau of Mines would show that lignite was not valueless for steaming purposes.

During the last seven years our company alone has produced and sold for steam purposes in Texas more than 40,000 cars of lignite coal, and this coal has been sold in a territory where fuel oil and slack coal were abundant at low prices. Now if lignite was valueless as a steam producer, it would be impossible for this company to sell 40,000 cars of coal in seven years. During the same period of time we believe that other lignite companies in Texas have sold as many as 60,000 cars.

As evidence that lignite coal properly burned has some value, we refer you to an evaporative test made at the plant of the Columbia Mfg. Co., at Dallas, Tex., and lignite is now being fur-

*President of Consumers Lignite Co., Dallas, Tex.

nished to this plant notwithstanding natural gas is here in abundance, fuel oil, until the last few weeks, has been sold at a very low price, and large quantities of coal from Oklahoma and Arkansas are offered in this market at reasonable prices.

The United States Bureau of Mines has accomplished a great deal for the lignite industry of the United States by calling attention to the value of lignite when converted into producer gas, but this Bureau has invariably done the lignite industry a great injustice by always stating that the lignite has no value as a steam producer.

The following is a report of the test:

REPORT OF A BOILER TEST AT THE PLANT OF COLUMBIA MFG. CO., DALLAS, TEX.

Object of test: To determine the difference in evaporation of lump lignite and black lignite.

Fuel used: Hoyt lump lignite coal screened over a $\frac{3}{4}$-inch screen, mined at Hoyt, Texas, and sold by Consumers Lignite Co., Dallas, Tex.

Equipment consisted of two O'Brien horizontal return tubular boilers, set in brick, with a 4-inch air-chamber wall vented to the outside. Each boiler is 72 inches in diameter by 22 feet long, with twenty-six 6-inch tubes, and has a common furnace with 84 square feet of surface. The stack is 4 feet in diameter and 100 feet high, set on a twin uptake over the two boilers. In the uptake is placed a bank of 2-inch pipes to further increase the feedwater temperature.

The grates, built for lignite, are 4 inches wide, 6 feet long, and the width of the furnace is 14 feet. Each linear foot has twenty-five $\frac{3}{8}$-inch round holes, and the air surface is 20 per cent. of the grate surface.

The furnace draft doors are bricked up solid, and in the center of each furnace is located an Argand steam blower, the center ring of which has eighteen 32-inch holes.

The lignite tested was weighed by Mr. J. A. Shortess. The weights for each hour were recorded on the data sheets. A sample of lignite was secured each hour at random from the pile, and placed in a box; and after the tests were completed an average sample was taken and sent to the laboratory for analysis.

All feedwater was measured by a turbine wheel meter, and read each hour.

Thermometers of the Schaffer & Budenburg type were used to take the feedwater and stack temperatures.

Analyses of the furnace gases were taken every 15 minutes and analyzed for carbon dioxide.

The test was started exactly at 11 A. M., May 16, 1912, and continued until 9 P. M. the same day, 10 hours' run.

The fireman had no special instruction as to how to fire the coal, and all asked was to keep the water in the gauge glasses on the strings which were placed at the beginning of the test.

The boiler tubes were blown an hour before the test, but not during the test at any time. The blow-off pipe was not opened any time during the test.

There are six furnace doors, and each door was alternately fired every few minutes by one fireman. The average length of time the doors were open during operation for firing each hour was 24 per cent. of the time. This observation was taken by a stop watch. The *CO* in the flue gases during the time doors were open was never over 3 per cent., which shows a fuel loss during that time of 60 per cent. and proves the necessity of opening and closing doors just as quickly as possible, which so far as the engineer knows is never given any attention anywhere in Texas.

The sample of lignite was analyzed by Landon C. Moore, and a certificate issued for 8,030 B. T. U. per pound. The moisture was 23.52 per cent., which is below the average moisture content of lignite throughout the state.

From the log the average for 10 hours was as follows: Steam pressure, 105 pounds; air temperature, 80° F.; uptake, 563° F.; feedwater, 192° F.; total fuel, 30,302 pounds; total water, 133,301 pounds; boiler horsepower, 410; fuel per square foot grate per hour, 36 pounds; average evaporation per pound of lignite per hour, 4.44 pounds.

The combined efficiency of the furnace and boiler on the average was 54 per cent., we should expect 60 per cent. at least.

The cost to evaporate 1,000 pounds of water at this plant with lignite delivered for $1.50 per ton, is 16.9 cents; or $1.50 worth of lignite will evaporate 8,880 pounds of water.

The test and the above report were made by J. E. Greenwood, M. E., of Dallas, Texas.

A Preventable Shaft Sinking Accident

Mr. Oscar Cartlidge, State Mine Inspector for the Ninth District of Illinois, gives the following account of an accident that goes to show how necessary it is to have top men and bottom men who will refuse to allow men to run risks:

On February 13, 1911, a deplorable accident occurred at the No. 3 mine of the Saline County Coal Co., Harrisburg, in which four men lost their lives.

This is a new mine, the shaft having just been sunk, and the sinking buckets were still in use. The afternoon shift were timbering and had come on top to eat supper. They had a platform built in the shaft about 80 feet down, the shaft being about 200 feet deep.

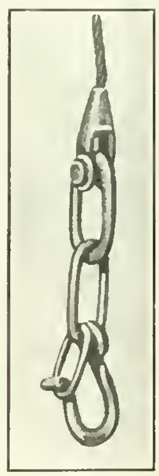

Fig. 1

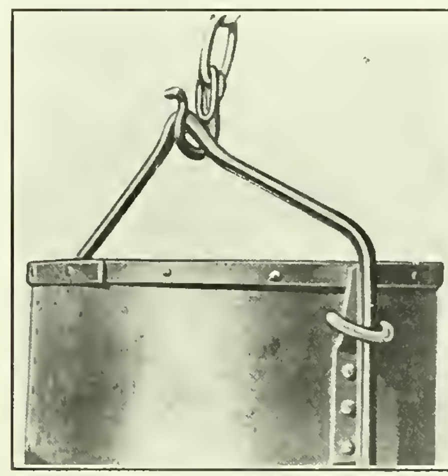

Fig. 2

The bucket was not allowed to swing in the shaft, being held in place by a follower and guides, and was attached to the rope by a hook and safety link. The rope was hooked to the bucket by one of the men who failed to fasten the safety link attached to the hook.

One bucket load of men was lowered to the bottom platform, the second load was in the bucket ready to be lowered, when the top man noticed that the safety link was not in place, and so informed the men. One of them said "let it go at that." The top man gave the signal to lower. Two men were standing on the south of the bucket to one on the north side, which caused the bucket to tip and catch on the edge of the platform. The hook became detached from the rope and the three men and bucket were precipitated to the platform below, killing them and one other who had preceded them.

The risk taken caused the death of four men, and left three widows and eight children without providers. The safety link used is shown in Fig. 1 in place, in Fig. 2 as detached.

The Panther Valley Mining Institute

(Written for Mines and Minerals)

The officials and employes of the Lehigh Coal and Navigation Co., whose operations are located between Mauch Chunk and Tamaqua, Pa., held a first meeting and a dinner, preparatory to beginning institute work, in the Opera House at Lansford, Pa., on the evening of October 5.

Three hundred and seventy-five men, officials, and employes, were present, and the guests at the speakers' table, all of whom had attended many gatherings of a similar nature, voluntarily and freely expressed the opinion that in the apparent character and natural intelligence of the men present, it was equal to any, and excelled many gatherings, of men in mining or other vocations, they had attended.

The large room was neatly decorated, the tables were conveniently and tastily arranged, and back of the speakers' table under an electrical design, partly hidden by ferns, was an excellent orchestra, which discoursed appropriate music during the dinner, and accompaniments to popular songs between the addresses.

After an excellent dinner, coffee and cigars were served, and the real business of the evening began. Mr. W. G. Whildin, General Inside Superintendent of the Lehigh Coal and Navigation Co.'s collieries, presided, and seated with Mr. Whildin, and Mr. Edwin Ludlow, Vice-President and Manager of the Lehigh Coal and Navigation Co., at the same table as guests, were S. D. Warriner, President of the company; Rev. J. J. Curran, of Wilkes-Barre, Pa.; E. W. Parker, Chief Statistician of the United States Geological Survey; Thomas Thomas, General Superintendent of the Lehigh Valley Coal Co., and President of the Wilkes-Barre Mining Institute; C. L. Fay, formerly Mining Secretary of the Y. M. C. A., and Organizer of Institutes; Rufus J. Foster, Vice-President of the International Textbook Co. and Manager of Mines and Minerals; E. R. Jones, a coal mine superintendent from the state of Coahuila, Mexico; Dr. L. E. Rollet, of West Virginia; and Isaac M. Davies, State Inspector of Mines, of Lansford.

In a brief speech outlining in a most general way the objects of the meeting, and expressing his hopes for the success of the movement, Mr. Whildin introduced as the first speaker Rev. Father Curran. In his address, which called attention to his sympathy with mine workers and his personal assistance given them during the strike of 1902 and since then, he emphatically stated that he was as much in sympathy with educational movements, which tended to make the mine workers more efficient, more intelligent, and to raise their standard of life, as he was to see them get a maximum wage. He commented on the real interest the leading officials of the present were taking in the uplift of the mine workers, as compared with the lack of interest of 35 years ago, when, as a young man, he worked in the mines. He clearly showed that there was an interdependence on the part of the workmen and the officials. That this interdependence should be recognized and encouraged by both sides. This meeting, he said, arranged by the officials, showed their interest, and he hoped the men would do their share to not only obtain the advantages in an educational way themselves, but to urge others, and particularly those of the non-English speaking races, to take advantage of them also. With a heartfelt wish for the success of the Panther Valley Mining Institute, Father Curran had to leave the hall hurriedly to catch a train that would enable him to be at home the next morning to officiate at his church services.

Mr. Thomas followed Father Curran with a sketch of the history of the Wilkes-Barre Institute, showing its growth from a small beginning of less than 150 members to a membership of over 1,400. He also, in a forceful manner, told of the success of the movement from an educational and efficiency standpoint. Mr. Parker followed Mr. Thomas with an interesting address in which he spoke of the advantages to be derived from such organizations by both employer and employe. In addition he presented some very interesting statistics regarding coal mining which are of such a nature that they are presented separately on another page.

Mr. Parker was followed by President Warriner of the Lehigh Coal and Navigation Co., who in a brief address expressed his great interest in the movement and his own desire to forward it by every means in his power. He spoke of the need of greater knowledge and consequently greater efficiency in not only officials but mine workers also, and his determination, if possible, to make all promotions to official positions from among the ranks of the company's own employes. He called attention to the fact that while the "foot of the ladder was crowded, there was room on the upper rungs for those who had the ambition to acquire the ability to hold places thereon."

Mr. Warriner was followed by Mr. R. J. Foster, who briefly sketched the difference in the attitude of the heads of the large companies today, in the matter of education and uplift of the employes, to that of 30 or 40 years ago. He showed how improvements in the conditions in anthracite mines commenced in earnest as soon as they were taken over by the large companies, and that constant improvement had been going on ever since. While it was true accidents still occurred, and probably always would, that if the extent of the workings and other conditions in the mine were the same today as they were 40 years ago, the results would be wonderfully in favor of those of today. Even with more adverse conditions, there is a great improvement. In contrasting the old policy of the heads of the companies regarding the education of the employes, he related a personal experience with one of the most prominent engineers and managers of 20 years ago. This gentleman, he said, was a most estimable man in many ways, and was at one time his superior officer. In speaking of the International Correspondence Schools, which at that time were beginning to show results, he said: "I have no sympathy whatever with your undertaking. You may not realize it, but you are sowing the seed for great trouble in the future. By educating these men you are putting false notions in their heads, making them dissatisfied with their positions in life and encouraging them to demand more than the employers will concede to them." This narrow view, Mr. Foster said, was not held by the higher officials today. In every case, in the anthracite field, and as far as he knew in the various bituminous fields, the managers of the larger companies were encouraging the education of their employes, and assisting by every legitimate means in the social uplift of the men. He briefly expressed the hope that Mr. Whildin's expectations of the growth of the Panther Valley Institute would be more than realized.

Mr. Foster was followed by Mr. C. L. Fay, who reviewed the origin and history of the mining institute work, and in a somewhat detailed manner explained the objects and results obtained. As an enthusiast in the work he covered the field in a thorough manner and gave much advice as to what the aims should be, and how they were to be accomplished At the close of his address, Mr. Whildin stated that owing to the lateness of the hour, and the fact that many of those present had to catch the last cars for home, he would refrain from calling on Mr. Ludlow and one or two others qualified to speak on the subject, and adjourned the meeting.

A unique feature of the dinner was the parodies on popular songs composed by Mr. Whildin and which were sung by the entire company accompanied by the orchestra. In each case the parodies had either a local significance or had reference to the institute.

The enthusiasm shown by those present, presages abundant success for the movement.

Annual First-Aid Contests

An Account of the Contests Held by the Different Companies in Various Parts of the Country

SUSQUEHANNA COAL CO.'S MEET. The third annual competitive first-aid contest between the Susquehanna Coal Co., Mineral Railroad and and Mining Co., Summit Branch Mining Co., and Lytle Coal Co., all under the management of Robert A. Quin of Wilkes-Barre, was held September 14, at Shamokin, Pa. The special train that left Wilkes-Barre at 6 A. M., carrying the officials, first-aid teams from Nanticoke, and their friends, arrived at Shamokin in time for the Nanticoke teams to reach Edgewood Park, and engage in the first contest at 9:30 A. M. The officials of the Susquehanna Coal Co. close their mines, and on this holiday and excursion, invite the operators and other mine officials in the hard coal field to be their guests. On this outing old friends meet, new friendships are formed, and in fact, the day is as enjoyable to the coal men as a county fair to the farmers. The mingling of the mine officials of the various collieries, which are widely separated, compensates for lost time, the expense for brass band, special trains, and luncheon; for the men exchange ideas to their mutual advantage and that of the company. This year 43 first-aid teams entered in the elimination contests out of which 29 qualified for the final contests. Drs. F. L. McKee, G. M. Stites, J. M. Maurer, and B. C Guldin, all company men, were judges in the elimination contests. This arrangement proved satisfactory and caused one surgeon to say that after his experience as a judge, he would not, in the future, condemn another judge. After luncheon at which about 1,000 sat at tables, the final events were conducted, with Dr. J. B. Rogers, Pottsville; Dr. D. H. Lake, Kingston; and Dr. J. W. Geist, Wilkes-Barre, as judges.

The one-man event was won by John Wadzinski and his subject, Russell Ogan from Nanticoke No. 5 Colliery, No. 2 shaft. Prize, French bronze medal.

Two-man event, was annexed by Ray Penman and Patrick McCarthy, with Frank Ramsey, subject. Prizes, French bronze medals. In the preliminaries the Pennsylvania Outside, and No. 1 Slope team, to which these men belonged, received 100 mark in the four events.

Joseph Eyster, John Davis, James Campbell, and Charles Weaver, subject, all from Luke Fidler Outside, won the three-man event, receiving French bronze medals as prizes. Their score was 98.

The full-team event was won by Hickory Swamp Outside, composed of P. H. McGinnis, Captain; Ralph B. Platt, William Dockey, Clyde Castetter, Thomas Elliott; John Anderson, subject. Prize, silver cup and gold bronze medals. The cup must be won three times to be held permanently. The Glen Lyon team, won it at the second annual contest.

The prizes were presented to the winners of the one-man event and two-man event by A. L. Williams, Esq., Wilkes-Barre, Pa.; in the three-man event and full-team event, by Hon. F. B. Moser, Shamokin, Pa.

The surgeon who coached the winning team received a silver medal. The field was arranged exactly as the year before, as was shown in November, 1911, Mines and Minerals.

PHILADELPHIA & READING FIELD DAY

Some 10 years ago W. J. Richards, vice-president and general manager of the Philadelphia & Reading Coal and Iron Co., at that time general manager of the Lehigh & Wilkes-Barre Coal Co., had his attention drawn to the advisability of first-aid work, by an accident which happened at one of the latter company's collieries while he was on the ground. A short time after, at a conference of mining men, he suggested the matter of organizing first-aid work at the mines, and, a few months later, when he assumed the management of the P. & R. C. and I. Co. he put his ideas in force. The outgrowth of his first experiment is the splendid force of 76 first-aid corps, numbering nearly 500 trained men, recruited from the ranks of the mine workers, that held their eighth annual competitive drill at Lakeside Park, East Mahanoy Junction, Schuylkill County, Pa., on September 21.

Judges and Officials at Red Cross Contest, Inkerman, Pa.

The first-aid corps, mine officials, and invited guests, numbering between 1,600 and 1,700, were conveyed to the park from the various localities in special trains, which arrived on the ground shortly after 8 o'clock. Accompanying the corps were three brass bands, behind which the first-aid men and mine officials marched to the park, in review before Mr. Richards and the invited guests.

Dr. George H. Halberstadt, of Pottsville, Pa., the superintendent of first-aid work for the company, directed the competition, and Dr. J. B. Rogers, of the Pottsville Hospital, acted as judge.

Everything on the field being in readiness, the competition began very promptly. The first contests were by districts, of which there were ten. Ten preliminary contests were first held. The corps of each district drew, by lot, a number, and all the corps of that district competed in the same numbered contest as shown in the following list:

1. Compound fracture of skull and jaw. 2. (*a*) Foreign body imbedded in left cornea. (*b*) Crush of right hand. 3. Dress burns of head, neck, body, and arms.

4. Crush of pelvis and laceration of hips. Dress hip with spica. 5. Handling by one, two, three, and four bearers—cross obstruction. 6. Rescue patient from electrical contact—carry 10 feet. Artificial respiration. 7. Crushed foot, laceration of leg to middle third. Spiral reverse bandage. 8. Compound fracture of forearm with laceration of hand and fingers. Dress hand and fingers with spica. 9. Compound fracture of leg with dislocated thigh. 10. Fracture of spinal column.

Packer No. 5 Team, Lehigh Valley Coal Co.

Bear Ridge Colliery Team, P. & R. C. & I. Co.

The winning teams in the preliminary contests were as follows:

Event No. 1, Otto Colliery, Minersville District. Event No. 2, Wadesville Colliery and Bridgeport Transfer, St. Clair District. Event No. 3, Bear Ridge Colliery, Gilberton District. Event No. 4, Good Spring Colliery, Tremont District. Event No. 5, Henry Clay Colliery (inside corps), Shamokin District. Event No. 6, Potts Colliery (Mammoth Section Corps), Ashland District. Event No. 7, West Shenandoah Colliery (inside corps), Shenandoah District. Event No. 8, St. Nicholas Colliery (inside corps), St. Nicholas District. Event No. 9, Locust Gap Colliery (outside corps), Mt. Carmel District. Event No. 10, Tunnel Ridge Colliery (inside corps), Mahanoy District.

These 10 corps then competed in the final contest, which was to dress injury to foot, leg, thigh, and hip; spiral reverse leg and thigh; figure of 8 of knee, and spica of groin.

In this final contest the Bear Ridge Colliery corps, consisting of Peter Shoppie, leader, Thomas Hobin, subject, John T. Thomas, Dennis Sheehan, and Thomas McGrue, were declared the winners. The second place was won by the Tunnel Ridge Colliery (inside corps). The other district winners in order of grade were Wadesville and Bridgeport Transfer, Locust Gap (inside corps), St. Nicholas (inside corps), West Shenandoah (inside corps), Henry Clay (inside corps), Otto, Good Spring, and Potts (Mammoth section). The closeness of the contest and the efficiency of the various corps is evidenced by the fact that with a rating of 100 points for perfection, the lowest team had a credit of 94. The blue ribbons, the prizes, for the winning corps, after introductory remarks by Mr. Richards, were presented by Morris Williams, of Philadelphia, president of the Susquehanna Coal Co. Hon. O. P. Bechtel, of Pottsville; Dr. Herbert M. Wilson, engineer of the U. S. Bureau of Mines; Rev. W. H. Lindermuth, of Pottsville; Dr. J. C. Biddle, superintendent of the Ashland Hospital; and Hon. J. R. Jones, presented the red ribbons to the other corps who had won places in the final competition.

Owing to the number of competing teams, the work occupied the entire day until nearly 6 p. m., except for about an hour, during which an excellent course dinner was simultaneously served to 1,670 persons at tables erected in the grove, by a Philadelphia caterer, who had a large corps of competent waiters.

Previous to the presentation of the prizes, the nearly 500 members of the various corps, under command of Doctor Halberstadt, to the music of the three bands marched in review before Mr. Richards and the guests.

In addition to the competitions, one of the company's new and improved ambulances was on exhibition. It attracted attention on account of its convenience and the comfortable provisions it contained for the transportation of the injured.

Lehigh and Wilkes-Barre Meet

The third annual field day of the first-aid teams connected with the Lehigh & Wilkes-Barre Coal Co. was held September 21, at Sans Souci Park, between Wilkes-Barre and Nanticoke, Pa. All the collieries of this company were represented by first-aid teams. Hollenback sent two; Empire, one; South Wilkes-Barre, three; Stanton, two; Sugar Notch, two; Lance, two; Nottingham, two; Reynolds, one; Wanamie, three; Maxwell, three; Audenreid, two; Honey Brook, four; making in all 27 teams, or 162 men. There were six events; the full teams rating first and second in events 4 and 5, competed in two difficult problems. This eliminated all but Sugar Notch Outside, Lance Outside, Lance Inside, and Nottingham Inside.

The one-man event was won by Stanton Colliery; the two-man event by Nottingham Colliery Inside. This team was in the final events and for neat, quick work, had no superiors, but they lost through inattention to small but important details.

The three-man event was captured by four men from the Lance Colliery Outside. The colliery's full team, composed of Edward Collins, David Cummings, Charles Wilkinson, Charles Atwell, Charles Meyers, and Charles Kostruzna, won the first prize at the meet.

Dr. F. L. McKee, company surgeon, is to be congratulated on the excellent work of his pupils. The young men are also to be congratulated on their uniformly good work. The members of one or two teams were more nervous than if they had been engaged in an accident. This is not a bad sign, as it shows self-consciousness coupled with a desire to excel.

Dr. J. W. Geist, of Wilkes-Barre, was the judge, and as he did not know the men and they did not know him, everything was entirely satisfactory. Those in charge of the demonstration say it was a vast improvement over the second annual field day, and the writer does not see how teams could look better and work more neatly.

LEHIGH VALLEY COAL CO. CONTESTS

The Lehigh Valley Coal Co. held a successful first-aid contest at Hazle Park, Hazleton, Pa., September 21, that being a central point for the different divisions of the company. Each of the six divisions was represented by one team selected at preliminary contests held prior to the general meet.

The teams selected to compete for their respective divisions and their ratings were as follows:

Lackawanna Division, Stevens Colliery, West Pittston, 95 per cent.; Wyoming Division, Westmoreland Colliery, Wyoming, 98 per cent.; Lehigh-Coxe Division, Drifton Colliery, Drifton, 94 per cent.; Delano Division, Primrose Colliery, Mahanoy City, 95 per cent.; Mahanoy-Schulkill Division, Packer No. 5 Colliery, Lost Creek, 99 per cent.; Pottsville Division, Blackwood Tunnel, Blackwood, 82.5 per cent.

The Packer No. 5 team, composed of John McLean, captain; Joseph Curvin, John Sheridan, Charles Calbert, Henry Carey, and Thomas Brown, won the contest, the Westmoreland team being a close second

None of the teams knew what problems they were to solve until they were handed to the captains on slips of paper.

In the one-man event Thomas G. Evans, Stevens; Anthony Gludding, Primrose; John McLean, Packer No. 5, and James Morris, Westmoreland, tied. An extra event was then ordered, which was won by T. G. Evans with 99 points, A. Gludding coming second with 95 points to his credit.

The judges, Dr. E. G. Heyer, of Hazleton State Hospital, and Dr. A. G. Fell, of Wilkes-Barre, paid particular attention to the manner in which the corps handled their subject as well as to the particular method of bandaging. They complimented every team for their work, which was right because the proficiency of these men in this work has saved, and will no doubt continue to save, the lives of underground workers. After the third event the teams and their guests were served with a dinner.

Mr. Atherton Bowen, who has trained the teams, was complimented on the uniformity with which the teams worked; and Mr. John Lloyd, inspector of equipment, for the arrangements of the contest and the comfort of the guests and spectators.

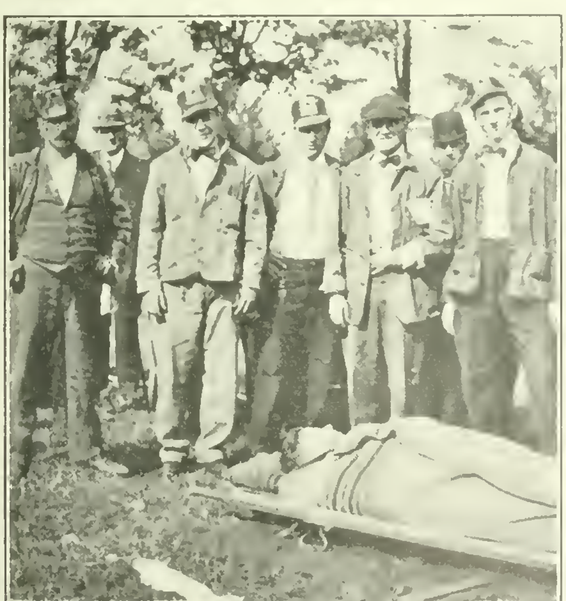
PENNSYLVANIA COAL CO. CONTESTS

The seventh annual first-aid meet of the Pennsylvania Coal Co. and the Hillside Coal and Iron Co. was held at Inkerman, Pa., September 21. Those in attendance were given a spectacular and clever exhibition by the six teams representing the various districts in which the above companies have collieries. To make the conditions more nearly similar to those in the mines, obstacles were erected on the field and the space in which the men worked was curtailed, thus adding materially to the difficulty in dressing, yet at the same time increasing the interest of the spectators, as it disclosed the ingenuity of the men in overcoming obstacles. As an illustration, the fifth event for full teams had the following problem to contend with: Severe scalp wound on top of head, compound fracture of the left thigh at middle with injury to the large artery; dislocation to right hip, toes turning outward; treat, place on stretcher, and transport up and down steps, over loaded car, and load into ambulance standing on ground. The judges, Drs. W. S. Fulton, F. J. Bishop, and D. A. Capwell, of Scranton, awarded the first prize, the "Captain May Loving Cup," to the Law Shaft team, Central Colliery, Avoca District. The team consisted of G. Kellum, S. Bernard, Thomas Edwards, J. Lewis, J. Colburn, and T. McDermott. The average number of points scored by each district team is as follows: Avoca, 97⅘; Mayfield, 95; Forest City, 94⅘; North Pittston, 94⅗; Dunmore, 94⅗; South Pittston, 93⅗.

All of the men competing were awarded gold badges or buttons, while those who had been perfect in attendance at first-aid instruction were surprised with $10 gold pieces. Mr. Reese, mine inspector of the Fourth Anthracite District, presented the Mayfield District team, who won second prize, with a box of cigars. Captain W. A. May, president of the companies, addressed the teams on first-aid work, after which Hon. C. C. Bowman presented the prizes. This was the second elimination contest of the Pennsylvania and Hillside first-aid corps, and the first five teams were entered in the Red Cross meet for the "Muckle Cup," which was won last year by the Brisbin team of the D., L. & W. Coal Co.

D., L. & W. FIRST-AID CONTEST

A first-aid contest between teams representing the various departments of the Lackawanna Railroad was held at the Central Y. M. C. A. building at Scranton, Pa., on September 21. Twenty-four teams from the coal-mining department and five teams from the railroad department, competed against one another for the honor of holding the President's cup, which was presented this year, for the first time, to the best team in the whole Lackawanna system. There was also at the same time a contest between the teams from the coal-mining department, for the Superintend-



Lance No. 11, Outside Team, L. & W. Coal Co.

Law Shaft Team, Penna. Coal Co.

ent's cup, which was won last year by the team from the Brisbin mine.

In the contest for the President's cup the team from the foundry connected with the railroad shops, at Scranton, was victorious, being Thomas Harding, captain; John Cullen, Michael Walsh, Walter Moore, John Landuskie, and John Healy, subject. The team from the Central mine was runner up for the President's cup, as it had already won the superintendent's cup. This team was composed of the following men: Joseph Taylor, captain; Anthony Tierney, David Davis, Ivor Jones, Caradoc Thomas, and William Lascomb, subject.

The contest was ably managed by Dr. J. M. Wainwright, 15 events being run off between 1 o'clock and 5:30 in the afternoon. The teams were divided into four sections, each section having one judge in the first series of five events, in which each team competed.

The winners in this contest were the teams from the Brisbin, Central, Holden, and Truesdale mines, and the Railroad and Foundry teams. These then competed in a second series of events in which the Central and Foundry teams were chosen to compete in the final events to determine the winner of the president's cup. Drs. Fulton, Henry Smith, R. G. Wall, and W. E. Keller, acted as judges.

After the contest, T. E. Clark, general manager of the railroad, made the speech presenting the president's cup and delivered the Red Cross diplomas to those who had studied for them. C. E. Tobey, superintendent of the coal-mining department, made the speech presenting the superintendent's cup to the Central team. A third cup was given by the Y. M. C. A. for the best team trained under its supervision, and it was won by the Foundry team.

All the teams in the contest proved that they could do remarkably competent first-aid work, the problems given being such as would test practical first-aid ability. After the contest a dinner was served by the company to all the contestants, and each member of a team was presented with a gold bronze medal on which was a red cross pendant from a blue enameled pin on which was printed "Lackawanna Company."

Brisbin Mine Team, D. L. & W.

Pine Brook Team, Scranton Coal Co.

Anthracite Red Cross Contest

The fourth annual first-aid contest for the Muckle cup, was witnessed by a large number of men and women spectators at Inkerman, September 28. The cup was presented in the name of the Red Cross Society by Mrs. John Muckle, of Philadelphia, president of the Pennsylvania Red Cross Society. In order to hold the cup it must be won three times by the same team, but so far the same team has not won it twice; however, it is considerable honor to hold it once. In 1909 the Avoca team, of the Pennsylvania Coal Co., was successful; in 1910 the Woodward Colliery team, of the D., L. & W. Co., captured the trophy, and this year, 1912, the Pine Brook Colliery team, of the Scranton Coal Co., composed of the following men, was successful: Arthur Young, captain; John W. Jones, Nathaniel Thomas, Samuel Thomas, Dennis Duffy, and William Morgan.

The Temple Iron Co.'s Mt. Lookout Colliery team, Harry Sax, captain, was awarded second place, and the Fernwood Colliery team, Jas. R. Pollard, captain, of the Hillside Coal and Iron Co., took third place. The teams entering this contest were representative of the various companies, and being coached by company surgeons do their work differently. Great rivalry exists between the teams and surgeons, but that professionalism will enter into the contests as some have suggested is unlikely, the managers and surgeons of the coal companies being opposed to any such featuring of strictly humanitarian work. In the judging, some doctors have thought their teams were not given full credit. It is possible that if these doctors will act as judges in some future contest they will agree with one of the surgeons at the Shamokin meet, who stated that never again would he claim a judge had ruled against his team unfairly. As this contest is an open event it should be patronized by more than six coal companies for several good reasons: The cup was presented by the president of the Red Cross Society of Pennsylvania to stimulate good-natured rivalry in this kind of work; it is the first public prize offered to first-aid mine teams in the United States, and since the contests are judged by army surgeons sent to the meet by the Government, they are virtually both national and state affairs.

The judges at this meet were Captain William H. Moncrief and Lieutenant H. J. Hallet, army surgeons, from Governor's Island, New York, and Captain P. W Huntington, army surgeon, from Philadelphia, Pa. One at least of these men had never attended or acted at a miners' first-aid contest, and not knowing one team from another except by number, their judgment was determined by what they considered the best team work.

The affair was under the management of Dr. F. F. Arndt, of Scranton, with Mr. Rosman I. Vail of the Railroad Department of the Y. M. C. A. Secretary.

The Delaware, Lackawana & Western Co. entered the four district teams which won at the company contests on the previous Saturday. These were from Holden, Central, Truesdale, and Brisbin collieries. The Pennsylvania Coal Co. entered the Avoca Shaft team. The Hillside Coal and Iron Co. entered teams from Forest City, Dunmore, Fernwood and Mayfield; Scranton Coal Co. entered their Pine Brook and Raymond collieries teams; the Temple Iron Co. sent their Mt. Lookout and Lackawanna collieries teams; the Parrish Coal Co., Plymouth, sent one team, as did the Price-Pancoast Coal Co.

We are of the opinion that if the other coal companies sent teams they would not have regretted the experience. The winners of second and third place were awarded Red Cross bronze medals. It is probable that the suspension of mining operations during the first part of this year had considerable to do in keeping some teams from entering this contest, for the companies are now bending every endeavor to make up the shortage of coal brought about by the stoppage of mining.

At the Pittsburg First-Aid Conference the triangular bandage was adopted as the one to use for first-aid work. This will in a measure cause a number of first-aid teams, who have used the roll bandage, to commence work over again; there are, however, so many things in favor of the triangular bandage, that its use will not be difficult to learn, in fact, its manipulation is easier for the team and less painful to the injured man.

SCRANTON COAL CO. MEET

The Price-Pancoast Coal Co. of Throop, has one colliery which is under the management of John R. Bryden, who is also manager of the Scranton Coal Co. Dr. J. F. Jacobs, who is surgeon of both companies, offered a silver loving cup for competition, and on October 2, the best of the teams met at Guernsey Hall, Scranton. Doctor Arndt, of Scranton, and Doctor Van Sickle, of Olyphant, acted as judges and were compelled to go over some of the problems twice and see the patient unbound before they could render their decisions; in the end, however, the Price-Pancoast team won the cup, beating the Scranton Coal Co.'s Pine Brook team, which won the Muckle Cup at the Red Cross contest held at Inkerman on September 28. From this it is evident that an injured person would be equally safe in the hands of either team; since in a close contest a very slight act must be counted, by a careful judge either for or against a team, even though in practice it is comparatively unimportant, and such matters being largely matters of personal preference might affect different judges differently. In the anthracite fields, at least, much attention is paid by the judges to the way the men handle the bandages with supposed dirty hands and the way they handle the patient while performing their work.

FIRST AID AND HELMET CONTEST AT TRINIDAD

There are within a few miles of Trinidad, Colo., large coal mines operated by the Colorado Fuel and Iron Co., the Victor-American Fuel Co., the Cedar Hill Coal and Coke Co., the Chicosa Fuel Co., and the Rocky Mountain Fuel Co.

Maitland Team, Winners at Trinidad, Colo.

Hickory Swamp, Outside, Team, Mineral R. R. & Mining Co.

Beginning September 25, 1912, there was held, at Trinidad, the Las Animas County Fair. In some respects, this was an old-fashioned, annual county fair, but this year the region's two main industries, agriculture and coal mining, were given equal prominence. The program for the Fair therefore brought into town not only ranchers and cowboys, but miners and mining engineers from that part of the state.

The program of miners' events had been prepared under the direction of H. H. Sanderson, mining engineer, who has devoted much time and attention to first-aid and helmet work instruction. Thursday was "Miners' Day" and there was a large attendance.

Previous to this meet, the various companies had been furnished sets of the rules that would govern, and had been invited to send teams. For weeks, accordingly, teams worked in nearly every camp, training for this meet. There were thirteen entries and these all participated.

H. H. Sanderson With Rescue Apparatus

Each first-aid team consisted of six men—a captain, a patient, and four operators—and every man was required to be a bona fide employe about the mine represented by his team. It was further stipulated that not more than three men on a team should have participated in the similar contests of the preceding year. Each helmet team comprised five men—a captain and four miners—and the same restriction was made concerning engagement in the contests of 1911. In all other respects, the rules were substantially the same as are adopted elsewhere in such contests.

The participants in the first-aid events were the following teams, who took places in line according to numbers drawn by lot: 1. Segundo; 2. Berwind; 3. Piedmont; 4. Starkville; 5. Walsen-Robinson, second team; 6. Frederick; 7. Sopris; 8. Primero; 9. Maitland; 10. Walsen-Robinson, first team; 11. Tercio; 12. Morley; 13. Tabasco.

Four events took place on the race course in front of a large grand stand. The judges were four surgeons, of whom two are stationed at Fort Logan, Colo., on the medical staff of the Regular Army. All four judges were unprejudiced by any company connections and were total strangers to every man on the teams.

The specifications of the events had been withheld from everybody (except the committee in charge) until the contests started, when the judges were each supplied with complete copies. Immediately preceding each event, a sealed envelope was handed to the captain of each team, and this contained the specifications for that particular event only, in typewritten form. These were then read by each captain to his team and, simultaneously, by megaphone, the same were announced to the spectators and to the teams, so that there might be no misinterpretations. After a few moments allowed for questions, signals were given and the work begun. Thereafter there could be no explanations nor suggestions offered by anybody.

It would be difficult to conceive better system than was displayed throughout these events. It was almost military in its quiet and smoothness. For each event, each of the four judges selected four or five of the teams for his special attention, and it was so mutually arranged among them that each judge inspected each of the teams at least once during the contest. The teams proved to be so well matched that the arrival at final averages required careful deliberation on the part of the surgeons. The winners were: First, Maitland team, grade 95 per cent.; second, Morley team, grade 93¾ per cent.; third, Walsen-Robinson, first team, grade 90 per cent. The Maitland team represented the Victor-American Fuel Co., while the Morley and the Walsen-Robinson teams were from the Colorado Fuel and Iron Co. The men on the Maitland team were: David Aitkens, captain; Alex. McBurnie, Robert Shaw, William McLennon and Alex. Wilson, operators; Arthur Quinn, patient.

All the teams, with the exception of the winning team, were in neat Red Cross regulation uniforms. The Maitland team was uniformed in neat white soft shirts and blue overalls.

To the winning team was voted a silver cup that, a year before, had been captured by the Primero team, with the stipulation that its permanent possession depended upon being won thrice. In addition to this, six polished aluminum Wolf safety lamps were presented to this team. The second prize consisted of six automatic lighters.

Helmet Contest.—There were but three entries in the helmet contest, the winners being declared in the following order: First, Primero team, grade 90 per cent.; second, Frederick team, grade 87 per cent.; third, Morley team. The Primero team comprised: Thomas Warburton, captain; Robert Scott, George Fortune, John Jurchek, and M. J. Green, miners. The judges were H. H. Sanderson, Thomas C. Harvey, and Bert Lloyd.

For this contest, a temporary structure had been erected and arranged to represent entries in a mine. Instructions to the teams stated that a man had been overcome by gas at the extreme end of these workings, and to reach him it would be necessary to pass over a bridge (overcast), over a rock fall, through a low breakthrough and a brattice. The building was filled with noxious fumes from burning manure and sulphur. The air was so heavy therefrom that the spectators peering into the windows could scarcely follow the movements of the men who were obliged to use their electric lamps, the safety lamps, with which they were also equipped being useless in the foul atmosphere.

The task involved the removal of a dummy, representing the victim, as far as the entrance, where the dummy was exchanged for a live patient upon whom the balance of the work was performed. The helmets used were of the Draeger type. The contest elicited unusual interest among the spectators.

The prizes were the same as for the first-aid contest with the exception that there was no silver cup. Each participant in both contests was presented with a beautiful bronze medal.

FIRST-AID CONFERENCE

A conference was called by the Bureau of Mines to discuss mine rescue and first-aid work at Pittsburg, Pa., September 23 to 25. On the first day of the conference, committees were appointed to consider and report upon certain questions in regard to first-aid and mine rescue work. These committees reported on September 25, and the recommendations were adopted as submitted. Finally the Committee on Organization reported and made the work of the others void by the following resolution:

Resolved, that this Conference be made a permanent organization; that the presiding chairman, Mr. H. M. Wilson, be elected the President of a Temporary Committee to be composed of seven members; that there be elected a Vice-President; that Mr. C. S. Stevenson be elected Secretary, and that the other members of the Committee be appointed by the President; that the purpose of the Temporary Committee shall be to draw up a constitution and by-laws, and otherwise complete the organization; and, that until there be such permanent organization, all details in connection with first-aid and other matters be passed over.

The above resolution was discussed in detail and finally adopted by unaminous vote.

Trade Notices

Change of Address.—Notice is given by John Davis & Son (Derby), Ltd., of All Saints' Works, Derby, England, that their address in the United States has been changed from Baltimore to care of J. F. McCoy Co., 157 Chambers St., New York, who are now sole representatives for the United States.

Change of Chicago Office.—The Jeffrey Mfg. Co. has moved its Chicago headquarters to offices on the seventeenth floor of the recently completed McCormick Building, one of the most up-to-date fireproof office buildings in Chicago. S. S Shive, sales engineer, is the district manager in charge. The Jeffrey Mfg. Co. maintain fourteen branch offices in the United States and over one hundred agents in the leading commercial centers of the world.

The Western Electric in Cleveland. The Western Electric Co. has taken over the business of the Cleveland Electrical Supply Co., of Cleveland, retaining the entire personnel of the supply company which it supersedes, with the exception of R. F. La Ganke, vice-president and manager, who is retiring from active business. H. A. Speh, of the Buffalo house succeeds to the post of manager. Louis Griesser, sales manager, has been twenty years in the electrical business at Cleveland. The Cleveland house has, in Mrs. H. L. Hausman, the only saleswoman in the company's employ. A telephone sales department has also been organized under the supervision of F. E. Triebner, formerly of the electric company's Nashville office.

Steam Turbine Driven Centrifugal Pump of 100,000,000 gallons per day capacity is to be installed in the Ross Pumping Station of the Pittsburg Water Works, by the DeLaval Steam Turbine Co., of Trenton, N. J. This pump will be the largest steam turbine-driven centrifugal pump ever built in this country, the rated capacity of 100,000,000 gallons per day against a total head of 56 feet amounting to over 980 water horsepower. The pump is guaranteed to show a duty of 115,000,000 foot-pounds per thousand pounds of dry steam, all steam used by the condensing equipment being charged to the main unit.

Crushed Coke Plant.—The Alicia crusher is located at the plant of W. Harry Brown at Alicia, Fayette County, Pa. The plant, consisting of 400 rectangular ovens, began operations October 1. The coke production is about 25,000 tons per month, of which 6,000 tons will be crushed and screened into egg, stove, chestnut, pea, and dust sizes

Chicago Office.—For the convenience of middle western customers, J. H. Williams & Co., makers of drop-forgings, Brooklyn, N. Y., have opened an office and warehouse at 40 South Clinton St., Chicago, Ill., where a stock of their many drop-forged specialties will be carried on hand.

Consolidation.—The Taylor Iron & Steel Co. announces the acquisition of the Wm. Wharton, Jr. & Co., Inc., of Philadelphia, Pa., with works at Philadelphia and Jenkintown, Pa., and its subsidiary corporation, The Philadelphia Roll & Machine Co. The Taylor Iron & Steel Co. has in recent years devoted itself to the manufacture of steel castings of a special high-grade nature, Tisco manganese steel being the principal one. Tisco manganese steel castings are particularly applicable for use in railway track parts, safes, vaults, conveyer chain, sprockets, special wheels, the wearing parts of rock crushing and cement grinding machinery, centrifugal pumps, the wearing parts of steam shovels and dredges and other parts of heavy-duty machinery subject to wear, abrasion, or shock. The Wharton company manufactures switches, crossings, special rails, and track parts for steam and street railways. Their specialty is the application of Tisco manganese steel to these parts.

On October 1, 1912, the Taylor Iron & Steel Co. changed their corporate title to the Taylor-Wharton Iron & Steel Co. The organization of the Taylor Iron & Steel Co. will become the organization of the Taylor-Wharton Iron & Steel Co., namely: President, Knox Taylor, Vice-Presidents, A. B. Borie, Prof. H. M. Howe, V. A. Angerer; Secretary and Treasurer, W. A. Ingram.

A New Canadian Company.—The C. O. Bartlett & Snow Co. of Canada, Limited, has been granted a Dominion charter to deal in, manufacture, and install, elevating and conveying machinery, power transmission machinery, engines, boilers, hoisting machinery, brick machinery, garbage reduction and destroying machinery, paint machinery, grain and cereal machinery, and to carry on a general line of engineering, manufacturing, and construction work. The head office of the company has been opened at 282 St. Catherine St., Montreal, with Herbert S. Hersey, General Manager. This company is the outgrowth of the extensive Canadian business of the C. O. Bartlett & Snow Co. of Cleveland, Ohio, and although the connection between the Ohio company and the Canadian company will be very close for some time, the organization and management are entirely independent. The Canadian company has been granted Canadian rights to all patents and licenses owned by the Ohio company and this, taken in connection with the vast engineering data and designs of the original company coupled with the wide acquaintance and engineering experience of Mr. Hersey and the engineers associated with him in handling the Canadian business, places the new company on the basis of an old established concern with years of business experience behind it and with a business reputation of the highest standard as well as a large clientele from which to draw a substantial amount of business from the start. The C. O. Bartlett & Snow Co. has installed a number of the best and most up-to-date coal-mine equipments during the past few years in the Crow's Nest Pass District as well as having done a large business in connection with the cement interests of Canada and with the coal, gypsum, and asbestos interests of the Eastern Provinces. Therefore, on account of the increasing business of Canada and the development in mining, lumbering, etc., a wide field is open for the new company.

Correspondence

"Anxious" Answered

Editor Mines and Minerals:

SIR: In the last issue of MINES AND MINERALS I notice a request by "Anxious" for information regarding a rock dump that had been described in MINES AND MINERALS some time ago. If he referred to the dump now in use at the Cokedale mine, Colorado, I wish to advise that there is but one rock dump of this type in existence. We had great quantities of rock to handle and a great deal of shallow ground to fill up, so I designed the dump in question and had it built in our local shop. It was designed to fit our type of pit car and while it worked very successfully it might not be as satisfactory with another type of car. The description of this dump is in the May, 1910, issue of MINES AND MINERALS, page 592.

If after reading this description your correspondent is satisfied that a dump of this kind would answer his purpose, I shall be glad to give him any assistance I can, in designing a truck for the kind of pit cars he is operating.

Trinidad, Colo. W. B. LLOYD

Gases from Acetylene Lamp

Editor Mines and Minerals:

SIR:—Please publish the following questions in your Correspondence Column.

(1) What effect (if any) do the gases given off from the "acetylene pit lamp" have on the miner? (2) What are the elements of the gases given off by the carbide, and what is "carbide" made of?

Tasker, N. Dak. T. S. ALMOND

Societies

The winter meeting of the Coal Mining Institute of America will be held in Pittsburg, Pa., December 18 and 19. The following tentative program has been arranged by the Executive Committee:

Forenoon, the first day, December 18: President's address Paper—"A Brief History of the Coal Mining Institute of America," by Wm. Seddon, first Secretary of the Institute. Paper—by Eugene B. Wilson, Scranton (subject announced later).

Afternoon, the first day, December 18: Paper—"Roof Action," R. D. Hall, New York. Paper—to be presented by representative of the Pittsburg Testing Station, U. S. Bureau of Mines (subject announced later).

Evening, the first day, December 18: Institute dinner and social session, probably to be held in the Fort Pitt Hotel. Name of special speaker to be announced later.

Forenoon, the second day, December 19: Discussion—"Rib Drawing by Machinery," led by W. L. Affelder.

Business session.

Luncheon, at School of Mines Building

Afternoon, the second day, December 19: Paper—"Gas Producers from the Mining Man's Standpoint," name of writer to be announced later. Paper "Coal Crushers," by G. R. Delamater, Philadelphia. Discussion—"Oil and Gas Wells in the Bituminous Coal Fields," led by A. P. Cameron.

Committee appointed on Local Arrangements for the December meeting: W. E. Fohl, S. A. Taylor, and J. B. Johnston.

AMERICAN MINING CONGRESS

The 15th Annual Convention of the American Mining Congress will be held in Spokane, Washington, November 25 to 28, inclusive.

The serious work of the Convention is done by its Resolution Committee, composed of one member from each state, selected by the delegation from such state. Any member of the Convention may introduce in writing any resolution upon matters pertaining to mining and in this way secure its consideration. The chairmen of the different committees are as follows: General Revision of Mineral Land Laws, E. B. Kirby, St. Louis, Mo.; Smelter and Freight Rates, E. A. Colburn, Denver, Colo.; Federal Legislation and Metal Mining Affairs, D. W. Brunton, Denver, Colo.; Alaskan Affairs Falcon Joslin, Fairbanks, Alaska; Coal Mining Affairs, Walter M. Bogle, Fisher Building, Chicago; Prevention of Mine Accidents, W. R. Ingalls, New York; Workmen's Compensation, John H. Jones, Pittsburg, Pa.; Standardization of Electrical Equipment, in Coal Mines, George R. Wood, Pittsburg, Pa.; in Metal Mines, H. S. Sands, Denver, Colo.; Mineral Statistics, George W. Ritter, Salt Lake City, Utah; Forestry Relations, T. J. Grier, Lead, South Dakota; Bureau of Mines, Seely W. Mudd, Los Angeles, Cal.; U. S. Geological Survey, Dr. H. Foster Bain, San Francisco, Cal.

TRADE PRESS ASSOCIATION

At the Niagara Falls meeting of the Federation of Trade Press Associations of the United States, a resolution was passed extending greetings to the National Federation of Retail Merchants, whose convention is to be held in St. Louis, November 19 to 21, and recommending that the Trade Press Association be represented at the meeting, the purpose of the two organizations being similar.

A recent French report shows that for 1910, the output of coal per man increased, the wages also being slightly higher. It is referred to in the report as a "phenomenon," the previous experience having been that higher wages have resulted in diminished output per man.

Why Is a Stopping?

Results of Improperly Built Stoppings—Different Methods of Effective Construction

By Oscar Cartlidge

FROM the way some mine managers build them, one would think stoppings are a necessary evil imposed by law, and to be disposed of in the quickest and cheapest possible way, without regard to efficiency.

Now the sole purpose of a stopping is to prevent the air-current from short-circuiting. If the stopping leaks and part of the air returns to the upcast shaft before reaching its ultimate destination, labor, material, and horsepower are wasted in proportion to the amount of leakage.

The kinds of material generally used in stoppings in coal mines, and the method of construction, are: ship-lap or rough oak boards, plastered; ship-lap or rough oak boards. not plastered; slate walls, plastered; slate walls, not plastered; concrete monolith walls; concrete blocks; blocks made of cement and cinders, and brick.

Actual measurements, where some of the different kinds of stoppings are used, gave the following results, and indicate clearly that not all mine managers are devoting their best thought to the important subject of mine ventilation.

In a certain mine there was a door in the return between the eleventh and twelfth southwest entries. Just below the twelfth southwest in the return was a regulator. With the door open, 5,000 cubic feet of air per minute was passing through the regulator, and 4,920 through the door. At the last open cross-cut between these two entries—a distance of 900 feet from the door—no reading was to be had with the door open. With it closed a reading of 4,488 cubic feet was obtained. Between the door and the open cross-cut, were 12 ship-lap stoppings, plastered with wood fiber. This shows an efficiency of 91 per cent.

In this same mine an intake registered 9,040 cubic feet per minute; the last cross-cut 7,200 cubic feet. There were seven ship-lap stoppings plastered with wood fiber, showing an efficiency of 80 per cent. The cost for a stopping of this kind, with an area of 70 square feet,

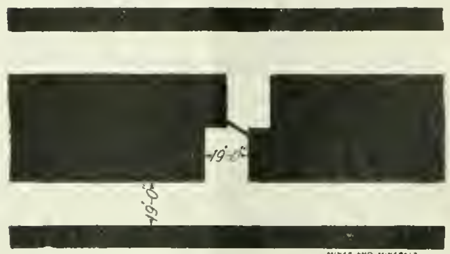


Fig. 1

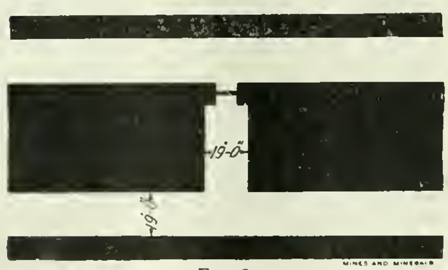

Fig. 2

counting labor and material, is about $7; and its average life is about 3 years. It will have to be replastered every 6 months at a cost per year of $1.50.

In another mine the intake of the fourth southwest had 4,860 cubic feet. At the last cross-cut no reading could be obtained. There were 30 rough board stoppings, not plastered, and two doors. Efficiency *nil*.

In this same mine the main west entry showed 6,825 cubic feet with 1,000 cubic feet at the last cross-cut. There were 19 rough board stoppings, and two doors. Efficiency 15 per cent. The cost of rough board stoppings for an area of 70 square feet, including labor, is $5.50; and the average life is 3 years.

At another mine the second southwest intake had 21,560 cubic feet, the last cross-cut 13,860 cubic feet. There were 10 stoppings made of patent lath, and one door made to swing both ways. Five of these stoppings were plastered with wood fiber, and five were not. Efficiency 64 per cent. Cost and life same as ship-lap.

Another mine measured 9,940 cubic feet at the intake of the first southwest, and at the last cross-cut there was 8,151 cubic feet. Between this pair of entries were 30 cinder block stoppings, two temporary ship-lap stoppings, not plastered, and one door. Efficiency 82 per cent.

Cost for an Area of 70 Square Feet

63 blocks 6 in. × 9 in. × 18 in. at 9 cents....	$5.67
Cement	1.00
Labor, 2 men, one day at $2.84..............	5.68
Total	$12.35

As to the life of this kind of stopping, no reliable data could be secured; but some two years old are still apparently as good as ever.

In another mine where the slate which falls from the roof is utilized there was a reading at the west intake of 25,810 cubic feet. At a distance of 1,030 feet there was 22,100 cubic feet, an efficiency of 92 per cent.

These slate walls are built double at a distance apart of 2 to 6 feet and filled between with loose material. After letting stand a sufficient time to settle, one wall is plastered with a mixture of wood fiber and sand.

The cost of a stopping of 70 square feet area will be, at the prevailing rates:

Three sacks fiber at 30 cents................	$ .90
Hauling slate and building stopping, two men, 8 hours, at $2.84....................	5.68
Two men, 8 hours, at $2.61 (drivers).........	5.22
Two men, 2 hours, plastering................	1.42
Total	$12.32

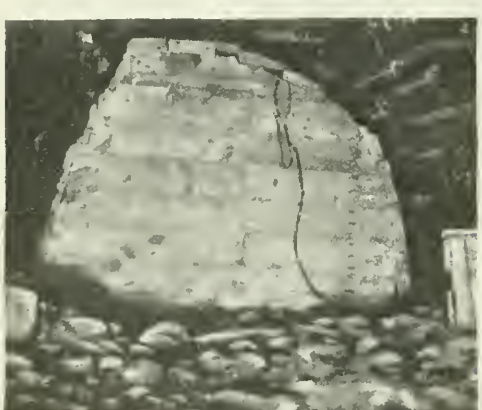

Fig. 3. Ship-Lap Plastered Stopping

Fig. 4. Patent Lath Plastered Stopping

Fig. 5. Board Stopping, Plastered

Stoppings in this mine over 2 years old are perfectly good.

The concrete monolith, brick, and concrete block stoppings, from the standpoint of efficiency, cannot, of course, be improved upon. Those made of cinders and cement, while they have the advantage of being of light weight and cheap, may not last so well; for the acids from the cinders will probably in time have a disintegrating effect on the cement.

Many advocate the plastered wood, because it offers but slight resistance to an explosive force; but when we consider that a 6-inch wall made of concrete blocks, if laid in lime, would readily blow out if an explosion should occur, and that such a wall is practically permanent; that the cost through a period of years, is less; and that if blown out, the blocks would not be destroyed as lumber would be; it is apparent that the advantage lies with the block stoppings. Stoppings made of lumber also have this disadvantage, that they cannot be plastered close to the face of the entries on account of vibration from the shots knocking the plaster off.

The slate wall, if left unplastered, is practically worthless, and in Illinois is not permitted. But if it is plastered with cement or wood fiber, it makes a fine and permanent stopping, if care is used in the construction of the walls.

Ship-lap and patent lath, if plastered, makes a tight stopping; but is a mere makeshift if the plaster is omitted.

In the case of ship-lap, the fiber will adhere much longer if the surface of the boards is "roughed up" with a pick or other pointed instrument.

The cost of a stopping depends on the area of the cross-cut; and a little head work will sometimes be the means of reducing the cost on this important item of mine ventilation.

In Illinois, yardage must be paid on all work less than 18 feet wide; and cross-cuts must be made not more than 60 feet apart. To avoid paying yardage, cross-cuts are often made more than 18 feet wide where the roof is strong enough to permit it; but when this is done the cost of the stopping almost equals the yardage saved.

To overcome this, some operators have adopted the plan of offsetting the cross-cuts one-half, or more, of their width, as shown in Fig. 1. Others drive the cross-cut wide from one side and take one or two cuts narrow from the other, as shown in Fig. 2.

Both are good plans to follow in stub or cross-entries in machine mines (with a possible advantage for No. 2); for if the stopping is narrow it not only costs less, but the chances for leakage are lessened.

If a series of stoppings is so constructed that most of the air is lost before it reaches the working faces, the health of the workmen is menaced by reason of the deleterious air in which they are compelled to labor; their efficiency is reduced and money lost to the company in horsepower consumed in producing a ventilating current that does not ventilate. The inspector is compelled to show up the mine manager in a bad light; and frequently has to withdraw men from the working places, causing an additional loss to the company and a loss to the men who are deprived of the work. And, in addition to all these, there is also the ever-present danger of explosion and fire which may result from gas by reason of bad ventilation.

All of us have seen many a good overcast that was nearly useless because of leaky stoppings, and many a fine fan throwing great volumes of air into a mine, and which was lost before it ever reached a miner.

What excuse can there be for a poor stopping?

Determining Coal Values

*By E. G. Bailey**

Manifestly the value of coal, as measured by its heating and evaporative powers, must be determined by actual experiment. The fundamental question is, shall the experiment be conducted on a large scale, as in the case of a boiler test, or on a small scale, but with great refinement, as in the method pursued by the chemist. In truth the methods are not so different as they appear.

The chemist in the laboratory conducts a miniature boiler test as truly as does the engineer in the power plant. The latter always expresses his results in "equivalent evaporation from and at 212° F. per pound of coal." His feedwater is not necessarily at 212 degrees, and it is an unusual case if his steam is at the same temperature. Suppose a case where the temperature of the feedwater is 110° F. and the gauge pressure is 150 pounds. From a steam table we find that there were 1,115.6 British thermal units used in evaporating each pound of water fed to the boiler into dry steam. Had the water been fed to the boiler at 212 degrees and evaporated at atmospheric pressure, the heat used would have been only 965.8 British thermal units per pound. Dividing 1,115.6 by 965.8 gives 1.155, which is the factor of evaporation. Multiplying the weight of water fed to the boiler by this factor, gives the "equivalent evaporation." This calculation makes the results obtained under various conditions comparable. Take another illustration of a boiler in a central hot-water heating system plant, where the return water is all pumped into the blow-off connection of a boiler and passes out the steam pipe after having been heated and not evaporated into steam. If the water enters the boiler at a temperature of 120 degrees and leaves at 175 degrees, it will have absorbed 55.4 British thermal units per pound, and divid-

*Chief of Coal Department of the Arthur D. Little Laboratory, Boston, Mass.

ing this by 965.8 gives .05736 as a "factor of evaporation." No engineer is going to say he cannot make a boiler test under such conditions, and in such a test, if there were 169.6 pounds of water pumped through the boiler per pound of coal fired, the equivalent evaporation in pounds of water evaporated from and at 212° F. per pound of coal would be 9.73.

The determination of the calorific value of a coal in the laboratory by means of a bomb calorimeter is so similar to this last illustration that it, too, is simply a boiler test. The bomb is nothing more than a perfectly tight steel boiler, but instead of having the water in the boiler and the heat applied from the outside, the conditions are just reversed; the fuel is burned in the bomb, or boiler, and the water completely surrounds it, so that all of the heat is absorbed and indicated by the rise in temperature of the water. If 1 pound of coal was burned and the surrounding water, including the equivalent of the bomb and other metal parts, weighed 2,000 pounds, and the temperature rose 7.250° F., we would have as the factor of evaporation 7.250 divided by 965.8, or .007507. Multiplying the pounds of water per pound of coal, which in this case is 2,000, by this factor, gives 15.014 as the equivalent evaporation from and at 212° F. per pound of coal. However, instead of reporting the results in terms of equivalent evaporation, as the chemist used to do and as is still common in England, he calculates results in British thermal units. From the above figures, one readily sees that the heat developed by the burning of the pound of coal was 2,000×7.250, or 14,500 British thermal units. If we take the results as calculated on the evaporation basis, we have 15.014 pounds water evaporated from and at 212° F., multiplied by 965.8 (the number of British thermal units required to evaporate 1 pound of water under these conditions), giving 14,500 British thermal units developed per pound of coal. So that with the calorimeter the chemist really conducts a boiler test and obtains 100 per cent. efficiency. As a matter of fact, the chemist uses but 1 gram of coal and 2,000 grams of water in the calorimeter test, but the same results are obtained as if proportionally larger quantities of each had been taken. All through the work of the chemist, accuracy replaces quantity. He can weigh $\frac{1}{200000}$ part of an ounce as accurately as the engineer weighs pounds, and with his thermometer he reads thousandths of a degree instead of degrees.

The disagreement between the evaporation as determined on the boiler test and the British thermal units from the calorimeter are more frequently due to errors or variations in conditions in one or both tests. How closely can the engineer check the results on different tests from the same lot of coal, and likewise what is the variation between the British thermal units determined from different samples taken from the same cargo?

A competent engineer, who has made a large number of evaporative tests, found a variation of 17 per cent. between different tests on the same coal. These tests, however, were of only 4 hours' duration, which was the most probable reason for such a large error. Evaporative tests made at the fuel-testing plant of the United States Geological Survey show variations of 3 to 5 per cent. on coal from one car burned under as nearly identical conditions as is possible to obtain. Variations in the rate of evaporation seriously affect the efficiency. The thickness of the fire, intensity of draft, and evenness of the bed of fuel are so closely related to boiler efficiency that in making a test it should be made so thorough that a heat balance can be calculated showing the distribution of heat as it escapes in the various sources of loss, as well as that used for evaporation. Such data add weight to an evaporative test and show whether or not the coal, the load, the fireman, or the grates should be credited with the good or poor results. If an engineer obtains only 65 per cent. efficiency he should determine whether the excessive losses are due to high flue temperature, incomplete combustion, or an excessive air supply. The more important data of a couple of tests given in Table 1 will illustrate this point. The coal used was from the same car.

The coal was not at all responsible for this difference of 5 per cent. in the boiler efficiency, but it was practically all up to the fireman. Table 2 gives the losses which may largely be controlled by him.

There are certain features in coals that the chemist has as yet been unable to determine with accuracy from the analysis. The most important one is the kind and amount of clinker formed. This varies so much with the conditions under which the coal is burned that a practical test is necessary. But when the engineer does make a test, how often does he determine the per cent. of clinker formed? This item is frequently of great importance, but it affects the capacity of a plant much more than it does the efficiency. The coking properties of a coal may also affect the capacity of a plant, while the efficiency might not be affected in the least. What the engineer should determine is what coals he can burn without being in danger of a shut-down with the heaviest load, and leave it to the analysis to determine which of these coals will develop the most heat units per dollar. This does not mean that the British thermal units alone should be considered, but the volatile and ash would be considered as affecting the boiler efficiency, and comparisons made in this manner are more accurate and less expensive to obtain than if determined by a long series of evaporative tests.

Coal Washing and Briquetting

The Plant of the Alstaden Colliery Co., Ltd., at No. 2 Hibernia Mine, Germany

The Alstaden Colliery Co., Limited, has two mines near Oberhausen, Germany. At the No. 2 Hibernia mine anthracite is mined, and the plant described in this article was designed to treat this kind of coal.

Before the engineers undertook the design of this plant, they conducted a series of exhaustive experiments to ascertain the physical properties of the coal and its peculiarities during the usual methods employed in washing, after which they decided on the best system to follow for its treatment.

The quantity of coal to be treated was 900 tons in 16 hours. The system decided on was to break the coal into small pieces and then subject it to a washing operation. In order to produce a marketable briquet, it was found necessary to wash only the coarse grains contained in the fine coal and to mix the unwashed dry dust with it after it had passed through the washing process. The dirt mixed with the coal as it comes from the mine is removed by the process employed, and enables briquets of high grade to be made from the fine coal.

The material as it comes from the mine is conveyed in mine cars from the shaft cage and fed to a shaking screen by means of a mechanically driven revolving tipple. The screen plate is perforated with 3.15-inch diameter round holes; and material below this size falls direct into the receiving hopper *A* shown in plan and elevation, Fig. 1. The coal which passes over the screen is delivered on to a picking belt, where the coarse dirt is removed by hand. From the picking belt the coal goes to a pair of rolls, which reduce it to nut size and smaller, after which it falls into the hopper and is raised by an elevator to a shaking screen punched with 1.97-inch diameter holes. The coal passing through the screen falls into hopper *A*; that which passes over the screen is delivered to a jaw crusher by which it is broken into pieces below 1.97-inch size and is discharged into hopper *A*. In order that the large coal may be stocked in the summer, a chute is provided at the end of the picking belt, by which the coal can be delivered into tram cars. The rock picked from coal is loaded into rock cars on the picking belt platform. The rock cars are raised by an elevator *C* to the level of the cage landing and hauled to the waste heap, where they are dumped. A second steam elevator *D* is provided for raising the coal stored in the stock yard to the tipple platform. From the hopper *A* the coal is raised by means of elevator *E* to the washery shown in Fig. 2, where it is delivered to and divided by two shaking screens *F*, shown also in Fig. 4, and furnished with screen plates having perforations 1.57 inches, .59 inch, and .12 inch. The classified products from 3.15 inches to 1.57 inches, 1.57 inches to .59 inch, and .59 inch to .12 inch are delivered into separate troughs, along which they are flushed by a stream of water to the six compartment washer *G*, shown also in Fig. 5. The largest size is treated in the first compartment, the intermediate size in the next two compartments, and the smallest size in the three remaining divisions. The largest and intermediate sizes are discharged from the jigs into two troughs along which they are flushed by the overflowing water to two draining and classifying screens *H*, Fig. 2, which are above the nut coal bins. These screens are furnished with plates having 1.97-inch 1.18-inch, .59-inch, and .315-inch diameter perforations, into which sizes the coal is separated. The two sizes, 3.15-inch to 1.97-inch diameter and the 1.97-inch to 1.18-inch diameter are delivered on a picking band which is provided to enable a light bituminous shale, which it is impossible to separate by washing, to be eliminated by hand. The belt delivers the coal into the two outer compartments of the storage tower. The nut coal from 1.18-inch to .59-inch diameter and from .59-inch to .315-inch diameter is discharged into two bins as these sizes are too small for hand picking. To prevent this coal from being broken as it is being deposited in the bins, an anti-breakage spiral chute is fitted to each division of the loading bins. The discharge gates in the bottom of the bins are arranged in combination with draining screens and sprinkling devices, by means of which the coal is rinsed with fresh water before passing down automatic anti-breakage chutes into the broad gauge cars. The fine coal below .31 inch removed with water from the nut coal at the top of the bins by the drainage screens, is conveyed along the troughs to the sump *I* of the drainage elevator *K*. This elevator, which is furnished with perforated buckets, lifts the coal and delivers it into either of two

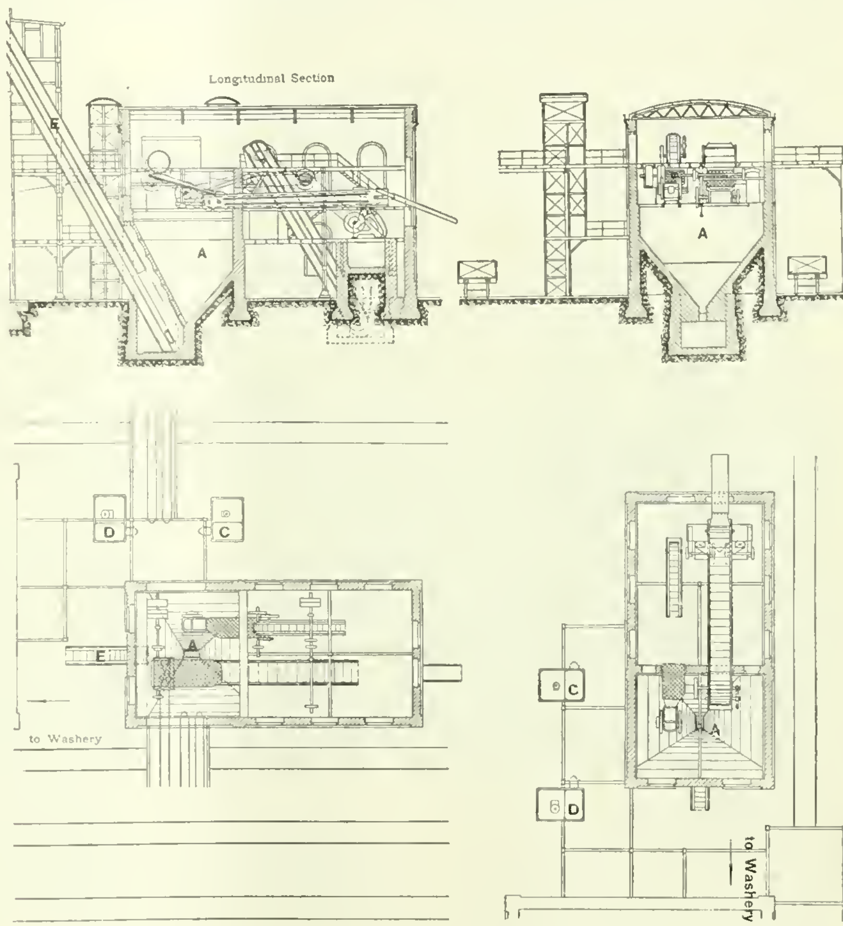

Fig. 1. Screening and Crushing Plant

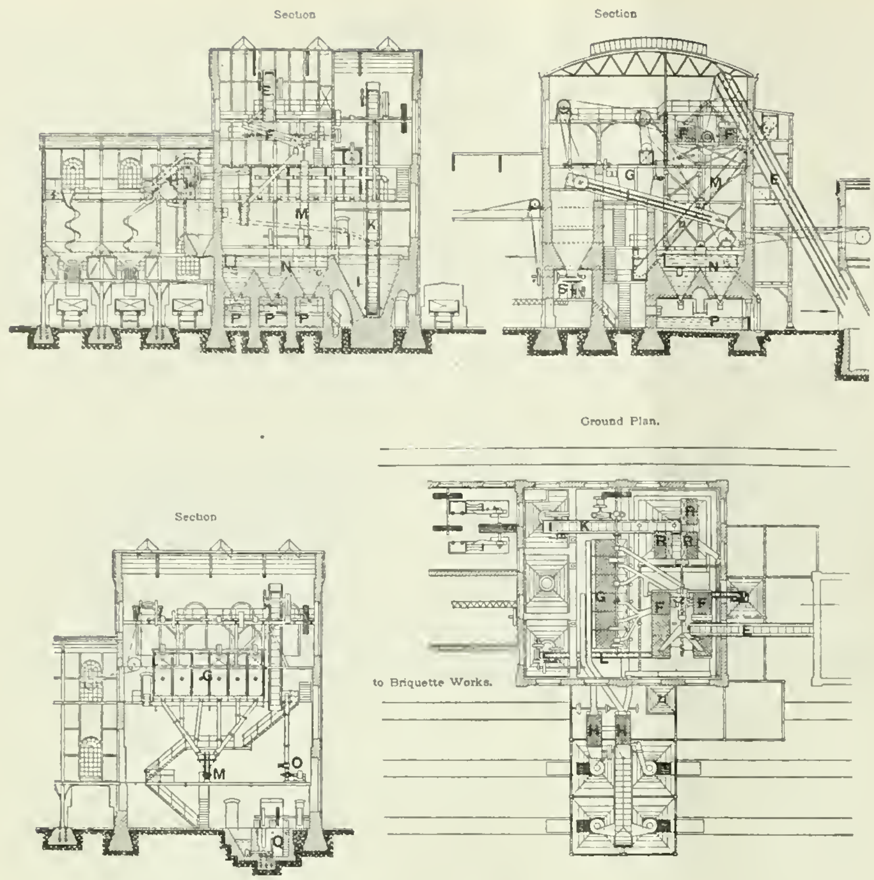

Fig. 2. Coal Washery

compartments provided for storing the fine washed coal. The hopper divisions are fitted with drainage devices and the coal becomes relieved of most of its moisture. The fine dust coal below .12-inch diameter eliminated by the main classifying screens passes down a chute leading to a scraper conveyer *L* and is carried to a third compartment in the fine coal tower. The dirt eliminated by the jigs in washing passes down through pipes leading from the bottom of each division of the jig hutch to the boot of the dirt elevator *M*, by which it is drained and delivered to the dirt collecting hopper. The dirt hopper is so placed that the material can be discharged into cars on the cage level. All water used in the system is returned to the fine coal draining elevator sump *I*, where the fine coal accompanying it settles down and is removed by the elevator *K*. The surplus water containing fine material in suspension passes over a sill into the pointed settling tanks *N*. In these tanks the suspended particles settle, while the clarified water passes down a pipe leading to a large centrifugal pump *O*, by which it is raised and reused. The fine material collected in the spitzkasten *N* is drawn off at the bottom by opening suitable valves, and flows to one of the three sludge sumps *P*, where it is drained. The sludge is subsequently loaded into tram cars and taken to the boiler house, where it is mixed with the boiler coal and used for firing purposes.

The water which overflows from the sludge sumps, together with the water employed for rinsing the nut coal, carrying with it any fine coal which may have been produced in the loading and discharging operations, is conducted to the centrifugal pump *Q* by which it is delivered into the elevator sump *I* and is subsequently used over again in the washing process after undergoing clarification in the spitzkasten, so that no water escapes from the plant with the exception of that contained in the washed products in the form of moisture.

As there is a probability that at some later date it may be considered advisable to wash the fine coal below .12-inch diameter, the plant is arranged so that three additional fine coal washers *R* can be subsequently installed.

The washing and screening plants are driven by one horizontal compound steam engine. The engine is connected to a central condensing plant, but it is arranged so that it can be worked non-condensing if required.

Briquet Plant.—The briquet plant is designed to produce 30 tons per hour of briquets weighing 6.6 pounds each. It is arranged in duplicate, each section consisting of one oven and three presses with all subsidiary apparatus. Only one section of the plant has been erected but a second section will be added.

The fine washed coal and dust coal upon being discharged from the storage towers is received upon revolving tables, which enable the coal to be drawn off regularly and in any desired quantity and also in any desired proportion of washed

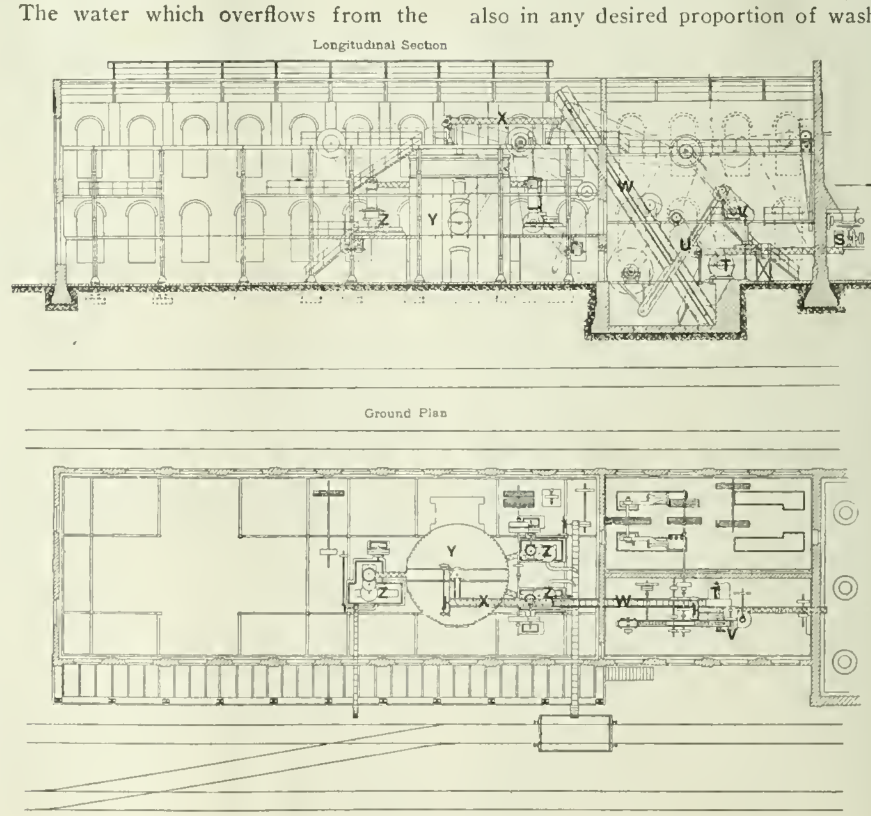

Fig. 3. Briquet Plant

and dust coal. The coal is deflected from the revolving tables by means of a diverting plate and falls into the trough of a scraper conveyer *S*, Fig. 3. The scraper conveyer takes it to a screw conveyer by which it is delivered to the disintegrator *T* where the dust and washed fine coal become intimately mixed and reduced to a fine state.

The pitch is brought to the plant in railway cars and is stored in a chamber running along the whole length of the building. From the storage chamber the pitch is conveyed to the jaw breaker from whence the crushed product is raised by the elevator *U* and delivered to the small disintegrator *V* by which it is reduced to a fine state. Beneath the disintegrator there is a small storage hopper out of which the pitch is withdrawn in regular quantities by means of the revolving table which is arranged with a deflecting plate. The pitch falls into the trough of the screw conveyer previously referred to, which conveys the washed and dust coals from the coal storage hoppers to the plant. The coal and pitch are conveyed to the disintegrator *T* by which they are intimately mixed together. The mixed product falls into the boot of the elevator and is raised by this elevator and delivered to the screw conveyer *X* by which it is fed evenly and continuously into the oven *Y*. The oven consists of a circular brick chamber having a revolving floor. Beneath the floor a series of heating fires are kept continually burning, which keeps the oven at the required temperature. The heat is sufficiently intense to dispel the remaining moisture in the coal and to heat the coal and pitch to the degree required. The mixture is deposited in the center of the floor and as the floor revolves the material is continually turned over by fixed stirring plates, which at the same time gradually deflect the charge to the periphery of the floor. The heated mass is discharged by means of fixed scraper plates and passes to the three presses by the agency of the screw conveyers. Before reaching the presses *Z* the material first undergoes a kneading process in the steam heated vertical kneading arrangements. After passing through this process the material is delivered on to the molding plates of the press and is subsequently compressed into briquets of the size required. The briquets then pass automatically on to conveyer belts of the wire woven description and are conveyed to a chute from whence they are taken off by hand and loaded into railway cars.

The whole of the machinery in the briquet plant is driven by a horizontal compound steam engine of the same size and type as that provided for actuating the screening and washing apparatus. Both engines are placed in one engine room which permits of their being easily and conveniently attended to.

The buildings of the screening plant, washery, and briquet manufactory are all built of substantial brickwork with the inner fittings for supporting the various apparatus, shafting, etc., made of structural iron work. The roofs are made of iron work and are covered over with cement composition; and the floors are partly made of plates and partly of concrete, so that the whole plant is composed solely of masonry and iron.

We are indebted to the Coal Department of the Humbolt Engineering Works Co., of Cologne-Kalk, Germany, for information in this article.

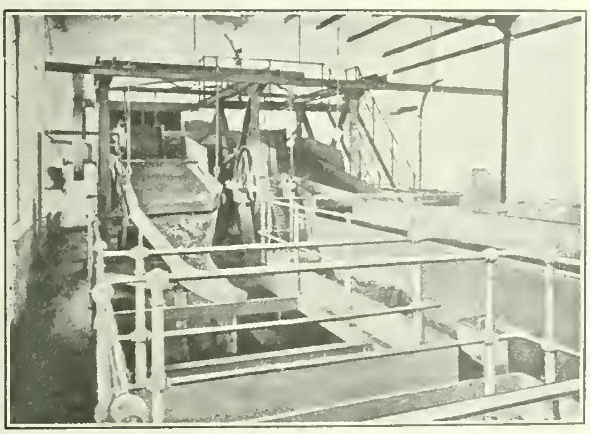

Fig. 4

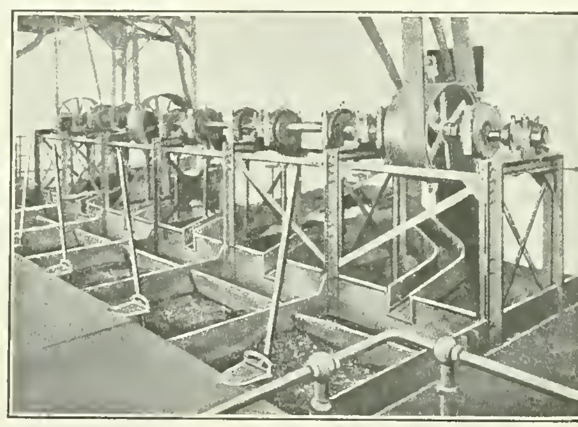

Fig. 5

An Early Instance of First Aid

Some years ago a witty Irish miner working a breast in the Mammoth Seam in the pitching measures of the Hecksherville Valley, Schuylkill County, Pa., having favorable conditions for a heavy shot, fired it. After he and his laborer had waited a short time in the safety of a cross-heading for the smoke to clear away, he said, "Moike, g' up now an' thrim off the sides an' top, an' I'll g' out fur th' ambulance."

A Method of Socketing or Capping Winding Ropes

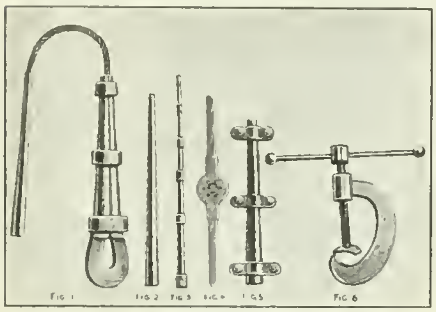
In an article in Transactions of the Institution of Mining Engineers, Douglas Jackson says:

The socketing of winding ropes has always been a subject of deep interest to colliery managers, and is now even more so, seeing that the new Mine Act (English) stipulates that ropes must be recapped at intervals of not more than 6 months.

The ordinary methods of capping ropes have given good results in the past, and in the majority of cases have held firm during the whole life of the rope. It is generally known, however that the attachment of the socket to the rope is the weakest part, and would be most likely to give way before the breaking strain of the rope is reached. With deeper pits and increased loads raised at a much higher speed, the risk of the socket slipping is undoubtedly greater.

This fact has led the writer to devise and adopt a simple method of capping, which can be applied by the colliery blacksmith, with no risk whatever of the socket slipping. The tools used in preparing the rope for the cap are shown in the accompanying illustration (Figs. 1 to 6). In Fig. 1, a socket is shown fixed at one end of a piece of rope, while the other end shows the white-metal cone completed and ready to receive the cap. Each size of rope requires its own set of tools, made in proportion to the diameter. The length of the cap should be equal to 22 times the diameter of the rope, and the large diameter of the cone should be equal to twice the diameter of the rope.

The socket for a winding rope is generally made of soft steel, or of Low Moor iron, with a breaking strain of about 40 tons per square inch; but it is better to err on the safe side, and assume the breaking strain at, say, a quarter less, or 30 tons per square inch. Fig. 2 shows the mandril, which is made of hard steel and turned in the lathe to the desired diameter and taper. This mandril is used by the blacksmith as the pattern or block on which to fit and finish the completed socket. Fig. 3 is the spike, with rings about 2 inches apart, and is turned in the lathe to the same taper as the mandril, but is less in diameter by the thickness of two strands of the rope and rings. The rings are sawn through lengthwise, in order to give them an easy hold on the spike. The twister (Fig. 4) is used to twist the strands of the rope round the spike and rings back to their natural lay or original position. The hole in the center



Tools for Socketing Winding Rope

is large enough to allow of the rings on the spike passing through, and the six smaller holes, spaced equally apart, receive the strands of the rope. The clamp (Fig. 5) is made in two halves, with three half glands riveted on each half, the inside head of the rivets being countersunk. The two halves, when bolted together, fit on the mandril.

To prepare the rope for socketing, the strands at the end of the rope must be sawn to an equal surface, the socket rings passed on to the rope in their order, the length of the socket measured off, and the rope lapped round for a few inches with soft wire. The rope is then fixed in the vise, the strands unfolded, and the central core cut out. Each strand is then put through one of the small holes in the twister; the spike with its rings is placed in the position of the central core of the rope, and the strands are gradually twisted around it: when the twister reaches the top of the spike, the top ring will be a little below the end of the strands. The clamp (Fig. 5) is put on and screwed tight; this presses the strands firmly against the rings of the spike, and so holds them in position. The spike can now be turned round and withdrawn, leaving the rings inside a properly tapered cavity ready to receive the metal. A hot rod should next be put down the center so as to heat the small ring at the bottom, and the white metal then poured in at the top. Should a leak take place at the bottom of the clamp, a touch with wet waste will stop it at once. When sufficiently cooled, the clamp should be taken off and the short ends of the strands dressed off. The finished cone will now be exactly of the same dimensions as the mandril. The socket should now be heated at the bend, the cone put into its position, and the socket closed gently down with the screw clamp (Fig. 6). The socket rings are then driven into position, and the operation is complete.

In the system here described, the cone is well formed and solid, so that there can be no corrosion of the wires, and, in addition, the strands of the rope have their natural twist.

The writer had six tests made with short lengths of rope, and not one of them broke under the breaking strain given in the rope-maker's tables.

Another test was made with a short length of rope. One end was socketed by the rope maker, the other in the manner already described. The result was that the rope broke inside the rope-maker's socket with a strain of 75 tons, or 78 per cent. of the breaking strain of the rope, which was stated in the maker's tables as 96 tons. After examination the cause of the breakage was seen to be that the rope maker in socketing his end of the rope had adopted the method of turning back the strands over an iron ferrule, and interweaving the ends into the rope again. The taper made was therefore imperfect, and no two strands were subjected to the same strain.

Richard's self-tinning plastic white metal was used for the socketing of all the ropes tested, its melting point being as low as 500° F., and its contraction in cooling almost *nil*.

In a paper read before the Alabama Coal Operators' Association, J. B. McIntyre says: "Probably no one item works so much injury to mine tracks as acid mine water, so that proper drainage becomes a matter of prime importance.

Derailing Switches for Slopes

*By Simon H. Ash, E. M.**

It has been stated that the only reliable method of derailing a runaway car or trip on a slope is by means of the automatic safety switch that is always set to run the cars off the track, except when the operator closes it for the cars to pass down the incline. This kind of switch is closed by the ascending car or trip and is opened automatically after the cars have passed.

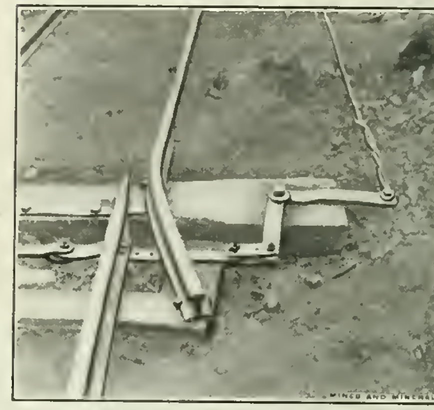


Fig. 1

It is thus always set to run a descending trip off the track, and depends upon the man at the top of the incline to see that the switch is closed at the proper time.

If the headman makes no mistake the trip will reach the bottom in case there is no other accident before or after it has reached the switch; however, there is always an element of uncertainty when man must be depended on in such cases; and this, with numerous other considerations, have been factors in condemning inclines where they could be avoided. While in some cases it has been considered advisable to build from 1 to 2 miles of tramway in order to avoid inclines, even with such expensive means they at times are necessary; therefore, improvements along the lines of safety are eagerly sought.

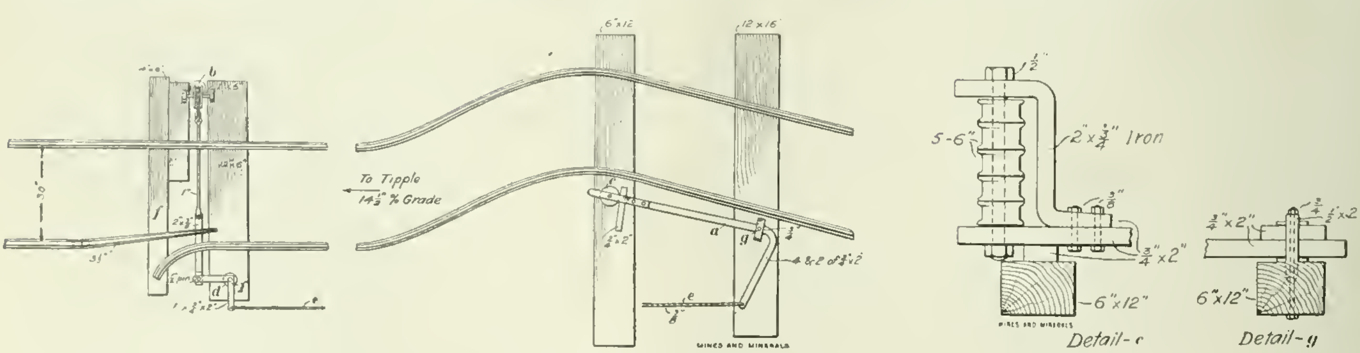

Fig. 2. Details of Derailing Switch

Owing to the increased danger arising from the long gravity planes necessary to handle the coal in the Roslyn district of the state of Washington, various devices were tried to derail runaway cars and pre-

*Engineer for R. C. C. Co.

vent the excessive damage done, as well as to protect the lives of men on the tipple. At the No. 1 mine of the Roslyn Cascade Coal Co., William Mackay, general manager, the gravity plane is 3,400 feet long, averages 14½ per cent. grade, and is almost a perfect tangent with the exception of two small curves, the location of one of which was taken as the position for the safety switch described. A plan and elevation of the derailing switch, which is working most excellently, is shown in Figs. 1, 2, and 3. The switch is operated automatically by the hoisting rope, which, by means of pulleys and a connecting rope operates the two levers that throw the switches, shown in Figs. 1 and 3. The switch is always held open to derail the trip until the hoisting rope has passed below the lever *a*, Fig. 2. This lever is held in position by means of the weight *b* suspended by a chain over the pulley, as shown. As soon as the hoisting rope passes below the lever *a* it engages the pulley *c*, Figs. 2 and 3, which moves the lever *a*, which in turn operates lever *d*, Figs. 1 and 2, by means of the tiller rope *e*, which is 160 feet long, sufficient to allow a 15-car trip to be a safe distance from the switch. The lever *d* on moving closes the latch *f*, thus throwing the switch for the main line. Should any cars break loose above the lever *a* the switch would fail to operate and the cars would be derailed.

The above device is at work on an outside engine plane, but a somewhat similar device, shown in Fig. 4, is in operation in the slope of No. 2 mine, which is sinking on an average grade of 28 per cent.

There are so many chances for cars running down a slope that the sinking operations are always a cause of anxiety; therefore, the installation of this device near the slope bottom is a source of relief to the men and the management. The plan of operating the slope device is the same as for

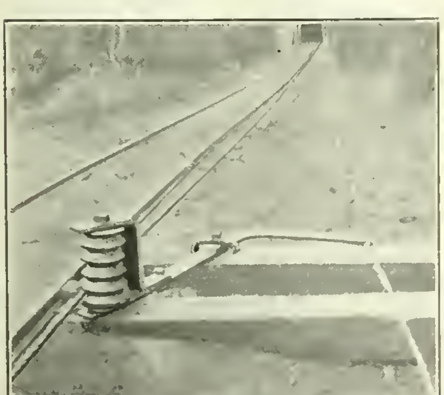

FIG. 3

the engine plane; that is, by means of hoisting rope, levers, reach rope, and weights, except a different method is used for obtaining the desired leverage by placing the pulleys in the center of the track and using a different method of keeping the derailing switch thrown.

The object of the weight *a* in Fig. 4 is to balance the weight of the pulleys and lever *b*, and to always return the pulleys to their necessary position. The lever switch *c* by means of the weight *d* serves the same purpose as the weight *b* in Fig. 2 in keeping the derailing switch thrown open.

The great advantage obtained by putting

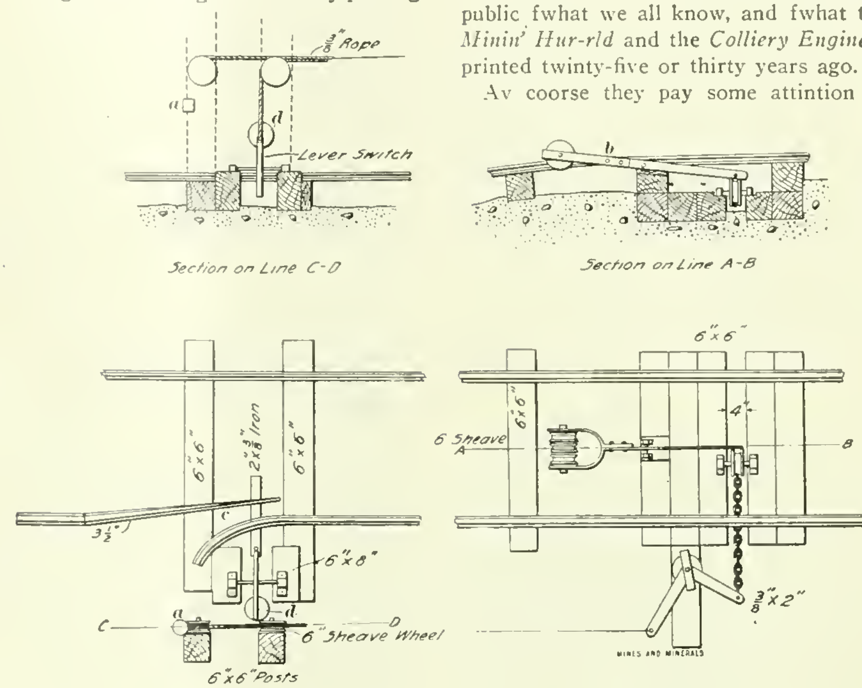

FIG. 4

the pulleys in the center of the track, as shown in Fig. 4, is the doing away of any curves in the track and only necessitates the track being slightly elevated.

Capacity of Rolls

The capacity of a set of rolls for ore crushing depends largely on the evenness of its surfaces. If the rolls are worn so as to become grooved, and so that they do not meet except in spots, their efficiency is reduced, often as much as 50 per cent. A set of well-constructed 14" x 27" rolls, with even surfaces, and running at 100 revolutions (700 feet peripheral speed) per minute, and taking ordinary quartz ore from the crusher at .5-inch size, will reduce it approximately as follows: To pass 8-mesh screen, 3,500 to 4,000 pounds per hour; to pass 12-mesh screen, 2,500 to 3,000 pounds per hour; to pass 15-mesh screen, 2,000 to 2,500 pounds per hour; to pass 20-mesh screen, 1,500 to 1,800 pounds per hour.

In a recent French report, reference is made to a reduction in the number of fatal accidents in French coal mines, which fell from 1.17 per 1,000 men employed in 1909, to 1.08 in 1910, and although the figures for 1911 are not yet published, it is believed they are equally satisfactory.

Hogan on the Bureau of Mines

Written for Mines and Minerals

Say, Reilly, this Bureau of Mines makes me tired. Here they are spindin' money and makin' a great hullabaloo out near Pittsburg explodin' coal dusht in an ixpirimintal mine, and provin' to the minin' public fwhat we all know, and fwhat the *Minin' Hur-rld* and the *Colliery Engineer* printed twenty-five or thirty years ago.

Av coorse they pay some attintion to gas too, an' they have a laboratory where they tesht the gas, an' powdher an' safety lamps. I'm not sayin' that they don't do some good things, but whin they tell the results of their teshts they put it in words that you an' I can't understhand. Sure if it's gas they're talkin' about they give it a name be which few ould miners (and manny of thim are well acquainted wid mine gases mind ye), wouldn't know it. Sure they spake of ould fashioned fire damp as methane; black damp, be the same token, they call carbon dioxide, and white damp they call carbon monoxide. But whishper, Reilly, the fire damp is jist as hot, the white damp as deadly, and the black damp as chokin' be the big names as be the names be which you know thim. I wuz talkin' to Father McGovern about it the other day, an' sez he, "Hogan, don't let the names bother ye. The names the min in the Bureau give the gases don't change thim a bit. You know thim be wan name, an' they bein' eddicated call thim be the chimical or scientific names." But Reilly, it does bother me. Sure whin I wuz a bye the hedge schoolmaster niver taught me chimistry, if he knew it himself; an' most av the min in the mines are no bether. I've no objections to the high choned names, if whin they call the gas by thim, they'd interdooce thim to us by sayin', "this is Carbon Dioxide *nee* Black Damp" as the Chicago society reporters say whin they spake of me rich daughter Mary Ann as Mrs. Patricius Monaghan, *nee* Hogan, the lasht bein' her name before she married Pat. But, lave thim call the gas fwhat they will, I'll have no hard kick if they'll find some way to make it less harmful than it's been in the pasht.

Will they do it? Well, Reilly, I don't know will they. There are some min in the Bureau that know something about minin'; but there are more av thim that have a lot to larn, and 'tis thim that seem to have the most to say. Sure if ye'd belave what they tell the newspaper min, and all they print in the bulletins, ye'd think the shuperintindints an' bosses, let alone the miners, who have spint their lives in the mines, know nawthin' av minin'; an' that a few min in the Bureau who know betther how to get a govern-mint appropriation than they do to dhrill a hole an' fire it, or set a prop, know it all.

Begorra, the more I rade about the Bureau in the newspapers an' the bulletins, the more I think it wuz organized for three purposes: First to get an appropriation, second to sphind it, and third to make the wurrk of the miner aisier an' safer, and to taich the minin' companies how to consarve the coal resoorces av the counthry. Av coorse the laiste important objicts av the Bureau, as I see it, are mintioned lasht.

Ye're right, Reilly. The minin' companies are doin' a lot to make the mines safer, an' they've larned how to mine the coal betther than they did whin you got yer first job as a miner after laborin' wid Davy Evans. Av coorse the savin' av the coal is good business, Reilly, an' ye can thrust the coal companies to look out fer number wan. There are times, as you well know, whin I'm not willin' to spake manny good words fer the companies, but there are others whin I musht, iv I want to be fair. Look at the first aid work. That's a grand thing, and it wuz the Big Boss of the Readin' company that set an example in it, that was soon follyed be all the others. The companies furnish all the appliances, pay the docthors for taichin' the byes, an' give thim opportunities to learn the wurrk, which is all for the good of the min. Be this manes, and the intherest the officials take in the wurrk, the min and the companies are partners, an' aich larns to know an' respict the other. An' whin aich Fall they have the competitive dhrills av the different crews, it's a great sight to see the officials, from the big boss down, matin' the min on an aqual footin', an' good feelin' an' respict prevailin' on both sides. Besides the first aid work, manny iv the companies are doin' a great dale more. Look at fwhat Tom Lynch is doin' in the coke regions. I wuz out there on Christmas to see Pat Tormey, an' he wuz tellin' me av all the pains the bosses at the Frick Coke Company's mines had to take to prevint accidents. Ivery place around the mines where there is anny danger, there's a sign of warnin' an' the words "Safety the First Considheration" are stuck up everywhere so that both the bosses an' min are always reminded that the savin' av a life or a limb is av more importance than a big production. In the ould days, Reilly, there wuzn't much considheration given to the safety of the miners, an' it's only be good luck an' the blessin' of God that the two av us are here now. It's different now wid most of the companies, an' if the extint of the mines and the production wuz the same, wid the same coal to mine that we dug forty years ago, there wouldn't be half the accidents there were thin. But conditions have changed in the hard coal regions, as you know, Reilly. The mines are deeper, more machinery is used, an' the minin' requires more judgment an' skill on the part of the min' than it did forty years ago. This accounts in a large missure for manny of the accidents. Av coorse most of thim that do happen might be previnted, aither be more care on the part av the min or the officials. But, Reilly, it's always aisier to see how to prevint an accident after it's happened than before.

Now, as I've been argyin, Reilly, the companies are workin' hard to prevint accidents, an' be minin' institoots an' other manes, they're taichin' the foreigners English, an' all av us simple rules to make the work safer. If the lads dhrawin' pay from the Governmint would larn just fwhat is being done, and thry be workin' in harmony wid the mine officials to improve things, insthead of claimin' credit for provin' things we all know, and av sayin' other things we know are wrong belittlin' the repytashuns of the bosses, they wouldn't be the laughin' stock av both the bosses an' the miners.

Sure they have some lad in Washington that dishes out all kinds av sthories to the reporters, till ye'd think the hid of the Bureau wuz lookin' fer a job as ladin' lady in a burlesque throup. The latest thing they've brought out is a sthory that the companies are wastin' 80,000,000 tons av hard coal ivery year. Whin ye think, Reilly, av how the companies are minin' coal that was abandoned thirty, forty, and fifty years ago, an' in the fresh ground they are workin' they're takin' out about two-thirds av the coal, at first work, an' thin robbin' back until they lave but little av the pillars, how the divil can they be wastin' almost as much as they mine? I see by the papers that a lad named Parsons workin' fer the Bureau diskivered this, and Docthor Holmes has been tellin' the people about it, and how the soft coal miners are wasting over three times as much ivery year. I'm thinkin', Reilly, that Parsons has been asleep for the past thirty years. Begorra, if he wuz writin' history, instead of sayin' "Home Rule wuz at hand for Ireland," he'd tell about the battle of the Boyne, and make ye belave it happened yestherday.

Why is it that hard coal dusht don't exphlode? Well, Reilly, afther forty years workin' in hard coal, you know it don't exphlode, don't yeh? Well, if you know it, lave it go at that. I know that soft coal dusht does explode, and you know hard coal dusht don't. Bechune the two of us we *know* what the Bureau of Mines is larnin'. Av coorse, whin yeh come down to the raison av it, all I can tell yeh is that the soft coal has more gas in it than hard coal, and a bit of hate warmin' the flyin' dusht makes it give off the gas, an' if it's lighted there's the divil to pay. What kind av gas is it? Well, Reilly, it's gas all right, and be the same token I'd call it fire damp, but the larned min av the Bureau call it somethin' that sounds like "fol de rol highbrow carbons." Ye ask, did I rade about the canary burds? Av coorse I did, an' though I've no use for the color of the little things, the poor burds can't help that, and it's a shame to be killin' thim be experimints in the mines whin English sparrows are so plintiful, an' nobody wantin' thim: Mebbe it's because canary burds cost more that the Bureau uses thim, fer there's nawthin' chape about the Bureau ixcipt the salaries it pays to the few lads in it who do know something about minin'.

Do I think anny good thing will come from the Bureau? Av coorse I do. Some of these days, if they live long enough, the min at the head of it 'll larn a little about minin', an' whin they do, they'll thry to larn more from the min who have spint their lives in the mines. Sure it isn't much you or I know, Reilly, about the fol de rol highbrow carbons an' such things, but we do know how to dhrill a hole and fire a shot, and how to set a prop, an' a few things like that. We might be able to taich thim a little, an' thin' whin it comes to the bosses, big an' little, that know all we know, an' more too, and have eddication as well, they can taich the lads in the Bureau as much as their heads 'll hould. Besides, Reilly, the Bureau has done some good work in thrainin' Rescue Corps, an' in testin' powdhers an' ile an' things like that, an' I'm hopin' that in the coorse av the nixt tin or twinty years, the boss av the Bureau will realize that the min at the head av the minin' companies have at laiste a little knowledge av' minin', an' that the harder his press agent at Washington works the less respict the min at the mines have for his Bureau. Well, Reilly, it's gettin' late, so I'll take the full av me pipe and lave ye, so ye'll be gettin' a good night's slape. Good night, to ye, me bye.

Commercial Sampling of Coal

Precautions Necessary that the Sample May Accurately Represent the Lot When Selling by Analyses

*By C. E. Scott**

Among consumers of bituminous coal there is an increasing tendency toward the chemical analysis, as a measure of quality. This is true in cases where the coal is not bought on analysis basis, as well as in contracts where the analysis is specified. The large users of steam coal are well informed on the quality of the various coals available to them, many having chemical laboratories sufficiently well equipped to make thorough tests, while the small consumers are aware of the fact that there is a very wide variation in the quality of different coals, and even they are awake to the importance of knowing the actual quality of the coal they buy. Consequently, it is now quite common for the coal company to be asked to furnish an analysis of the coal it expects to deliver on a certain contract. The consumer keeps this analysis and makes arrangements with some laboratory to take samples at certain periods, and send him the results. These results are then compared with those furnished by the coal company, and should any of them show higher ash or lower British thermal units, a complaint is immediately registered, and often an allowance asked for.

Whether this particular analysis or sample represents the coal is rarely questioned by the consumer; check analyses are occasionally requested, but duplicate sampling rarely.

In handling the complaints arising from the shipments of some 20,000,000 tons, in the past 2 years, it has been found that over 50 per cent. of such complaints as were covered by analysis specifications, were caused by inaccurate sampling. In the chemical analysis there is little chance for error, providing the work is done by a reasonably intelligent analyst; and in many investigations no case is recalled where the analytical work was at fault. There is as yet no uniformity in the method for the determination of the heat value of a coal; however, a bomb calorimeter, such as the Mahler or Atwater, where the coal is burned in oxygen, under pressure, is the type that has proven most accurate, and is the commonly accepted standard.

The weakest point in the present system of testing coal, as delivered at the plant, is the method of taking the sample and preparing it for analysis. The improper sampling of a lot of coal, such as a pile, a car, or a barge load, is so evident that it has finally become the subject of much discussion, and is now realized to be a very important feature of coal testing. Poor sampling is so general that it has been found in plants that consume thousands of tons monthly, in plants where coal has been bought on specification basis for several years, and in plants where skilled chemists are employed.

It is evident that the fact has been overlooked, that an analysis of coal is merely an approximation, and the value of the opinion based on the analysis depends on the approximation of the results determined. Where the interpreter of the analyses available on certain coals is not familiar, by previous experience, with the coal under discussion, it will be necessary for him to take more than ordinary precaution in passing an opinion on the commercial value of a coal. It seems that analyses heretofore have been considered of equal value, and no consideration of weight has been placed on the care and the quantity of the material handled.

Those who have considered their work well done, by sending samples to the best chemist available, have failed in their object, unless they have employed equal skill in the interpretation of the results so received. This interpretation depends on the knowledge of coal in general, together with a knowledge of the particular coal under examination, and the detailed facts of preparation of the sample.

The size of the sample used in the laboratory is of necessity limited to a few grams of coal, pulverized to 80 or 100 mesh. This laboratory sample may represent 50 or even 500 tons. When originally taken it should contain large pieces and fine coal in their respective proportions. The limits of variation permissible in a coal analysis are narrow, and where the chances of error are so manifold as in the sampling of coal, the greatest care should be exercised.

The most common error, such as taking only the lumps, or the discarding of everything above a certain size, will produce different effects on different coals, and this is a fact heretofore almost entirely overlooked by those in fuel-testing work.

In the case of low volatile, friable, columnar structure coals, an excess of fine coal in the sample will have a tendency to reduce the ash. It has been known to cause an error of 20 per cent. of the total ash. As an illustration, the following results are given:

Size of Coal	Per Cent. of Ash
Over No. 6 mesh screen	12.88
Under No. 6 mesh and over No. 10 mesh	10.48
Under No. 10 mesh and over No. 20 mesh	9.34
Under No. 20 mesh	8.86

The analysis of a properly taken sample of this coal is as follows: Moisture, .70; volatile, 17.08; fixed carbon, 71.28; ash, 10.94.

The effect of this error (excess of fine coal in the sample), with a high volatile, harder structure coal, is directly the opposite, and the ash is increased to several per cent. above the normal.

In the following results, column No. 1 shows the ash percentage in samples where that portion of the sample that remained on top of a 60-mesh sieve was discarded, while column No. 2 shows the ash in the same samples with the entire sample put through the 80-mesh sieve.

	No. 1	*No. 2*
	12.76	10.60
	13.36	10.59
	18.11	14.63
	12.59	11.33
	12.49	10.70
	11.13	9.42
	11.21	8.25
	10.88	9.87
Average	12.82	10.67

This is a coal that runs about 37 per cent. volatile matter.

In the former case the difference in the analysis of the different sizes of coal is due to the position of the impurities in the seam, as well as their character and that of the coal in which they exist. The shale is found in a finely divided state in the seam and is hardly perceptible. It acts as a sort of binder, holding together enough coal to form large lumps, and it is almost invariably true, that the parts of the seam which break down into the smaller sizes are free from this impurity. In addition to this, the coal is softer and more friable than the shale.

In the latter case, the coal is free from shale in the seam proper, and the shale entering the product of the mine comes from the floor or roof. The coal is harder than the impurity; and in handling, the greater percentage of shale is reduced to the smaller sizes and carried into the slack or fine coal, the ash in these sizes thereby being increased.

Errors in sampling not only occur in the taking and making up of the original sample, but are often found in the crusher house or sampling room. The man usually designated to take the sample is a fireman or laborer about the plant; or, if a man especially detailed or employed to do this work, he is paid little more than day-labor wages, and after receiving his first instructions is left to do the sampling without being watched. He is not aware of the effect on the sample, of even the slightest variation from the rules he was told to follow. A case is recalled where a sampler of more than 15 years' experience in the sample house of a large consumer of coal and coke was found to be the cause of serious trouble. The laboratory results on coal began to show excessively high ash.

*Chief of testing department of the Consolidation Coal Co., Fairmont, W. Va.

Complaint was made to the coal company furnishing the coal. Investigations followed and the methods used in the laboratory of the consumer were found to be unquestionable, the manner in which the sample was taken was above criticism, each step being carefully carried out, but in the final operation of making up the laboratory sample, this man was rubbing the samples until about half went through the 80-mesh sieve, and throwing away that which remained on top. By a series of tests to determine the effect of this error, it was proven to have increased the ash in the samples from 2 to 8 per cent. above normal. This was with a coal of about 38 per cent. volatile matter and of hard structure. The time at which this man began throwing away part of the sample checked the date upon which the laboratory results began to show excessive ash.

Heretofore, whether coal has been sold on an analysis basis or not, the collecting of the sample has been left entirely with the purchaser, and little attention has been paid to this part of the work, and even today there seems to be no rule or system followed in collecting samples. In some cases a sample is taken for each car load delivered, another company may take one sample for a certain number of tons delivered, still another, one sample for every cargo received, regardless of the number of tons it contains, while we find another, one of the largest and most important consumers of soft coal in the United States, taking one 5-pound sample to represent a cargo of approximately 5,000 tons. It can readily be seen that there is a limit to the number of tons one sample may fairly represent; also it is evident that the size of the original sample should be in some definite proportion to the number of tons it represents. The variation in two samples of coal, from the same pile, is often quite largely due to the difference in the analysis of the lump and the fine coal, and it is difficult to obtain proportionate parts of these different sizes in each sample; especially is this true if the sample is small. Since variation in different samples does occur, the average of the greatest number of carefully taken samples gives the most accurate figure as to the quality of the coal being sampled. If one sample only is taken, then the larger the original sample the more likely it is to be representative, as the chance of error decreases as the size of the sample is increased, likewise does the chance of error decrease as the number of samples is increased, even though the coal being sampled is uniform in quality.

Recently 100 cars of run-of-mine coal were sampled for sulphur determinations. The average of the 100 samples was 1.196 sulphur. These 100 results were divided into two sets of 50 each, by putting every alternate one in the same set; one set averaged 1.198, the other 1.195; then in the same manner into three sets of 33 each, with the following averages: 1.192, 1.182, 1.214; then into four sets of 25 each with the averages as follows: 1.201, 1.221, 1.194, 1.168. Then into five sets with the following averages: 1.153, 1.241, 1.094, 1.215, 1.276. Then into 10 sets with these averages: 1.113, 1.145, 1.037, 1.203, 1.193, 1.338, 1.152, 1.228, 1.281, 1.272. The maximum variation from the average of the 100 samples is .142, in the 10-sample set, which is approximately 12 per cent. of the total sulphur; in the 20-sample set the maximum variation is .102 or 8.5 per cent. of the total sulphur. On individual analyses $\frac{1}{10}$ of a per cent. is a slight variation, but in a coal that runs 1.20 on the average, it is hardly permissible in the majority of cases where accurate averages are desired, consequently 20 samples would not have been a sufficient number to give the desired results on these 100 cars of coal. From the 25-sample set the maximum variation is .028, and this is probably the smallest number of samples that would represent these 100 cars with desired commercial accuracy for this class of coal.

One hundred ash analyses were averaged and divided in the same manner, and even though the coal used is very uniform in ash content, nevertheless the difference in the average of the 20-sample set and the 100-sample set, was too great to allow the 20 samples to be considered sufficient for the determination of the ash in the 100 cars of coal.

In deciding the number of samples necessary to be taken from any one consignment of coal it would be unsafe to draw definite conclusions unless several hundred analyses had been made of the coal in question, and its uniformity or lack of uniformity determined, and its accurate average established. In the sampling of coal delivered at the plant this is rarely ever done, and the conclusions drawn from individual analyses, or sets of five and ten analyses, are given too much consideration and weight and are often erroneous.

Few contracts, if any, have been made, which stipulate in detail rules to govern the method to be pursued in collecting and preparing samples for analysis. It is now self-evident, however, to many shippers, that a sampling clause, which will compel the taking of representative samples must be inserted in all contracts, where coal is sold on an analysis basis, or where the purchaser expects to have analyses made of his deliveries; and it is the purpose of this paper to set forth, in part, rules which may aid in the adoption of standard methods for coal sampling.

The methods given below are, in a general way, those used by the testing department of the Fairmont Coal Co., Somerset Coal Co., and the Consolidation Coal Co.

Where samples can be taken mechanically, such as taking a definite quantity from a hopper or chute, at regular intervals, by the means of a slot or door which is opened and closed automatically and dropped into a crusher and quartering machine, it is advisable to do so, as it eliminates the personal element and the danger of chance samples. At plants where the annual consumption of coal is large, the advantages of mechanical sampling are many and the saving would more than offset the cost of installation and operation.

Local conditions and facilities to some extent govern sampling, but the principal points may be followed out at any plant, whether the coal is received by barge, railroad, car, or wagon.

"The size of the sample shall not be less than the proportion of one part in one thousand, and the minimum size of any one sample shall be 100 pounds, the maximum number of tons one sample shall represent shall be 1,000, and preferably much smaller than this, 250 tons. All the impurities, such as slate and pyrites, should be broken down in the original sample, and if this is done as each shovelful is taken, it makes the work much easier. In collecting the original sample from a railroad car it should be taken as the coal is being discharged; where the coal is delivered to the point of sampling in wagons, one large shovelful should be taken from each wagon; where it is delivered in a barge, the sample shall be taken as the barge is discharging (if the discharging is accomplished by the aid of a bucket or belt conveyer it is advisable to take advantage of this and obtain a small shovelful from the buckets or off the belt at regular intervals); where the sampling must be taken from a pile, a shovelful shall be taken from all accessible parts of the pile, and the shovel shall be filled from the coal underneath the surface. As the coal is collected it must be placed in a box, barrel, or can, of sufficient size, which has been thoroughly cleaned out before using. A lid should be kept on the container at all times to prevent dust, ashes, etc., from collecting on the sample.

"When the total sample is completed it shall be put through a crusher or dumped on to a clean wood or cement floor, or on a canvas cloth, and crushed down by means of a hammer until no pieces larger than 1 inch remain. The sample shall then be mixed by shoveling it over itself into a conical pile and divided into four equal quarters, the two diagonally opposite quarters being discarded and the two remaining mixed together in the manner just stated. After quartering twice, the sample shall be crushed down to $\frac{1}{2}$ inch and mixed and quartered until it is reduced to about 10 pounds, when it shall be crushed to $\frac{1}{4}$ inch and quartered down to about 2 pounds. This 2-pound sample should not contain any pieces over $\frac{1}{4}$ inch in size. The sample is then placed in a can or jar with a tightly fitting lid and labeled, and sent to the sampling room."

The methods in the laboratory sampling room where the samples receive their final preparation have, within the last few years been materially simplified by the introduction of crushers, quartering machines, and pulverizers, which have done away with the bucking board, hand-power crushers, and quartering by means of a spatula. In a modern sampling room where power is used to do the crushing and pulverizing,

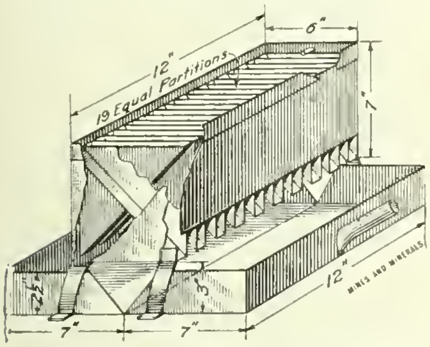

Fig. 1

the number of samples that can be put through in a day's time is almost unlimited, and the accuracy with which these machines do the work has been proven, and has helped to make this part of the work more reliable and simple. Nevertheless, there are some machines on the market, both for pulverizing and the quartering which are both inefficient and unreliable.

Samples, other than regular ones, come to the Fairmont laboratory in money bags, fruit jars, cans, and mailing cases of every description. They are at once turned over to the sampler, whose first duty it is to take note of the mark or label (if a sample has no mark or label to indicate its origin, it is put aside until a letter or advice bearing on it is received). The sample is then put through a jaw crusher, which crushes it down to a No. 8 mesh size, and if the weight of the whole sample does not exceed $\frac{1}{2}$ pound it is next put through a disk pulverizer and crushed down to No. 20 mesh size. If the sample weighs 2 or 3 pounds it is quartered down to about $\frac{1}{2}$ pound after leaving the crusher, and then put through the pulverizer. After it has been crushed to No. 20 mesh it is finally quartered to 2 ounces and placed in a laboratory sample bottle, in which has already been placed a ticket showing the marking of the sample as it came to the laboratory. From the bottle it is put through the disk pulverizer and pulverized so that the entire portion of it will pass through a No. 80 mesh sieve, and rebottled. It is then entered in the record book and given its laboratory number.

The crusher and pulverizer are belted to a line shaft, which is run by a small motor. Quartering is accomplished by passing the sample through a riffle sampler, which is a box of small diagonal chutes, which open at the bottom, alternately on opposite sides of the box, as shown in Fig 1.

Passing the sample through once, halves it and does it very accurately. By test it has been determined that it cuts the sample into two halves, within $\frac{1}{5}$ of 1 per cent. when the samples do not contain anything larger than No. 10 mesh size. The analysis of the two halves will check within a tenth of 1 per cent. in ash, sulphur, and British thermal units.

In addition to the riffle sampler there is a quartering machine known as the Forest-Coolidge automatic sampler, designed for the purpose of handling large samples of ore, coal, and coke.

There are small crushing machines for the first crushing, while for pulverizing samples to 100 mesh a power disk pulverizer is a very efficient machine. It does the work of a bucking board, with the aid of a very small motor. Its capacity is equal to that of the crushers, so that while one sample is being put through a crusher another may be working through the pulverizer.

For cleaning machines, tables, plates, etc., in the sampling room, an air blast with a sufficient length of rubber tubing to reach all machines is a great improvement over a hand bellows and brush.

The New Steel Mine Support

At a recent visit to the Penn-Mary coal mines attention was called to a new steel mine support. It consists of rails both for legs and for cap pieces. The cap and legs are bolted together at their intersection by two steel plates as shown in Fig. 1. These plates are formed in dies under a steam hammer, so as to grip the rails tight and give a simple and rigid construction. While the method of joining is simple, nevertheless the plates must be forged to conform to the size of the rail. When properly made this set of timbers is strong and serviceable.

Fig. 1

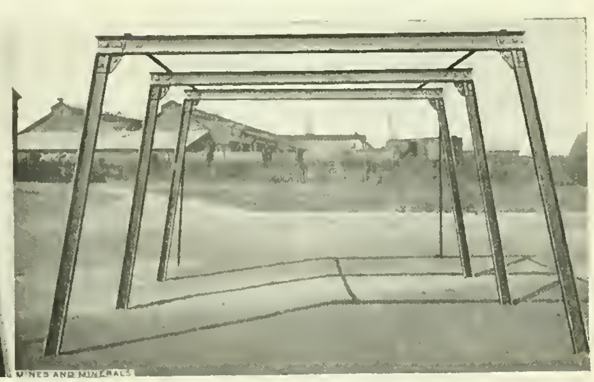

Fig. 2. Steel Mine Support

Fig. 2 shows a set of three timbers joined together and set up for the purpose of photographing. As will be noticed they are tied together at the top by means of steel rods, and if necessary can be tied on the sides as well. Foundations for all steel timbers should be of concrete, strong stone, or have an iron base plate.

Self-Burning Limestone in Syria

While making a trip through the Hauran district of Syria, south of Damascus, east of the upper Jordan, United States Deputy Consul John D. Whiting states his attention was attracted to a curious stone which might be described as a self-burning limestone. Some natives were burning it and he was enabled to see the operation.

At this place the rock lay in a stratum between ordinary limestone; it was of a grayish black color, and when freshly broken had an odor of petroleum. Nearby were outcrops of what looked like the same material many rods long and 20 to 30 feet thick.

The quarrying is easily done with primitive picks and other tools, as the rock is quite soft and full of seams. The stone is broken into small pieces with hammers and piled up against the bank of rock. A wall of the same material about 2 feet high is roughly laid up around the pile on three sides, making a pile of small stone 8 to 10 feet long and nearly as wide, and 2 feet at the front, rising to nearly three times that height at the back where it lies against the bank.

In building the wall around the pile small holes are left for draft and in which to start the fire. When the kiln is ready to burn, a few small bunches of straw are placed in the holes mentioned, lit with a flint and steel, and in a short time the whole pile has ignited. The men then begin working on a new kiln while the other burns and cools.

After about 12 hours of burning the stone has all become converted into lime, except the stones in the wall and the very top layer, which are only about half burned. When cool, the lime is air slacked and sifted to remove any pieces not thoroughly burned, which are thrown into a new pile to be fired again.

While there he saw four kilns in all stages of the process except the firing. The workmen said that it made a very black smoke with a bad odor like kerosene burning. The lime is white and said to make a very strong plaster, superior to the ordinary lime burned with brush.

Facts About Anthracite Mining

History of the Growth of the Industry Which Also Shows Increased Economy in Production

By E. W. Parker

AT THE initial meeting and dinner of the Panther Creek Valley Mining Institute, at Lansford, Pa., E. W. Parker, Statistician of the U. S. Geological Survey, in his address presented the following interesting historical facts, suggestions, and satistics:

We are just about at the hundredth anniversary of the birth of the anthracite mining industry. Historians generally consider that the industry began in 1820, when 365 tons, one ton for every day of the year, were shipped from the Lehigh region to Philadelphia. Prior to that, however (in 1807), 55 tons are reported to have been shipped to Columbia, Pa. For the purposes of this meeting—not as a statistical or historical fact—we can split the difference and consider that it began in 1813, and that we are now in the hundredth year of the anthracite industry. From the small beginning of one ton a day, the production of anthracite has grown to such an extent that at the present time the production is as much every 2½ minutes as the total production was in 1820. Then you produced 1 ton a day. Now you produce 2½ tons every second of the 24 hours for 365 days in the year. Anthracite production has not gone ahead by leaps and bounds during the last few decades as has the production of bituminous coal. The increase in anthracite has been somewhat more rapid than the increase in population, for in 1880 the anthracite consumption was about one-half ton for each inhabitant, in 1890 and 1900 it was about two-thirds of a ton, and in 1910 it was about four-fifths of a ton. In 1880 the per capita consumption of bituminous coal was less than 1 ton, and today it exceeds 4 tons. The production of Pennsylvania anthracite exceeds the entire coal production of any country in the world outside of the United States, with the exception of Great Britain and Germany (and of course the United States), and represents a total value, in 1911, of approximately $175,000,000. It employs an army of nearly 175,000 men. From the earliest time to the close of 1911 the total production of anthracite has amounted to about two billion long tons.

To the credit of the mining men of the anthracite region be it said that whereas, a few years back, but 40 per cent. of recovery was accomplished, and 60 per cent. of the coal lost, now these percentages are practically reversed. Formerly 1½ tons were lost for every ton marketed, now at least 2 tons are marketed for every ton lost. This practical conservation put into effect in the anthracite region of Pennsylvania, has probably extended the life of the fields, or the expectancy, as they say in life insurance circles, fully 100 per cent. To still greater accomplishments along these lines, to the maintenance of a proper relationship between the cost sheet and the returns from the sales department, and above all to the safeguarding of the lives and health of the army of employes, are the purposes, I believe, to which this mining institute of the Lehigh region is to be devoted.

I am sincerely in earnest when I say that some of our professors of conservation might learn some valuable lessons in practical conservation by a study of conditions in the anthracite region of Pennsylvania. It was here that real conservation in the United States had its birth, in the work of such men as Eckley B. Coxe, P. W. Sheafer, Franklin B. Gowen, William Griffith and others whose investigations into the waste in mining preparing, and utilizing of anthracite, and suggestions made for lessening it, showed what might be and has been accomplished in real conservation. History will write along with these, as men equally entitled to places in this hall of fame, the names of May, of Phillips, of Richards, of Warriner, of others of their class and of our late and deeply lamented friends, Luther and Lathrop.

Not the least of the reforms put into practice in recent years is that of conserving the efficiency of the miner that has been brought about through the spring reductions in price. This plan was put into effect in 1901. One of the effects of this is seen in your monthly record of shipments. For instance, in 1911 the shipments of the six months from April to September averaged 5,734,070 long tons per month. The average shipment for the first and last three months of the year were 5,924,980 tons, a difference between the winter and summer months of less than 200,000 tons. How it has benefited the miner is shown in the fact that in the five years from 1895 to 1900 the average working time in the anthracite region ranged from 150 to 174 days, with a mean average of 163 days. In the five years from 1906 to 1911, inclusive (leaving out 1909), the average working time ranged from 195 to 246 days with a mean average of 218. The shortest year in the later period contained 21 more working days than the longest year of the earlier period, and the average for the later period was 33.7 per cent. more than the earlier. With these figures and with the knowledge of the advance in wages in 1903 and 1912, the prosperous condition among the mine workers in the anthracite region is not difficult to understand.

In forming this Institute the men of the Lehigh region are taking a long step in the right direction. During the last few years the establishment of local organizations of this kind has made considerable progress and they are meeting with marked success. The Geological Survey desires to cooperate with and lend all the aid it may to this and sister societies of the same character; for, as I said at the start, we get more than we give, in association with men who make up such organizations. It has been my pleasure and my privilege to attend meetings of the Coal Mining Institute of America, the West Virginia Mining Institute, the Lake Superior Mining Institute, and others, and I have been deeply impressed with the excellence of the ideas brought out in the discussions at the sessions. Frequently men who would balk at preparing a set paper will be induced to get on their feet and "have at 'em" in the meetings, in consequence of which much good stuff is brought to light. Moreover, the local character of associations of this kind makes them all the more helpful. Organizations whose membership is scattered over wide areas always have difficulty in getting a representative collection at their meetings. On the other hand, at the meetings of the Lake Superior Mining Institute, for instance, from 70 to 80 per cent. of the membership will be present, and the same percentage will apply to other local associations The West Virginia Mining Institute has accomplished a world of usefulness in the bituminous regions of that state. Its membership is composed largely of mine superintendents, foremen, and other practical workers on whom a great part of the responsibility for the safety of the mines and miners as well as the economical production of coal depends. The opportunities afforded by the sessions of the Institute to discuss, not only in open meeting but in informal talks with their fellows, local problems in which all are more or less interested, are of immense benefit.

During the last year, the bituminous coal-mining men of Kentucky have organized an institute among themselves, and I note that a movement is well under way for the organization of the Western Coal Mining Institute, which will embrace the states of Colorado, Wyoming, New Mexico, and Utah.

No other branch of the mining industry offers such scope in possible usefulness to these local institutes as does coal mining. We are all doing what we can to ameliorate both the hazardous and exacting life of the miner. In doing this, however, the greatest obstacle to be overcome is the miner's opposition to any restriction of his personal liberty. What is needed here, as in the bituminous region, is concerted action to secure legislation for the enforcement of discipline in the mines and the imposition of severe penalties for infractions of laws and regulations. The miner has to be protected more against himself, his own worst enemy, than against any other source of danger. I do not know of any case, however, where legal penalties are imposed upon a miner for disobedience of rules, even though such disobedience might place in jeopardy the lives of hundreds of coworkers. The miner's callousness to the danger to which he is exposed, from the time he enters the pit mouth, is the greatest difficulty with which the management of the mine has to contend. Concerted action by organizations such as yours will be most effective in securing reforms.

I have been somewhat impressed by the recently published report of the Bureau of the Census, on Mines and Quarries, covering 1909, in which it appears that the value of the anthracite product in that year was $149,180,471 (the Survey's figures for the same year were $149,181,587) and the expenses amounted to $139,324,467, showing that in a production of 72,384,249 long tons, the difference between the outlay for expenses and the income from sales was less than $10,000,000, or about 13 cents a long ton. The bituminous production was valued at $427,962,464, and the cost sheets showed a total expense of $395,907,026, a difference of $32,000,000. As the output was approximately 380,000,000 short tons (379,744,257 short tons, to be exact), the margin to allow for losses incidental to explosions, fires, and other accidents, and for profit on the business, is 8.4 cents a ton. The margin on anthracite per ton is about 40 per cent. more than that of bituminous, but I doubt if any one contemplating investing his savings would consider either an attractive proposition. It is certainly not sufficient to secure the maximum degree of safety, nor the maximum recovery of coal, for it is an axiomatic proposition that every ton of coal extracted, above a certain percentage, costs so much more per ton. It is in the solution of such problems that the local institute may find a field of great usefulness.

A mine superintendent should be responsible to his superiors for results only. A competent man takes pride in accomplishment, and anything that injures that pride detracts from his efficiency.

Book Review

Energy and Velocity, Diagrams of Large Gas Engines: Their Use and Layout, by Paul L. Joslyn, 70 pages, 62 diagrams, cloth bound, price $2. The Gas Engine Publishing Co., publishers, Cincinnati, Ohio.

With small gas engines, it is not so expensive nor so difficult to change some points, and it frequently happens that very radical changes in construction are so effected. But with the gas engine of several thousand horsepower, it is impossible to do this, so everything must be worked out in advance. In this book, the author gives the methods of laying out energy and velocity diagrams for large engines operating on blast furnace, producer, or natural gas, with instructions as to their use, etc. The data given are the result of actual designing on some of the largest engines built.

Practical Field Geology, by J. H. Farrell and Alfred J. Moses. 273 pages including index; 62 illustrations. McGraw-Hill Book Co., publishers; price $2.50. Professor Moses is one of the first mineralogists of our times, as was his predecessor in ancient times, therefore his guide to the sight recognition of 120 common but important minerals must be worth investigating. J. H. Farrell, E. M., is not so well known as a mining geologist, however, his company is good; his preface rings truthfully; and his book reads as if he knew his subject. He opens his preface as follows:

"When 'Omer smote 'is bloomin' lyre,
He'd 'eard men sing by land an' sea;
An' what he thought 'e might require,
'E went an' took—the same as me."
—*Kipling.*

He gives credit to those whose assistance he has invoked, but not credit to those his assistants invoked, owing no doubt to the intricacy of the curve.

Virginia Geological Survey, Morgantown, W. Va. A new volume is described in the following extract from the printed circular of the Geological Survey:

Detailed County Report on Doddridge and Harrison Counties, under date of September 1, 1912, 712 pages +XVI, with 29 plates of illustrations and 5 figures in the text, and a case of 3 maps (soil, geologic, and topographic) of the entire area. In addition to the detailed study and description of all the rocks, streams, and industries, with hundreds of oil and gas well records within the area, the geologic map gives the structural contours on the Pittsburg coal, showing all the anticlines, synclines, and structural terraces. The line where the Pittsburg coal disappears in Doddridge County is shown on these maps with scale of one inch to the mile, as are all roads, streams, houses, etc. Price, with case of maps, $2. Extra copies of geologic, or topographic map, 50 cents each.

The Mineral Industry, Vol. XX. This book of 997 pages contains the statistics, technology, and trade items of the mineral industry, and supplements previous volumes. It has been edited by Charles Of, assisted by 78 writers who have made a study of some specialty. All the important elements are reviewed statistics and advances made in their recovery are recorded, and in addition the economic geology of a number of non-metallic, yet important, minerals is treated. There are special chapters on Placer Mining; Ore Dressing and Coal Washing; A Review on Mining Decisions in 1911; Assaying and Sampling; and Mineral Statistics covering imports and exports and productions in this and other countries. Price $10. Publishers McGraw-Hill Book Co., New York City

The Business of Mining. This book by Arthur J. Hoskins, M. E., is published by J. B. Lippincott Co., Philadelphia. It comprises 224 pages, including index, and is illustrated with half-tones on special pages. There are 23 chapters devoted to advising mine investors how to safeguard their money, and in endeavoring to establish mining as a legitimate business. Similar pleas have appeared in all technical journals for many years, but this is the first time, it is believed, where they have been placed in book form, and so made accessible to the general public. Mr. Hoskins has written a concise nontechnical exposition of the principles involved in profitable mine investments, and if his advice is followed there will be fewer "soreheads." It may be stated without much fear of contradiction that before a real man dies he has invested in some phase of mining. Some invest a little money so that others will invest a good deal and develop the country for them; others, with a gambling instinct, make their investments bets, kissing their money good-bye; again others with "cupidity lust" invest more than they can afford to lose, and usually without any precaution; finally there are mining stock investors, who, working on the stock exchange, do not help mining enterprises at all.

Concrete Costs. This book was gotten up for engineers, architects, contractors, superintendents, and foremen, to promote the introduction of scientific management. It is by Fredrick W. Taylor and Sanford E. Thompson, the authors of *"Concrete Plain and Reinforced,"* has 700 pages, 8 vo; 81 illustrations, and 23 chapters. John Wiley & Sons, publishers, New York City. Price $5. The book contains much useful data and will be appreciated by all who use concrete. Most of the text will be learned in practice, but the tables will be valuable to both the experienced and the inexperienced.

Answers to Examination Questions

Examinations for Second Grade Mine Foremen Held in the Bituminous Regions of Pennsylvania, 1912

Ques. 1.—What are the duties of a mine foreman relative to his daily visits to each working place; what should he observe, and what instructions should he give the workmen?

Ans.—The mine foreman must employ a sufficient number of assistants so that he or some one of them may visit each working place at least once a day while the men are actually at work. Particular attention must be paid and, if need be, more frequent visits must be made to pillar workings, particularly if a fall is expected. While at the face, he should see that the coal has been properly mined, that is, has been under-cut, center-cut, top-cut, or sheared (side-cut) to a depth at least as great as the depth of the shot hole to be used. Should the mine generate explosive gas and the coal be 5 feet 6 inches, or more, in thickness, the seam, in addition to the ordinary under-cut, must be sheared to the depth of the shot holes in all places 10 feet or less in width.

He shall direct the miner, while making a cut, to set sprags under the breast of coal so that it may not fall upon him; and these sprags shall not be more than 7 feet apart. He shall direct the miner to either take down or properly secure any loose pieces of slate or coal; shall see that the holes for blasting are properly placed, and shall designate the angle and depth of the holes, which shall not be greater than the mining, and shall direct the greatest amount of explosive that may be used in each hole as well as the method of charging and tamping, and "in a general way," shall instruct the workmen "how to mine coal with safety to themselves and others."

At the end of the shift the assistant foreman must enter in the record the conditions as to safety of all the working places visited by him, making a separate note of any unusual occurrence he may have noted; which report the mine foreman must read and sign in ink not later than the next day.

Ques. 2.—What are the legal requirements as to cut-throughs in rooms and entries; and the supplying of the workmen with timbers?

Ans.—The distance apart of cut-throughs in room pillars is determined by the district mine inspector, but in no case shall it exceed 35 yards (105 feet) or be less than 16 yards (48 feet). The distance apart of entry cut-throughs is not given, but a reference in Section 2 of Article 4, indicates that it is the same as for rooms. In all mines all new stoppings between the main intake and its return shall be built of masonry, concrete, or other incombustible material, and "shall be of ample strength." In addition, if the mine generates explosive gas, new stoppings and old ones which are being replaced in cross-entries shall be constructed of incombustible material. In non-gaseous mines, stoppings on cross-entries may be made of wood. Stoppings are required in room cut-throughs and they may be built of wood, or brattice cloth. All stoppings shall be kept in good condition.

Props and cap pieces, the former cut with square ends and as near as practicable to the proper length for the thickness of the seam, shall be delivered to the working faces or as near them as they can be hauled in mine cars. In order to secure timber the miner must notify the person in authority one day in advance, "giving the number, size, and length of props and cap pieces required." In event of emergency, the props may be ordered at once, and if not to be had on short notice, the place must be vacated until they are supplied. The place and manner of leaving orders for timber shall be specified in the mine rules and will naturally be different at different mines.

Ques. 3.—What does the law require for the protection of workmen along haulage ways, where different systems of haulage are used?

Ans.—Except in entries where rooms are turned at regular intervals of not more than 90 feet, and the room necks are kept clean for at least 3 feet back from the rib, it is necessary on animal and mechanical haulage roads to cut shelter holes at least every 90 feet; which holes shall be at least 2½ feet deep by 4 feet wide and shall be whitewashed and kept clear of obstructions. The regulations are the same on main haulage roads where machinery is used, except that shelter holes must not be more than 15 yards (45 feet) apart, and may be dispensed with if rooms are turned at regular intervals of not over 45 feet and kept clear of obstructions for 3 feet back from the rib. All shelter holes shall be driven level with the floor and on one side of the entry only. If, in the judgment of the district mine inspector, the roof is strong enough, there must be maintained along one side of the entry a continuous clear and clean space 2½ feet wide from the side of the car to the rib.

Like other parts of the law of 1911, this section is confusing. There is a distinction made between "mechanical hauling" and "hauling done by machinery," which is hard to understand. Further, while Section 8 of Article IV permits traveling on main haulage roads, provides for shelter holes, etc., the last part of Section 4 of Article VI as clearly prohibits this if the main entry be used as an intake. As perhaps more than 90 per cent. of the main entries in the state are intakes on which haulage is done, traveling on haulage-ways is practically prohibited in one section of the act and permitted in the other.

Ques. 4.—What means are necessary in order to properly conduct the air-current to the face of the workings? Mention, also, the essential points necessary to be observed with respect to each of them.

Ans.—The principal means are doors, stoppings (brattices or curtains), and air bridges (overcasts or undercasts).

Doors, except of a temporary nature such as when made of canvas, should be as air-tight as it is possible to make them. Main doors should be built in pairs so that one may be closed when the other is open. As far as possible they should be set where the roof is sound. The frame, when of timber, should be heavy, set well in both roof and floor and should be well caulked between the side frames and the rib. All important doors should be built of heavy timber and together with the frame should be covered with sheet iron to prevent danger from fire. Modern practice requires that door frames be of concrete or of timber set in concrete and the ribs for some distance on each side thereof be coated with this material. In some mines the doors are made of a uniform size, so that, in event of one being broken or otherwise destroyed, it may be immediately replaced by one taken from a stock kept on hand for the purpose. Canvas doors, consisting of cotton duck or brattice cloth nailed to a light frame of scantling, are frequently used for temporary needs and in emergencies, but should be replaced by substantial and permanent doors as soon as possible.

Stoppings of canvas are frequently used to convey the current from the last break-through to the face in gaseous workings Such stoppings, as well as canvas curtains hung across an entry to deflect the air-current up a room, are only temporary and are removed when the occasion for their use has passed. In large mines, permanent stoppings on the main entries are commonly made of concrete, masonry, hollow tile, or brick, from 9 to 18 inches or more in thickness, and not infrequently are reinforced with steel rods, old rails, or the like. Brattices of plank are used in breakthroughs between rooms universally, and frequently on entries. In the latter case they do not give satisfaction, as it is almost impossible to prevent their leaking.

In the matter of air bridges, overcasts are preferable to undercasts, as they are easier and cheaper to drive and generally cheaper to maintain. In wet mines undercasts are generally out of the question as they would be flooded with water and their area thus diminished. While overcasts in many mines are still leaky wooden boxes, in the better class of mines all main air crossings at least display great skill and care in their construction.

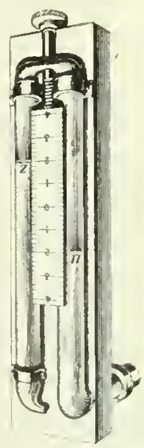

Fig. 1

They are not infrequently regular arches of brick, masonry, or reinforced concrete, or may be built of heavy rails or I beams covered with cement. As they are intended to last throughout the life of the mine which may be from 20 to 50 or more years, it is apparent that a permanent overcast which requires no repairs and does not leak and waste air-current, and consequently power, is, in the end, vastly cheaper than the short-lived, leaky wooden air box which has to be constantly repaired and frequently renewed.

Ques. 5.—A dam in an entry supports a vertical head of water of 80 feet, sectional area of dam is 70 feet. Find the total pressure (in short tons) on the dam.

Ans.—Taking the weight of a cubic foot of water at 62° Fahrenheit and under a barometric pressure of 30 inches of mercury to be 62.29 pounds, the pressure per square foot upon the dam is $80 \times 62.29 = 4{,}983.2$ pounds. As the dam has an area of 70 square feet, the total pressure in pounds is $4{,}983.2 \times 70 = 348{,}824$; and dividing by 2,000 (the number of pounds in a short ton), the total pressure $= 348{,}824 \div 2{,}000 = 174.412$ short tons.

Ques. 6.—Name and describe the different instruments used by the mine foreman to examine the condition of the ventilation of a non-gaseous mine. Explain the principle and application of each.

Ans.—The principal instruments are an anemometer, together with a tape to measure the area of the airway, for measuring the velocity of the air-current; and a water gauge to measure the resistance, due to friction, to the passage of the air through the mine. The best modern practice requires, in addition to these, a thermometer and a psychrometer or hygrometer to determine the humidity of the mine air, that it may be learned if it is sufficiently dry to absorb moisture from the workings and thus render the coal dust liable to explosion if opportunity is afforded. This instrument is described in detail on page 722 of the July issue of Mines and Minerals where will be found as well a description of the barometer, safety lamp, the use of canary birds, etc., commonly employed in gaseous mines.

The anemometer consists of a series of blades or vanes fixed upon an axis, which may revolve, the whole enclosed in a metal frame. The blades are so arranged that one revolution of the anemometer corresponds to 1 foot of travel of the air-current, the number of revolutions being recorded on a dial or series of dials. The anemometer is held in the air-current for any convenient number of minutes (usually 2 or 3) which is determined by a watch, when the reading of the dials will give the number of feet traveled by the air in this length of time. The total distance divided by the number of minutes the anemometer was in motion will give the number of feet traveled by the air in 1 minute, in other words, the velocity; as 1 minute is the unit of time in estimating velocities in problems concerned with ventilation. The area of the airway in square feet is determined by measuring its height and width with a tape, and this area multiplied by the velocity, as recorded by the anemometer, gives the volume of the air-current in cubic feet per minute.

The water gauge is a glass tube bent in U shape as shown in Fig. 1 with both ends open. One end of the tube is bent at right angles and is fitted with a brass extension tube which is inserted in a small hole bored in the brattice separating two airways as shown in Fig. 2. The purpose of the instrument is to measure the difference in pressure between two airways. Water is poured in the tube and, when there is no difference in pressure, is level in both arms. When the pressure in one airway exceeds that in the other, the water will sink in one arm, the intake, and rise in the other, the return. The difference in levels between the water in the two arms is read on the scale shown in Fig. 1. Any difference in water level as read from the scale on the water gauge represents a ventilating pressure necessary to overcome the friction due to passage of air under conditions prevailing. Each inch of water represents a drag of 5.2 pounds per square foot or a ventilating pressure of 5.2 pounds per square foot. The constant 5.2 is derived from the weight of water, 1 cubic inch of which weighs .036 pound, hence a square foot would exert a pressure of $.036 \times 144 = 5.184$ or practically 5.2 pounds to the square foot.

Ques. 7.—What precautions should be taken in a dry and dusty non-gaseous mine to insure the safety of the workmen?

Ans.—Dry and dusty mines are far more dangerous than gassy and very wet ones owing to the liability of the fine dust to explode through the agency of

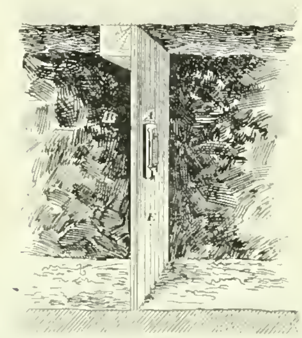

Fig. 2

a blown-out shot, a mine fire, or the arc produced by the short-circuiting of an electric current, the effects of what otherwise would be of trifling damage to life or property being spread throughout the mine by the burning fine dust everywhere present.

Naturally, the first step is to reduce the amount of dust made in the work of mining and hauling to daylight. The amount of dust made at the face may be greatly reduced by undercutting the seam by hand or machinery; by drilling no hole of greater depth than that of the mining; by placing the holes and charging them with permissible, short-flame powder so that they will do the work required of them and no more; by firing the holes by electricity, or otherwise, after the men have left the mine, shot firers being employed who, before firing the shot or shots, have thoroughly wetted down the roof, floor, ribs and all dust for from 60 to 80 feet back from the face; and by seeing to it that the loaders clean up and load out all slack and more particularly the fine bug dust made in machine mining.

Mine cars should be as tight as possible so that they may not leak slack on the headings while being hauled from the room to the parting, some companies using sheet-steel cars without gates, that are dumped in rotary dumps. Cars should not be loaded with too much topping or in such a way that lumps may roll off and be ground into powder by mules or motors. In some mines, near the mouth of each room entry is arranged a spraying device under which the loaded cars pass and where their contents are thoroughly wetted.

Despite all efforts more or less dust is made, which is carried and deposited through the mine by the air-currents, and the handling of this is a serious problem, the best means to this end being in dispute. All old and abandoned workings should be tightly sealed at the mouth of the entry going into them, to prevent dust being carried into them; then an explosion otherwise started cannot gather force by sweeping up the dust that may be in them. All entries should be cleaned up at regular intervals and the dirt carried out and dumped at the surface, and not loaded into breakthroughs and room necks as is too frequently done.

At this point ideas as to the proper method of treatment differ. The common method of dust treatment in the United States is to wet down all the entries, roof, floor, and ribs, often enough to insure that all the dust is so moist that its explosion is impossible. This is the most satisfactory way, but is very expensive owing not only to the cost of the pipe lines for conveying the water, but more particularly to the wages of the men employed. To overcome the expense of this method, many mines heat the air at the drift mouth and there saturate it with moisture by means of steam jets, the idea being that the air-currents upon cooling will deposit moisture throughout the mine and do away with the necessity of sprinkling by hand. It is now generally admitted that this "preheating and premoistening" are not satisfactory, as the current soon deposits its water and unless recharged will begin to absorb moisture from, and thus dry out, the dust the same as an ordinary air-current. In view of this, most mines where preheating and moistening are used wet down a greater or less amount of entry by hand sprinkling, water cars, etc.

Chemicals which absorb moisture have been, without much success, used on the floor of haulageways, and very recent experiments in England indicate that if the proportion of oxygen in the air is kept down to 17 per cent., dust explosions will not occur, but a satisfactory method of reducing the content of oxygen to this amount has not yet been devised.

At many mines in England, and at one in this country, what may be called the rock-dust method of treatment is in successful operation. This consists in spreading very finely ground clay or shale over the floors, throwing it upon the roof and ribs, and depositing it upon shelves made for the purpose. It has been shown that clay dust, when mixed with coal dust, will render the latter inert and non-explosive.

Ques. 8.—Name the inexplosive gases found in the mines of this state, giving their composition and specific gravities. What effect have these gases on the workmen and what methods would you adopt to remove them?

Ans.—The inexplosive gases met in mines are nitrogen, oxygen, and carbon dioxide, formerly called blackdamp. Nitrogen constitutes 79.3 per cent., by volume, of the air and has a specific gravity of .9713. It is odorless, colorless, tasteless, and not poisonous. Its province is to dilute the oxygen. Should its proportion be increased, which, of course is accompanied by a decrease in the proportion of oxygen, death from suffocation will follow. Oxygen, specific gravity 1.1056, constitutes 20.7 per cent. by volume of the air. Like nitrogen it is odorless, colorless, tasteless, and nonpoisonous, and is the supporter of life and combustion. About 1 per cent. of the air is composed of certain inert gases similar to nitrogen, such as argon, xenon, etc. It is not desired to remove any of these atmospheric gases and the aim is to keep the mine air of the same composition as that outside. A slight change in the proportion of nitrogen to oxygen does not result in any ill effects upon the men, but if the proportion of oxygen is lowered too far by increasing the amount of inert gas, through the introduction of carbon dioxide, methane, etc., or by the addition of slight amounts of such highly poisonous gases as carbon monoxide or sulphuretted hydrogen, death will occur by suffocation in the one case and by poisoning in the other. The other inexplosive gas common in mine air is carbon dioxide, blackdamp, or CO_2. It has a specific gravity of 1.529 and is therefore found near the floor, in dip workings, and the like. It is odorless and colorless but has a peculiar sweet taste. It is not poisonous, but causes death by suffocation, if in large amount, by reducing the proportion of oxygen in the air below that necessary to support life. It may be removed by carrying brattices up to the place where it is found, the gas being diluted and swept away by the air-current.

The question as submitted to us requires a description of the inexplosive gases. A very full description of all the gases met in mines, explosive as well as inexplosive, will be found on page 81 of the September issue of Mines and Minerals.

Ques. 9.—If, in a mine employing 200 persons, it was necessary to double the minimum quantity of air for persons, as required by law, how many splits of air would be required? If the main intake airway was 42 square feet area, what would be the velocity of the air-current?

Ans.—The law specifies that not more than 70 persons shall work in any one split unless the state mine inspector decides that this is impracticable, in which case as many as 90 may be allowed. In either case there would be three splits; in the first, two of them might have 70 men each and the third, 60 men ($70 + 70 + 60 = 200$); and in the second case, there might be two splits with 90 men each and one with 20 men ($90 + 90 + 20 = 200$). The minimum amount of air would be 150 cubic feet per man per minute in non-gaseous mines, and 200 cubic feet per minute in gaseous mines. In the first case 200 men would require $200 \times 150 = 30{,}000$ cubic feet of air a minute, and in the second case, $200 \times 200 = 40{,}000$ cubic feet of air a minute. Doubling the quantity of air per man will not increase the number of splits required by law. The quantity of air in the one case will be, however, $30{,}000 \times 2 = 60{,}000$ cubic feet per minute, and in the other $40{,}000 \times 2 = 80{,}000$ cubic feet.

The velocity of the air-current in the intake would be either $30{,}000 \div 42 = 714$ feet per minute, or $40{,}000 \div 42 = 952$ feet per minute, depending upon whether each man received 150 or 200 cubic feet of air a minute. If the quantity of air be doubled, the size of the airway remaining the same, the velocity would be doubled and would be, respectively, 1,428 and 1,904 feet per minute.

(To be continued in December)

Carbon Monoxide in Illuminating Gas

Existing legislation shows no tendency to limit the carbon monoxide content of gas, although it is the only constituent of illuminating gas, which, in the amounts ordinarily found, is poisonous. Coal gas contains from 5 to 10 per cent. of carbon monoxide; water gas 25 to 30 per cent. To limit the amount of carbon monoxide in the gas sold might limit the amount of water gas made. Such regulations as would prevent the operation of water-gas plants now in existence would be very severe, but the extension of present plants should not be directed toward increasing the use of coal gas rather than of water gas. The use of water gas may possibly not be much more dangerous than coal gas. A large proportion of the cases of death or illness by gas poisoning are suicidal; and the character of the gas would have only a small influence upon the result. A large number of deaths and cases of poisoning called "gas poisoning" are due not to the gas itself, but to the carbon monoxide formed by combustion of the gas with insufficient supply of air, due to faulty appliances. It is possible that the protection of the public from danger will be found rather by regulation of appliances, and the general education of gas users as to proper precautions, than in the limitation of the carbon monoxide content of the gas itself.

ORE MINING & METALLURGY

Rock Phosphate in Kentucky

The Geological Formations in Which Phosphate Is Found—Deposits That Are Worked—Manner of Formation

By James H. Gardner

THE occurrence, in commercial quantities, of rock phosphate in Kentucky has recently been demonstrated near Midway, in Woodford County, by the Central Kentucky Phosphate Co. For more than 40 years, the phosphatic rock beds in the Ordovician limestone of central Kentucky have attracted the attention of stratigraphers and local chemists but no attempt was made to investigate their economic value.

In 1877, Dr. Robert Peter, stated that strongly phosphatic rock was associated with the limestone beds in the north-central counties of the state, but it is reported that a negro was the first to bring to light the fact that rock phosphate occurred in commercial quantities in Kentucky. In the summer of 1905 while digging post-holes on the farm of Mr. H. L. Martin near Midway, he discovered what he considered phosphate rock similar to the brown rock phosphate in Tennessee. Mr. Martin verified the negro's opinion, and from that time prospecting has continued. Prof. C. J. Norwood, called attention in the Geological Survey Report of Progress for the years 1904-5, to the apparent practicability of using the phosphatic limestone and rock phosphate in the untreated form as "agricultural lime." In the same report, page 26, he quotes from a memorandum by Professor Miller as follows: "There is hardy a locality where the top of the Lexington limestone (Ordovician) has been exposed in upland situations, as the result of slow denudation of the overlying beds, where thin plates of this phosphate cannot be found, and recently samples were collected from a locality in Woodland County that indicated a deposit there of phosphate of very promising character. They ran as high as 33 per cent. phosphoric acid (72 per cent. calcium phosphate). The samples first collected consisted of plates of leached limestone from half an inch to an inch and a half in thickness and weighing from 1 to 3 pounds. These lay scattered very thickly over the surface of a roadside slope, and on digging down were found disseminated through the soil nearly to the bed rock—here from 1 to 2 feet below the surface. In the light of all that is known at present, the most favorable district for prospecting is in that comparatively level and very fertile belt of country extending northward from Versailles to Midway, and again beginning on the other side of South Elkhorn, in Scott, and extending in the same direction to where the land begins to fall off to the level of North Elkhorn. Fayette County also offers a very promising field. The soil at the phosphate horizon is a very deep red, and is characterized by the presence of a 'honey-comb' coral of the genus Columnaria," Fig. 3.

Fig. 1. Contact of Phosphate Deposit With Limestone Floor

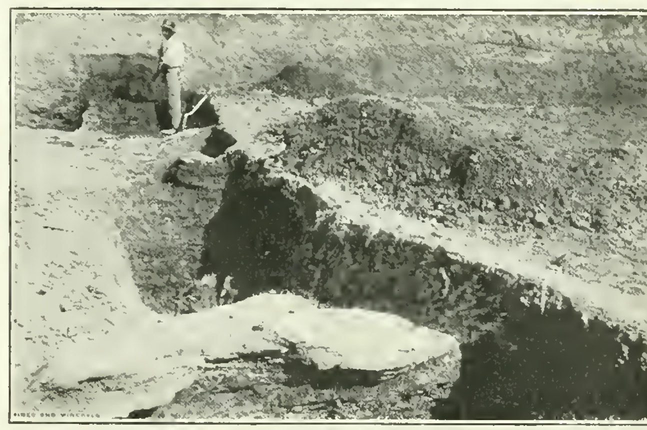

Fig. 2. Sudden Deepening of Phosphate, Also Limestone Extending Into Phosphate Bed

During the interval from 1905 to 1911, there were periods of excitement with reference to the possibilities of the Kentucky field. Three or four companies secured options on land; large bonuses were paid farmers for options running a short time and some of these were allowed to lapse, thus giving en exaggerated idea of values, and to some extent retarding development. None of the companies have begun developments, with the exception of the Central Kentucky Phosphate Co. that started the erection of a plant in 1911 which has been in operation since November of the same year.

Until the present time, rock-phosphate developments have been confined to the area near Midway but notable exposures are reported from Scott, Mercer, and Jessamine counties. The lands containing the rock-phosphate beds are fertile and possess high value for farming purposes, constituting the best there is of the far-famed Blue-grass Region, and being worth $200 per acre for farming and grazing purposes alone. To what extent the Kentucky field may be broadened will be determined only by thorough prospecting, and the attitude assumed by the

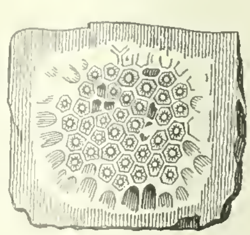

Fig. 3. Columnaria

farmers. The Lexington limestone comes to the surface over a large area in central Kentucky, and the outcrop of the base of the overlying Winchester follows a meandering course for a long distance around the Lexington, making an inlier of the latter on the Jessamine Dome of the Cincinnati geanticline. It seems highly probable that the deposits of rock phosphate will be confined to the western and southern portions of this inlier.

The phosphate deposits of the Kentucky field belong to the class known as brown rock phosphate, the essential base of which is tricalcium phosphate $Ca_3\,(PO_4)_2$. The phosphate is in the form of loose rock, consisting of thin plates and finely comminuted material mixed with some clay, the whole being of a dark-brown color. The hard rock plates vary from light-gray to dark-brown in color and are usually rather dense. In specific gravity they average about 3. They are more resistant to weathering than limestone, although occasional pieces in freshly exposed workings are very porous and soft. These plates vary in size from the granular form up to pieces that weigh several pounds. In the mine of the Central Kentucky Phosphate Co., pieces have been found that measured 6 inches in thickness and were 3 or 4 feet long. Along the east and southeast areas of the outcrop of the Lexington limestone, a considerable distance from the phosphate field, very large deposits of chert are found at about the phosphate horizon, but in that territory there is a notable absence of commercial phosphate, though some of the chert is highly phosphatic.

In chemical composition, the rock phosphate of Kentucky varies in "bone phosphate of lime" or tricalcium phosphate, from about 40 to more than 80 per cent. The analyses in Table 1, taken from a report by W. H. Waggaman* present an idea of the phosphate value of the better grade of rock.

Table 1. Phosphate Percentages of High-Grade Kentucky Rock

Location	Analyses	
	P_2O_5	$Ca_3(PO_4)_2$
Farm of M. D. Steel, 2½ miles south of Midway, Ky.	34 02	73.35
Cogar farm, ½ mile south of Midway, Ky.	33.75	73.74
Slack's farm, 3 miles northwest of Midway, Ky.	37.10	81.08
Outside State University grounds, Lexington, Ky.	26.13	57.10
Smith's farm, 2½ miles east of Georgetown, Ky.	27.14	59.43
Cut, 6 miles south of Lexington, Ky.	34.10	74.52

Table 2. Composition of Different Varieties of Kentucky Phosphate

Description	SiO_2	$Fe_2O_3—Al_2O_3$	P_2O_5	$Ca_3(PO_4)_2$
Light yellowish-brown	24.29	17.18	21.34	46.71
Brown, chocolate, close-grained, thin-bedded	2.63	2.75	35.71	78.17
Brown, chocolate, porous, hard	4.88	3.67	34.00	74.43

The specimens analyzed consisted of plates of rock phosphate free from any considerable amount of clay.

Waggaman also gives in the same bulletin (page 28) the complete chemical composition of three different varieties of rock that occur in the same deposit near Midway as shown in Table 2.

The brown rock phosphate in Kentucky occurs as elsewhere, in the form of loose-rock deposits that lie near the surface. The commercial deposits occur in blanket form on limestone and are covered by clay and soil. The workable deposits vary from 1 to 6 feet in thickness and are very irregular; both the bottom and top of the beds are limited by inconstant factors in their origin. The rock phosphate deposit originates from secondary concentration in the process of weathering of phosphatic limestone, consequently the mantle which it forms over the uneven surface of the limestone is similar to that of any deposit of red limestone clay. The level of unweathered rock is irregular and naturally the bottom of the phosphate conforms with it: at places it suddenly deepens and at others "rock horses" rise into the phosphate beds. The top of the phosphate bed is more regular than the bottom, and more nearly parallels the surface topography; but it is by no means constant. The cover of clay and soil varies from about 2 to more than 10 feet, being thicker on the tops than on the sides of hills and ridges.

The Ordovician limestone, from which the deposits have originated by denudation and decomposition, is only slightly phosphatic in its fresh state. The phosphate is at first in the form of rich but very thin, dark-colored layers along the bedding of the limestone and in the form of disseminated material throughout the stone. So far as is known, this condition prevails to a sufficient extent for the formation of commercial deposits only at the one horizon near the contact of the Lexington and the Winchester limestone formations; as a result, the deposits are possible only in districts where this particular stratigraphic horizon forms the surface of the country, or at least lies well above drainage. In regard to the two forms of brown rock-phosphate in the Mount Pleasant field of Tennessee, Waggaman† states: "The blanket deposits sometimes cover wide areas. They usually lie near the surface of gently undulating hills where the under drainage is favorable to their formation. Almost ideal conditions existed in the Mount Pleasant for the production of such deposits. In this section the highly phosphatic Bigby limestone lies very near the surface and is underlain by an easily soluble fine-grained limestone through which the percolating waters readily drain. The leaching began where the surface water gained access to the beds along the joint planes, but gradually worked through the entire mass, carrying away the carbonate of lime in solution, leaving the less soluble phosphate of lime. The blanket deposits are always more or less wavy; owing to the irregularity of the leaching. Large columns, boulders, and cones of unaltered phosphatic limestone occur throughout the deposits."

It is apparent that in the origin of the brown rock phosphate in the Kentucky field, chiefly two processes have been at work. In the first place, percolating ground water carrying carbon dioxide converts limestone into the soluble bicarbonate of calcium and carries it away. It does not so readily dissolve the calcium phosphate constituents of the limestone, and consequently the thin layers or plates of phosphate that are evident in the fresh rock are left as inherited products from the stone's decay, just as pieces of chert are left. Furthermore it appears that thick porous pieces in certain instances may have resulted simply as the left-over matrices of stone layers running high in their content of phosphate. The second important process is the one that has been of chief value in the building up of deposits of sufficient grade to be commercially worked at the present time. This is simply the process of secondary enrichment so common in the origin of ore deposits. The phosphate is concentrated near bed rock by being leached from the higher portions of the bed and carried down by descending solutions; here the process of replacement of limestone takes place, phosphate being substituted for carbonate. The clay as well becomes highly charged with phosphate and the richest portion of the deposit is thus built up directly on top of the limestone bed rock.

The ultimate origin of the phosphatic material in the fresh limestone is an

*Bureau of Soils, U. S. Department of Agriculture, Bull. No. 81, page 25.

†Ibid, pages 7 and 8.

interesting question for scientific discussion. It is evident that the phosphate has not been deposited secondarily, but is innate with the stone; it was lain down as a part of the limestone beds. Inasmuch as the limestone is of marine origin, carrying a marine fossil fauna, we are necessarily forced to conclude that the phosphatic content came also from the sea. In the fresh limestone as seen in a new quarry face the intercalated phosphatic layers are dark colored, due to carbonaceous material; thus we have the element carbon in the free state, associated with the phosphate, as would be expected if it had been produced by organic life. It is generally concluded among geologists that organic life is the original source of the phosphorus segregation. Probably the conditions under which life existed in the sea are as important as the nature of the species. The remains of shell life are evident in great prominence and the very small gasteropod "Cyclora minuta" is especially abundant at the phosphate horizon.

The Ordovician sea in which the phosphatic material of the limestone originated was probably rather shallow. It was an epicontinental body of water extending over a large geographic province. What may have been the local conditions in this broad and long sheet of marine and brackish water wherein the phosphorus element was secreted to such an extent, is as yet unknown. The ripple-marked and cross-bedded character of the limestone strata and the phosphate lenses indicate that wave action affected the sediment as it was deposited; this fact would indicate that the water was not deep in which the phosphate-producing life brought about such important results along with the forms of life that secreted calcium carbonate in building up the deposits of limestone. At this mine the deposit of phosphate rock varies in thickness from 18 inches to 6 feet and is covered by from 2 to 6 feet of clay and soil. Stripping is done by means of ordinary horse scrapers and an acre or more of covering is removed in advance of mining. The raw product goes through the plant without washing, and no acid phosphate, or super-phosphate, is produced. The rock is merely dried, screened, and ground. By means of pick and shovel, the rock is loaded at the mine into dump wagons and hauled to the plant. A chain conveyer carries it to the top of an inclined rotary cylinder heated by direct firing with coal. The dry cylinder is carried by a continuous bucket elevator to the screen of about three-quarter inch mesh. The plates of phosphate passing over the screen fall into a storage room; this is the highest grade rock, and is guaranteed to run 76 per cent. bone phosphate of lime; it is sold to the American Agricultural Chemical Co. for the manufacture of acid phosphate.

The rock passing through the screen goes to the grinder and is reduced to a powder 90 per cent. of which will pass a 100-mesh screen. This material runs about 63 per cent. bone phosphate of lime; it is carried to the storage room and from there is loaded into cars for shipment and direct application to the soil. At the present time the plant has a storage capacity of 1,500 tons and a daily output of 30 tons, but it is expected that the output will soon be increased to 100 tons per day. The ground rock is sold direct to farmers. In the finely ground form the phosphoric acid soon becomes available to plant life, especially if the phosphate is used in connection with manure.

Drake Oil Well As It Appeared in 1864

Authentic Petroleum Lore

Back of 1859, people looked upon petroleum as a sort of freak of nature a little bit like Ponce de Leon's famous Spring of Perpetual Youth. What little petroleum was obtainable was secured from the surface of various streams in the oil districts, or by digging pits and scooping out the oil which seeped in from the surrounding soil.

About 1850, a demand for salt induced a number of prospectors to sink wells, from which they expected to get brine, and thus to make salt by the evaporation process. In sinking these wells, very often oil was brought up with the brine and one man in particular, a certain Samuel M. Kier, built up quite a business in petroleum, or "Rock Oil," as a medicine.

This crude oil he put up in 8-ounce bottles with a good old patent medicine circular attached, lauding the virtues of the oil as a cure-all and giving directions about its use.

Among other things it was recommended for cholera morbus, liver complaint, bronchitis, consumption, and other ills too numerous to mention. The dose was three teaspoonfuls, three times a day.

In 1858, this man Kier sold some refined petroleum to a Joseph Coffin, of New York, for 62½ cents a gallon, to be used for illuminating—but no great trade was developed prior to the operations of "Colonel" Drake, of Titusville fame.

The Seneca Oil Co. sent Colonel Drake to Titusville, in 1859, to secure petroleum oil in quantities, for refining. They had been encouraged by Professor Silliman of Yale College, to believe that fortunes could be made out of this oil if properly refined.

After a great deal of difficulty, Drake put down a well that eventually reached the enormous depth of 69½ feet, in August, 1859. Coming to the well one morning, he and his assistants were amazed to find their dry hole filled to the brim with oil. The next day a pump was installed and some 25 barrels of the precious liquid was taken out.

The success of this well, and the fact that crude oil was then selling for about a dollar a gallon, induced others to sink wells, and soon a veritable boom was on.

Land that formerly could be purchased for a song jumped to fabulous figures, one farm of 50 acres had been originally purchased for a yoke of oxen, but now sold for over four million dollars.

Drake's derrick was only 34 feet high —a very crude affair. His tools were not of the best, and drilling went on at the rate of 1 or 2 feet a day. Modern derricks are usually above 80 feet high, which allows for handling long lengths of tubing.—*Leschen's Hercules.*

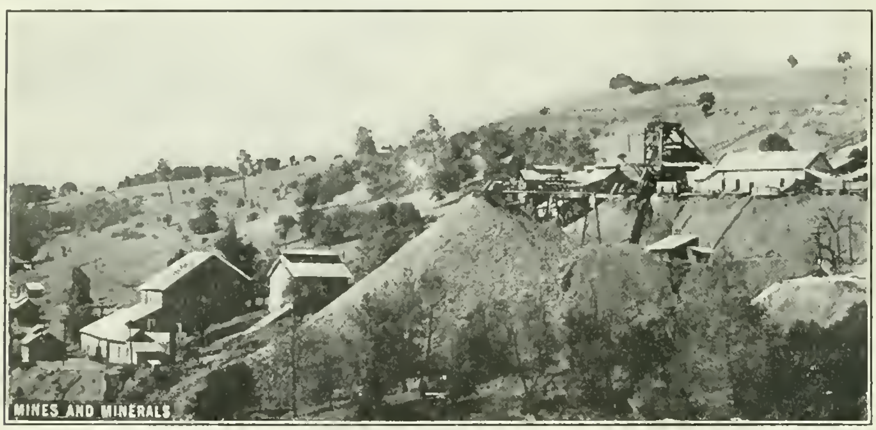
Results of Deep Mining in California

The Deepest Gold Mines in America, Showing the Persistent Nature of the Gold Deposits of the Mother Lode

By Al. H. Martin

Deep quartz mining in California has progressed to an extent unapproached in most American commonwealths. This is due largely to the excellent results generally attending deep explorations, the free-milling character of ore, and the fact that California mining was firmly established before the industry was foreshadowed in many other states. Deep mining has made particular progress in late years, with the northerly portion of the Mother Lode and the Grass Valley district claiming paramount attention. The splendid results attending the operations of the Kennedy and South Eureka in Amador County, and of the North Star and Empire at Grass Valley, have been principally effective in encouraging mining to great depths. The greatest energy along these lines has been recorded in the Amador County portion of the Mother Lode. This mammoth auriferous gold zone embraces Amador, Calaveras, Placer, Tuolumne, and Mariposa counties, with Amador and Calaveras the principal producers. Amador is particularly deserving of attention, as within her confines are found the deepest gold mines in America. The general formation of the Mother Lode is clay-slate, at times altering to greenstone-schist. Veins also occur in a serpentine belt, but while larger they usually lack the values contained by the slate and schist deposits. Some of these veins range 50 to 150 feet wide, with numerous ledges exceeding a width of 20 feet. The average value of mined ore on the Lode approximates $3.80 per ton, but in the large deep mines values are considerably higher.

Among the principal mines of the Lode are the Kennedy, South Eureka, Argonaut, Eagle-Shawmut, and Utica group. The Kennedy has been developed to a vertical depth exceeding 3,550 feet, and the Argonaut has attained an incline depth of 3,600 feet. The South Eureka is down 2,800 feet on the incline, and the Eagle-Shawmut has been developed to an incline distance of 2,700 feet. Numerous properties have been opened to a depth exceeding 1,500 vertical feet. The North Star, Grass Valley district, has been developed to an incline depth of 5,400 feet, and the Empire, same district, has an incline shaft 3,500 feet deep. The Kennedy and other companies are planning to sink deeper, the ore showing in the lower levels being particularly encouraging for deeper activities.



Argonaut Mine and Mill

Of all the mines in California that have stimulated deep operations, the Kennedy unquestionably claims the premier honors. As the deepest gold mine in America this property has demonstrated the remarkably persistent nature of the Mother Lode gold deposits, and given an impetus to developments throughout the affected region. Previous to the opening of commercial ore at the 1,200-foot point the Kennedy was considered practically a failure, having been condemned in 1880 after several years of fair production, and lying idle until 1885. In the upper workings the veins were found badly broken, with values constantly varying, and the deposits showing indications of terrible compression during the formative period. Faulting was frequent, and the ore values frequently vanished. Experience gathered in the Keystone, Oneida, and other properties, encouraged the reopening of the Kennedy in 1885, after the shaft had attained a depth of 900 feet. The greatest improvement in character and strength of ore developed after the 2,300-foot level was gained; and from that point to the present lowest working level (3,450 feet), ore conditions have proven exceptionally satisfactory. The veins occur in a slaty formation, with considerable free gold and sulphurets showing. North of the shaft the shoots have an average width of 11 feet and have been developed about 500 feet. The southerly shoots range from 5 to 6 feet wide, with average lengths of 700 feet. On the 3,450-foot level the main vein displays a width of 15 feet. Values throughout range from $5 to $10 per ton, with the average around $6.50. Occasional rich streaks of quartz are encountered. This ore is carefully guarded and mixed with the lower grade to maintain a fairly uniform monthly standard. The three-compartment shaft is 3,550 feet deep and will be eventually sent down to intersect the hanging-wall and foot-wall veins. It is expected to tap the former at an approximate depth of 3,900 feet and the latter near the 4,400-foot point. Two compartments are used for ore, the third for water. A 1,200-horsepower engine operates the hoist. Skips with a capacity of 3½ tons are operated, the trip from the 3,450-foot level to surface being made in 1¼ minutes. The skips handle the small amount of water without difficulty. The ore is broken by piston drills, four air compressors furnishing energy to the machines. The ore is shoveled direct from the various levels into mule trains and sent to the 100-stamp mill. The annual production approximates 180,000 tons, valued at about $1,000,000. Mining and milling costs average around $3 per ton. The demonstration of strong and rich auriferous deposits below the 2,300-foot level by this company, and the subsequent favorable results, have resulted in the opening of numerous old properties, and the inception of a new era of progress throughout the northern portion of the Mother Lode. It has also had a benignant influence in deeper work in other portions of the belt, and in adjacent fields.

The South Eureka probably ranks after the Kennedy as the property that has given the greatest impetus to deep work on the Lode. This property was developed to a depth of 2,600 feet, and was on the point of being abandoned when an 80-foot drift from the 2,500-foot level intersected a 50-foot vein averaging $6.50 per ton. This was subsequently opened at the 2,600-foot point and upper levels, and a tottering prospect was converted into one of the best mines in the state. The three-compartment shaft has an incline depth of 2,800 feet and is provided with

4-ton skips traveling at the rate of 1,250 feet per minute. The two main veins occur in a slate formation, with soft gouge dividing the quartz from walls. The ledges are gradually converging toward each other and are expected to meet near the 3,000-foot point. A considerable percentage of sulphureted ore occurs, and this is shipped to the Selby smelter at Vallejo Junction. The free-milling quartz is treated by an 80-stamp mill. 12,000 tons are crushed per month, mining and milling costs averaging $2.63 per ton.

The deepest incline mine on the Lode is the Argonaut, developed to a depth of 3,600 feet. This property encountered commercial ore near the 600-foot level, but the first important discoveries were made at the 1,600-foot point. The vein on the 3,450-foot level shows a width of 20 feet. On the recently opened 3,600-foot level the vein is reported 30 feet wide. The deposits occur in slate, and the ledges are less broken than in neighboring properties. Operations are handicapped by distance of shaft from main ore points, and its unsatisfactory pitch. The shaft is three compartment and equipped with an electric hoist operated by a 500-horsepower Westinghouse motor. The 40-stamp mill crushes 200 tons per day.

The North Star mine, at Grass Valley, has been developed to an approximate depth of 5,400 feet with the 5,300-foot the deepest working level. The vertical depth of the workings is about 2,066 feet. In the upper levels, now exhausted, the vein averaged about 18 inches wide, with values running about $18 per ton. Below the 2,500-foot point the vein widened out to 6 feet with the crushed country rock persistently mingling with quartz. This necessitates the breaking down of the whole mass to obtain best results. Values for the entire width average $10.745 per ton, and 95,401 tons were treated in 1911 at an operating cost of $509,925, with $46,481 additional for developments. Net earnings for the year were $468,681. This company has conclusively demonstrated the persistent nature of the Grass Valley ore bodies, and it is likely the veins will be found persisting as far as economic conditions will permit following. The vein occurs in a fine-grained dark-green rock composed of uralite-diabase and uralite-porphyrite, with the walls strong and generally well marked. The company operates two 40-stamp mills and a cyanide plant. Of the total extraction, 77.1 per cent. is obtained by amalgamation and 22.9 per cent. by cyanidation. It is stated 98 per cent. of the total ore content is recovered. For years the North Star has ranked as the foremost quartz gold producer of California, its annual yield surpassing $1,025,000.

The Empire, developed to an incline depth of 3,500 feet, is controlled by a private corporation, and little of value has been given out by the management. The ore occurs in diabase and granodiorite and has an average width of 10 to 18 inches. Values are stated to range $15 to $40 per ton, with occasional streaks of remarkably rich quartz encountered. The shaft is three-compartment. The mill comprises 40 stamps, and the annual yield is estimated at about $750,000. Like the North Star vein, the Empire ore bodies have proved remarkably persistent, and the results obtained have stimulated deep workings by other companies in the district. A detailed account of this remarkable property appeared in the September, 1911, issue of Mines and Minerals.

The instances cited indicate the great interest manifested in deep quartz mining in the northerly districts of California. It has been found necessary to handle the generally low-grade ore on a large scale to insure successful results, as the $3 a day and 8-hour shift means a somewhat high labor cost. Electricity is gradually superseding water-power, with a corresponding cost reduction. As most California ores, particularly along the Mother Lode, yield readily to simple milling, there is no need for erection of costly and complicated reduction plants, such as are required in reducing refractory material. Among the noted old mines on the Mother Lode, that have been recently rehabilitated and are being sent to pronounced depth, are the Plymouth Consolidated, Keystone, Oneida, Central Eureka, Lightner, and many others. And most of this activity is traceable directly to the results obtained by the Kennedy, South Eureka, and other progressive operators.

※ ※

The mining industry of Formosa for 1911 was as follows: Number of mines—gold, 9; gold-copper, 1; gold dust, 27; copper, 2; mercury, 1; coal, 270; petroleum, 39; sulphur, 16. Production—Gold, $1,065,400; gold dust, $48,882; silver, $32,525; copper, $264,513; coal, $468,317; petroleum, $3,243; sulphur, $22,950.

Economic Efficiency in Lead Concentration

*By R. S. Handy**

While running a series of efficiency tests on frue vanners in the new unit of the Bunker Hill & Sullivan west mill, I included a few tests to determine the economic effects of various speeds in the forward motion of the belt, all of the other mechanical conditions being constant. The tests

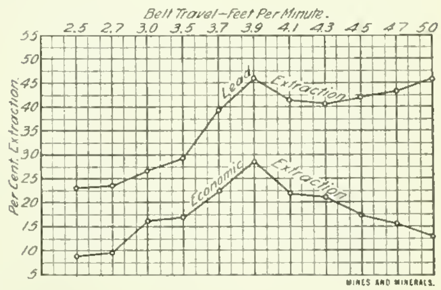


Fig. 1

produced some interesting results, as shown in the accompanying table and graphic representations.

The tests were run on a Chalmers & Williams 6-foot Frue vanner, with a slope of ¼-inch per foot, fed with thickened overflow from an Esperanza drag classifier, all through 200 mesh. The dilution of the feed was one part solids to 7.8 parts water; wash water, 3.57 gallons per minute; speed, 200 revolutions per minute. One test per day was made at intervals covering a period of a month, which accounts for the variations in the feed assays of the different tests.

The results are tabulated in Table 1 (which is self-explanatory) and are shown graphically in Figs. 1 and 2. The economic extraction referred to is the ratio of the value of the feed—figured at the full price for the lead and silver contents—to the net value of the concentrates as they are sold to the smelters, using the same base prices. The idea was to determine under what conditions the most money is extracted from a given quantity of metals in the feed, and whether the relationship of the lead extraction to the net returns would be somewhere nearly constant.

* Mill Superintendent, Bunker Hill & Sullivan M. & C. Co., Kellogg, Idaho.

It developed that the lead extraction and the economic extraction increased steadily with increasing belt speed (Fig. 1) until a travel of 3.9 feet per minute was reached, after which the lead extraction remained fairly constant, while the economic extraction decreased rapidly with increasing belt speed.

The test No. 6, which produced the best economic extraction, was a fair average of all the tests so far as feed and tonnage were concerned. The vanner was running at practically the adjustment shown in test No. 6 when the tests were started.

An interesting point to note is that the excess sand pulled over in the concentrates after the sixth test did not increase the lead extraction. This is in line with other experiments with concentrating machines on this character of feed, and indicates, I think, that the content of free, crystalline lead particles is about 55 per cent. (since 20 per cent. extraction can be obtained in retreating the tailings), and that the remainder of the lead is mechanically included in the flocculent matter that flows with the surface water off the vanner. To demonstrate this, roughly, I screened some of the tailings on a fine, silk cloth and washed the muddy water through with clear water. Thirty per cent., by weight, in the form of clean sand was left on the cloth and assayed 1 per cent. lead, while the light, flocculent matter through the cloth assayed 6.14 per cent. lead.

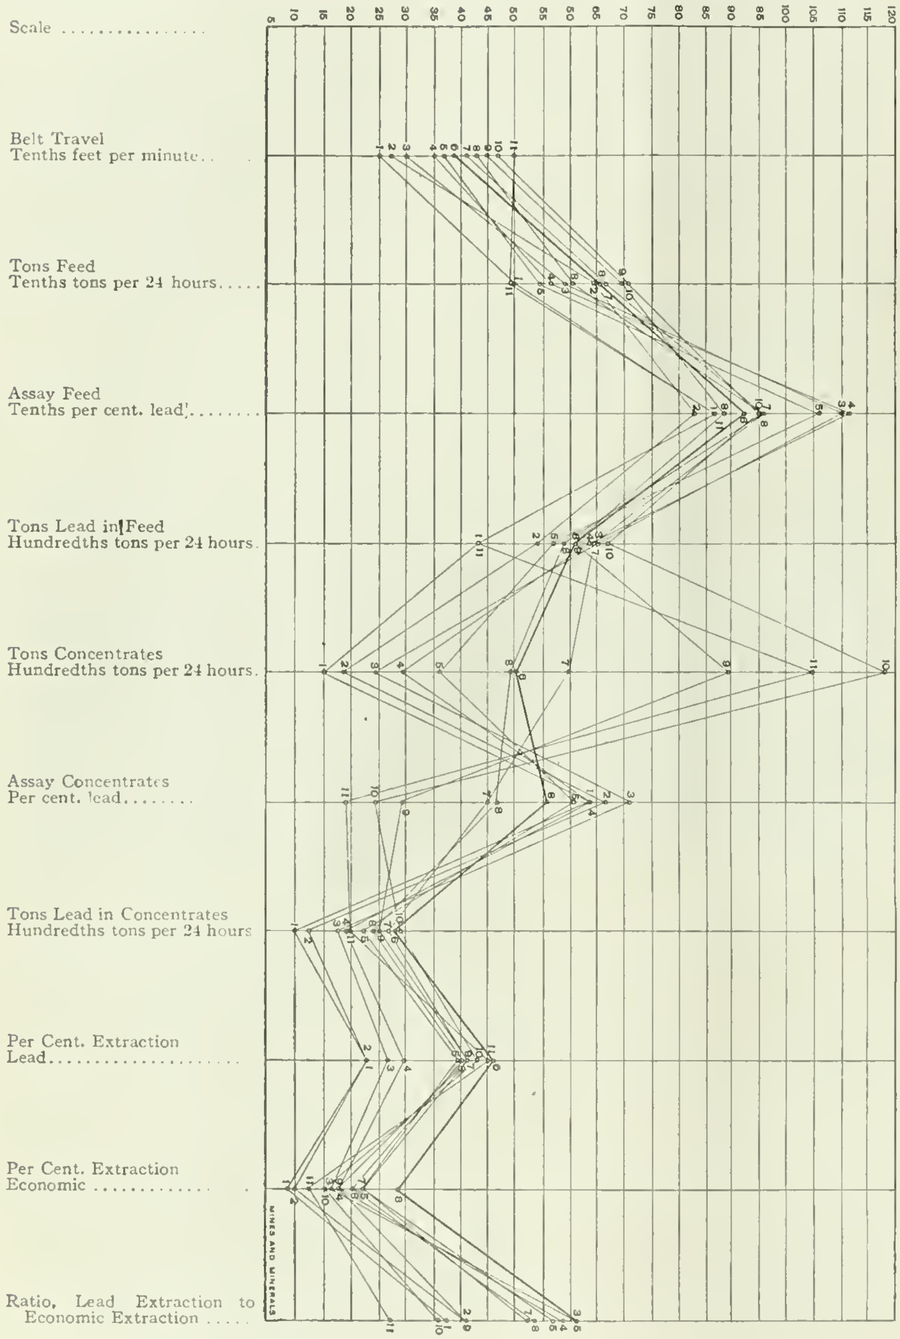

Fig. 2

The main point brought out in these tests is that in concentrating lead ores, where the cost of transporting and refining the product is such an important economic factor, there is a point in each concentrating process at which the adjustment of the lead extraction to the grade of concentrates gives the highest economic recovery. This is well illustrated in Fig. 2, in which the two important factors are represented graphically. The highest economic point seems here to be very sharply defined.

It may be well to explain that with the Bunker Hill ores it is not necessary to consider the silver in making tests, as the ratio of the silver to the lead is, for all practical purposes, a constant.

Manganese in Gold Amalgamation

Manganese oxide (MnO_2) is often found associated with ores of gold and silver, particularly the former. Noted instances are Butte, Mont., Leadville, Colo., and Tombstone, Ariz. The action of manganese dioxide on mercury is not well understood and its evil effects are often the cause of much annoyance, notably in pan mills. It is thought by many that in some manner nascent oxygen is given off from the black manganese oxide, and this in some manner affects the mercury. In pan mills caustic lime is often added with good effect, and it may be that a similar result might be obtained by adding quicklime to the mercury in a plate mill. In some mills concentration before amalgamation has been found to give better results than are obtained in the usual practice. In concentration before amalgamation much of the deleterious mineral present—usually manganese oxide, molybdenite or graphite—is washed away with the gangue, and the precious metal, relieved of these substances, amalgamates more readily. In other cases concentration alone has been found to result in a saving of a higher percentage of the gold than could be obtained by amalgamation alone in the presence of manganese, graphite, or molybdenite. In the treatment of some silver ores by the pan amalgamation process, where much base metal is present, the addition of a small amount of manganese oxide has been found to have a beneficial effect, producing a higher-grade bullion than was otherwise obtainable.

Bismuth is a reddish-white metal and is very brittle. Its specific gravity is 9.83, and it melts at 264° C. or 507° F. Like water, it may be cooled 6 degrees or 7 degrees below its freezing point, but when solidification sets in, the temperature rises to 480° F. and continues to rise until mass is solid. It expands .03 of its volume on solidifying, a property which it communicates to its alloys.

Practical Cyaniding—Part 4

Slime and Its Treatment—Intermittent and Continuous Decantations—Thickeners—Filter Presses

*By John Randall**

As used in mill practice the term slime includes all material passing through a 200-mesh sieve, and often sand as coarse as 150 mesh is allowed to go into the slime, as it assists filtration by making the cake more permeable. When ore is crushed to impalpable powder, the fine gold and fine silver will go quickly into solution. As lime will absorb its weight in water, it has been a problem in the past to separate the gold cyanide solution from the slime; however, in recent practice this is accomplished.

From the very commencement of the cyanide process, slime, or colloidal hydrates, in the ore gave trouble. Efforts were made to prevent the formation of slime by crushing the ore comparatively coarse, that is, to 20-mesh screen. But this did not free the gold in some ores, so that the extraction was imperfect. Besides, in some cases, when crushing to a 20-mesh, from 30 to 60 per cent. of the ore would slime, which made percolation and drainage difficult. Finer crushing was then adopted and the pulp was separated into sand and slime, each of which was subjected to separate treatment.

The gold and silver are dissolved from slime generally by agitation in Pachuca tanks, Fig. 1, or mechanical agitators, and as a rule present no difficulties; but it must be borne in mind that when slime and solution are lying at rest in a tank no extraction is taking place. Changes of solution are necessary, especially so in case of silver ores, and air must be persistently applied if reducing agents are present.

Gold and silver are recovered from slime by decantation, vacuum filtration, or filter pressing. Decantation is the oldest method, and may be classed as intermittent and continuous, the successful application of the latter is quite recent. Vacuum filters are of two kinds, the thin cake, such as the Ridgeway and the Oliver; and the thick cake, such as the Moore and Butters. Filter presses are of two kinds, as the plate and frame type used for a long time in many industries, and another type in which the filter leaves are enclosed in a chamber or cylinder. They are more properly called pressure filters. The Swetland and Kelley are widely different forms of this type.

Intermittent decantation was the first method practiced for recovering the gold cyanide solution, the slime being alternately agitated with barren solution and then allowed to settle or thicken at the bottom of the tank when the clear solution containing a considerable part of the gold was decanted to the zinc boxes. This operation was repeated several times with a fresh portion of solution, water being added with the last wash to make up for the moisture sent to waste in the tailing after the last decantation. From three to four decantations were generally made, making it necessary to pass a very large amount of solution through the zinc boxes as well as requiring large storage capacity for the wash solutions. Intermittent decantation also required that the tanks should be large compared with the tonnage, as the pulp while thickening occupied but an inconsiderable portion of the tank near the bottom. These intermittent operations also involved considerable labor cost, but the process is still practiced on a large scale in South Africa in the older mills, the agitation being effected by drawing the material from the bottom of the tank and pumping it to the top with centrifugal pumps. The only reason for continuing the practice is the cost of changing the equipment. No new mills are being built on this plan.

Continuous decantation has been used and a moderate degree of success achieved by thickening continuously in large cone-shaped tanks. If a considerable degree of thickening is attempted it is likely to give trouble on account of the talcose material building up on the slopes and then sliding down at intervals, choking the outlet.

Series decantation is a method of continuous decantation in which the slimed ore passes through a series of thickeners and is alternately thickened and washed, the same wash solution being successively used for the several washes by being passed through the series in a direction opposite to that of the ore. The first work done upon series decantation in America, as far as adapting the method to mill practice is concerned, was done in the Black Hills of South Dakota in 1901, in which four washes were given the slimed ore, and the work resulted in patents taken out in 1902 by John Randall for an apparatus to carry out the method in a series of thickener cones. The inherent difficulties in thickening in cones and the fact that vacuum filtration was then beginning to attract attention away from other methods, caused series decantation to attract little attention in this country until the introduction of the Dorr thickener.

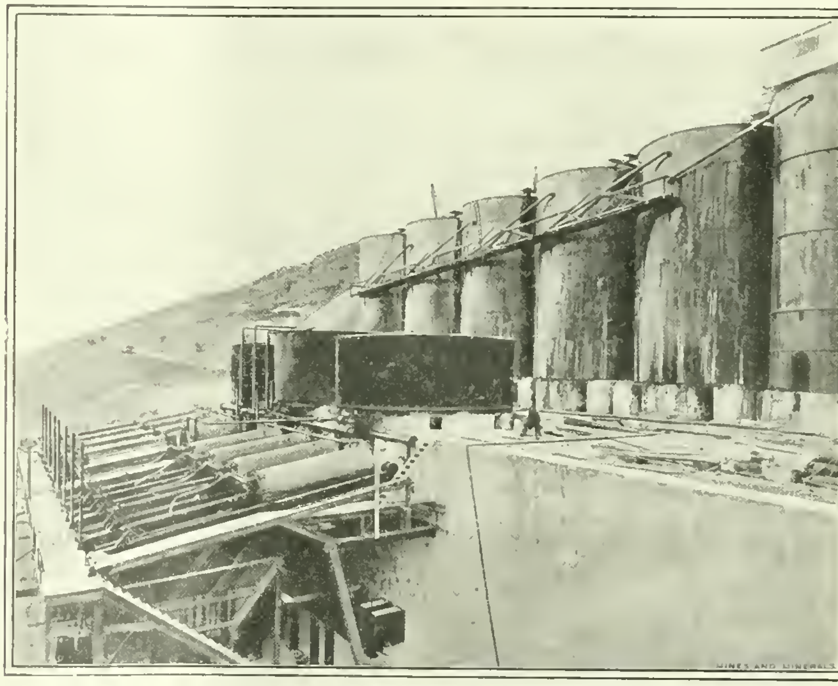

Fig. 1. Pachuca Tanks, at Right

At about the same time that Mr. Randall was installing his series decantation plant in the Black Hills, the Denny brothers worked out the same method in South Africa, their apparatus differing considerably from his in detail. The Denny apparatus provides for three operations: first, dewatering the battery slime, next cyanide treatment for securing extraction, and lastly two series washes for recovering the gold-bearing solution.

The Dorr thickener having come into

*Boulder, Colo. Part I appeared in August Mines and Minerals.

extensive use, series decantation is thereby made convenient and practicable and is receiving the attention it deserves. This thickener removes the settled slime by means of slowly moving scrapers, obviating the trouble caused by the slime building up on the slopes of the cones and sliding down at irregular intervals. Changes of solution necessary either for securing extraction or for recovery of metal-bearing solution are effected by running thickeners in series either with or without agitators between them. In some plants where the solution is quite low in cyanide, this method is displacing filters. The system greatly reduces the amount of solution required to be passed through the zinc boxes over that required by other methods of decantation.

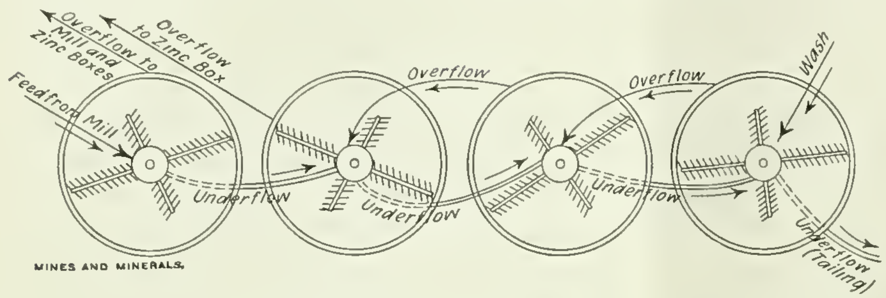

Fig. 2. Thickeners in Series

In computing results for any ratio of wash to ore or for any method of applying the wash, only the solution is taken into account. If it is assumed that the slime is thickened to 50 per cent. moisture, then an amount of solution equal to the ore is moving down the series, toward the right in diagram Fig. 2. If we denote the ratio of solution to ore by r, the amount of solution moving down the series will be $\frac{1}{r}$ and the amount moving in the opposite direction will be $r-1$ and the value v per ton for the contents of any thickener is

$$v=\frac{p+f(r-1)}{r}$$

In which p represents the value per ton in the preceding thickener and f the value per ton in the following thickener of the series.

Example.—Three thickeners, l, m, and n, are operating in series, one part of the solution passing through the series from l to n in the thickened slime issuing from the underflow of each and finally leaving the series as underflow from n. The overflow passes up the series from n to l, one part of water being added at the last thickener, n, and one part of half-strength solution added at the next to the last thickener, m. All the overflow leaves the series at the first thickener, l. The feed of slime coming into the series at l contains two parts of standard solution to one part of ore. What is the strength of the solutions in each of the three thickeners, regarding the strength of the standard solution as unity?

In thickener l two parts of solution are entering with the feed and two parts are entering it as overflow from m. In thickener m one part of solution is entering from the underflow of l, one part of half-strength solution is entering it from the mill, and one part is entering it from n. As to the last thickener n, one part of solution is entering it as underflow from m and one part of water is being added. From these conditions we derive the following equations:

$$x=\frac{2+2y}{4} \qquad (1)$$

$$y=\frac{x+\frac{1}{2}+z}{3} \qquad (2)$$

$$z=\frac{y}{2} \qquad (3)$$

Solving for x, y, and z we have the values $\frac{3}{4}$, $\frac{1}{2}$, and $\frac{1}{4}$, or expressed in percentage, 75, 50, and 25 per cent. of standard strength of the solutions in the thickeners l, m, and n.

Example 2.—(a) Four thickeners, k, l, m, and n, are operating in series under the same conditions as in the last example, the half-strength solution being added to the next to the last, and the water to the last. What is the strength of the solution in each? (b) What is the value for the last of a series of five thickeners operating in the same manner? Ans. For last thickeners. (a) $20\frac{10}{17}$%, (b) $18\frac{4}{7}$%.

The above results are instructive, showing as they do that increasing the number of thickeners does not materially affect the value in the last one after the third. However, increasing the ratio of wash has a very marked effect. This is illustrated by the following example, which might be met in mill practice, the gold value instead of the solution strength being computed:

Four thickeners are operating in series on the same principle as outlined in Example 2 under the following conditions:

1. The value dissolved is \$5 per ton of ore, the dissolution of value being completed before the pulp enters the first thickener. The entire battery product, consisting of 6 tons of solution to 1 ton of ore is sent to the first thickener. From the overflow of this thickener 1 ton of solution is returned to the batteries to every 4 tons sent to the zinc boxes. Of course 1 ton of solution per ton of ore passes out at the underflow with the thickened slime. It will therefore be seen that no washing occurs in the first thickener, it being in the battery circuit only.

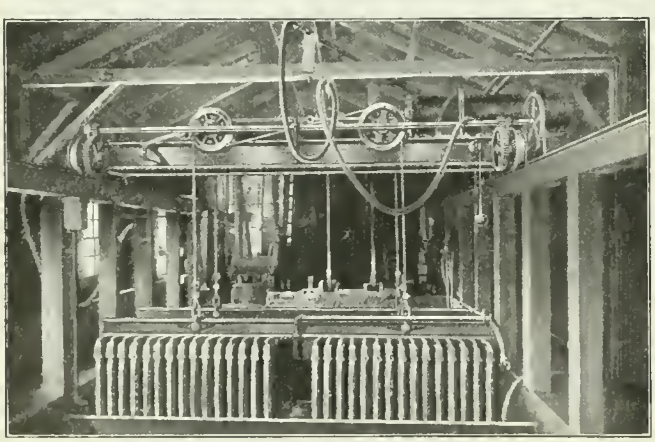

Fig. 3. The Moore Filter

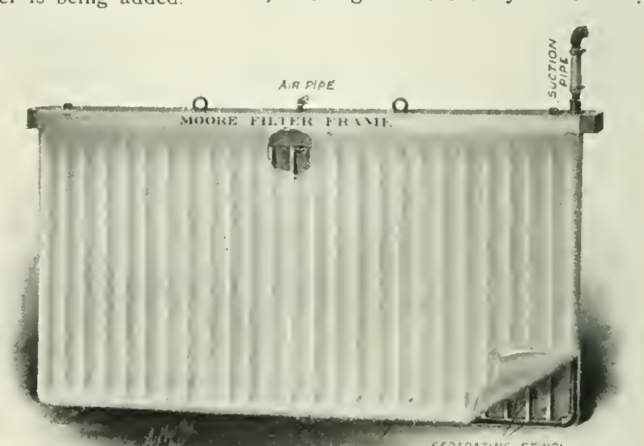

Fig. 4. Moore Filter Frame

2. One ton of water to each ton of ore is added at the last thickener to balance the moisture loss in the discharged tailing.

3. Four tons of wash solution containing \$.50 gold per ton is added at the third thickener for each ton of ore. The overflow solution leaves the series from

the second thickener and is returned to the batteries.

Let w, x, y, and z, respectively, equal the values in gold per ton of the solutions leaving the first, second, third, and fourth thickeners. Then will

$$w=\frac{5x+w+\$5}{6}$$

$$x=\frac{5y+w}{6}$$

$$y=\frac{x+2+4(.05)}{6}$$

$$z=\frac{y}{2}$$

Solving for the values of w, x, y, and z, $w=\$1.29$; $x=\$.29$; $y=\$.089$; $z=\$.044$; making a recovery of a little over 99 per cent. by washing in three thickeners.

The above example is from a flow sheet worked out for an all-sliming mill crushing in solution and having a capacity of 100 tons of ore per day. Through the courtesy of the Dorr Cyanide Machinery Co. the following flow sheet is given:

Solution Flow Sheet. For 100-Ton Mill Using Dorr Thickeners for Recovery of Gold Solution

	Tons Debit	Tons Credit
First thickener		
Coming from batteries	600	
Going to zinc boxes		400
Returned to batteries		100
Underflow with pulp to second thickener		100
	600	600
Second thickener		
From third thickener overflow	500	
From first thickener underflow	100	
Overflow through batteries		500
Underflow with pulp to third thickener		100
	600	600
Third thickener		
Barren solution from zinc boxes	400	
From fourth thickener overflow	100	
From second thickener underflow	100	
Overflow to second thickener		500
Underflow to fourth thickener		100
	600	600
Fourth thickener		
From third thickener underflow	100	
Water	100	
Overflow to third thickener		100
Underflow to waste		100
	200	200

It will be noted that in this arrangement only 4 tons of solution per ton of ore is required to go to the zinc boxes. A mill constructed on this principle is being operated by the United States Reduction and Refining Co., at Florence, Colo., on a large accumulation of tailing. This method of recovery is applicable where a quite weak cyanide solution can be used, where the gold is readily brought into solution, and where it is desired to equip a mill at a moderate expense.

A very attractive field for the practice of series decantation in thickeners is where changes in solution strength are required in order to secure extraction. This condition is quite commonly met in ores yielding colloidal slime in wet crushing.

Filter presses of the ordinary Dehne, or plate and frame, type have for some time been successfully used in the treatment of high-grade gold slime, principally in Australia, but the labor involved in opening the press and separating the frames each time the tailing is discharged has prevented its adoption in the United States, where low operating cost is of primary importance. The success of the Dehne press, however, has stimulated invention, and presses are now built that do not require to be opened in discharging and which give good results on fairly permeable slime cakes.

Pressure filters of various makes are used with success and are economical in operation. A fair knowledge of how to operate them may be gained from a description of each.

Vacuum filters of the thick-cake type as the Moore, Fig. 3, and the Butters, Fig. 5, came rapidly into use over the entire mining world as soon as they were placed upon the market, which was about the year 1902. Their extensive use merits a general discussion and description apart from each make of filter.

Pressure filters require air-tight tanks, while vacuum filters are operated in open tanks. Vacuum filters are constructed to make use of the difference in pressure between the weight of the atmosphere and a partial vacuum produced by a pump connected with the interior of a submerged filter leaf. Owing to the limited pressure at command, less than 14.7 pounds per square inch, the time required to build a cake is more than is required by either the filter press or the pressure filter. This difference in time, however, is more than compensated by the number and size of the filter leaves that are handled in open tanks. For example, 66 filter leaves, each 6 feet wide and 8 feet long, make up a filter basket at the Liberty Bell mine in Telluride, Colorado, which has a daily capacity of 300 tons of dry slime. This is equivalent to a filter area of 6,336 square feet, or 15 times that of a tank filter having the same capacity.

Vacuum filter plants are constructed with movable and stationary filter leaves; that is, in one case the filter leaves are moved from tank to tank during the process, while in the other case the filter leaves remain in the same tank while the solutions are changed.

There are two kinds of filter leaves that may be used in vacuum filters. The one shown in Fig. 4 consists of a pipe frame attached to a wooden rail. The upper part of the pipe composing the lower rail of the frame is cut away to form a trough in which the filtrate collects. In this trough are placed the vertical wooden separating strips, after which the entire frame is enclosed in 8-ounce duck. The canvas is stitched between the separating strips in order to give the frame stiffness and strength. To one upright side pipe, is fastened a nipple, and to this is attached a flexible hose terminating in an elbow, which joins a vacuum pipe, not shown. Filter leaves of this description are usually 5 feet wide by 10 feet long, and are arranged in baskets; that is, a number of leaves are fastened to steel I beams so that they may be lifted at one time.

In Fig. 5 is shown the other vacuum filter leaf. The frame consists of a $1\frac{3}{4}'' \times 5\frac{3}{4}''$ wooden top rail a with the remaining three sides made of $\frac{1}{2}$-inch pipe b. The top of the lower pipe is perforated with $\frac{5}{16}$-inch holes through which the filtrate enters the pipe. The filter mat consists of a layer of cocoa matting, covered with an envelope of 8-ounce duck, stitched at intervals of 1 inch as shown by the dotted lines. The canvas is rein-

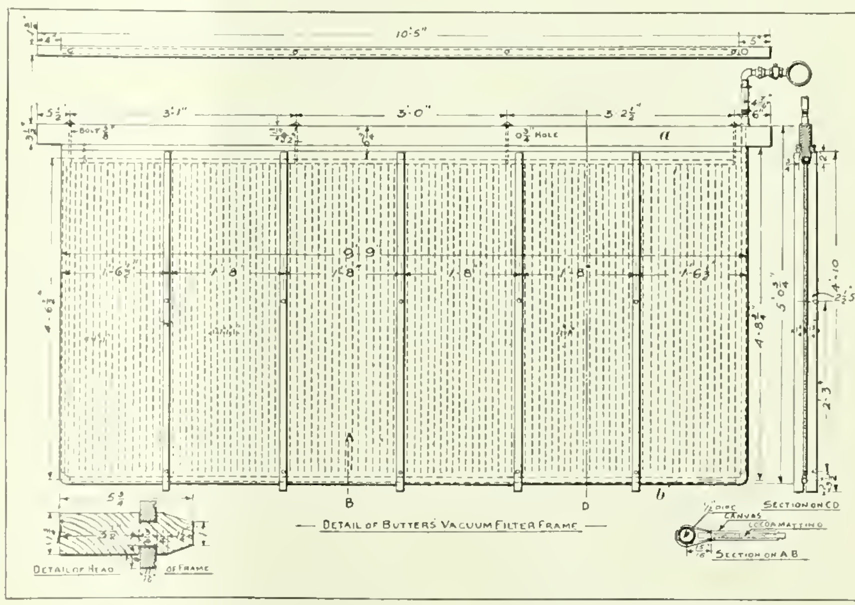

Fig. 5. Butters Vacuum Filter Frame

forced by wooden strips on each side of the frame, as shown. There is a horizontal line of stitching below the top rail where the matting ends, and above this the canvas is made impervious by being coated with waterproof paint. The canvas over the pipes is also painted to prevent slime adhering to any part of the filter except the mat. The strips of wood that hold the canvas to the top rail are grooved and made to project as shown in the section, the object being to prevent the liquor from the top frame trickling over the surface of the slime cake when the filter is removed from the bath of slime pulp. To show the relation of the bottom rail pipe b to the matting and canvas, a section through line AB is given. The filter area on each frame shown is 80 square feet, and each filter, when bare, will occupy a space of 2.68 cubic feet; when loaded with 1 inch of slime cake it will require a space of 9.34 cubic feet. Owing to the projection of the slats, the distance between the centers of two consecutive filter leaves is 4⅛ inches, which furnishes sufficient space for the accumulation of a cake 1 inch thick. The top rail of the filter frame projects at each end beyond the filter, so that it may rest on brackets in the tank. The filter leaves shown in Fig. 5 are bolted together in baskets of four each, and are used in the stationary vacuum filter process.

Specific Gravity of Slime Pulp.—Before the size of the apparatus needed in a cyaniding plant can be determined, the number of cubic feet that the pulp mixture and the filtrate will occupy must be definitely known. The volume of these mixtures varies with their specific gravity, which, therefore, must always be determined. While the specific gravity of slime pulp may be ascertained by means of the hydrometer, this method is not satisfactory owing to the difficulty experienced in keeping slime uniformly suspended in the pulp. A better method of finding the specific gravity is to weigh the mixture.

Rule.—To determine the specific gravity of slime pulp, place a measuring flask graduated to 100 cubic centimeters upon the scales and counterbalance it. Then fill the flask to the 100-cubic-centimeter mark with the slime pulp and weigh. The weight of this pulp is the difference in weight between the empty and the charged vessel, and this divided by 100 will be the specific gravity of the pulp.

This rule is based on the fact that 100 cubic centimeters of distilled water weighs 100 grams, for water is the unit in specific gravity calculations.

Example.—What is the specific gravity of a slime pulp 100 cubic centimeters of which weighs 122.9 grams?

Solution.—From the rule just given, if 100 cubic centimeters of the slime weighs 122.9 grams, the specific gravity is $122.9 \div 100 = 1.229$. Ans.

The specific gravity of *dry slime* varies. If the slime is wet and then dried to a hard mass, the specific gravity may be found by applying the following rule:

Rule.—To determine the specific gravity of dry slime, weigh the slime in air and then in water. The weight of the slime in air divided by the difference of the weights in air and in water will be the specific gravity.

Example.—A mass of dry slime weighs 480 grams in air, but when submerged in distilled water shows a loss of 380 grams; what is its specific gravity?

Solution.—Applying the rule just given, the specific gravity of the slime is $480 \div 380 = 1.263+$. Ans.

Another method of determining the specific gravity of dry slime, and the only method available when the slime is in a loose pulverized state, is as follows: Having weighed a quantity of the dry slime, place it in a 100-cubic-centimeter flask and thoroughly mix with water. Then fill the flask up to the 100-cubic-centimeter mark with water from a burette. The weight of the slime in air divided by the difference between 100 cubic centimeters and the total amount of water that flowed into the flask will then be the specific gravity of the slime.

Example.—What is the specific gravity of a dry slime that weighs 48 grams, if 50 cubic centimeters of water is required to mix it thoroughly, and 12 cubic centimeters more is required to bring it up to the 100-cubic-centimeter mark?

Solution.—From the statement just made, the specific gravity of this slime is

$$\frac{48}{100-(50+12)} = 1.263. \quad \text{Ans}$$

It is possible to find the number of cubic feet in 1 ton of slime pulp if the specific gravity of the slime pulp or the specific gravity of the dry slime and the required dilution are known.

Rule 1.—To find the number of cubic feet in 1 ton of slime pulp, divide the number of pounds in 1 ton by the number of pounds in 1 cubic foot of the pulp.

Rule 2.—To find the number of cubic feet in 1 ton of slime pulp, multiply the number of pounds in 1 ton, divided by the weight of 1 cubic foot of water, by the proportion of solution in the pulp. To this add the product of the proportion of slime in the pulp and the number of pounds in 1 ton divided by the weight of 1 cubic foot of water multiplied by the specific gravity of the dry slime.

Example 1.—How many cubic feet are there in 1 ton of a slime pulp that has a specific gravity of 1.205?

Solution.—Since 1 cubic foot of water weighs 62.5 pounds, 1 cubic foot of the pulp will weigh $62.5 \times 1.205 = 75.312$ pounds. Therefore, 1 ton of the slime will contain $2{,}000 \div 75.312 = 26.556$ cubic feet. Ans.

Example 2.—How many cubic feet will there be in 1 ton of slime pulp that consists of 3 parts of solution to 1 part of slime, if the specific gravity of the dry slime is 2?

Solution.—Applying Rule 2, 1 ton of the pulp will contain

$$\left(\frac{2{,}000}{62.5}\times\frac{3}{4}\right)+\left(\frac{2{,}000}{62.5\times 2}\times\frac{1}{4}\right) = 24+4 = 28 \text{ cu. ft. Ans.}$$

To find the dilution from the number of cubic feet of pulp mixture in 1 ton, first find the specific gravity of the dry slime, and then the specific gravity of the pulp mixture, and assume that the cyanide solution has a specific gravity of 1. The dilution may also be found by applying the formula

$$D = \frac{1(a-b)}{a(b-1)}$$

in which

D = dilution;

a = specific gravity of dry slime;

b = specific gravity of pulp mixture.

Example 1.—What is the dilution of a pulp mixture that has a specific gravity of 1.125, if the specific gravity of the dry slime is 2?

Solution.—Applying the formula just given,

$$D = \frac{1\times(2-1.125)}{2\times(1.125-1)} = 3.5 \text{ to } 1. \quad \text{Ans.}$$

Example 2.—What is the dilution of a pulp mixture, if the specific gravity of the dry slime is 2.5 and there are 26.5 cubic feet of the solution in 1 ton?

Solution —As there are 32 cubic feet of water in 1 ton, the specific gravity of the mixture is $\frac{32}{26.5} = 1.208$. Then, from the formula, the dilution is

$$\frac{1\times(2.5-1.208)}{2.5\times(1.208-1)} = 2.5 \text{ to } 1. \quad \text{Ans.}$$

Cyanide solutions never approach a strength of 1 per cent., or 20 pounds to the ton of water; that is, $\frac{1}{100}$ more than the unit of measurement taken, or $\frac{2{,}020}{62.5} = 32.32$, and $\frac{32.32}{32} = 1.01$, is the specific gravity of a 1 per cent. cyanide solution; 1.02 is that of a 2 per cent. solution; etc. The calculation given above is therefore near enough for all practical purposes.

If the specific gravity of a dry slime is known, the weight may be readily found.

Rule.—To find the weight of dry slime, multiply the weight of 1 cubic foot of water by the specific gravity of the slime.

Example.—What is the weight of 1 cubic foot of dry slime that has a specific gravity of 2.4?

Solution.—From the rule just given, 1 cubic foot of the slime will weigh $62.5 \times 2.4 = 150$ pounds. Ans.

Weight of Slime on Filter Leaves. When the area of the filter leaves, the thickness of the cake, the specific gravity of the dry slime, and the moisture in the cake are known, the weight of the slime on the leaves may be obtained.

Rule.—To find the weight of slime on the filter leaves, find the amount of slime in cubic feet. Multiply this amount by the percentage of moisture present to find the quantity of water in the slime. Then multiply the cubical contents of the slime by the difference between 100 per cent. and the percentage of moisture in the slime, to obtain the amount of dry slime. Each of these products is then multiplied by the weight of 1 cubic foot of water and the specific gravity of the water and slime, respectively, and then divided by the number of pounds in 1 ton. The sum of the weights thus obtained is the weight of the slime on the leaves.

Example.—Find the number of tons of slime cake on 410 square feet of filter, when the specific gravity of the dry slime is 2.4 and the cake 1.75 inches thick contains 20 per cent. moisture.

Solution.—Since the slime cake contains $\frac{410\times1.75\times144}{1,728}=59.79$ cubic feet, it contains $59.79\times.20=11.958$ cubic feet of water and $\frac{100-20}{100}\times59.79=47.832$ cubic feet of dry slime. Therefore the slime cake contains $\frac{11.958\times1\times62.5}{2,000}=.3736$ ton of water and $\frac{47.832\times2.4\times62.5}{2,000}=3.5874$ tons of slime. The weight of the cake is, therefore,

$.3736+3.5874=3.961$ tons. Ans.

By carrying out a series of calculations with dry slime of different specific gravities, the number of cubic feet of pulp in 1 ton and the specific gravity of the pulp for different dilutions are obtained. These may be tabulated for ready reference in the mill as shown in Table 1.

EXAMPLES FOR PRACTICE

1. When a slime pulp has a specific gravity of 1.4, how many cubic feet of the pulp will equal 1 ton?

Ans. 22.857 cu.ft.

2. How many cubic feet will there be in 1 ton of slime that, when dry, has a specific gravity of 2, and, when filter pressed, retains 30 per cent. of moisture?

Ans. 20.8 cu. ft.

3. What will be the volume in cubic feet of a ton of slime pulp solution, diluted 2 to 1, the specific gravity of the slime being 2.25 when dry?

Ans. 26.073 cu. ft.

4. The available part of a filter-press frame has an area of 3 ft. × 5 ft. There are 91 such frames, and the cakes are made 1¼ inches thick. What will be the number of tons of slime that a press of this size can treat at one charge, assuming that the slime when dry has a specific gravity of 2 when it retains 30 per cent. moisture in the press?

Ans. 6.83 + tons per charge.

5. When dry slime has a specific gravity of 2.6, and is mixed with 4 parts by volume of solution, what will be the specific gravity of the mixture?

Ans. 1.32

Weight of Slime Cake.—Slime cake varies slightly in weight, but on a vacuum filter a cake 1 inch thick will weigh about 8 pounds per square foot. A filter leaf having an area of 80 square feet, or two sides 5 ft. × 8 ft. each, will carry 640 pounds of slime cake. On an average, the cake will contain 35 per cent. of moisture, which leaves 416 pounds of dry slime per 80 square feet. Assuming that the original slime pulp contained 3 parts of solution to 1 of dry slime and that the filtering plant contained 60 leaves, the quantity of solution that will pass through the filter when forming a 1-inch slime cake may be calculated as follows: The total load on the frames $\frac{640\times60}{2,000}=19.2$ tons, 35 per cent. or 6.72 tons of which is moisture. The dry slime will weigh $\frac{416\times60}{2,000}$ 12.48 tons, and as each ton of dry slime was diluted with 3 tons of solution, there were $12.48\times3=37.44$ tons of solution. Deducting 35 per cent., or 6.72 tons, of the total load for moisture, there remains 30.72 tons of solution as the quantity that passed through the filter. The quantity of filtrate that passes through any number of filters for any dilution can be obtained from the formula

$$Q=a\,n\times\frac{d\,c-(b-c)}{2,000}$$

in which

a = area of filter leaf, in square feet;
b = weight per square foot of slime cake 1 inch thick;
c = weight per square foot of dry slime cake 1 inch thick;
d = number of parts of solution to one part of slime;
n = number of filter leaves;
Q = quantity of filtrate, in tons.

In this formula the weight per square foot of a slime cake 1 inch thick is usually taken as 8 pounds; the weight per square foot of a dry slime cake 1 inch thick is taken as 5.2 pounds.

Example.—A tank 22 feet long, 10¼ feet wide, and 7 feet deep, accommodates 60 filter leaves ¾ inch thick, having an area of 60 square feet. (*a*) When the filter leaves are in the tank and spaced 4⅛ inches between centers, what will be the capacity in tons, for pulp solution having a specific gravity of 1.25? (*b*) What will be the capacity of the tank for the pulp solution when the slime cake on the filter leaves is 1 inch thick?

Solution.—(*a*) Total capacity of the tank is $22\times10\frac{1}{4}\times7=1,578.5$ cubic feet. The space occupied by the filter leaves is $72\times120\times\frac{3}{4}\times60=388,800$ cubic inches, or 225 cubic feet. The space that the slime pulp may fill, therefore, is $1,578.5-225=1,353.5$ cubic feet.

Having a specific gravity of 1.25, the pulp will weigh $62.5\times1.25=78.125$ pounds per cubic foot. The pulp solution in the tank will therefore weigh

$$\frac{1,353.5\times78.125}{2,000}=52.87 \text{ tons. Ans.}$$

(*b*) Since the filter leaves are ¾ inch thick, the total thickness of the leaf and the cake on each side of it will be 2¾ inches. Therefore, the space filled by the coated leaves, in cubic inches, will be $72\times120\times2\frac{3}{4}\times60=1,425,600$, which is 825 cubic feet. As the tank contains 1,578.5 cubic feet the space that the slime pulp may fill is $1,578.5-825=753.5$ cubic feet. Since 1 cubic foot of slime pulp weighs 78.125 pounds the tank will contain

$$\frac{753.5\times78.125}{2,000}=29.43 \text{ tons. Ans.}$$

The Bureau of Mines announces two examinations to fill vacancies; one for a mine sanitary engineer at a salary ranging from $1,800 to $2,400 per annum; the other for a mineral technologist at a salary of $3,000 per annum. The applications for these positions close on Nov. 9 and 8, 1912, respectively.

Causes of Fires in Metal Mines

Extensive Use of Timber Furnishing Conditions Favorable to the Starting of Dangerous Conflagrations

By T. A. Tefft

FIRES in coal mines arise from numerous sources, as there is fuel for consumption; but it would seem that among the barren rocks and non-combustible ores of the metal mines there is nothing to burn, and that a fire in such a mine would be impossible; and if, in spite of seeming reason, a fire therein did occur, it would be not alone a phenomenon, but a paradox.

And yet in a metalliferous mine a fuel body exists in the timbering.

In a coal mine the layer of mineral is dug out, except the pillars and props which are left standing to support the roof. When the stratum is excavated and there are no like deposits above in the members of the formation, then most of the pillars are dug away and the roof is allowed to cave. In such mining, timbering is a science but slightly called into play. It is different in a mine in which shafts are sunk 2,000, even 3,000, feet into the earth, and where tunnels are miles long; in which caving is never allowed, and drifts, stopes, and winzes are kept open, even after all the ore is taken from them. In such mines, with their many levels and galleries, the art of timbering to sustain the sides and roof rises to the highest forms of mechanical study. This is intensified by the various degrees of integrity of the formations through which the workings are run. When this is solid rock, the subject is comparatively simple. But when, as is often the case, one or both walls are of friable rock or loose conglomerate containing boulders, or when it is serpentine or talc, often wet, and sometimes with water that is scalding hot, when the foot- or hanging wall may swell with an irresistible pressure after the drift is dug, then timbering is a problem worthy of the keenest intellect.

While the mines of the West were yet new and small, timbering consisted of mere "stulls" or sticks of wood braced into an opening immediately against that part of the wall which showed a bulge, and there was no system in their disposition. This method is used even now in some small mines or prospecting drifts where timber is scarce, the wood employed being tamarack, juniper, or cottonwood; when this is unobtainable, green yucca is pressed into service with favorable results.

But in large mines, timbering has come to be one of the most important branches of engineering, and into their labyrinthine recesses is driven, stick by stick, whole forests of logs. The wood most used is the sugar pine, but for no other reason than that it is generally the wood most abundant on the mountains near the mines.

From one plan and method of supports to another, timbering has advanced to what is called the "square-set" system, an admirable arrangement of frames and braces, but which requires an immense quantity of wood; so that these subterranean galleries, which ramify through miles and miles of the earth in a single locality, are really great cities of wooden buildings. As such, a fire in them, when it manages to communicate from one level to another, becomes a dangerous and serious matter.

Thus it can be seen that there is abundance of material in a metalliferous mine with which to support a fire, and this material is frequently in a condition very readily to invite combustion. The air forced through all parts of a mine, with the high temperature which is generally present in deep mines, soon seasons the greenest wood and makes it dry as tinder; then a lighted candle, held too close to a post or cap, may ignite some fibers of old bark and so carry the flame behind the sprags or lagging, subsiding there in a smoldering fire which eats and chars but does not blaze.

This manner of burning was strikingly exemplified some years ago in a fire at the Green Mountain mine in Plumas County, California. They had an engine on one of the levels fed by steam pipes into the mine from a boiler above ground. The heat of the steam chest so carbonized the wood of several posts on the side of the level that a candle flame, touching one of them, flashed into ignition, and before the men could get out of the mine, the fire, through a "dry" process, had spread so that two of the men were caught below and were asphyxiated.

Nor is wood the only combustible substance found in metalliferous mines. Some years ago it was given out that bituminous shale was burning in a certain silver mine in the West. This was received with an incredulous laugh by mining engineers and mineralogists all over the West, but the statement is probably true. It is certainly not without precedent that bituminous shale should form a foot-wall of a metalliferous vein, even though the impregnation of bitumen might not be detectable in the rock with the naked eye. Bennett H. Brough, in the "Transactions of the North of England Institute of Mining and Mechanical Engineers," mentions that such shale exists in a lead mine in Derbyshire, and that explosive gas emanating from it collects in fissures of the lime rock wall; and at the Silver Islet mine, an argentiferous deposit on the north shore of Lake Superior, gas shot forth from a drill hole and threw a flame nearly 40 feet long. Some men were drilling in the foot-wall when gas began to escape from the drill hole. It did not flow copiously, but they withdrew the drill, and one of the men for purposes of inspection held a lighted candle close to the hole. Instantly there sprang from the orifice a jet of fire which, as the hole inclined obliquely, blew with a furnace roar far down the level. When the first burst of ignition was over, which momentarily filled the entire opening with flame, the men hurried out of the shaft. They returned shortly after without a candle, and drove a wooden plug into the hole. When the gas had been forced out of the workings by pumped air they held a candle to the spot again, and again the gas ignited, there being a leakage notwithstanding the plug.

Marsh gas is quite common in iron mines, which often lie contiguous to beds of lignite. It occurs, too, in salt mines, generated through decomposition of vegetable substances, and lodges in the crevices as firedamp.

And there are other inflammable gases besides light carburetted hydrogen which are sometimes found in mines and cause fires. No mineral is more commonly distributed through the masses of metalliferous veins than iron pyrite, a chemical combination of iron and sulphur. The oxidation of this, which may occur through contact with water and air, evolves sulphuretted hydrogen, an inflammable gas; and as the process of its generation is attended with great heat, it might be possible for ignition to be started through this process, and combustion spontaneously to ensue. Fires starting from decomposing pyrite are common enough in coal mines, and there is no reason to suppose that, with a chamber densely filled with sulphuretted hydrogen emitted from such a source, it might not be lighted from the retort that produced it. Decayed wet wood in a moist atmosphere will engender an inflammable gas similar to marsh gas; this has frequently been found in abandoned parts of metalliferous mines where the timbers have rotted and the air is foul.

Divers phenomena are noticeable in connection with deep-mine fires, and among the most prominent are those affecting ventilation. It is well known that a fire above the opening of a mine, as the burning of a shaft house, will draw all the air out of the lower recesses, and will at once smother all the life there is below. And the fact that fire above will draw the life-sustaining air from below, even when the air is abundantly pumped into the apartments beneath the fire, was fully and with fatal results demonstrated in the great conflagration which occurred on the Comstock lode in 1869.

The methods of extinguishing fires in deep ore mines are much the same as those employed in coal mines, though the damaging results from such operations are usually much greater in the former than in the latter. The most common way to suppress a fire in a mine is to flood it. In a coal mine this can be done with but little injury to the future working of the property; but in a metalliferous mine it is very different. The timbers become saturated, swell, and burst, allowing serious caves where such would otherwise not occur. And then, though water will unquestionably put out a fire wherever it reaches it, there are parts of a metalliferous mine which may still be dry and burning when the mine is filled with water so that it will run over the top of the shaft. These are the stopes and winzes, those perpendicular cul-de-sacs or inverted wells rising from a level into the vein from which the ore is dug. These being filled with air and their timbers burning, the water will rise in them only as far as it is permitted by the resisting air; and so a portion of them remains dry while the oxygen in the volume of atmosphere which they contain will sustain the slow and stubborn fire until the water is removed, and so continue as a source of foul gas generation and communication for future spreadings of the fire.

The use of carbon dioxide as an extinguisher affects combustion in a mine much the same as water: the fire is quenched where the gas reaches, but being a heavy fluid, it moves and rises much the same as water, and is in like manner repressed by the confined air in the stopes. It does not, however, damage the timber as does water, neither does it moisten it, and as soon as the gas is driven out of the mine the timbering is left dry as before, ready to rekindle almost upon the touch of a spark.

Steam as an extinguisher was exhaustively tested as long ago as the Comstock fire. All shafts were sealed, and for 71 hours steam was forced into the mine. At the end of that time water was thrown down the shafts to clear the atmosphere, and men were sent below. The fire was found to be still burning, and as soon as the air reached it, it began to blaze. The hatches were thereupon replaced and steam was again turned on for nearly 4 days longer. Men then entered the mine with hose and a hand-to-hand fight commenced. The hose party advanced and put out the fire, while gangs followed who cut out the burnt timber and replaced it with new. There was some caving, but the debris of this was removed and the cavities timbered up. It was in this way that the fire was gotten under control; but 3 weeks after so much was done and the men had resumed regular work in taking out ore, the fire again took head and it was necessary once more to close the shafts, turn on steam, and proceed to do the battle with the hose as before. And when this had been continued long enough to show its inadequacy as a method of fighting fire, it was finally decided to set apart the worst of the fire districts in the several mines and wall them up, cement them air tight, and leave the coals to extinguish themselves with the fumes which their combustion exhaled, a phenomenon which will take place if the air is entirely excluded. The fire in other parts of the mine was finally suppressed; yet 6 months after the burning was supposed to have been wholly quenched, men working in the upper levels of the mines would drive their picks where fire still smoldered.

The losses occasioned by fires in deep mines may be little short of the full sum invested in the underground improvements of the property. Not only must the timbering be replaced, but even the excavating must, to a large extent, be done anew. The vein, too, may, whenever it is exposed, be spalled and disintegrated, its sulphides burnt out, the ore melted into matte, that it may be difficult to mine. In short, a fire in a deep mine may be a ruinous calamity; and that they do not oftener occur may be adjudged, under present system, more a matter of good fortune than care. In some mines, however, wise adaptation to the advances of science has removed nearly every element of risk from this source. The lighting of the workings with incandescent lamps has abolished the smoky and danger-breeding candle, and the replacing of sawdust with infusorial earth in the manufacture of giant powders allows no chance of ignition from explosives.

Articles describing fires in metal and other mines will be found in MINES AND MINERALS, Vol. 32, pages 19, 253, 340, 342, 435.

Blister Plates for Sampling

R. Baggaley states in *Metal Industry* that segregation may cause one part of a bar of blister copper to contain even twice as much silver or gold as another. In casting the blister as it comes from the converters, plates 17 x 24 x 2 inches are cast in a mold, which has 240 small projecting buttons, this leaving 240 dots in the plate. The plates are then drilled through at these dots. As 240 plates form a carload, the sample will represent 57,600 drillings in the shipment of such a quantity.

Sand Filling on the Rand

By Edgar Pam, A. R. S. M.

(Concluded from September)

Mr. A. R. Hughes in discussing Mr. Pam's paper says: As the filling of worked-out stopes with sand has provided quite a new experience for underground men on the Simmer and Jack mine, it is with considerable diffidence that I venture to give my experience and a short description of the methods employed in connection with the work.

The stope is admirably situated for this purpose as it is enclosed by a dike on the east and south sides and by a block of ground on the west, which is being worked toward the east. From the main drive on the south side of the dike a cross-cut extends north. From this a box-hole rise has been put up about 18 feet entering the bottom of the stope, and on the west side of the dike there is an intermediate drive leading through to No. 1 shaft, as shown in Fig. 4.

A bulkhead made of 3" x 9" deal, supported by 8" x 8" upright timbers was placed across the intermediate to the east

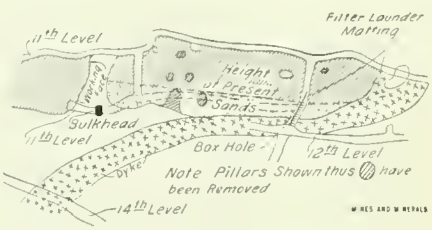

FIG. 4

of the working face, the 3" x 9" deals being perforated and covered with cocoanut matting on the face next to the sand, thus forming an outlet for drainage on the west side of the stope. It will now be apparent that an enclosed space has been provided with the exception of the box hole entering the stope on the south or bottom side. This box hole is used as the main outlet for drainage. A dry wall was built across it through which a 6-inch pipe projects into the stope. A filter frame 12 inches square covered with cocoanut matting and extending up the stope above the level of the sand was placed over the 6-inch pipe, thus forming an efficient filter through which all the drainage must percolate before escaping into the level below, as shown in Fig. 5. The square filter is made in 12-foot-6-inch lengths, one end being made 14 inches square for about 2 feet to fit over the length previously fixed, so that when the sand rises to about 2 feet from the top of the filter the next one can be placed over it, and by this means the filter is always kept above the level of the sand, as shown in Fig. 6. Inside this frame a covered wooden launder is placed to maintain an opening should the filter frame collapse. The drainage from the sand is a small stream of about one-third of a ton of clear water free from cyanide to every ton of sand deposited, and although about 200 tons of current residue is lowered daily, men are still at work in the stope taking out pillars, etc., and suffer no inconvenience from cyanide or any of its products.

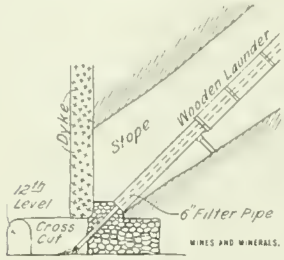

Fig. 5

The sand is conveyed from the bottom of the bore hole in wooden launders 9 inches wide and 7 inches deep and a grade of 15 degrees over which the pulp flows freely when diluted with a small spray of mine water. The sand forms a compact mass on which men can walk comfortably in from 2 to 4 hours after filling has stopped. The cleaner and more freely leachable the sand the better, as slime tends to retard drainage and pockets water between the points where the launders deliver sand.

It is pointed out here that there should be several stopes ready for filling when it is proposed that the whole of the current sand residue be sent underground, as the removal of pillars, etc., takes time, and when dealing with the daily production of sand from the cyanide works, filling must go on without interruption. For a stope less favorably situated for sand filling than that described, I would suggest that stulls be made of stout mine poles hitched at the top and bottom, lagged over with old pipes and rails, and packed with waste rock to a thickness of about 4 feet, the inner face being covered with cocoanut matting. This would afford perfect drainage and the sand being in a dry state would exert very little pressure against the stulls, and there would be no uncontrollable mass of sand and slime saturated with water to become a real source of danger in the mine.

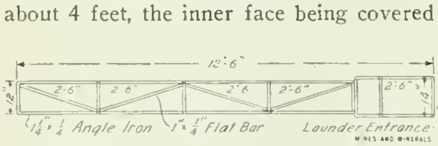

Fig. 6. Framework of Launder

Since 1862, Nova Scotia gold mines and prospects have yielded about $20,000,000 in gold. The recorded production for the year 1862 is just about equal to that of 1911.

South African Shaft Sinking Practice

Our readers are no doubt aware that the government of the Transvaal has undertaken mining, and has, for some time, been sinking four very large shafts with a view to operating mines along the most up-to-date, economic lines. These different shafts are being sunk according to one plan, and therefore the description of the practice at any one shaft will convey a comprehensive idea of what can be accomplished by federal management and ownership. The State's mines are operated, for sufficient reasons, under the title of The Government Gold Mining Areas Consolidated.

What is perhaps a world record in rapidity of shaft sinking is described at some length in the *South African Mining Journal*, from which the following material has been abstracted.

Mr. Martin H. Coombe is manager of the work at the "Southeast" plant, and he is ably assisted by three "sinkers," Messrs. Robar, Lowson, and Readhead, who deserve equal mention with him in having established the remarkable record that occurred recently. The previous record for similar work on the Rand was 213 feet, at the Modder Deep. The Southeast shaft went down 233 feet in the month of March, this year.

This shaft has seven compartments and the overall dimension of excavation is 10 ft. × 45 ft. The actual tonnage of rock hoisted during the sinking of the 233 feet was 8,155, or an average of 35 tons per foot of sinking. The sinking was done through 78 feet of shale and 155 feet of quartzite, one-third thus being in the shale that is recognized as the more favorable rock for rapid penetration, and in which previous records have been established. The record run began at a depth of 1,738 feet from the collar of the shaft.

All of the drilling is performed by hand, native laborers being exclusively employed for this work and for mucking. The crew comprises 82 "boys" (as the natives are called) with one overseer or "sinker" and one white assistant. Three 8-hour shifts are worked every day in the week. The shaft having been laid out with its long axis parallel to the dip of the strata, advantage of the bedding planes is taken in the placing and pointing of the drill holes. The natives drill double-handed, throughout the greater section of the shaft, using 7-pound hammers. Single-hand holes are drilled only along the ends.

Timbering is performed by four timbermen and eleven "boys." Two men and six boys are known as the "bottom set" men; one man and four boys put in the hitches, bearers, and permanent guides; and one man and one boy work on the brattices. All of this work is performed on the morning shift, which is from 7 A. M. to 3 P. M., and only for unusual reasons is any overtime permitted. After the sinking shift is in the bottom, and the hoisting of men has commenced, the two bottom set men go down with their lines, stage planks, blocks, wedges, and "boys." Their first duty is to block the next to the bottom set, using the bottom set to carry their stage planks. Once they have reached their place of work, they are not allowed to interfere with the skips until the "sinker" has finished cleaning up, has his drills sent down and his boys drilling. Then the engines are handed over to the timbermen who use them to hang the next set. From the time the first pair of wall plates is shackled until after the set is hung, filled in, tightened up, and temporarily blocked, and the timbermen are again on the surface with their equipment, is one hour to one and one-half hours. The timbermen are not allowed to take down any ground within the neat lines for the timbers, as the sinker is solely responsible for all such excavation.

During a single shift, 57 skips (114 tons) of rock have been hoisted from the bottom, one set of timbers has been blocked while another has been hung and filled in, four 30-foot guides have been hung and bolted to place, and the entire round of holes has been drilled, loaded, and blasted. During this time, all the hitches were cut, bearers were installed, and all timbers lowered, and with no interruption to the steady work of every man. On each of the three compartments not used for hoisting, there are substantial pentices.

All timber used is pitch pine. The wall plates and end plates are 9"×9" timbers. The wall plates are framed in two pieces, respectively, 22 ft. 9½ in. and 20 ft. 8½ in. in length, and these are simply butt jointed on a divider, making a total length of 43 ft. 6 in. The dividers are 7"×9" sticks and are 6 ft. 6 in. long, the outside width of the shaft frame thus being 8 feet. Sets are placed at 7-foot centers. The skip guides are 4"×8" pitch pine carried on channel brackets bolted to the dividers. Bearer sets are placed approximately every 120 feet, hitches never being less than 4 inches deep. The framing of guides, ladders, rings and other timbers for the four different shafts is done by three men, by hand. No particular care is given to maintaining a sink (sump), nor is there any pump in use at the bottom; since no water is allowed to get to the bottom of the shaft, it being caught in a number of "rings" above the 600-foot mark and is discharged into, and hoisted in, the regular skips used for rock. It is desirable, when using skips for hoisting in balance during sinking, to have the bottom as level as possible. In this instance, there are two hoisting engines, each handling two skips occupying respective pairs of compartments between the middle compartment and the two end compartments. Effort is therefore made to shoot the benches in such a manner that the two skips of each pair will have practically the same landing level. This facilitates the loading of the rock and obviates any of the troubles that would arise if either skip were necessarily lowered more than its mate, such as kinking of the rope, running one skip light, or taxing the men unduly by high shoveling.

Blasting takes place every 8 hours, and from 40 to 45 holes complete a round for each shift and square the shafts. These holes are from 3 ft. 6 in. to 5 ft. deep. Four are drilled abreast, the length of the shaft, the side holes always being placed according to plumb-lines hung from the last set of timbers. The ventilation is accomplished without resort to machinery, a wooden chimney being constructed up through the headgear and down the entire length of the pump compartment. This provides a natural draft of from 20,000 to 25,000 cubic feet of air per minute, so that, 10 minutes after blasting, the bottom is clear of smoke and fumes. All illumination is by acetylene lamp.

The shaft is equipped with a modern steel head-frame, 110 feet high from shaft collar to platform, covering all the compartments. Two double-drum hoists are installed, one a geared engine with 10½" x 33" cylinders, the other a first-motion engine with 22" x 48" cylinders. All the drums are 8 feet in diameter and use 1⅛-inch cables. The skips are of 45 cubic feet capacity. The shaft collar is of massive concrete extending down to solid rock and built up 5 feet above the surface.

Six of the compartments are of the same dimensions, viz., 6 ft. 6 in. x 5 ft. in the clear. The pump compartment, occupying one end of the shaft, is 6 ft. 6 in. x 8 ft. 6 in. in the clear. This section contains a ladderway 2 ft. 8 in. wide, while spaces are reserved for pipes and columns and for repairing cages.

Once a month, wire plumb-lines are dropped to check the lines of timbering. One point of special note is the remarkable progress maintained in timbering; for during 61 consecutive days (2 months) 64 sets of timber were put into place as above described.

No shift bosses or timber foremen are employed, the opinion being held that such persons are superfluous and, in fact, are really hindrances. The men work upon a bonus system and efficiency is of the highest order. The state mines are therefore said to be breaking, hoisting, and dumping rock from these shafts at a cost per ton less than that of many neighboring mines in their stoping and hoisting of ore.

Air-Balanced Hoisting Engine

Device by Which the Power Developed by the Descending Skip Compresses Air to be Used in Hoisting

*By R. H. Corbett**

During one of the excursions of the August meeting of the Lake Superior Mining Institute the Franklin Jr. copper mine was visited. The works at this mine are comparatively new as is evidenced by the modern head-frame and ore bin shown in Fig. 1. On the incline just outside of the covered portion of the head-frame, the 7-ton skip which carries 10 tons of ore at one trip is shown. The photograph was taken just after the skip had discharged into the circular ore bin or rock house.

To the right may be seen the tower for carrying the rope from the head-sheave to the drum of the hoisting engine. This explanation and illustration will give those engineers who have not had an oportunity to visit the copper mines of Michigan an idea of the progressiveness of the copper men, and their willingness to adopt any improvements, or when not to be found, to devise their own. This is clearly shown in the following article which was written for this meeting —Editor.

Fig. 1. Rock House at Franklin, Jr., Mine

An air-balanced hoisting engine was built in conformity with the ideas of R. M. Edwards, General Manager of the Franklin Mining Co., and the other Dow properties in the Lake Superior copper district. Mr. Edwards long held the opinion that for deep mining operations a single-compartment shaft would be desirable, provided that a balanced hoisting engine could be built to operate a single skip or cage and he considered that the simplicity of a single-compartment shaft and its equipment would warrant any complication of the hoisting engine which would produce the desired result. It was apparent to him that if the power developed by the descending skip could be applied to compressing air, it would furnish a solution of the problem.

When the time arrived for ordering a hoist, the matter was placed in the hands of Mr. Bruno V. Nordberg to design an engine and work out the details of an air-balanced hoist to meet the requirements. Following this the hoisting engine under discussion was built. This is a horizontal duplex machine with the steam cylinders attached to the frames. The air-compressing cylinders are located immediately back of the steam cylinders. The air pistons are attached to extensions of the steam piston rods, the whole forming a complete hoisting engine and air compressor combined. Means are provided for allowing the steam to run free while lowering the skip, and the air pistons run free while hoisting. The engineer regulates the speed of the descending skip by controlling the quantity of air compressed. By means of the operating lever on the platform he absolutely governs the work done in the air cylinders between the limits of full cylinder capacity and no load.

The air-compressing cylinders have four Corliss valves. The two lower ones admit free air to the cylinders in the

* Houghton, Michigan.

usual way. The two upper valves are provided especially for regulating the capacity and are the ones controlled by the engineer while lowering. The air delivered under pressure passes through spring-loaded discharge valves located in the cylinder heads. The regulating valves are fitted with releasing mechanism and dashpots like a Corliss steam engine. When they are open they afford a direct passage between the bore of the cylinder and the air-inlet pipes through the channel on top of the cylinder casting; therefore no air can be compressed while they are open.

To illustrate their valve action, suppose the air piston is moving toward the end of the cylinder while lowering the skip. If the regulating valve is open, the air in front of the piston will be forced back into the inlet pipe. If, however, the engineer trips the valve and the dashpot closes it at any desired point in the stroke, then the air left in the cylinder will begin to compress until it finally passes out through the discharge valves. The arrangement is such, that the further the engineer moves his lever the more air will be compressed and the more the resistance will be increased on the air pistons. The air cylinders are only used for regulating the speed while lowering. The usual steam-operated brakes are provided for landing the skip.

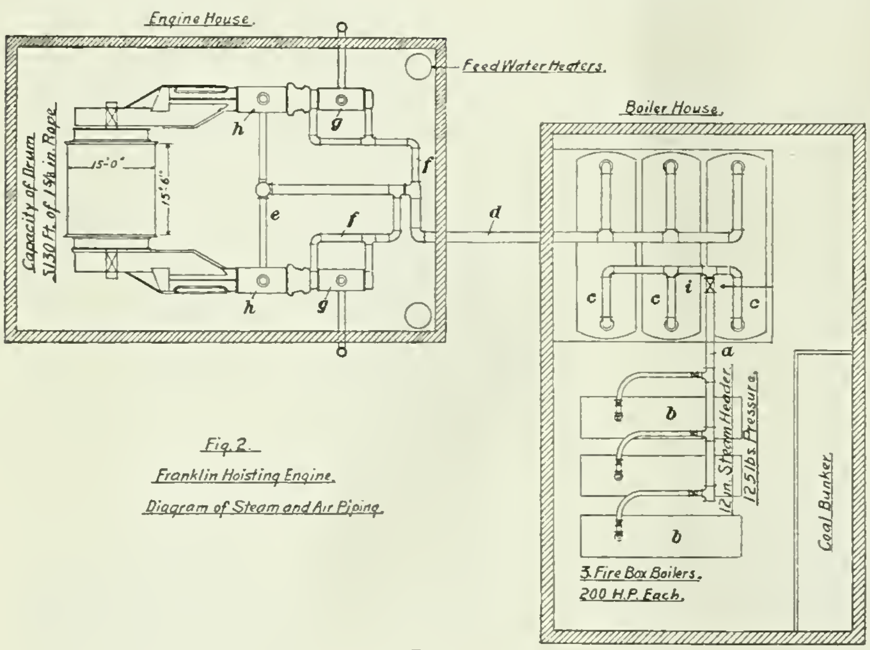

Fig. 2

To enable the steam pistons to run free while the engine is lowering, the exhaust valves on the steam cylinders are arranged to be released from their connections and remain wide open and stationary until they are hooked up again when the engine is reversed for hoisting. The releasing and hooking up mechanism is connected to a small steam-operated thrust cylinder provided to furnish power for this purpose. The operating valve on this cylinder is attached to the reversing gear of the hoisting engine; therefore when the engineer reverses his engine the exhaust valves are either released or hooked up again, as the case may be, without further attention on his part.

While compressed air is usually in demand around a mine, it was decided in the present instance, that it would be best to mix it directly with steam from the boilers and use the mixture in the steam cylinders for hoisting the load. Three cylindrical air receivers each 10 feet in diameter and 32 feet long were installed for storing the compressed-air mixture with the steam. They furnish ample storage space at the present time for both steam and air.

Fig. 2 is a diagram of the general arrangement showing how these receivers are connected with the boilers, air compressors, and steam cylinders. A 12-inch steam pipe *a* connects the boilers *b* with one end of the receivers *c*. A 16-inch pipe *d* from the opposite end of the receivers is carried to the throttle valve *e*. The 12-inch discharge pipes *f* from the air compressors are connected to this same 16-inch line. This forms a convenient way for the compressed air to reach the receivers when lowering and also to supply the steam cylinders *h* with pressure for hoisting. A reducing valve *i* is placed in the 12-inch steam pipe between the receivers and boilers. It is set to maintain about 75 pounds pressure on the receivers. The boiler pressure is usually about 125 pounds.

In explaining the operation of this feature of the hoisting engine, we will say that in the first place the receivers are filled with steam at 75 pounds pressure. The skip is then lowered into the mine and the air compressors begin to discharge compressed air into the receivers to mix with the steam they already contain. By the time the skip reaches the bottom of the mine the pressure in the receivers will rise to 95 pounds, the increase being due to the compressed air forced in by the descending skip. When, therefore, the hoisting commences there is the 95 pounds pressure to start with. As the skip moves upward the pressure in the receivers gradually drops to below 75 pounds as the engine is now using the air stored in the receivers by the previous trip downward; however, the reducing valve opens after the pressure drops and steam is taken directly from the boilers to complete the trip upward. When the hoist stops, the pressure in the receivers will rise to 75 pounds in the receivers through the reducing valve connected with the boilers and be in readiness for the next trip down.

The engineer handles three levers in controlling this hoist, the throttle lever, reverse lever and brake lever, the same number as on other hoists in this section. The throttle lever, however, usually stands in a vertical position when the hoist is stopped. If the engineer pushes it forwards it operates the throttle valve, if he pulls it backwards it acts on the regulating valves on the air cylinders. With this exception the hoist handles about the same as other hoists in the copper country.

The following are the principal details: Diameter of steam cylinders, 46 inches; diameter of air cylinders, 36 inches; stroke of all cylinders, 72 inches; diameter of piston rods, 7½ inches; size of crankpins, 12 in. × 12 in.; size of crosshead pins, 8⅝ in. × 12 in.; size of main bearings, 20 in. × 40 in.; diameter of hoisting drum, 15 feet; length of hoisting drum, 15.5 feet; capacity of drums, 5,130 feet of 1⅝-inch rope; weight of skip, 14,000 pounds; weight of rock, 20,000 pounds; weight of rope per foot, 4.15 pounds; number of boilers required, 2; capacity of each boiler, 200 horsepower; number of feed-water heaters, 2.

The boilers are the Lake Superior fire-box type with crown and arch tubes.

Shaft dips 47 degrees from horizontal.

Difficulties

The following letter has been received by a well-known contractor in town from a man who is sinking a shaft in South Lorrain:

"Dear Friend:—The men arrived all right with boots and oil clothes. We start the 8-hour shift today. There is seven pair of them boots 11 by 12. Can't get them down the shaft, so I send them out."—*Cobalt Nugget*.

Gulch Mining in Gilpin County

History and Description of Some Old Colorado Placers that Are Now Being Reworked by Hand

By Arthur J. Hoskins

IT is probably generally known among metal mining men that the first lode mining in the Rocky Mountain region is credited to Gilpin County, a very small part of central Colorado. Sixty years ago, this whole, great, western area was spoken of as the Pike's Peak Region. Expeditions of pioneers, geographers, and geologists had traversed the country previous to that time, but no settlement took place until gold was discovered and mined. As is often the case, civilization followed in the wake of mineral discovery.

The discovery of gold in California, in 1849, created a notable overland travel of adventurous persons from the eastern states. Georgia, it would seem, contributed a large quota of these sturdy, pioneering gold seekers. They sought the Californian fields, and the most difficult part of their task lay in the wearisome cross-country travel. Some went to the Pacific Coast by ship via the Horn, but probably the majority of these miners occupied berths in prairie schooners.

It is no wonder that these prospectors would give attention to the first mountainous country encountered by them in their long tedious travels, for they were probably well aware that rough areas are more productive of precious metal bodies than are the plains. So, when parties of these men reached and sought suitable points for passage across the front range of the Rockies, they selected and traversed stream beds as affording the easiest grades. Also, quite naturally, they tested the "dirt" as they proceeded.

It is said that one party consisting of seven Georgians, en route for California in 1849, established winter camp on the South Platte River, it being decided in-

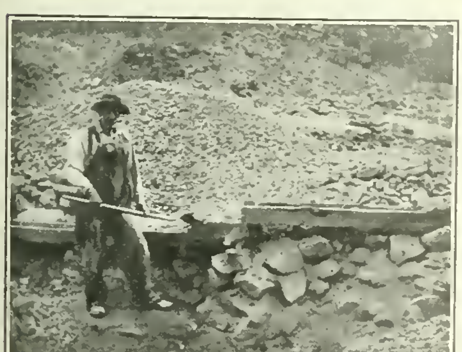

Fig. 1. Gold Washing at Russell Gulch

advisable to attempt crossing the mountains before the next spring. These men are reported to have washed a small amount of gold from the channel of the river, but the following spring, they proceeded on their way westward before accomplishing much in Colorado.

Nine years later (1858), it happened that a party of Georgians entered the cañon of Clear Creek and, finding "colors" in the gravel of the stream, they combined their progress toward California with an investigation of the merits of what is now Colorado. Their prospecting along the channel of this stream gradually led them to the forking of the stream, and separate parties proceeded thence up the respective branches. According to present nomenclature, these two forks traverse different counties, the north fork being in Gilpin County, while the south or main fork is entirely within Clear Creek County.

Good results were obtained by these prospectors in both branches. The methods and devices used in this prospecting were necessarily of the most primitive kind; but they were effective if not highly efficient, for the research of these men culminated in the discoveries of some of the mother lodes in both branches. It thus appears that the first locations of *lode* claims were nearly contemporaneous, although it is conceded that the North Fork obtained first results. History states that placer gold was discovered at Jackson's Bar (now Idaho Springs), in January, 1859, by G. A. Jackson, and that during the same year, numerous lodes were located in that vicinity. The prospectors who proceeded up the North Fork of Clear Creek met with especially good results washing along the channel of a dry gulch branching from the creek about 3 miles above the forks, and, in honor of one of their number, they named this Russell Gulch. This has subsequently become well known for its many lode mines as well as placers. Among the arrivals in this area, was a John Hamilton Gregory, from Georgia. He and two companions prospected the main channel of the North Fork, and in May, 1859, their search brought them to the outcrop of a splendid vein where the town of Black Hawk now stands, and which was taken up as the Gregory Lode. This was undoubtedly the first lode claim ever taken up and worked in Colorado. Accordingly, just as California tells of its "forty-niners," so Colorado remembers its "fifty-niners."

Since the discovery days, placer mining has been carried on along both forks of Clear Creek. Of late years, naturally, the operations are on a very small scale since the ground has been pretty thoroughly turned over and washed, and there remain very few patches of virgin gravel. Much of the gravel has been handled repeatedly, each time in an effort at recovering the very fine particles of gold. The many mills that were built in and around Black Hawk for the local treatment of ores were far from efficient in their saving of the yellow metal; a very

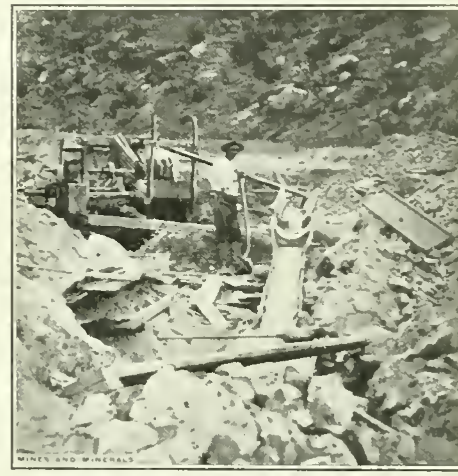

Fig. 2. Washing by Hand at Black Hawk

considerable portion of the gold originally in the ores entering the mills was discharged with the tailing into the channel of the creek. The North Fork is not a large stream and when the hundreds of stamps in the camp were working on ore, the water was turned to a very thick mud. Much of the failure in amalgamating the gold was probably due to the viscous condition of the feed-water, for often the shortage of this supply necessitated its conservation and reuse.

The gold losses in the mills have been recognized by Nature and the bed of the creek has constituted a sluice for the recovery of the metal that eluded Man. Just how far we may explain the more recent enrichments of this channel on the theories of gold precipitation from solutions is doubtful. Some persons assert that gold is "growing" in this channel all the time by a process of enrichment, the metal being transported thither in the acid waters from the mineralized veins and precipitated by ordinary chemical reactions. If we may believe this, we have two explanations why gulch miners find it profitable to rewash the bed of this stream at intervals of about a decade.

There were no railroad facilities in this region until the year 1872 when a narrow-gauge road was completed from Golden (at the mouth of the cañon) to Black Hawk. This same year a 4-mile branch was built up the other fork. Below the forks, a few miles down stream, the creek occupies a veritable cañon, but above the forks, both branches are in open valleys. The average width of the North Fork is not over 10 feet, whereas the South Fork carries, probably, ten times as much water.

During the earlier decades of this country's activities, a few expensive installations of ditches, flumes, and giants were in use, and these turned over comparatively large areas of the channel. But, at present, placer mining is confined to the slow, arduous accomplishments of a few scattered men who handle very limited quantities of gravel in a season, but who appear to make their living in this manner. Figs. 1 and 2 are typical of the scenes passed while traveling in a train to Black Hawk during the season from April to October.

As observed in these views, the gulch miner nowadays is satisfied with a very simple, inexpensive outfit. One wonders if such apparatus is really of any account. It would seem that the physical labor involved in digging and handling this dirt would warrant the use of apparatus that would assure a more nearly perfect efficiency. These men, however, use a simple sort of a "tom" into which is conducted a small stream of water from an old pipe or wooden V-shaped trough. Gravel and sand are shoveled into a screen occupying a horizontal position about half way from the bottom of the "tom." On this screen, by means of the shovel, the materials are turned over and subjected to the action of the water that carries the finer stones and the sand into the lower compartment where they start flowing down the inclined and carpeted sluiceway to the tailing pile.

No quicksilver is used in most of these affairs, Brussels carpet being relied upon to catch and to hold the heaviest particles, such as gold and the sulphides of iron, lead, and copper. Once or twice a day, each miner must cease his shoveling long enough to remove and rinse his carpets in a tub of water. The material thus collected in the tub constitutes his shipping product and is expected to contain any gold that went into his device.

There are doubts as to the efficiency of these devices. In the first place, the water flowing in the creek is usually very muddy and its mixture with the treated sand gives to the whole pulp a rather slimy consistency that is adverse to the settling of any light particles, especially flaky ones such as gold "colors." Then, again, there is a continual scouring action going on against the surface of the carpet that would appear to prevent the accumulation of gold in the nap. Finally, the length of any one of these sluices is so short that gold would be given little show to work its way down through the stream even were the water clear.

The writer was unable to secure figures from any of these men stating their recoveries and profits, but all conceded that they were "making wages." At one place, a woman acts as assistant to her spouse and performs the lighter portions of the work.

Some of these persons have lived in this gulch for 30 years or more, and it is almost beyond belief that they can subsist upon the meager profits that seem possible in the handling of ground that has been washed repeatedly. Of course, living in the simple manner in which they do is very inexpensive. Besides, they probably utilize the winter months, when gulch mining is not possible, in other activities.

These persevering people perform acts in our industrial conditions that are generally supposed to belong to the past. They are remnants of a former period. They are interesting figures for tourists who travel between Denver and Central City; but very few persons leave the train and hold conversation with these miners. These gulch miners, however, deserve attention, for they are most cordial in their manners and are possessed of much interesting history relative to this section of our western mining country.

Rhigolene

Fancy and Fact Concerning a Newly Discovered Product of Oil Wells Which Is a Gas in Liquid Form

An admiring optimistic California friend sends the following Chapter I on Rhigolene. The Editor is not responsible for the statements in Chapter I, which were so unique he requested F. W. Brady to write Chapter II on the same subject.]

CHAPTER I

A marvelous discovery, which scientists claim will prove to be one of the greatest of the age, has been made by W. C. Cutler of Sawtelle, Cal., whereby it will be possible to hereafter utilize a rich natural resource which has been going to waste for centuries. The result of this development will be to provide a cheap gas for fuel and illumination and at the same time to manufacture ice and supply cold air for purposes of refrigeration. The process is so simple that every household may be equipped at small expense with its individual plant for this quadruple service. The expense of installation and operation is so small that the innovation will prove a boon to desert as well as cold climes, to farm houses and city residents, to all people everywhere. These things are made possible through the conservation of rhigolene, a little known magical liquid or gas which has heretofore been permitted to escape in endless quantity from wet gas wells throughout the country.

The story of the discovery of rhigolene and its economic application to these manifold uses is interesting, and followed the unsuccessful efforts of Mr. Cutler to secure a quantity of the mysterious fluid, although having searched the world over for a small quantity of it. Government chemists could throw but little light on the subject and the quest ended where it started, the sum total of information gained being that rhigolene was gasoline of high quality, used in rare cases as a local anesthetic and producing a low temperature through evaporation. The inability of the experimenter to secure a quantity of this fluid caused him to employ the highest grade of gasoline obtainable in his tests. These demonstrated that through a system of coils he was enabled to produce hoar frost. Still searching for rhigolene, he went into the oil fields in the hope that he might hit upon a process whereby the much coveted liquid gas might be obtained. By placing a large hood over the top of a wet gas well and confining the escaping gas, he succeeded through the medium of a vacuum pump in compressing the gas so that it was deposited as a liquid in a steel tank. Held here under pressure it remained in liquid form. His next move was to introduce the liquid into pipes, thus harnessing the volatile power that had previously been latent. Released under pressure as a spray, ice was formed in any shape or thickness required; the released rhigolene, being still cold, serving as a refrigerating agency while winding through coils to a tank. Here, held as gas and with pipes leading from the tank, it may be utilized for either heating or illuminating purposes. Tests of the gas have demonstrated that for both heat units and for purposes of illumination it is superior to the ordinary carbon gas.

Mr. Cutler has recently secured method patents covering both process of utilizing the rhigolene in the manner stated and reaching into the sky and catching a valuable product that is today escaping from every wet gas well in the world.

The process by which rhigolene is induced to yield heat, light, and cold at the will of man is not difficult to understand. Like all great inventions, the simplicity by which results are attained strikes the mind with gratifying effect.

The domestic plant, which the inventor says will banish a swarm of household worries, is compact and may be made small enough to suit almost any purse or cottage and large enough for any fortune or castle. In brief, the production of heat and cold from rhigolene is described in the two words compression and expansion. First lessons in physics taught us all that a given amount of air or gas, at atmospheric temperature, contains a certain amount of heat, and that if compressed into a much smaller space the gas, while still holding the same amount of heat, will show a higher temperature. If expanded into greater space the temperature is lowered. If a liquid occupying a cubic inch of space evaporates into a gas which occupies 400 cubic inches of space, it can readily be seen how cold each of the 400 cubic inches will become. With rhigolene, which is liquid only under high pressure, the construction of a refrigerator was delightfully easy. The liquid is confined in a high-pressure steel tube, connected with a coil for refrigeration, into which the rhigolene is allowed to expand slowly, and down goes the temperature as though the wand of the frost god had touched it. The coils are covered with the white testimony of freezing and the gas passes into a larger chamber, where under less pressure it assumes its original state of natural gas and may be piped thence for heat, cooking, and light. With these facts in mind the imagination leaps at once to visions of freedom from the coal, light, and ice trust. What legislation has failed to do, invention promises. While monopoly and government wrestle and strive, the inventor in the seclusion of his laboratory turns their warfare into a bootless farce.

The cost of conservation is merely a nominal one, so low that the producer and dealer can be assured of a fair profit while the price to the consumer is kept within the reach of any income that can buy ice or fuel. The great saving of other products that goes with the gathering of rhigolene from the escaping wet gas is expected to prove a powerful factor in keeping down the commodity price of the liquid that yields the secret of light, heat, and cold.

Mr. Cutler, the discoverer of this method of capturing and conserving to the world this long lost resource, is an interesting though unassuming character. He is the inventor of more than two dozen useful or scientific devices, a number of which he freely gave to the world without patenting. From others he is receiving royalties that made it possible for him to become the most extensive date planter of the Colorado desert.

CHAPTER II

When a brand-new patent that proposes to change the established order of things and emancipate mankind from a "swarm of worries" explodes in our midst, we are bound to "sit up and take notice." No matter what the "life" of such patents may be, we cannot overlook the fact that all of them contain at least a milligram of truth, and in this case for conserving rhigolene, there is a good measure of ballast.

Rhigolene is a very light product from the fractional distillation of crude petroleum. Its specific gravity is about 62, or the Baumé scale from 90 to 95. Ordinarily it is lost with the wet gas escaping from oil wells. However, it can be said with both pleasure and satisfaction that the lighter vapors, or gases, from oil wells can be and are being compressed and liquefied. Also, this new industry, though only two or three years old, is growing very rapidly. While the imagination of the inventor of a process for harnessing rhigolene "leaps to visions of freedom from the coal, ice, and light trusts," it would be well for us common mortals to keep under cover and try to find other means of making a salary of fifteen dollars per week pay living expenses of $17.26.

The status of the "natural gasoline" industry today is about as follows: The first attempts to make gasoline from natural gas consisted simply in compressing the gas from oil wells to some 150 to 300 pounds and cooling it. This process resulted in liquefying some of the gas which was collected in a tank. The portion of the gas not liquefied was turned into the supply mains and sold for fuel; that is, this was done where such lines were installed, otherwise the gas was wasted. Also there was a considerable loss from the lighter gases that "weathered" from the liquid that had been made. As much as one-half of the gasoline would pass off and be wasted. By using a higher compression, a greater amount of gas would be "fixed," and by blending this light gasoline with kerosene, the heavier oil could be made more volatile and more specially suited for gas-engine service. Another plan was to collect the high-grade gasoline first and then to compress the gas from this and produce a "wild" product to be used for blending with heavier oils.

There was considerable loss of gas, just the same, and the proposed plan to make the entire gas supply available, as based on experiments conducted by experts in the employ of the Government is as follows:

First, by light compression take out the ordinary gasoline, which can be stored and transported in the usual way. Second, by higher compression and cooling of the remaining gas, there will be an extraction of a light high-grade gasoline used for blending with the heavy naphthas made at the refineries. It must be understood that these gas products are made in plants located in the oil fields, while the oil refineries are at a considerable distance from them. Also, the companies are independent of each other. Hence, the blending products must be sold to the refineries, or the heavier oils must be purchased from them by the liquid-gas people and the blending and selling of the product done in the field. At any rate the method requires some business management. Third, a higher compression with greater cooling of the remaining gas, this producing a liquid gas that must be stored in strong tubes or tanks and handled as a gas and not as an oil. This liquid could be transported with safety and used for heating and lighting purposes. Fourth, by a very high compression of the remaining fraction of the gas, a lighter liquid than from the third compression may be obtained. It is entirely practical to handle this product; as the Government experiments show that the maximum pressure was 755 pounds at 133° F., which is much higher in temperature than would be expected from any climate where the gas would be used. Steel tanks are now in common use for transporting gases at 2,000 pounds pressure. These tanks of liquid gas would be used to operate stationary gas engines, and also automobiles and aeroplanes. The gas from the liquid requires three times or so more air than ordinary natural gas, and hence the burners and mixers have to be modified for its combustion.

This liquid gas produced by a compression of from 250 to 755 pounds, depending upon the temperature, begins to boil at about 40° F., and hence it is something of a cooling agent.

However, before discarding our ice chests and giving the coal man the go-by, it might be well for us to find out whether or not a steel tank of this liquid gas will give all the refrigeration wanted when we are using the necessary amount of the gas for light and fuel. One gallon of the liquid will yield about 50 cubic feet of gas at 32° F. at sea-level pressure. With a specific gravity of .58 at 60° F., the gallon would weigh about 5 pounds, hence there will be 10 cubic feet of gas per pound of the liquid gas. We do not know the latent heat of the liquefied gas, but there are some problems involved in carrying out these dreams of the inventor that make more than one big "if" in the way of our emancipation from the high price of oil and the drudgeries of life.

Assay of Cyanide Solutions

Assay of KCN solutions (Lindemar). Ten assay tons of solution is heated until hot, and ammonical copper nitrate added until permanent blue color, H_2SO_4 is then carefully added in excess, the solution stirred and immediately filtered. The paper is folded and carbonized in a scorifier, transferred to a crucible, fused, and cupelled.

Some Problems in Mine Surveying

A Formula for the Determination of a Plane, the Direction and Slope of Two Lines Therein Being Known

By C. R. Forbes*

THE mine surveyor is often called upon to solve problems involving the determination of a plane, knowing the direction and slope of two lines therein, or problems involving the intersection of two planes.

The ease with which such problems can be solved by use of the following formula is not generally recognized, although the formula could be given frequent application and is one of value to the engineer.

The formula referred to is derived from

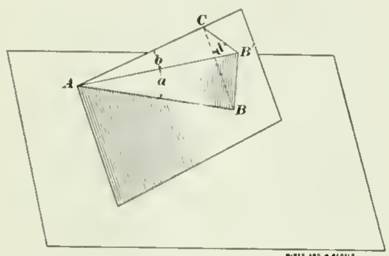

FIG. 1

the relation existing between an inclined line and a horizontal line in the same plane and the dip of the plane, and is as follows:

$$\tan a = \sin b \cdot \tan d$$

Where a is the angle of slope of any line in the plane, b is the horizontal angle or difference in bearings between this line and a horizontal line in the plane, and d is the angle of dip of the plane. The derivation of the formula is readily seen by reference to Fig. 1, and is as follows:

$$(1) \quad \tan a = \frac{B\,B'}{A\,B'}.$$

$$(2) \quad \tan d = \frac{B\,B'}{C\,B'}.$$

Eliminating $B\,B'$ from 1 and 2.

$$\tan a \; A\,B' = C\,B' \tan d.$$

$$\tan a = \frac{C\,B'}{A\,B'} \cdot \tan d.$$

$$\frac{C\,B'}{A\,B'} = \sin b.$$

$$\tan a = \sin b \cdot \tan d.$$

In the following problems, which are given to illustrate application of this formula, a vein or seam is represented, theoretically, by the plane. Mine openings (such as inclines and slopes), or sloping lines of outcrop are shown as inclined lines in this plane. Any horizontal line in a seam of coal or vein of ore will determine the strike.

PROBLEM 1.—A coal seam strikes N 20° W, Fig. 3, and dips 10 degrees to the westward. Find the direction of an incline to be driven in the seam on a −5-per-cent. grade.

Formula: $\tan a = \sin b \cdot \tan d$.

$$\tan a = .05.$$

$$d = 10°.$$

To find b. Substituting in formula:

$$.05 = \sin b \cdot \tan 10°.$$

Solving:

$$b = 16° \; 28'.$$

Direction of incline, N 36° 28′ W, or S 3° 32′ E.

PROBLEM 2.—The outcrop of a vein on a hillside runs N 60° E and slopes 20 degrees

FIG. 2

to the eastward. An inclined shaft sunk on the vein dips 40 degrees to the southward and runs S 10° E. Find the dip and strike of the vein, Fig. 2.

Formula:

$\tan a = \sin b \cdot \tan d$, for any line in a plane;

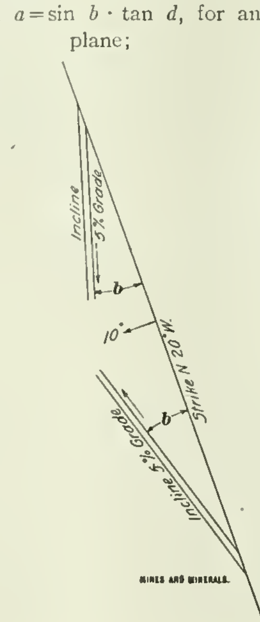

FIG. 3

$a = 20°$ for line of outcrop;

$a = 40°$ for line of shaft.

Since the two lines lie in the same plane, whose dip is d, we may write the following two equations:

$$(1) \quad \tan 20° = \sin b \cdot \tan d.$$

$$(2) \quad \tan 40° = \sin (b + 110) \cdot \tan d.$$

Solving for b:

$$\frac{\tan 20°}{\sin b} = \frac{\tan 40°}{\sin (110 + b)}$$

$$\tan 20 \cdot \sin 110° \cdot \cos b + \tan 20° \cdot \cos 110° \cdot \sin b = \tan 40° \cdot \sin b$$

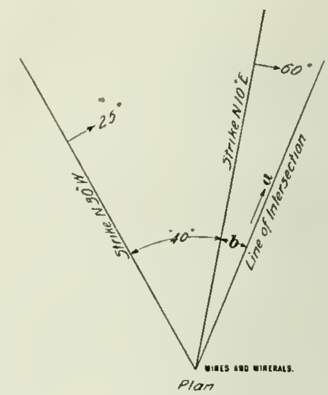

FIG. 4

$$\cot b = \frac{\tan 40°}{\tan 20° \cdot \sin 110°} - \cot 110°.$$

$$\cot b = 2.4534 - (-.36397) = 2.81737.$$

$$(\cot 110° = -\tan 20°)$$

$$b = 19° \; 28'. \quad 60° - (19° \; 28') = 40° \; 32'.$$

Substituting value of b in (1),

$$\tan 20 = \sin 19° \; 28' \cdot \tan d.$$

$$d = 47° \; 31'.$$

The vein strikes N 40° 32′ E and dips 47° 31′ to the eastward.

PROBLEM 3.—Find the direction and slope of the line of intersection of two veins, one of which strikes N 10° E and dips 60 degrees to the eastward, the other strikes N 30° W and dips 25 degrees to the eastward, Fig. 4.

Formula: $\tan a = \sin b \cdot \tan d$. a = slope of line of intersection; b = horizontal angle between line of intersection and strike of one vein; $(b + 40°)$ = horizontal angle between line of intersection and strike of other vein. Since the line of intersection lies in both planes, we may write the following two equations:

$$(1) \quad \tan a = \sin b \cdot \tan 60°.$$

$$(2) \quad \tan a = \sin (40° + b) \tan 25°.$$

Solving for a and b:

$$a = 20° \; 15'; \; b = 12° \; 18'.$$

The direction of the line of intersection of the two veins is N 22° 18′ E and its slope is 20° 15′ to the eastward.

The above problems are intended to illustrate some of the applications of this formula and its great convenience in solving problems of this kind. Readers will be able to recognize its usefulness in very many modifications of the data here assumed.

* Professor of Mining, School of Mines and Metallurgy, Rolla, Mo.

Iron Mining in Missouri

Revival of Work on Deposits Formerly Extensively Mined and Still Capable of Large Production

*By Lucius. L. Wittich**

MISSOURI no longer occupies the important position it once did in the production of iron ores, but recent activities in new districts and the resumption of operations in regions formerly worked extensively, may increase the output materially in the course of the next year or so. The eastern portion of the Ozark uplift, which includes the major portion of the state south of the Missouri River, is where the largest iron ore mines are located. The production of specular hematite comprises the greater portion of the output, although some brown ore and a small amount of magnetite is mined. The average annual iron-ore production from the state is about 100,000 tons. Much of this ore is hand picked and shipped to furnaces in Ohio, where it now brings approximately $4 a ton for grades carrying close to 60 per cent. metallic iron.

FIG. 1. IRON MINES AT PILOT KNOB

Discoveries of iron, according to history, were made by Marquette in 1673. The Ashebran furnace at the Shut-in, not far from the Shepherd Mountain mines, was built in 1815. Missouri was thus the first state west of Ohio in which iron was mined and smelted. At many points throughout the state ruins of the early-day furnaces may be seen. Fig. 3 shows the remains of the furnace operated by the Big Muddy Iron & Coal Co., on the slope of Pilot Knob.

Mining was started at Iron Mountain, St. Francis County, in 1844. Two years after this a blast furnace was erected, and two years later, in 1848, another furnace was blown in. The Valley Forge, started in 1851, ran until 1866, iron blooms being produced. A third furnace was started in 1855, and the Iron Mountain district became more or less famous throughout the country, the chief deposit being looked upon as a mountain of almost solid iron ore.

At Shepherd Mountain, in Iron County, south of St. Louis, where the first iron mining in Missouri was undertaken, operations are still in progress, although the mine was idle for many years. The Puxico Iron Co. is working the magnetite ores of this mountain in addition to mining at Pilot Knob, 1¼ miles to the northeast, and also at Puxico in Stoddard County, farther to the south.

The Shepherd Mountain deposits were worked as early as 1815, but the production was limited. Operations were conducted at various times up to the civil war and were not resumed again until the present company took a lease on the property. Deep diamond drilling in 1888 showed a formation much more extensive than any that had been worked.

The iron mining boom resulted in the construction of the St. Louis, Iron Mountain & Southern Railroad to Pilot Knob, thus affording shipping facilities to other furnaces. Prior to this the output was sent overland to Ste. Genevieve on the Mississippi River and transported by boat.

The opening of the deposits at Iron Mountain and Pilot Knob marked the beginning of a 30-year epoch of great activity in iron mining in Missouri, and the state was considered an important center in the production of this ore. The annual production ran close to the half-million ton mark at times until 1888, when the output declined precipitously, due to the working out of the more extensive ore bodies. About this time also discoveries of large deposits of high grade Bessemer ore were made in the Lake Superior region and a resultant slump in the price of iron ore and iron products materialized, discouraging operators in the Missouri districts, who had received as high as $10 a ton for their product on several different occasions, this high figure having been attained in 1866, 1867, and 1873, the latter year, in fact, seeing the price go to $12 a ton.

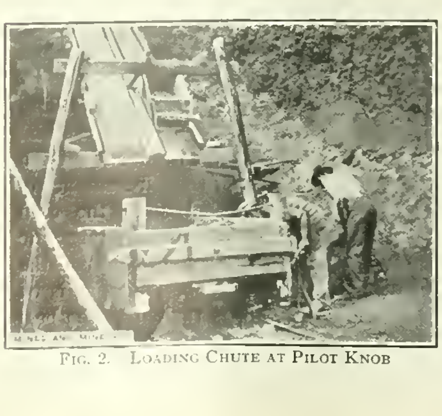

FIG. 2. LOADING CHUTE AT PILOT KNOB

The one iron furnace in blast in the state at the present time is in Dent County and is owned by the Sligo Furnace Co., of St. Louis. The output of the central Ozark district is taken at this furnace. The mines to the east face the necessity of paying a heavy freight rate in shipping to eastern furnaces.

FIG. 3. RUINS OF FURNACE AT PILOT KNOB

Iron Mountain, in St. Francis County, is a low, conical hill, rising barely 230 feet above the level of the surrounding country. Its base covers about 300 acres. In 1872, this property produced 269,480 tons of iron ore, and during recent years varies from 7,000 to 60,000 tons. Three kinds of ore are found: Boulder ore embedded in the surface clay; ore in veins extending to a considerable depth in the porphyry; and the conglomerate ore occurring in beds between the porphyry and the overlying Cambrian limestones.

It was because the boulder ore so completely covered the mountain that the early idea pictured the place as a body of solid iron, and it was not until after the early mining had resulted in the crust of boulder ore being removed that the true nature of the formation was made clear. Veins were next encountered, after which diamond drilling was conducted to locate the masses of conglomerate.

Pilot Knob, like Iron Mountain, rises like a peak from the surrounding plain, but is much higher, attaining an altitude of 600 feet, the main mining operations having been conducted at the apex of the hill. These have been abandoned many years, however, and the present operations are being conducted in an open cut on the north slope of the mountain. Here the conglomerate, consists of a matted mass of ore and porphyry boulders; the ore being weathered crumbles readily beneath a pick. Fig. 1 shows this formation and the long chutes down which the ore is sent, a distance of 100 feet, in boxes holding 350 pounds each, to be emptied into tram cars with a capacity of 3 tons each. The loaded box in sliding down the chute, Fig. 2, is the motive power for pulling up an empty box, the two passing on a switch half way up the incline. The tram car is pushed a distance of 1,000 feet and emptied into a freight car for transportation to the East.

The ore from this mine is sold on a basis of 50 per cent. metallic iron, a premium or deduction of 8 to 10 cents a unit prevailing for ores carrying above or below this basis. The cars carry from 60,000 to 90,000 pounds.

Because of the complexity of the formation in the 60-foot face being worked, careful hand sorting is required. The ore will average 56 per cent. iron, 10.15 per cent. silica, 4.37 per cent. alumina, and .021 per cent. phosphorus.

Embedded in the surface clays, over the north slope of the mountain, indicating the long weathering of the main ore bodies, are numerous boulders of iron ore and porphyry which occur in commercial quantities. This area is smaller than the underlying conglomerate, and to the present time little effort has been made to mine this boulder ore. The iron content is lower than in the conglomerate, barely exceeding 50 per cent., while the silica is as high as 30 per cent. By carefully hand picking the surface ore the iron is brought to 53 per cent. To the north of the open cut the company has a winze into 40 feet of ore, which shows a higher percentage of metallic iron and a higher percentage of silica.

Extensive drilling operations indicate the presence of other ore bodies, one of which is on the northwest slope of the mountain. The deposit is large, and drilling has indicated that it is almost vertical. Development of this ore body will in no wise retard work in the conglomerate body farther to the east, nor will it replace this latter development, as there is enough of the conglomerate blocked out to insure steady operations for a number of years. Ore is known to exist beneath the southern slope, but the deposits are small, and, according to drill records, are at greater depth than those on the north slope, the best deposits occurring at a depth of 600 feet. Ore was encountered in other holes at a depth of 400 feet, the deposits, in places, being 50 feet in thickness and ranging in richness from 51.8 per cent. to 21 per cent. ore.

From its workings on Shepherd Mountain, a short distance southwest of Pilot Knob, the Puxico Company procures a higher grade of ore, an average assay showing 60.83 per cent. iron; .07 phosphorus; silica, 8.23; and sulphur, .02. The mountain is somewhat higher than Pilot Knob, reaching an elevation of about 700 feet above the surrounding country. Development here is of especial interest because no iron production from this mountain, prior to the recent activities, has been reported since the civil war. Much of the ore is highly magnetic and commands a higher price than the product from Pilot Knob. The ore is of Bessemer grade and is ranked as the best of Missouri iron ores. At the north base of the mountain, where much drilling has been done, black iron ore is found at a depth of 600 to 617 feet. At present, mining is confined to a deposit near the top of the mountain, where a dull blue specular hematite, mixed with magnetite, occurs. The company is working deposits occurring adjacent to the open cut extending down the southwest slope of the mountain, which was worked years ago and which is almost 1,300 feet in length.

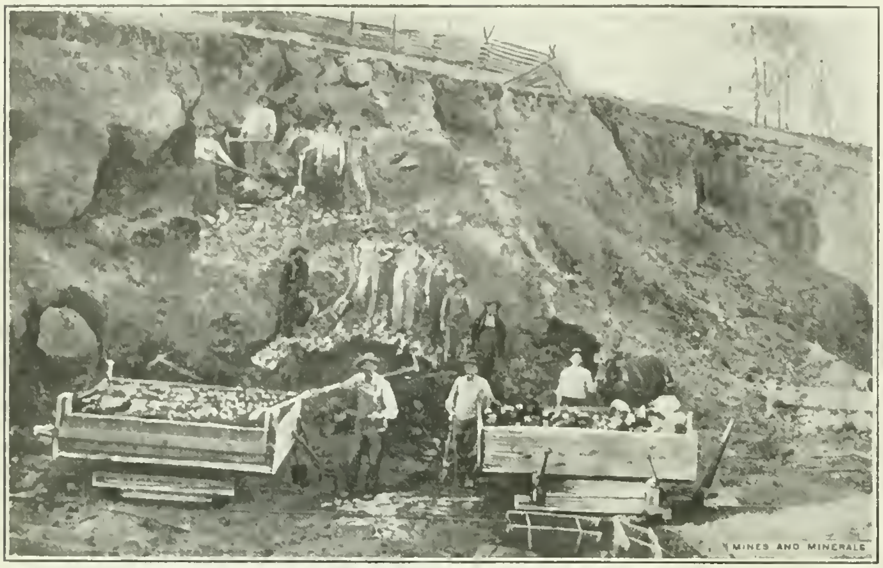

Fig. 4. Pico Iron Mine, Puxico, Mo

On the south slope of the mountain, small deposits of ore have been mined in open pits, but the chief deposits consist of the fissure veins at the top, the stratified veins at the north base of the mountain, and the residual deposits of boulder ore.

In Stoddard County, in the extreme southeastern corner of the state, low-grade iron ores have been mined since 1901, and since 1905 shipments have been steady. The largest producing mine in this county is the Pico, shown in Fig. 4.

The Pico mine lies on the southeastern rim of the Ozarks, where the Cambrian limestones outcrop in the foot-hills, and is about 1 mile north of the town of Puxico. Toward the top of one of these foot-hills an area of several acres is covered with an outcrop of cherty brown ore. Open pits afford the best method of development and a number of these have been excavated, the largest being about 50 feet deep, 200 feet long, and 100 feet in width. Here the ore has been found to extend beneath the strata of residual surface chert and clay, and reaches the Cambrian limestone, although in the smaller pits the ore deposits were comparatively small, being pockety and very irregular.

The iron content is comparatively low, rarely reaching 50 per cent. and often dropping to 44 per cent. The silica content ranges from 10 to 20 per cent.

G. W. Crane, assistant state geologist, in his 1912 report on iron ores of Missouri, dwells at length on the origin of ores. Condensed, his theory is that the brown ores, in their present formation, are the result of sedimentation from descending waters, while the specular hematites, he believes, owe their origin to igneous action. He cites the fact that the bulk of these ores lie within a radius of 5 miles of Pilot Knob, a region of early volcanic eruptions.

Two Kinds of Sulphur Mining

In the sulphur mines of Sicily young boys climb for 400 feet bearing in a stifling atmosphere 40-pound loads of sulphur ore upon their backs. In Louisiana a bore hole containing two concentric pipes is driven to the ore; a hot solution of calcium chloride is forced through one pipe to melt the sulphur, which is then pumped to the surface through the other.

Asbestos

Examples of Its Early Use—Derivation of the Mineral—Different Varieties and Their Values

By Warren W. Currens*

Asbestos is described in the writings and records of the ancient civilizations. The Romans were familiar with a cloth woven from asbestos fiber and used to wrap around human corpses during preparation for cremation. Several specimens of this ancient cremation cloth are preserved in the Vatican Museum. Marco Polo, when traveling through Siberia, in the thirteenth century, was shown some cloth which withstood fire. The ancient process of manufacture involved crushing in mortars, fiberizing, and spinning. The lamps of the "Vestal Virgins" were supplied with asbestos wicks. In the year 1720, asbestos was found in the Ural Mountains. During the reign of Peter the Great, a factory for the manufacture of asbestos articles was established but it was not successful because the uses for such goods at that time, were limited.

The value of the non-combustible properties of the mineral was not realized until about 40 years ago. Since 1860, enormous exploitation and development have made the asbestos industry commercially prominent. The progress made in the invention of mechanical methods for utilizing the raw material has been wonderful.

In 1877, asbestos was found in the Province of Quebec in the serpentine hills of Thetford and Coleraine. Large fires had cleared away the timber and exposed the rock to weathering. This surface weathering simplified prospecting in the district and large areas were taken up near Thetford and Black Lake.

Since 1890, the old crude methods of hand cobbing the ore have been replaced by mechanical plants. These plants are more economical and have brought about a prolonged life for the industry. New fields for the mining of fiber have been discovered but the Canadian fields rank first the world over.

The name asbestos is derived from the Greek and signifies incombustible. The French Canadians call the mineral "pierre a cotton"—cotton stone. It has been referred to as a mineralogical vegetable and a "physical paradox."

In mineralogy, three minerals are classified under the name asbestos; namely, antophyllite, amphibole, and serpentine. The first two resemble each other chemically, being silicates of lime, magnesia and alumina. The third, serpentine, is a hydrated silicate of magnesia and may be represented by the formula,

$$Mg_3Si_2O_7 2H_2O.$$

Antophylite has no commercial importance. There are five varieties of the amphibole mineral, viz., tremolite, actinolite, asbestos, mountain leather (also called mountain wood and mountain cork), and crocidolite.

The first three of these are similar in external appearance and chemical composition, but the asbestos is readily distinguished by its easily separated, long, silky fibers. Tremolite occurs in long, stout crystals of dark gray color and in columnar masses. Its use commercially is limited. It is sometimes used in manufacturing mineral wool. Actinolite is a lime-magnesian silicate with iron. It occurs in magnesian rocks, such as talc. It is used in weighting paper, in roofing, and in various forms of adulteration.

Asbestos, tremolite, actinolite, and other varieties of amphibole pass into fibrous varieties, the fibers of which are sometimes long and flexible. These varieties are called asbestos, hornblende asbestos, or amphibole asbestos. The name chrysolite is applied to the superior serpentine fiber mined in Canada. The Italian asbestos is properly so called, but is often confused with the better chrysolite.

Mountain leather and cork are not asbestos and are easily distinguished therefrom.

Crocidolite is sometimes called blue asbestos. The fibers are long, flexible, and easily separated by the fingers. Large quantities are found in Gringualand, South Africa. The mineral has a silky luster and a dull lavender-blue color. An attempt was once made to substitute crocidolite for chrysolite on the market but failed. Crocidolite has the composition of 50 per cent. silica and about 40 per cent. oxide of iron. Good asbestos fiber carries 50 per cent. silica and only ½ per cent. iron oxide. The crocidolite fiber, because of its high iron content, disintegrates with heat and becomes rotten, the iron salts disintegrating by weathering.

Serpentine has three distinct fibrous forms, viz., picrolite, soapstone (talc) and chrysolite. Serpentine, as a rule, is found in massive form. It also occurs with a banded, schistose, and slaty structure. Its color varies from black, through the different shades of green, to light green. The luster is resinous to pearly or waxlike, but is seldom earthy. The rock surface in some places has a greasy feel similar to talc, but it is readily distinguished by its greater hardness. Picrolite and chrysolite have similar chemical compositions, but their physical properties are entirely different.

Serpentine is derived from olivene or peridotite and is hence sometimes classed as a hydrated peridotite or olivene. By the action of carbonated water on olivene, the iron and some magnesia are carried off, the resulting rock being serpentine. Olivene contains fissures, the alteration occurring along them; and the alteration product appears as a fringe of crystals with fibers lying at right angles to the olivene faces.

Picrolite resembles coarse asbestos. The fibres are 8 to 12 inches long, rough to touch, brittle and not easily separated. The color is dark to light green, sometimes gray or white. Picrolite is not a substitute for asbestos and finds little commercial use.

Chrysolite is, as stated above, a variety of serpentine but it has a lower specific gravity and is distinctly fibrous. The hardness varies from 3 to 3.5; the specific gravity is 2.2 to 2.3. The luster is usually silky and the color is green or greenish yellow. The fiber, to be of commercial importance, must be long, fine, infusible, flexible, and must have some tensile strength. Chrysolite easily withstands temperatures of from 2,000 to 3,000 degrees Fahrenheit.

The spinning qualities of asbestos are of importance and these vary with different fibers. Good fiber carries a percentage of water, varying between 13.5 and 14.5 per cent. This content bears a close relation to the flexibility of the fiber. If the fiber be subjected to great heat and some water be expelled, the fiber becomes brittle. Good fiber may be distinguished from bad by subjecting the fibers to tearing, twisting, and bending between the fingers. A good grade of asbestos will give white, silky fibers that may be twisted into threads. Poor asbestos splits up and breaks when rubbed between the fingers. Hornblende and chrysolite have the common property of resisting heat, but only chrysolite offers superior spinning and working properties.

"Vein fiber," or "cross-fiber," are terms applied to fibers which are found to lie at right angles to the vein walls. Veins intersect portions of the serpentine in every direction and with no definite arrangement, sometimes crossing each other. The thickness of veins varies up to several inches. The length most profitably mined varies from one-fourth to one-half inch. In many places, the fiber is divided by a seam of serpentine, carrying magnetite or chromic iron ore. The veins are sometimes displaced by faults, and the fibers are then drawn out along the fractures

*Mining Engineer, Denver, Colo.

and may appear long because of the overlapping. Hornblende asbestos never occurs as vein or cross-fiber.

Slip fiber is usually white. It fills slickensided fault-planes in serpentine resulting from slipping of one rock portion along the contact with another portion. The fiber is bedded on the slipping plane in a flat position, there being a definite parallelism in the arrangement of the fibers. The slip fiber, when mined and separated from the rock, is in no way different from the vein fiber.

Origin of Asbestos Fiber.—The steps in probable origin of asbestos as worked out by Fritz Cirkel*, are outlined as follows:

1. The intrusion of olivene through the earth's crust from below.
2. A gradual alteration of the rock to serpentine through hydration with perhaps a loss of silica and an accompanying increase in volume.
3. A slow readjustment of the rock masses, resulting in the formation of joints and slickensides.
4. A subsequent formation of fissures as receptacles for asbestos fiber. These fractures could occur through the shrinkage of the rock or the injection of granite dykes.
5. Infiltration of serpentinous solution from the side walls, by a process of segregation and subsequent slow crystallization of chrysolite.
6. A second slow readjustment of the magmatic rock mass and the formation of "slip fiber."

The first five steps will account for formation of "vein fiber," while the sixth explains the derivation of "slip fiber" from vein fiber.

Diseases of Metals

Not only mankind, animals, and plants, but also inorganic bodies, have their diseases which slowly but surely lead to their destruction if help is not extended to them in time. The similarity goes even so far that, just as there is in the organic bodies a bacillus, the carrier and disseminator of diseases, an infection may take place in inorganic bodies, especially metals, through contact with a diseased metal.

A German scientist, Prof. L. Erdmann, was the first to make searching observations of organ pipes made of tin; however, Erdmann attributed those changes in the structure of the metal observed by him to the vibration of the pipes. Similar observations were made by Fritsche in St. Petersburg, in 1868, on the same metal in the form of large blocks. The phenomenon in this case was that those tin blocks gradually crumbled to pieces. The same scientist observed a similar change on metal buttons of Russian military uniforms which had been transformed during the long time they were stored at the quartermaster's depot, into an amorphous mass, very much to the astonishment of the inspecting officers. Fritsche produced a solid basis for this hypothesis by unquestionable experiments with Banca tin blocks. According to the minute description of the chemist, these diseased tin blocks showed sometimes a crumbled surface and sometimes warty bubbles or deep cavities, similar to pocks in animal organism. In most cases the metal blocks were tarnished and the surface showed faint, radiating formations. While Fritsche exposed a tin block to artificial cold, he could observe that the disease attacked the object at different places at the same time and caused striated or bubble-like wounds.

Since then many other scientists have tried to better explain this phenomenon. The best progress in this attempt was made by E. Cohen, Professor at the University of Utrecht, whose experiments were published in the *Revue Generale des Sciences*, a short time ago, which led to conclusive results. Cohen took as object of observation also a tin block of about 25 kilograms which had already begun to crumble. He found in this block two tin species, physically entirely different from each other, but whose chemical qualities were the same: one a white, bright tin, which was sound and could be put to practical use; the other a gray amorphous tin which covered the center of infection of the block. Through physical-chemical experiments Cohen came to the conclusion that this transformation from white to gray tin takes place at 18° C. and that the contact of sound tin with infected tin mutually favors this transformation, just as the inoculation of certain microbes causes a specific metamorphosis in animal organism. The formation of small warts was predominant in this transformation into gray tin and they covered the entire surface of the block within 3 weeks. Cohen rather cleverly called this disease which is contagious, the Zinnpest (tin pest). At the transformation of white into gray tin the specific volume of the metal increases by about 25 per cent. which causes these small wart-like formations. After the disease is further advanced these swellings finally crumble into an extremely fine-grained powder. Cohen did not hesitate to draw a practical conclusion from these results. Heretofore, only collections of costly tinware or valuable tin medals or coins had to suffer from tin pest without the conservators of the museums or the numismatologists being able to put a stop to it. A large number of medals and utensils, especially tin dishes and plates, perished through this disease, as any close observer will notice when he visits a large museum. Cohen claims that there is only one remedy: the rooms and glass show cases in which the tin objects are exhibited, should always be above 18° C.

The tin pest is not the only disease of metals. The famous scientist A. von Hasslinger a long time ago called attention to another kind of metal disease which was also contagious, but he did not devote his time to a searching examination. Cohen undertook to also solve this problem and named this phenomenon "Verhaertungskrankheit" (hardening disease). It would probably have been better named "Verdichtungskrankheit" (thickening disease). As object of observation, tin was used at first, and later on, tin plate. Cohen placed several tinfoils that were infected with this disease, upon the tin plate, and ascertained the fact that the surface which was covered by the tinfoil, became dull and crystalline. He explained this to be recrystallization, which is also caused by low temperature. This disease is not limited to tin and iron but extends also to other metals. Cohen diagnosed it especially on petroleum receptacles in brass lamps which had become leaky after 3 years' use. Although the chemical quality of the metal remained unchanged, its cohesion had disappeared and there were crevices and holes in it. The microscopic analysis proved that on account of the recrystallization the metamorphosis of the metal from a meta-staple to a more staple condition had produced these effects. Finally also lead is subject to this disease, which may be observed especially in the lead chambers of sulphuric acid factories. Cohen occupies himself at present with what he calls the "pathology" of iron. Highly interesting results may also be expected from this. The above-mentioned researches do not only interest chemists and engineers but also laymen and the housewives to whom they explain many disagreeable facts and thus aid them to prevent the latter.—K. K.

Homestake Electric Plant

The Homestake Mining Co., Lead, S. Dak., has completed its great hydro-electric generating plant. The water of Spearfish River has been diverted for a distance of 5 miles through tunnels driven most of the way through solid rock. The plant has been tested and found to generate upwards of 6,000 horsepower. The mills and other works of the company are now undergoing modification that will dispense with steam power, and it is expected that before fall all the works will be electrically driven. The mills will be arranged in units of 10 stamps, each having its separate 25-horsepower driving motor. The whole project is costing considerably over $1,000,000.

NEW MINING MACHINERY

New Electric Mine Pump

Pumping conditions at mines in one locality vary so widely from those in another that many kinds of pumps have been designed with a view to meet some of the requirements of all. To accomplish this, mine pumps must cover a wide range of capacities and working heads, and be constructed also to withstand the action of different kinds of water, which may be gritty in one case and corrosive in another or both. The large power mine pump shown in Figs. 1 and 2 was designed by the Deane Steam Pump Co. of Holyoke, Mass., to meet the requirements of the Baltimore No. 5 colliery of the Delaware & Hudson Coal Co., at Parsons, Pa., which involve muddy and acid water and high lift, in a shaft. The noteworthy features in connection with this pump are that it is electrically driven with plungers moving horizontally, instead of vertically, and in some other respects adopts the good points that have been reached by years of effort on the part of steam pump manufacturers. The stuffingboxes of the plungers can be packed from outside; the water cylinders are lined with wood to prevent the destruction of the metal through the corrosive action of the water; and the water end is supplied with pot valves. The pump is triplex single acting and constructed with an extra allowance of metal to compensate any loss that might occur from corrosion either inside or outside.

The valves and by-pass pipes are of acid-resisting bronze, and the same metal is used for lining throats and glands and for capping the ends of the plungers, which are specially subject to corrosion.

The water end is sectionalized with separate cylinders and valve pots, rendering it easy to inspect and repair any damage due to breakage. The valve seats are made easily removable by the use of special flanges that also are arranged so as to hold seats firmly in place. The valves are double ported of large area; rubber is used for the facing. A by-pass equipment makes it possible to start the pump with practically no load on the motor, and priming piping, and valves permit prompt and reliable starting. One large vacuum chamber and three air chambers insure smooth operation. The object of three air chambers is to obtain less headroom than would be required by one of an equivalent volume. Swing bolts and slotted flanges, or flanged joints subject to frequent disconnection, expedite removal of parts.

The power end of this pump possesses features worthy of examination. The crank-shaft is fitted with cast-steel crank-disks, with the crankpins pressed on and also keyed to the shaft. Each yoke that connects the cylinder to the frame is split in a horizontal plane to facilitate replacement of these heavy castings without completely removing others. The design of the yoke and the large diameter of the crosshead and guides renders the gland studs accessible and permits the adjustment of shoes and connecting-rods. The connecting-rods are interchangeable, with solid crosshead and forked crank-ends, that have wedge adjustments.

The gear-wheels have the herring-bone face and are supported between two frames, which with the heavy motor base and an outboard bearing for the motor shaft insure alinement. The method of mounting the motor, and the height of the base, will permit continued operation of the pump with even a considerable depth of water on the pump-room floor. The dimensions and capacities of the pump are as follows: Diameter of plungers, 12 inches; length of stroke, 12 inches; speed of pump, revolutions per minute, 48; speed of motor, revolutions per minute, 375; capacity of pump, gallons per minute, 825; working lift, 400 feet; motor, 125 horsepower, 440 volts, three-phase, 25 cycles.

The motor for this pump was furnished by the General Electric Co.

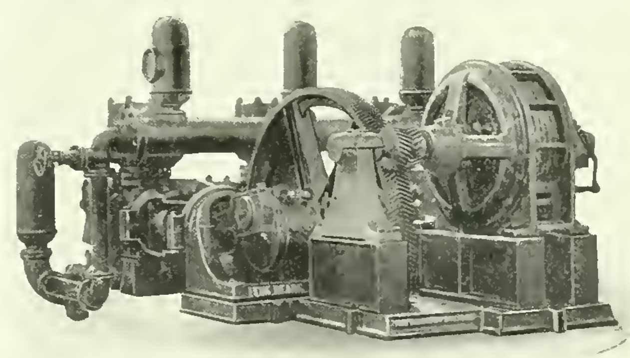

Fig 2 Rear View of Electric Pump

Fuses for Electric Lines

Fuses are regulated in size to carry a certain number of amperes, and to melt and open the circuit when it carries an overload. A common form of fuse metal is the fuse wire or fuse strip, made of lead composition and commonly sold by electrical supply houses. The Board of Fire Underwriters recommends the use of enclosed fuses to avoid possibility of damage or fire from the melted metal. To enable the user to know just what he is using and to buy it as cheaply as possible, the Daum refillable fuse shells were invented. They are made with heavy cast-brass, carefully machined, removable caps, screwed onto heavy vulcanized fiber tubes. In these can be connected any suitable size fuse wire. One size shell is designed for any number of amperes from 1 to 30, and larger ones have similar variations. It is only necessary to insert the proper size wire, and if it burns out put in another. The A. F. Daum Co., Pittsburg, Pa, will send particulars or sample shells on request.

Nonpareil High Pressure Covering

The Armstrong Cork Co., of Pittsburg, one of the largest manufacturers of cork in the world, utilizes waste cork for the manufacture of Nonpareil corkboard insulation and Nonpareil cork covering for brine, ammonia, and ice-water lines, and has added to its line a new type of high-pressure and superheated steam-pipe and boiler covering, known as Nonpareil high-pressure covering. This contains no cork, but consists of diatomaceous earth and asbestos fiber. Diatomaceous earth, sometimes called infusorial earth, is of very low specific gravity, and is made up of the skeletons or shells of microscopic plants known as diatoms, which existed in the sea bottoms ages ago. These minute bodies, which are practically pure silica, are hollow and contain air, therefore, diatomaceous earth is an excellent non-conductor of heat.

In the form of plastic cement it has been used for years in Europe for heat insulating purposes, and the Armstrong company has perfected a process by which it is successfully bonded together in sectional form so as to produce a strong, efficient pipe covering for high-pressure work.

It is claimed by the makers that this material is from 10 per cent. to 15 per cent. more efficient as a non-conductor of heat, than material previously in use, and in their catalog this claim is substantiated by tests made by several well-known authorities. The material also resists temperatures at which the older coverings calcine and disintegrate, thus making it particularly well suited for the insulation of superheated steam lines, breechings, etc.; also it is not affected by moisture or steam, and after being submerged in water for weeks, it will after drying, be found to be just as strong and efficient as it was in the first place. The covering is easy to apply, and the price, it is understood, compares favorably with that of any other high-pressure coverings on the market. It is made in sections 36 inches long for pipes of standard sizes up to 14 inches. For pipes of larger diameter. boilers, breechings, etc. it is furnished in block form, and for irregular surfaces the cement is furnished. Users of steam are invited to write for catalog, samples, and prices.

Sectional Unit Switchboard

Private telephone systems in homes, business offices, factories, and institutions have become necessities, and intercommunication is looked upon as the most efficient way in which to get results within an organization. The Western Electric Co. has placed upon the market an intercommunicating switchboard that follows out the sectional unit idea as used in filing systems and libraries. The purchaser need only buy as much equipment as his present needs demand; when the necessity for additional extension arises, he can buy another section of switchboard which will fit in with those already installed. This switchboard is for use when the number of telephones exceeds twenty or is likely to exceed twenty in a short time. The units fit together like those of a sectional bookcase; and, by adding units, it is possible to make a switchboard of 20, 40, 60, 80, or 100 lines capacity, which will be reliable, while inexpensive enough to fit a modest appropriation. A valuable feature of this switchboard is its arrangement for sounding a general alarm. This is a means of ringing and talking to all stations simultaneously, thus providing a fire or general alarm system without extra cost. Four systems, to give four different classes of service, may be furnished, and two of them provide means of connecting into the public telephone system.

Illinois Coal Statistics

Number of counties producing coal	52
Number of mines and openings of all kinds	879
New mines or old mines reopened during the year	176
Mines closed or abandoned since last report	142
Total output of all mines, in tons of 2,000 pounds	57,514,240
Number of shipping or commercial mines	380
Output of shipping mines, tons	56,096,695
Number of mines in local trade only	499
Output of local mines, tons	1,417,545
Total tons of mine-run coal	13,366,509
Total tons of lump coal	21,795,527
Total tons of egg coal	4,940,431
Total tons of nut coal	3,193,956
Total tons of pea coal	11,109,191
Total tons of slack coal	3,108,626
Tons shipped	51,502,382
Tons supplied to locomotives at the mines	924,854
Tons sold to local trade	2,615,678
Tons consumed (or wasted) at the plant	2,471,326
Average days of active operation for shipping mines	172
Average days of active operation for all mines	160
Number of motors in use	371
Number of mines in which mining machines are used	137
Number of mining machines in use	1,599
Number of tons undercut by machines	25,455,059
Number of tons mined by hand	32,059,181
Average number of miners employed during the year	39,149
Average number of other employes underground, men	31,687
Average number of boys employed underground	1,526
Average number of employes above ground	7,049
Total number of employes	79,411
Number of persons at work underground	72,362
Average price paid per gross ton for hand mining, shipping mines	$.636
Average price paid for gross tons for machine mining	$.496
Number of kegs of powder used for blasting coal	1,313,448
Number of kegs of powder used for other purposes	3,040
Number of pounds permissible explosive	328,075
Number of men accidentally killed	180
Number of men injured so as to lose a month or more of time	800
Number of gross tons mined to each life lost	319,524
Number of employes to each life lost	441
Number of deaths per 1,000 employed	2.26
Number of gross tons mined to each man injured	71,893
Number of employes to each man injured	99

Mines and Minerals

Vol. XXXIII.—No. 5. DECEMBER, 1912—SCRANTON, PA. Price, 25 Cents

PUBLISHED MONTHLY AT SCRANTON, PA.
ESTABLISHED 1881
INTERNATIONAL TEXTBOOK CO., PUBLISHERS
T. J. FOSTER, President S. P. ALLEN, Secretary E. H. LAWALL, Treasurer
RUFUS J FOSTER, Vice-President and Manager
EUGENE B. WILSON, Editor HUGH ARCHBALD, E. M., Asst. Editor
CHICAGO OFFICE: 1006 Michigan Ave.

NEW ZEALAND OFFICE: 63 DIXON STREET, WELLINGTON.
AUSTRALIAN OFFICE: 83 PITT STREET, SIDNEY.

SUBSCRIPTION RATES

Single Copies....25 cents
Yearly Subscription, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines...$2.00
To Canada....2.50
To all other countries....3.00

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us.

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

THE number of miners engaged in bituminous and lignite mining in 1911 was 549,750 and those in anthracite mining, 172,585, a total of 722,335. The average production per man was 738 tons for the year in the bituminous and lignite mines and 524 tons in the anthracite mines. In 1910 the corresponding averages were 751 and 498 tons.

THE cheapness of gold is probably the cause for the high price of platinum, although it has an unprecedented demand in the manufacture of jewelry. While it is a necessary metal in some industrial applications, in a large number of others substitutes have been found which have proved eminently satisfactory. While the average price of platinum was $28.87 per ounce in 1911, it has now risen to about $48.

Everybody Happy

THE Presidential election is a thing of the past and everybody is happy. All parties can rejoice over the fact that the daily papers have resumed the publication of news other than that of a partisan nature. The Democrats rejoice over the success of their party. The conservative Taft Republicans rejoice that inasmuch as Mr. Taft could not be elected, President-elect Wilson received a tremendous plurality over Colonel Roosevelt. The Bull Moose adherents rejoice because their candidate received a much larger vote than Mr. Taft. We are all happy. Until March 4, we are unanimously for President Taft. After that date we will be unanimously for President Wilson. The United States of America is the only great nation on earth that can conduct a revolution whose decisive battle is fought on one day and ballots instead of bullets are used for missiles. The administration will change on March 4, but our respected Uncle Samuel will continue to do business at the old stand with a new general manager.

Safety Lamps for Pennsylvania

JAMES E. RODERICK, Chief of Department of Mines in Pennsylvania, has issued the following notice to the bituminous coal operators of Pennsylvania: "The Act of June, 1911, provides for the use of approved safety lamps in all mines generating explosive gas. The term 'approved safety lamp' means any bonneted safety lamp approved by the Department of Mines.

"Section 8, Article 10, of that Act reads:

"'Whenever safety lamps are used in a mine by fire bosses or other persons, they shall be so constructed that they may be safely carried against the air-current ordinarily prevailing in that portion of the mine in which the lamps are being used.'

"A test of safety lamps was made at the National Bureau of Mines, at Pittsburg, and upon receipt of a report of the tests I have approved the following bonneted safety lamps for general use in the mines of this Commonwealth, to wit: Clanny, Davis Deputy, Wolf, Schenk (new type), Seippel, and Ackroyd & Best, where the velocity of the air ranges from 600 to 1,500 feet per minute. You will therefore govern yourself accordingly. No other safety lamps shall, for the present, be used in the bituminous mines of this Commonwealth."

The Protection of the Surface Over Coal Mines

If coal in seams comparatively near the surface is mined there must be a great loss in coal left as pillars or the surface and improvements thereon will be damaged. When the coal and surface are both owned by the same parties the question resolves itself into which is of the greater value, and it is easy of solution. When the surface is owned by one party and the coal by another, with no specified release for damages due to the mining, the owner of the surface is amply protected by law. But when, as is the case in the city of Scranton and its environments, most of the surface owners have deeds in which is incorporated a paragraph which not only reserves the coal to the original owner but provides that it may be mined regardless of damage to the surface, there is a state of affairs that is both troublesome and unfortunate. Most deeds for lots in the city of Scranton and neighboring towns, excepting in some few localities, have embodied in them the following paragraph:

"*Excepting and reserving, however, to the said party of the first part, its successors and assigns, all coal and minerals beneath the surface of and belonging to said lot, with the sole right to mine and remove the same, by any subterranean process incident to the business of mining, and also the sole right of passage through or under the said lot, to mine and remove the coal and minerals from any other lands by any subterranean process, without thereby incurring, in any event whatever, any liability for injury caused or damage done to the surface of said lot, or the buildings or improvements which now are or hereafter may be put thereon; and the party of the second part, for himself, his heirs, executors, administrators and assigns, does hereby expressly release and discharge forever the said party of the first part, its successors and assigns, and all persons who may have derived title to said coal or other minerals from said party of the first part, of and from any liability for any injury that may result to the surface of said premises, or anything erected or placed thereon, from the mining or removal of said coal or other minerals; Provided that no mine or air shafts shall be intentionally opened, or any mining fixture established on the surface of said premises.*"

Owing to this reserve and release in deeds there has been some damage done lots and buildings in certain sections in the city of Scranton, as well as to streets, water and gas pipes, sewers, etc. So far, except in one or two cases, this damage has been inflicted on comparatively inexpensive property; and the aggregate of all the damage so far done is very small when the extent of the city, its assessed valuation, and the extent of the business due to the mining industry is considered. There is no question but that the wide publicity given this damage due to mine workings and the exaggerated statements regarding it in metropolitan papers have caused a great deal more financial damage to the city than the actual loss to the individual property owners. However, the loss of but a few hundred dollars to an individual, if it is his all, or is the value of a modest home for which he toiled for years, is a great loss if considered by itself. Such loss should, if possible, be prevented, and a future element of danger to large sections of the city should be removed, if it can be, by rational legal means and cooperation on the part of the mining companies, the property owners, and the city as a corporation.

As is well known, the Governor of Pennsylvania has appointed an able Commission which is giving a great deal of time and thought to measures which will remedy the existing state of affairs. One remedy suggested by a former Mayor of the city and a member of the Commission in a paper read before the Commission and published in full in the Scranton daily papers, is so impractical that it did not receive serious consideration from the majority of the Commission or from any one familiar with the coal mining industry. His plan of having the "release for damage" portion of deeds abrogated by legal enactment is unconstitutional, as it would be a forfeiture of the property and rights of the coal owners distinctly specified by voluntary and legal contract. This is the opinion of prominent attorneys and jurists whom we have consulted.

To even attempt to secure the enactment of such a measure would not only result in failure, but it would also delay rational action, if it did not prevent it entirely. The scheme is impractical from other points of view. If, as proposed by former Mayor Dimmick, the legislature should enact a bill making null and void such contracts, even if its constitutionality was not questioned, it would cause a decadence of the city of Scranton and a shrinkage of property valuation to a ruinous extent. It would seriously retract the volume of production and the life of the mining industry. None of the coal under property owned by others than the mining companies could be mined unless the operator actually purchased all the lots and improvements overlying coal seams. If such purchase could be made at the assessed valuation of the properties affected, it would require many millions of dollars—more than the coal is worth. If the mining companies had to pay the present market price, or the exorbitant prices some property owners would naturally demand, the cost would run anywhere from $50,000,000 to $100,000,000.

In the territory tributary to Scranton, in a business sense, there is an annual production of about 20,000,000 tons of anthracite coal. Each ton represents the bringing into the territory of from $2 to $3 or say $50,000,000 per year. The circulation of this money represents the greatest portion of Scranton's commercial activity. If such legislation was enacted as Mr. Dimmick proposes it would be illegal and impossible for any lot owner to sell the coal under his lot. The whole valley from Forest City on the north to Pittston on the south is almost one town with many thousands of lot owners. All the coal under their lots would be tied up. There would be no certainty that this would afford sure protection, because coal surrounding these lots or in the neighborhood of such lots belonging to the mining companies could be entirely mined out and squeezes or side thrusts would probably affect buildings, even if they were located directly over comparatively large pillars. There are other reasons that might be cited for the impracticability of Mayor Dimmick's scheme but there is no use wasting space on them as the unconstitutionality of the proposed measure is objection enough.

There is, however, a practical way in which the question of surface protection in the city of Scranton can probably be solved. We say *probably*, because we have no right to speak for the coal mining companies who own the coal and have a legal right to mine it regardless of consequences to the surface. We believe that the mining companies will meet the surface owners in any rational plan that may be proposed.

There is only one way in which a maximum amount of the coal can be mined and the surface be protected, that is, by flushing from 50 per cent. to 60 per cent. of the mined area full of culm, sand, ashes or other suitable material in the shape of well-distributed artificial pillars. Nearly 30 years ago this plan was used at Shenandoah, Pa., with good results and it has been used at other points in the anthracite region. It has been adopted in Europe, and is now being used by the Philadelphia & Reading Coal and Iron Co., at Shenandoah, and Mt. Carmel, Pa. It is the plan suggested by Messrs. Griffith and Conner who examined the mine workings under the city of Scranton and made an able and voluminous report to the original committee appointed to investigate the matter.

At Shenandoah and Mt. Carmel the flushing is being done entirely at the expense of the mining company, because while it owns the coal it does not enjoy the privilege of a release from damages to the surface. In these instances the size of the seams mined and the superior quality of the coal warrant the expense that the company is voluntarily incurring. As the mining companies operating in Scranton and vicinity not only own the coal but have legal right to mine it regardless of damage to the surface, it cannot be expected that they will do the same. We believe, however, that they will do their share, and we offer the following as a general plan for the solution of the question:

Have appointed a reliable local board of commissioners, consisting of one general mine manager, one competent mining engineer, one practical miner, and two public-spirited business or professional men—three to represent the city and the lot owners, the mine manager and mining engineer to represent the mining company. Then have this board obtain an arrangement by which the cost of sufficient flushing to insure the stability of the surface should be borne proportionately by each of the three parties at interest; namely, the mining company, the lot owners, and the city at large as a corporation. The cost of the flushing might be divided, say, in the following proportions, as might be deemed fairest:

One-half of the cost to be borne by the mining company; one-fourth by the lot owners and one-fourth by the city at large, or possibly the proportion might be one-third by the mining company; one-third by the lot owners and one-third by the city at large. The one-fourth or one-third to be paid by the lot owners should be divided among the lot owners of the section being treated in proportion to the assessed valuation of their properties. This assessment against the lot owners might be paid in five annual instalments with interest, as is the case with paving and sewer assessments in Scranton. The idea of having the city pay a portion of the cost is to require property owners, whose lots are not and will not be undermined, to pay a portion of the expense in the shape of taxes. They are vitally interested in the prosperity of the city, and anything affecting the city, either beneficially or adversely, naturally affects the value of their real estate. The mining companies should pay their share, as by means of the proposed flushing it will be possible for them to recover a greater percentage of the coal remaining in the ground than otherwise. The work of flushing should be done by the mining companies, as they can do it better and cheaper than any one else.

The details of such a plan of operation would have to be worked out by the commissioners. A rational plan would be to lay the city out in sections, take each section in turn, as necessity requires, finish the work in that section and make the charges for that section separately from those of other sections.

On first thought we know that this plan will not be a popular one with real-estate owners. No man likes to pay out money if it can be avoided, but the real-estate owners of Scranton are up against a condition that must be met. The expenditure of comparatively small sums by each, to protect their real-estate holdings, which are worth many times their share of the cost of flushing, is good business.

As stated before, we have no authority from the mining companies to commit them to such a plan or to any proportionate division of the expense, but we believe from our knowledge of the managements of the companies that they will give favorable consideration to any rational plan and, we think, will be liberal in assuming some part of the cost.

Personals

Under an act of the legislature the office of the Kentucky Geological Survey has been removed to Frankfort, Ky. All communications should be addressed to J. B. Hoeing, Director of the Kentucky Geological Survey, Frankfort, Ky.

A. H. Elliott, Chemical Engineer; Louis D. Huntoon, Mining Engineer; and Bradley Stoughton have associated for the general practice of their overlapping professions, with offices at 165 Broadway, New York City.

Professor C. L. Bryden, 1015 Myrtle Street, Scranton, Pa., has a list of 98 men in America who have attended Freiberg, Germany.

E. B. Day, Vice-President of the *Coal and Coke Operator*, has resigned from that paper and is now on the staff of *Engineering Magazine*.

E. G. Bailey, M. E., is not now with the A. D. Little Co., but with the Fuel Testing Co., 220 Devonshire Street, Boston, Mass.

Sam. T. Long and Weed Smith, of Webb City, Mo., victors in 1911, again won the drilling championship of that district on October 20, drilling 35 and 13-16 inches in the allowed time and using 908 strokes.

James F. Beattie, formerly Division Superintendent of the Shawmut Mining Co., at Byrnedale, Pa., has been appointed General Superintendent of the Williams Mining Co., with headquarters at Oakridge, Pa.

Rush N. Hosler has been appointed Chief Engineer of the Rochester & Pittsburg Coal and Iron Co., Jefferson & Clearfield Coal and Iron Co., and Pittsburg Gas Coal Co., with headquarters at Indiana, Pa.

G. R. Delamater, of the Pennsylvania Crusher Co., will present a paper on "Coal Washing," at the December meeting of the Coal Mining Institute of America, to be held at Pittsburg, December 18.

Oscar Cartlidge, of Marion, Ill., has been appointed Manager of the Illinois Rescue Stations to succeed Mr. Richard Newsam who resigned last spring on account of ill health. Mr. Cartlidge is qualified in every way for this position and will undoubtedly be of great assistance to the mining industry of his state. Illinois is the only state having state rescue stations and cars.

The following men received degree of Mining Engineer from the Michigan College of Mines, August 31, 1912: Everett L. Booth, Chicago, Ill.; Raymond Aloysius Case, Sault Ste. Marie, Mich.; Marion Gilbert Donk, Washington, D. C.; Gordon Elliott, Globe, Ariz.; Jesus Jose Falomir, Mexico City, Mex.; John Percy Francis, Ishpeming, Mich.; Adelbert John Gleason, Biwabik, Minn.; Myron Henry Greve, Grand Rapids, Mich.; Fred Beaby Hanchett, Jr., Niles, Mich.; Kedzie Karl Hood, Houghton, Mich.; Prescott Samuel Huntington, Mason, Mich.; Frederick Edward Kurz, Green Bay, Wis.; Victor John Lanigan, Duluth, Minn.; John Munro Longyear, Jr., Marquette, Mich.; Samuel Lowenstein, Negaunee, Mich.; Lynn Sterritt McDonald, Sycamore, Ohio; Cyril James McKie, Bessemer, Mich.; Niel Stanley Mackie, Sault Ste. Marie, Mich.; Raymond C. Mahon, Iron River, Mich.; Theodore William Molthen, Hubbell, Mich.; Daniel Leighton Newkirk, Detroit, Mich.; Jose Antonio Paredes, Mazatlan, Sinaloa, Mex.; Isak Partanen, Hancock, Mich.; Louis Procissi, Calumet, Mich.; William Arthur Rigby, Norway, Mich.; William Andrew Robins, Jackson, Mich.; Eark Williston Stuart, Chesaning, Mich.; James Elmer Waterman Swent, Oakland, Cal.; Frederick Thomas Teddy, Ishpeming, Mich.; Frank Emmett Thurber, Holland, Mich.; Roy Lesstie Wahl, Houghton, Mich.; Harold Whittingham, Market Rasen, Lincolnshire, Eng.

David White has been appointed Chief Geologist of the United States Geological Survey to succeed Waldemar Lindgren who becomes Rogers' Professor of Geology at the Massachusetts Institute of Technology. Mr. White, who is a graduate of Cornell University, has been connected with the Geological Survey since 1886, his first appointment being to the position of assistant paleontologist. Later he was assistant to Prof. Lester F. Ward, under whom Mr. White specialized in the study of fossil floras of the older geologic formations. Mr. White is also Associate Curator of the National Museum and is president of the Paleontological Society, vice-president of the Geological Society of America, and a member of the National Academy of Sciences, as well as several other scientific societies.

Dr. F. L. Ransome will take up the work of Mr. Lindgren as chief economic geologist of metalliferous deposits. Mr. Lindgren will not sever his connection entirely with the Geological Survey, but expects to do some work in the West during the coming summer.

Oxone—Sodium Peroxide

Oxone generators are coming into use in most mine hospitals for the immediate generation of pure oxygen. As an anæsthetic or reliever of pain, oxygen is exceedingly useful to surgeons, and the oxone generator can be used for the immediate resuscitation of persons suffering from shock, insensibility from smoke or gases, or where it is deemed necessary to stimulate a person who has sustained an internal injury, such as a broken rib which would prevent artificial respiration being practiced.

Oxone is electrically fused sodium peroxide Na_2O_2 with a small percentage of a catalytic substance. It forms on cooling a grayish substance, hard and dense, which keeps indefinitely in sealed tins, thus making it handy for transportation.

When brought in contact with water or water vapor the "oxone" is decomposed, yielding oxygen and caustic soda as shown in the following equation:

$$\underset{\text{Sodium Peroxide}}{Na_2O_2} + \underset{\text{Water}}{H_2O} = \underset{\text{Sodium Hydrate}}{2NaOH} + \underset{\text{Oxygen}}{O}$$

$$78 \quad + \quad 18 \quad = \quad 80 \quad + 16$$

From this equation 1 pound sodium peroxide yields .205 pound oxygen, thus $.78:1=16:.205$.

The weight of 1 cubic foot of air at 60° F. and 30 inches of mercury is .0766 pound and since the specific gravity of oxygen is 1.105, 1 cubic foot of oxygen weighs $.0766 \times 1.105 = .084643$ pound and .205 pound will occupy 2.42 cubic feet or 4,181.76 cubic inches.

Foster in his "Textbook of Physiology," gives the following differences between inhaled and exhaled air:

	Inhaled Air	Exhaled Air
Oxygen	20.81	16.003
Nitrogen	79.15	79.589
Carbon dioxide	.04	4.380

According to this table, oxygen decreases at the rate of 23 per cent. and carbon dioxide increases in volume 109 times. Soper, in his book on "Air and Ventilation of Subways," states that "the average adult takes into his lungs 396 cubic inches of air per minute, 20.81 per cent. of which is oxygen; therefore, he requires 82.4 cubic inches of oxygen per minute, but 77 per cent. of this can be used again; therefore, he will consume 18.95 cubic inches of oxygen per minute. Since 1 pound of oxone will furnish 2.42 cubic feet of oxygen or 4,181.76 cubic inches, it would theoretically furnish sufficient oxygen to support life $\frac{4,181.76}{18.95} = 225$ minutes. When oxone is supplying oxygen for the breath in an enclosed space the carbon dioxide which increases rapidly must be cared for and this is done by the sodium hydrate formed, as follows:

$$\underset{\text{Sodium Hydrate}}{2NaOH} + \underset{\text{Carbon Dioxide}}{2CO_2} = \underset{\text{Sodium Bicarbonate}}{2NaHCO_3}$$

$$80 \quad + \quad 88 \quad = \quad 168$$

From 1 pound of oxone .8 pound sodium hydroxide is obtained; according to the equation, 52.4 per cent. of the sodium bicarbonate is composed of sodium hydrate; therefore, .8 pound sodium hydrate will require .4192 pound carbon dioxide to form sodium bicarbonate. The specific gravity of carbon dioxide is 1.529 and 1 cubic foot will weigh $.0766 \times 1.529 = .177$ pound· therefore, $\frac{.4192}{.177} = 2.37$ cubic feet of carbon dioxide. At each exhalation 4.38 per cent. of 396 cubic inches is carbon dioxide, or 17.35 cubic inches in 1 minute, at which rate it would require $\frac{2.37 \times 1,728}{17.35} = 237$ minutes before the sodium hydrate became converted into bicarbonate.

COAL MINING & PREPARATION

Battle Creek Mine, Tenn.

Methods of Handling theCoal Outside—Mining Methods Determined by Peculiar Geological Conditions

*By Wm. McIntyre, Jr.**

THE Battle Creek mine is 1 mile from Orme, Marion County, Tennessee. Orme is reached by a branch line of the Nashville, Chattanooga & St. Louis R. R. from Bridgeport, Alabama, although it is but a short distance west of South Pittsburg, where are the Thomas mines of the Tennessee Coal and Iron Co.

Fig. 1. Opening at No. 1 Mine, Orme, Tenn.

The Battle Creek Coal and Coke Co. has four drift mines situated on the eastern escarpment of the Cumberland Mountains, which are noteworthy mostly for good coal, inaccessibility, irregular stratification, and consequently difficult mining. The coal worked is termed the Battle Creek seam, and varies in thickness from 14 feet to 14 inches, but will as a whole average about 54 inches. The roof is slate and stratified sand rock and the floor is sand rock; it is not therefore the Swansea seam at Whitwell, that having a slate roof and fireclay floor with average thickness of 37 inches of coal.

The No. 1 mine, shown in Fig. 1, was opened in July, 1902, at an elevation of 1,540 feet above sea level. To get the coal down to the railroad at Orme, it was necessary to build a gravity plane 2,957 feet long from the upper to the lower tipple level. No. 1 opening is about 300 Fig. 5 the lower tipple. The coal bed is in a bluff about 20 feet above the upper tipple level. No. 1 opening is about 300 feet from the brow of the incline, but to reach the coal and continue in it through the mountain, it was necessary to make an 18-foot deep rock cut for about 180 feet. At this point the entry coal pinched, and work was stopped for a number of years; then, by driving through the squeeze about 30 feet, from 16 feet to 18 feet of coal was tapped. Originally the coal was dumped from mine cars into the top tipple and then into 10-ton skips which alternated on the three-rail gravity plane; owing to excessive breakage of the coal by these two extra dumpings, the plan was changed, and 11 loaded mine cars are sent down the plane in one trip, while 11 empty mine cars are pulled up the plane by their weight.

Mining was started on the double-entry system, with rooms on each entry, so that two large rooms were opened on the left and three rooms to the right-hand entry going in, and these are in high coal. The entry dipped so fast that it required a large heavy mule to pull one mine car to where the coal was found, and then the grade to the tipple is in favor of the loaded car.

The entries in Nos. 1, 2, and 3 openings are driven due west, and the rooms turned north and south as a rule. In this locality, while the coal bed has not been faulted to any great extent, the coal was formed on an uneven floor which causes it to pinch in one place and swell at another, as shown in Fig. 4 (*a*); further, the floor is rounded as if it was originally a pile of sand and this makes it necessary to give rooms the snakelike appearance shown in plan, Fig. 4 (*b*). The rooms are driven in the swags *a*, which run mostly north and south, consequently it is necessary to turn the track to avoid taking up floor; but sometimes it is possible to obtain easier haulage by taking up a little of the floor. The rolls or hogbacks are sometimes from 30 feet to 40 feet long and coal lasts from 100 feet to 300 feet; then, again, coal will last a day or two and then rock for a day or two. The roof of the coal bed is practically level sand rock and hard slate, which shows that the uneven floor conditions occurred before it was laid down. The

Fig. 2. No. 2 Opening, Orme, Tenn.

roof is strong in some places and so weak in others that it will fall for 5 or 6 feet high in an 8-foot entry.

Another opening, No. 2, shown in Fig. 2 is adjacent to No. 1, but about 800 feet away. This fine little mine is worked on the room-and-pillar system as are all other mines of the company when the rock does not cut out the pillars. Sometimes good rooms are in a swag. In No. 2 mine the coal runs from 3 to 10 feet high, with most of it between 5 and 6 feet. At present the mine is worked with four mules and 25 men, but rooms are being opened to increase the output. Mines Nos. 2, 3, and 4 are connected so that the 7-foot Stine exhaust fan pulls the air into No. 2, then to No. 3, and after it passes through the workings of No. 4

*Mine Foreman, B. C. C. & C. Co., Orme, Tenn.

mine it is discharged outside the mine. The coal bed in No. 3 mine is very irregular, owing to squeezes and faults which make its working uncertain and difficult for both the miner and the company. This mine had high coal to start with for about

Fig. 3. Upper Tipple, Orme, Tenn.

105 feet; then it pinched out quickly; next came a long stretch of rock with a little swag of coal every now and then, sometimes sufficiently high for a breakthrough into the air-course, and then possibly it would be necessary to drive from 70 feet to 80 feet before another pocket of coal was found. The manager and superintendent became almost discouraged over this, but continued through the irregular ground and reached some of the finest coal in the South. On this entry there are 12 rooms. Each one of them is separated from the other by a rock squeeze. The coal in some places is almost entirely cut out, and in one place it was necessary to go through a squeeze to get out about 200 tons of coal on the opposite side.

Waves in the ocean give an idea of about how the coal and rock lie in this mine. In the morning the miner may have good coal. When he is visited in the evening he will pass you and say "she is going to squeeze," or else he has "struck a hole and cannot find the bottom." In this mine three squeezes have been worked through in the last 4 years; one took about 2 years to cut through, and then a large pocket of fine coal was struck on the left side of the entry, and a small one to the right side of the entry, which went up so steep that a jig road had to be put in to hoist the empty cars and lower the loaded cars. After going about 80 feet the coal took a dip in the other direction, so that the miner had to shoot the coal in a hole and load the car above his head. There is a small Stine booster fan in the return air-course to assist the larger fan which is at mine No. 4.

The No. 4 mine was opened in 1902, and is the original Battle Mountain mine, from which the greater part of the coal has been obtained. It is 3,700 feet from the knuckle of the gravity plane and is connected by a narrow-gauge railroad over which the mine cars are hauled by a steam locomotive.

The main entries in No. 4 mine are driven on the three-entry system with cross-entries turned to the left and right, numbered up to 19 and 20 left and 11 and 12 right. The haulage inside this mine is accomplished by the tail-rope system which starts from the 16 left entry. Mules haul the coal to this entry. The main entries stop at this point because here the first squeeze in this mine was encountered. The right-hand air course was stopped, but finally it was cut around the squeeze in the coal, and strange to say the left air-course had coal all the way, never less than 4 feet until entries No. 15 and 16 were passed, where they encountered a roll at the end of the side track. About 1,600 feet from the main entry, right-hand entries were turned to the north in the same direction as the main entry before the roll was met. Some good coal was found here but squeezed in cross-entries 17 and 19; then it pinched out and in cross-entries 19 and 20 there is 2 feet of coal, which is about the same as a squeeze out, for that thickness of coal is not economical to work. The entry going north is in about 9 feet of coal, but the swag is only about 80 feet wide, with a rock squeeze on both sides. These entries are being driven as wide as rooms; all slate is gobbed; and the machine slack, which hurts the sale of coal, is loaded into mine cars and sent to the boilers at the mouth of this opening.

In No. 4 mine, entries Nos. 9, 10, 11, and 12 left are having the entry stumps

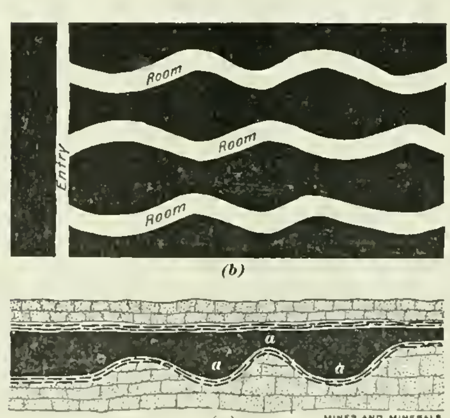

Fig. 4

drawn. New entries Nos. 9 and 10 are being driven west. The main entry squeeze took about 15 months to cut through, as there was a lack of air power to drive the rock drills. On reaching the coal, Nos. 9 and 10 right entries going

Fig. 5. Lower Tipple

northeast furnished coal for about 800 feet and then played out. These were driven about 1,500 feet further, sometimes in hard material, and sometimes in soft material; nothing was found, however, but a small streak of coal. Entries Nos. 11 and 12 right were then turned off at right angles from these entries, and still there was not enough coal found to work, but they were continued about 500 feet, then stopped and all the track taken out.

The company has never used diamond drills, but is is probable that they will make use of them to prospect the field in the future. As may be seen, conditions in this coal field are peculiar, it being uncertain whether the coal will be in a large or small pocket, as the floor of the mine rolls in serpentine courses. The main entry stayed in coal longer than any entry that was ever driven, and all the left-hand entries have been driven through from 1 to 4 squeezes, and worked until they came to solid rock. Sometimes it was possible to work around some of these pinches and thus save rock work.

To undercut coal seven Ingersoll-Sergeant punching machines are used. These give satisfaction, as they are flexible enough to cut coal on the many ups and downs in the floors. In some places the coal is faulted from 4 feet to 6 feet up or down but this is unusual. There is a very good slate or rock tipple that has been dumped over for 5 years. Occasionally it slides away with a part of the mountainside under it, but is brought back. For the outside haulage there is a 10-ton steam mine locomotive; and a gasoline motor that has given a good deal of trouble. No gases have been found in this mine, probably because of its height above water level; however, no chances are taken on this score, and

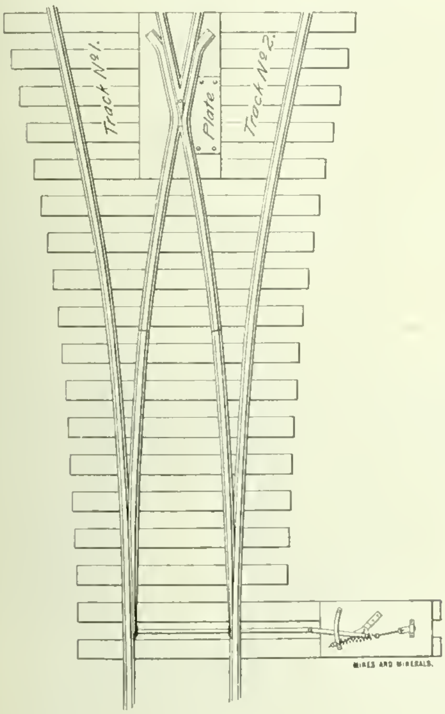

FIG. 1

ventilation is made to comply with demands for the "C" class of mines of Tennessee.

Class "C" mines include every coal or other mine employing over 20 men and 3 mules, that does not at present or may in the future liberate sufficient firedamp to be detected on the flame of a modern test lamp and has not been classed as a dry and dusty mine by the chief inspector of mines. The minimum quantity of fresh air that must be supplied to each person employed in the mine is 85 cubic feet per minute, and for each animal 500 cubic feet per minute. The inspector may demand more air than the above for each person, and has the power, if conditions warrant, to take the mine from one class and place it in another.

At the head of the incline there are two large rope drums, one in front of the other. The rope goes around both drums; five times over the rear and four and one-half times over the front drum. One-inch steel rope is being used for the 11 cars and the load that goes down an incline. Near the shipping tipple at the bottom there are two large rooms, which contain the air-compressor and a shaker screen engine. The mule stables are also at the bottom of the incline. Most of the miners ride on the incline trip to go to or from their work, Some of the miners ride down on "horses" made of a few pieces of 2-inch plank as illustrated on page 70 of MINES AND MINERALS for September, 1909.

Spring Frog and Latches

The following description of an automatic frog and latches has been furnished by James Stewart, superintendent for the St. Louis, Rocky Mountain and Pacific Co., at Van Houten, N. Mex. The incline on which it is used is double tracked and is on a pitch of 35 degrees, the tracks coming together at the bottom as indicated in Fig. 1. The idea of the frog is to do away with the guard rails in which the hoisting rope so often catches, sometimes resulting in wrecking the trip. The tongue of the frog, *A*, is dovetailed and bolted into the frog rails as shown in Fig. 2. One end of the piece *B* works in a slot in the toe of the frog *A*, and the other end is connected with the lever *C*. One end of this lever *C*, is pivoted by means of the arrangement *D*, the outer end carrying a roller. The arm *C* is held in place by the fluted spring *E*, as shown in the drawing. The frog is shown set for the left-hand track, No. 1. When the next trip comes down on the right side of the incline, the wheel of the car throws the tongue *A* into the proper position and the lever *C* assumes the position of the dotted line, where it is held by the spring *E*. The mechanism is covered by a steel plate with holes through which it can be oiled. The top of this plate is below the top of the head of the rail and is intended to remove any possibility of the rope being caught.

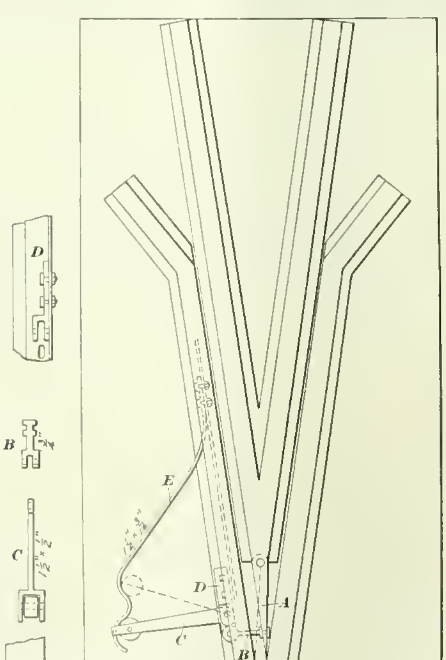

FIG. 2

The mechanism operating the latches is also covered with a plate of the same dimensions as that upon which it is fixed, and is shown in its several details in Fig.

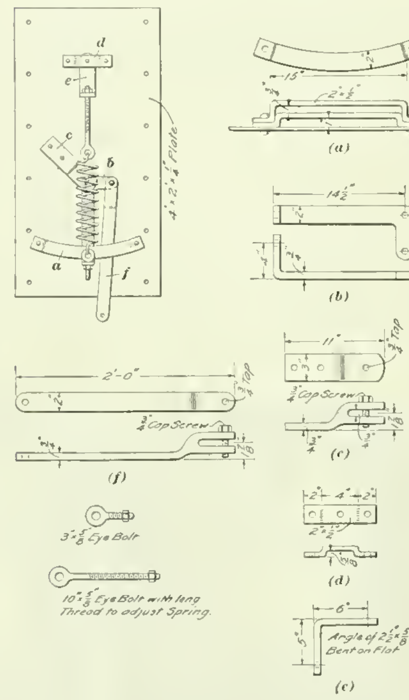

FIG. 3

3. In Fig. 1, the latches are shown set for the left-hand track No. 1. When the following trip descends on track No. 2, the latches are thrown. The lever carrying the springs is thrown over to the opposite side of the sector from that shown in Fig. 1, in which position it is held by the spring until set by another trip on the opposite track. Mr. Stewart uses a spring from an old automatic tipple.

The motor truck is now a real factor in mining. In the prairie and desert regions, the introduction of automobile traction haulage has had a pronounced effect in stimulating mining. Not only does it render a new camp more independent of railway facilities in getting started, but, having decent wagon roads, both mining and milling plants are able to operate successfully. Recognizing this modern idea, the county commissioners of many of the western states pay attention to the building of splendid roads. Throughout Utah, Nevada, and California, the citizens have awakened to this "good roads" sentiment. There is one highway now completed clear across the state of Nevada, and this has been built with the idea of boosting the mining industry.

Mine Supports in Germany

Various Forms of Timber, Steel, and Concrete Supports. Use of Rails, Pipe, and Flat Iron

Translated for Mines and Minerals

In the Schwallbach mine in the Saar district, Germany, the greatest pressure comes on the timbers from the floor and sides of the excavations, owing to the strong roof. Three-stick timbering only lasted a short time, and in addition there was considerable difficulty and expense incurred in keeping the galleries free from creep. The timbering shown in Fig. 1 (*a*), (*b*), (*c*), (*d*), (*e*), and (*f*) represents the various methods adopted to brace the three-piece sets. When using the bracing shown, the customary scarfing between the collar and legs of the set is omitted, and at first the somewhat cheaper form of arranging the braces as in (*a*) was selected. This proved unsatisfactory on haulage roads, and the forms of bracing shown in (*b*), (*c*), and (*e*) were chosen. The effect of floor pressure is shown in (*d*), where creep has caused the floor braces to buckle, owing to their being inserted too flat, and thus assisting in causing the legs of the timber set to be moved by the pressure. After this experience, the floor braces were pitched at greater angles, as in (*e*), and the legs of the sets were placed almost vertically. The braces then took the form of an irregular hexagon in which the two side pieces parallel with the legs are the shortest, while the upper and lower braces have the same lengths. Round sticks about 6 inches in diameter are used for braces, and, as shown, are separated from each other by longitudinal timbers, which makes a compact and solid frame. In this case the haulage road does not rest on the lower braces, but on ties, which are supported by sills made from the legs of old timber sets. The cost of three-piece timber sets was $2.26 per linear foot, and they lasted on an average about 3 months before they were replaced. The sets with the present method of reinforcing cost about $4.86 per foot, but they last 1 year, or four times as long as the three-stick set alone, which means that they are only one-half as expensive.

The cost of the first braced structure was $2.69 per foot, and lasted about 6 months, while the second design (*e*) promises to last over a year, which means that it is considerably cheaper than the three-set timbering without braces. The distance of the sets apart will depend entirely on the kind of material in the walls of the excavation and the pressure coming on the timber sets.

At the tunnel of the Consolidated Fürstensteiner mines, iron collars or beams are placed across the excavation. These rest on legs as shown in Fig. 1 (*g*). In this mine the roof exerts considerable pressure, and this particular form of collar has been adopted with great success where those made of rails alone have failed. The collar consists of two iron rails curved as shown, bound together at the ends and bolted to a flat iron tie piece.

The pressure acting downwards on the rails is transmitted to the flat iron straining piece, which receives the tensile strain through bolts and the turned up ends shown. It has been proven that these truss beams have five times the bearing capacity of straight iron rails. They have been in use over 1 year, exposed to exceptionally heavy pressure, where formerly five iron rails bound together were either bent or broken within 3 to 5 months and had to be renewed. The collar or truss, consisting of two iron rails with flat iron ties underneath, costs $21.25 for material and labor in Germany.

In the Essen-syndicate mine, "King Wilhelm," in the South Essen mining district, iron and concrete posts are used as mine supports. This mine is worked "longwall" and the traveling roads are kept open by pack walls. At the angle formed by the junction of two roads, "the lye," it is necessary to use extra care

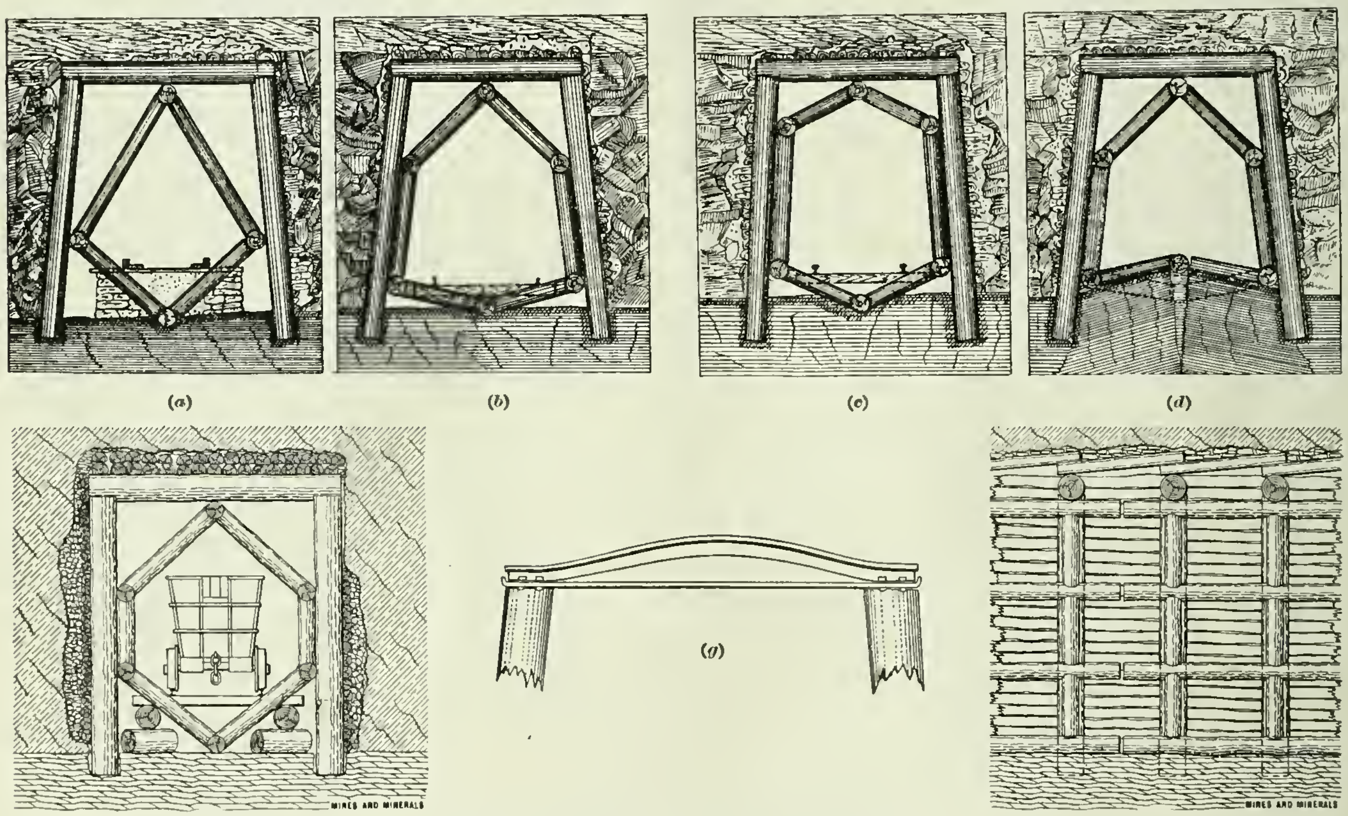

Fig. 1. Methods of Timbering Used in Germany

*Zeitschrift fur das Berg-Hutten-U. Salinenwesen.

with the walls, and usually timber, to make the supports sufficiently strong to prevent the roof settling. The iron and cement post introduced in Germany is shown in section, Fig. 3. The iron posts consist of old cast-iron or wrought-iron pipes flanged at the ends as shown. These are set up at the junction of two roads and the

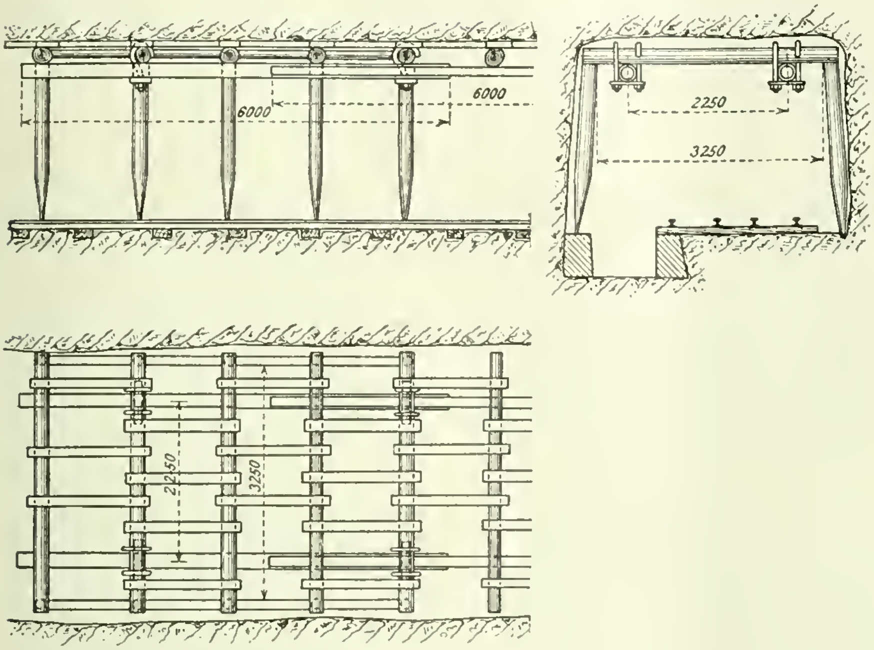

Fig. 2

pack wall partly built about them. The foot-rest is of plank and a sufficient number of wooden cap pieces are placed on the upper end to furnish the proper height for the roadway. The cap pieces at the base of the post are sunk in the floor, those at the top are strapped, as

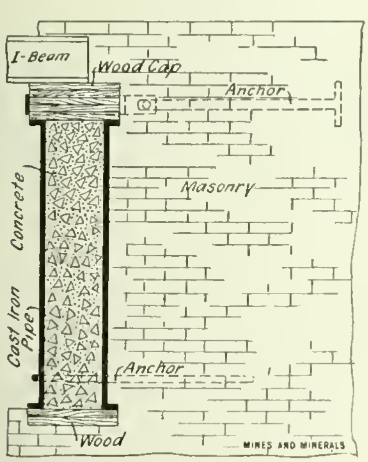

Fig. 3

shown, with an iron band and anchored in the pack wall. The lower part of the post is anchored in the same way in order to insure its remaining perpendicular and not being moved by a local movement of the pack wall near the road, the pressure of course at this place having a tendency to push the wall out into the empty space.

This kind of support has proved successful so far, but has not been in place over 1 year.

In the Bülten-Adenstedt iron mines belonging to the Ilseder Smelting Works, in the Goslar mining district, the ore bed is about 16.5 feet in height. The posts are therefore long and the collars, which are about 14 feet long, are supported by three posts fastened to the roof by an iron hoop (Fig. 2) and a wedge screw. The object of these hoops is to prevent the posts from being completely knocked out, as frequently happened when blasting before they were introduced. The hook arrangement facilitated work, as the props could be reset without great difficulty. In the Kings mine in the Königshutte coal mining district somewhat similar conditions prevail, and in order to save the posts from being knocked out through rock pressure or fall of rock or coal, the device shown in Fig. 4 is used instead of the hoop. It consists of an iron chain with a large ring at *a*, a smaller ring at *b* and a hook at *c*. The chain is wrapped about the post by drawing it through the large ring; it is then carried up over the collar, brought back, and the hook fastened in the ring *b*. In case a shot or rock fall knocks out the lower end of the post, the chain holds the post from falling and it can be put in place quite readily. This contrivance, which is made in the blacksmith shop, has stood the test wonderfully well.

The Reinhard system of movable props has been changed somewhat since 1910, and the new form shown in Fig. 5 has been adopted in the Reden mine in the Saar district, to some extent.

The post shown in section (*a*), Fig. 5, consists of a pipe flanged at the bottom for a wooden foot-piece, and a jack-screw and nut, with a movable head surmounting the jack-screw. The head is constructed so as to receive a rail upside down, and with a slot in which a wedge is driven and which when keyed tight will force the rail up against the roof.

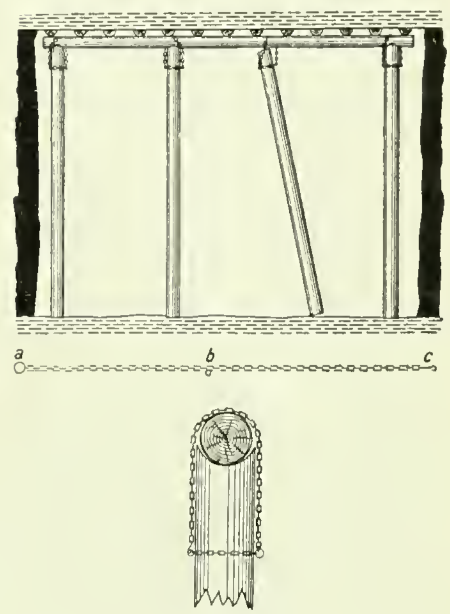

Fig. 4

The nut fits loosely into the upper part of the pipe. When making use of the portable prop a piece of plank is placed between the top of the head and the roof. The jack-screw is then worked and the

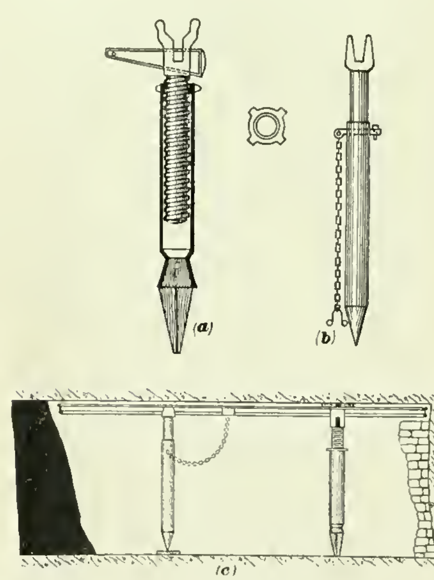

Fig. 5

post fastened rigidly in place. An old mine rail is lifted and placed in the head; one part being carried by the auxiliary prop (*b*), after which it is wedged in position. Lagging or wooden blocks are next driven above the rail.

The auxiliary post (*b*) consists of pipe, chisel shaped at the lower end and containing a movable shaft that projects from the upper end, and which can be fastened in almost any place by a pin as shown. The upper part of the shaft has a grooved head for taking the rail and holding it near the roof. The post is securely connected to the rail collar

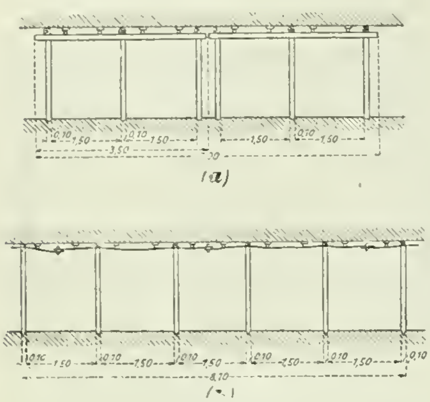

Fig. 6

by a chain. As the heading is advanced the rail collar is released and moved forward by knocking back the wedge in the movable prop. When the rail has been advanced sufficiently it is again wedged without the necessity of moving the main prop; however, the auxiliary prop is moved forward a distance corresponding with the movement of the rail. When the rail has been advanced to nearly its length, a new main post is placed under the center before any further advance is undertaken. The released main post is controlled by the jack-screw and can be used for another rail collar which has been advanced nearly its entire length. The distance from one rail collar to another depends upon the condition of the roof, but is generally from 2½ feet to 3½ feet. The principal advantage derived from the portable props, as compared with others, is that the roof is always supported during the moving ahead of the rail collars, because the main post remains in position and is not loosened. This avoids the danger generally present when placing timbers in a heading having poor roof. The system is recommended where the roof is traversed by vertical cracks and joints without being fissured so it has to be held up by special timbering.

When the collars are crushed above the posts so as to render them useless when recovered, as in the Heinitz mine in the Saar district, flat iron has been adopted with success. The flat iron bars as shown in Fig. 6 are placed exactly like wooden roof beams upon posts and held tightly in place by wedges driven between them and the roof. After several experiments, flat iron bars ⅖₁₀ inch thick by 2 inches wide proved most suitable. They are punched with holes in the ends in order that they may be tied together successively. One disadvantage due to the flexibility of the iron under heavy pressure and which caused the posts to crack, is overcome by tapering the lower ends of the posts so they will broom and permit the roof to settle without breaking the props. Through the use of the flat iron construction an economy in props is accomplished, as may readily be seen by comparing (*a*) and (*b*) Fig. 6. The prescribed distance between props, 5 feet, is maintained when flat iron roof beams are used, while where wooden posts are in use the adjoining ends of two beams require one post each. The weight of the flat iron having a section $2 \times \frac{1}{4}$ in. is about 1.69 pounds per foot which, with bar iron at 2 cents per pound, would cost 3.38 cents per foot. Provided the flat iron is in use 1 year and lengthened five times each month, the management estimates that about 95 per cent. of the money heretofore expended on wooden beams will be saved. Those parts of the flat iron which have been bent by the pressure of the wedges and posts are straightened out by hammering.

Air Compression

The efficiency of compressed air can be greatly increased by reheating. The gains are both direct and indirect. The chief direct gain is in the greatly increased efficiency of fuel used in the heating stoves as compared with the effect when coal is burned under boilers. It is commonly stated, and the statement is fairly correct, that when 1 pound of coal is burned in a reheater stove the commercial effect is as great as when 3 pounds are burned under a boiler. The increase in commercial efficiency when reheating air from 60° F. to 400° F. may be put at 35 per cent. The indirect gains are better lubrication of the compressed-air engine; less investment required, as a smaller plant will be needed; reduction of compressor engine friction as compared with the useful work done.

Briqueting Lignite

A number of tests have been made by the fuel-testing plant of the United States Geological Survey, and later by the Bureau of Mines, to determine the best methods of briqueting North Dakota lignite. It has been found that the lignite can be briqueted, some of it without a binder, and that its efficiency is thereby materially increased. The briqueted product also stands weathering and handling much better than the raw material.

Steaming tests have also been made with specially constructed fireboxes and grates and the results are highly satisfactory, as the efficiency of this lignite when properly fired is so increased as to compare very favorably with that of fuel of higher grades.

The following statement has been made concerning the efficiency of North Dakota lignite in the gas producer and gas engine:

"The result of the steam test was so unsatisfactory that there is nothing by which a direct comparison can be made of the efficiency of the fuel used in the producer-gas plant as compared with the efficiency developed in the steam plant. Nevertheless, a comparison of the results obtained on other coals under the steam boiler is instructive. It shows that to produce one electrical horsepower hour in the producer-gas plant required 2.29 pounds of dry North Dakota lignite, whereas to produce the same result in the steam plant, required 3.39 pounds of the best West Virginia coal. This means that the North Dakota lignite, with the moisture eliminated, will do more work when used in a producer-gas plant than the best coal of the country will do in a steam plant."

Danger Signals in Pennsylvania

In accordance with Section 3 of Pennsylvania Bituminous Mine Code enacted June 9, 1911, danger signals in all mines must be uniform and of a design approved by the Chief of the Department of Mines. This law was enacted because fire bosses used whatever seemed to be handy as danger signals. Some would place a piece of board across the track; others wrote the word "Danger" on a piece of sheet iron or an old shovel. Jas. E. Roderick, Chief of Department of Mines, approved the following signal. The size of the signal

Approved Danger Signal

is 10 in.×30 in. with an oval in the center 10 in.×14 in. The color inside the oval is red and the color outside is black. A signal 24 in.×30 in. with the other dimensions as described will be satisfactory. The last paragraph of Section 1 of Article 5, reads: "The meaning of all danger signals shall be explained to the non-English speaking employes of the mines in their several languages by the mine foreman, assistant mine foreman, or fire boss through an interpreter." A sample signal should be placed on the surface so that the non-English speaking employes can see it and be taught what it means when placed in any entry or at the entrance to a room or the entrance to any place in the mine where such signals are likely to be found.

Electric Shot Firing

Apparatus Designed to Permit Shots to Be Fired From the Surface at Will in Any Part of the Mine

By Lucius L. Wittich

EXPERIMENTS with the new electric shot firing system conducted by Erich Schietzel, the inventor, convinced those who witnessed them at Arma, Kan., that the invention is practical. The object of the invention is to eliminate the loss of life of shot firers, as all shots are fired from the surface and the mine may be vacated before the first blast is exploded.

Although Mine No. 8, of the Hamilton company, at Arma, is a new producer, having been placed on a tonnage basis November 7, 1911, some trouble has already been experienced from dust explosions, a serious accident of this kind having resulted from a windy shot early in October. On this occasion the two shot firers in the mine at the time narrowly escaped injury, and ventilation doors in the entries were blown from their hinges and more or less damage was done to mine equipment throughout the underground workings. Other mines in the southern Kansas district have experienced much trouble from dust explosions, and the operators of the Hamilton mines concluded that it was only a question of time until their new No. 8 property likewise would become subject to such disasters. As a rule the explosions have been bad enough only to damage the mine equipment, but occasionally a life is lost, and the annual death toll includes a number who have died in this manner. The pay of shot firers is high throughout the district, the rate ranging from $4 to $6 for an hour or two's work in the afternoon after the regular miners have quit their labors.

Mr. Schietzel, the inventor, formerly was employed by a German firm manufacturing electric shot-firing devices. The great drawback to the firer manufactured by this firm was the necessity of running two wires from the surface to each room, or group of rooms, to be shot. Where it was desired to shoot 40 or 50, or even more, rooms it can be realized that an intricate tangle of wires would of necessity be run down the shaft, and in such installation there would be serious danger of the wires becoming crossed. For years Schietzel worked on a device by which the rooms could be fired at intervals and at the same time do away with the necessity of running so many wires from the surface into the workings. The result was the invention of his sparker box which makes it necessary to run only two wires into the mine. It is claimed for this invention that it is the only one in existence requiring only two wires operated from a switchboard on the surface.

Fig. 1, an enlarged diagram of a portion of the mine workings of the Hamilton No. 8 property, shows the idea of installation of the wiring system, the safety switch boxes, and the sparker boxes.

The main wires are run down the shaft to the safety switch box *a*. When workmen are in the mine this switch is thrown out, and consequently all wires beyond this box, in the mine workings, are dead. Only the firer is to be equipped with the key to the safety boxes, and by a simple little device, a metal rod attached to the inside of the door, the switch must be thrown out when the door to the box is closed, as the rod will not permit of the door being closed when the current is on.

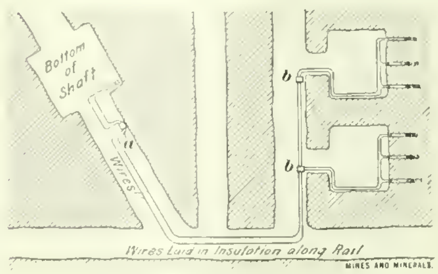

FIG. 1. WIRING FOR ELECTRIC SHOT FIRING

From the safety switch box *a* wires are run in both directions in the mine, connecting with the sparker boxes *b* which are placed at convenient and safe places on the entry at the necks of the rooms. Where it is desired to shoot more than one room at once, one box may answer for two or three or any number of rooms; but as the disadvantages connected with firing more than one room at a time are many, it is considered advisable to employ one box for each room to be fired.

From each sparker box, two leading wires extend into the room and are attached to the fuses.

The sparker box is $5\frac{1}{2}$ inches in width, 6 inches long and $2\frac{1}{4}$ inches in thickness. It is composed of metal. The front is removed by taking out four corner screws. Packing is used in setting the front in place in order that it will be water-tight. In Fig. 2 is seen the interior view of the sparker box, the front being removed. The two-wire system and connections at the top of the box are the main wires through which comes the current from the batteries or other power sources on the surface. Three of these wires, *A*, *B* and *C* are live wires. The wire *D*, in all sparker boxes, is a dead wire until after the room has been fired when the mechanism of the box throws the current into wire *D*, thus completing the circuit to the next box in which the wire *D* likewise is dead until after the room has been fired and everything is in readiness for the current to continue to the next box.

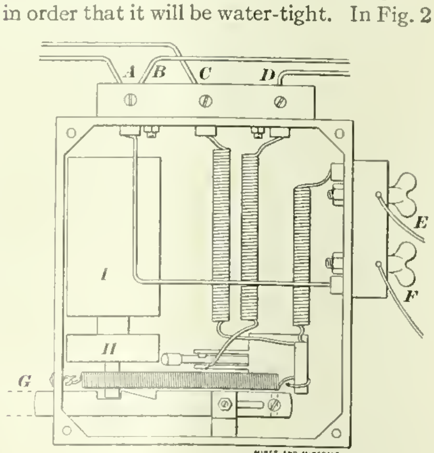

FIG. 2. INTERIOR OF SPARKER BOX

At the side of the box, the wires *E* and *F* are the leading wires and extend into the room. The miner uses his own judgment about placing these wires. It is policy to fasten them securely at the opening to the room, but they may be hung loosely on the wall, out of the way, in the main body of the apartment or tacked loosely to the timbers by the side of the road up to a safe distance from the face of the working place. The button *G* at the lower left-hand corner of the sparker box must be pressed in before the shots in the room are connected with the switchboard on the surface. The fact that the safety switch at the bottom of the shaft has not yet been turned and that there is no current in the mine eliminates the possibility of danger from this proceeding. Failure to press this button in disconnects the shots in this particular room from the switchboard and the shots, as a result, will not be fired, but the circuit will be left open in this box and in all other boxes where the miner has neglected to push the button and the current will pass on until it comes to a box that is connected with the shots. Even were the safety switch thrown on, and even though connections were completed with the surface, there would be no chance of an explosion until all was in readiness, as the discharge of the blasts is regulated by the operator at the switchboard.

After all is in readiness for firing the last step taken underground is the throwing of the switch to place the underground wiring in connection with the switchboard. Should lightning strike the wires somewhere above at this time, the result would be the firing of possibly two rooms, but such a circumstance would be rare. Even should it occur there would be comparatively little danger to the one remaining man in the mine as he would be at the bottom of the shaft awaiting to be hoisted, and even should a fire result from the blast, which would not be likely in view of the small amount of powder discharged, he would have a reasonable length of time in which to reach the surface before the force of the explosion would overtake him.

Connections from the sparker boxes to the blasts in each room are made to obtain a complete circuit. The method is simple, and even the miners who have never had experience in electric shot firing soon learn the method. Whoever is placed in charge of the firing has ample time during working hours to go from room to room and instruct the miners in making their connections properly.

A Kansas law provides that no more than three shots be placed in one room. At the Hamilton mine the workmen are generous with their powder. They use a cartridge about 4 or 5 feet in length. FF powder is in most common use. Each cartridge holds from 4 to 5 pounds of powder.

The switchboard was stationed in the engine room of the mine, the current being obtained from a dry battery. The inventor demonstrated his ability to fire rooms in either side of the mine at will. By switching the current he could fire shots in first one side of the mine and then the other, or he could first complete the firing of one entire side; then switch over to the other side. However, it is desirable to alternate, as this method permits the dust and gas created by the shots to clear away in each instance before firing the next room or entry.

Schietzel maintains that it is policy to fire the rooms nearest the shaft first in order that the smoke and dust may more rapidly lift should it be found necessary to go into the workings for any reason after one or two rooms have been fired.

The arrangement at the Hamilton mine enabled the inventor to begin firing the rooms nearest the shaft, thus winding up with the firing of the shots in the entries. The east and west entries had separate wiring. He could fire one, two, three, or as many rooms as he desired on the east side; then switch and fire as many as desired on the west side.

Two wires lead from the switchboard down into the mine. It is necessary that they be run through conduit or lead-covered cable down the shaft, and it is advisable to have them so protected throughout the mine.

At the top of the switchboard, Fig. 3, are three instruments, each equipped with a dial, the instrument to the left being an ammeter, the one in the center an ohmmeter and the one to the right a voltmeter. Beneath the ammeter dial is a switch, in a box which cannot be closed if the switch is connected with the battery. This is merely a safety precaution insuring a dead wire into the mine workings as long as this switch box is closed. In beginning the firing test, the inventor threw the switch to the ohmmeter, which tested the wires and connections. A correct reading on the ohmmeter is required in order to insure perfect connections. When the ohmmeter registers correctly the operator throws the switch downward, which connects the board with the batteries. At the right of the board, beneath the voltmeter is a second switch which throws the current into either side of the mine desired.

As rapidly as the battery or dynamo switch can be thrown out and replaced again just so rapidly can the rooms be fired. In case of a short-circuit a fuse plug in the center of the board will be blown out. The firing of the shots is registered by the ammeter. Should the switchboard be installed at a mine where the electrical equipment furnishes a current of 300 volts or more it would be stepped down with the rheostat located beneath the fuse plug. Only 75 to 100 volts and $2\frac{1}{2}$ amperes are required to operate the firing system. With this power the inventor claims shots may be fired to any distance. As the firing of the rooms is done consecutively, the operator knows at all times which room is being fired. A diagram of the mine workings can be utilized to advantage in the operation of the switchboard, and should any room fail to respond to the current the operator knows at a glance where to go to make an investigation of the trouble.

When the current reaches the first box, it exerts a magnetic influence on the disk H,

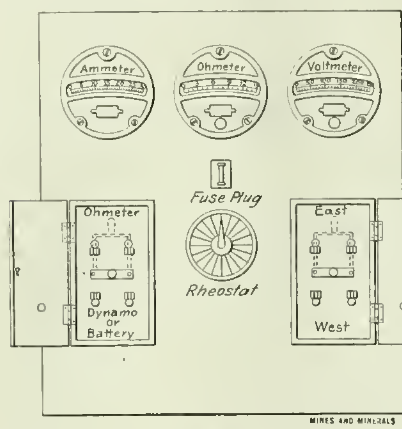

Fig. 3. Switchboard

which is drawn upward to the magnet I, thus releasing the rod G, which of necessity must be pushed in before the current can carry into the room where the shots have been prepared. The rod, thus released, returns to its original position, permitting the current to travel to the next sparker box. If this rod is not pushed in the first place, the current goes through this box to the next box. When the rod is pushed in, the current to the next box is disconnected and the only way the rod can be thrown out is for the room to be fired or for the lid of the box to be removed and the disk H lifted. This device prevents any one meddling with the box after the button has been pushed in and it has been placed in readiness for firing. Under ordinary circumstances it does not become necessary to remove the lid of the box, as the firing of the room springs the button back into original position and the current into that room is dead until the button is again pushed in.

As it is often found advisable to cause the shots in a room to be fired in quick succession, rather than simultaneously, a delay-action fuse can be used in connection with the shot-firing device herein described. One shot may be fired by a direct-action fuse, which ignites instantaneously and is sensitive to the electric current. The delay-action fuse receives the current at the same instant as the direct-action fuse and ignites a tape fuse which extends from the tube connecting with electric wires. The tape fuse may be timed to ignite the powder from 5 to 10 seconds later than the instantaneous fuse.

Several interesting demonstrations were made by the inventor. He did not have the entire mine wired when he started on his experiments, but eventually the entire workings were equipped and the necessity of a shot firer going under ground was eliminated. Some trouble was experienced with the union laborers before they would look favorably on the invention. They had complained that the possibility of serious accident from shot firing was great, yet they hesitated before giving sanction to a device which would eliminate the necessity of a man being in the ground when the blasts were fired. The shot firers who had been getting high wages for a few hours work were the ones who opposed the installation of the system. The demonstration was under the management of the Schietzel Electric Shot Firing Co., of Des Moines, Iowa.

United States Coal Exports

The value of the coal sent to foreign countries last year was $52,500,000, against $21,000,000 in 1902 and $8,333,000 in 1892, having increased over 500 per cent. in 20 years and 150 per cent. in the last decade.

Even these large figures of more than $50,000,000 worth of coal sent to foreign countries in the fiscal year 1912 do not include the value of that passing out of the country in the form of "bunker," or fuel coal laden on vessels engaged in the foreign trade, which aggregated nearly $23,000,000 in value, making a total of over $75,000,000 as the value of the coal passing out of the United States during the fiscal year.

The quantity sent to foreign countries was, according to figures compiled by the Statistical Division of the Bureau of Foreign and Domestic Commerce, 17,500,000 tons, against 7,000,000 in 1902 and 2,500,000 in 1892. Thus the quantity exported in 1912 is seven times as much as in 1892, and the value over six times as much in 1912 as in 1892. Coke exports also show a decided growth, the value in 1892 having been but $112,000 and in 1912, virtually $3,000,000.

A comparison of the quantity and value of coal placed for fuel purposes on board vessels engaged in foreign trade in 1912 can only be made with comparatively recent years, the figures of bunker coal laden on vessels in 1912 being 7,093,212 tons, valued at $22,802,876, against 6,003,794 tons, valued at $19,671,778 in the fiscal year 1909, the earliest date for which complete figures of bunker coal movements are available.

The Coal Dust Question

A "Wet Mine" Not Necessarily a Safe Mine—Practical Methods of Applying Stone Dust Described

*By Samuel Dean**

THE following is taken from Section 18 of the Colorado Coal Mine Regulations: "That in all coal mines known to generate explosive gas that the owner or agent shall provide and adopt a system by which water under pressure or otherwise shall be sprinkled and make damp all accumulations of fine coal dust from time to time that may accumulate on any haulage road, rooms, stopes, or other working places."

There is often a scarcity of water in the vicinity of the mines in the Rocky Mountain region, and should the law be revised at any time it would appear that this part of it should be given careful consideration.

Where stone dust is distributed through a mine in such a manner that small coal, or coal dust would become thickly mixed with, or diluted by the stone dust at the initial stage of an explosion caused in any manner, the mixture cannot come under the head of "coal dust," having regard to the view of the coal-dust danger as it exists today.

At Hastings, a Colorado coking coal mine, where an explosion occurred in June last, there is no shortage of water. The explosion traveled through naturally damp workings, which are being driven to the dip. A stream of water flows down the back slope, or intake airway, and water drips from the roof in places in the main slope, or haulageway, which is also the return airway.

Everything pointed to a quantity of gas near the face of a heading off the third south having been ignited by a defective Wolf lamp in the hands of a fire boss (about five-eighths of an inch of the gasket on the top of the glass was found bent over, and the lamp ignited explosive mixtures on the surface during tests made after the explosion). The condition of the body of a miner found in the third north heading about 650 feet from the point of origin, gave valuable information. This man was evidently standing with his back to the face of the north heading when he was met by the blast. From head to feet his body was punctured with small coal. In the pioneering cloud of the explosion there was not dust alone; the unfortunate man had been struck in the chest by a piece of coal or rock which left a deep wound 4 inches in diam-

*Delagua, Colo.

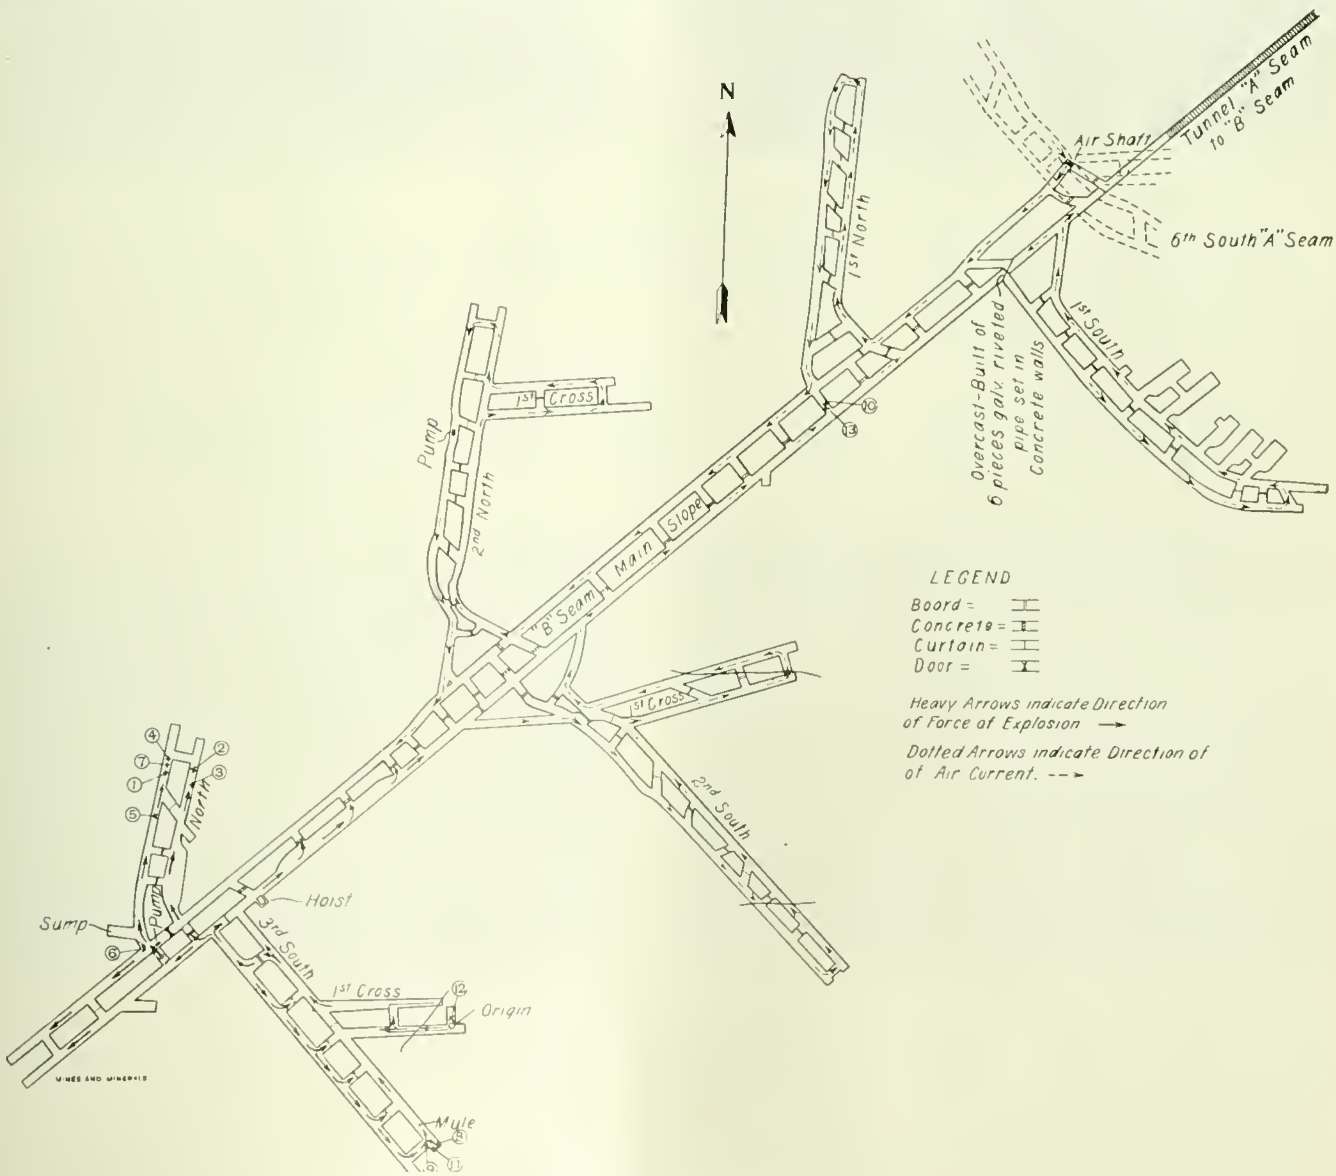

FIG. 1. PLAN OF WORKINGS IN B SEAM, HASTINGS MINE

eter, and there were other wounds from 1-inch diameter down to the size of a pin head. His hair was singed. The flame did not strike him first, otherwise he would not have been standing erect facing the onrushing small coal. The flame and the "cloud" may have been traveling together, but it is a reasonable conclusion that the flame obtained its fuel from the cloud of damp dust and coal assisted by a small percentage of methane in the air-current, and in that manner the explosion was propagated up the slope. Above the outby end of the rock tunnel from *A* seam to *B* seam (see plan), or over half a mile from the point of origin, beads of coke were found on the props, the coke adhering to the outby sides of the props. Coke was also found in other places nearer the point of origin.

It is important that all bias be removed when considering this explosion. The first State Inspector to enter the workings after the disaster declared that the explosion had traveled through a wet mine. Pools of water lay in the cross-entries driven north and south. Water was loaded with the coal at some of the faces and dripped from the cars as they were hauled up the slope. The wet and dry bulb readings taken before the explosion in all parts of the mine showed relative humidities which varied from 92 to 97 per cent. with an average temperature of 60° F. Yet some parts of the mine which were not touched by water, but only came in contact with the humidified air, would not be considered sufficiently wet by the critical observer. And it was possible to pick up handfuls of comparatively dry fine coal in places where it had fallen from the end-gate cars and been crushed by the traffic. But it is doubtful—and this statement is most important—if it is possible to constantly maintain, by artificial means, in a naturally dry mine, the damp condition which is general in all parts of this mine during the summer months. And it should not be forgotten that this explosion occurred in the summer time.

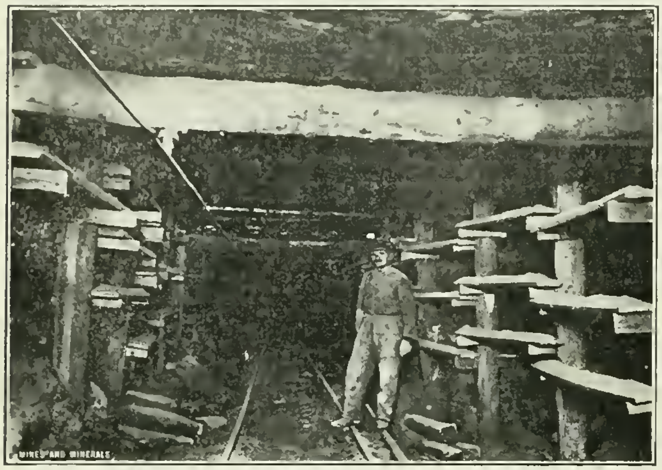

Fig. 2. Adobe Dust on Shelves on Sides of Airway

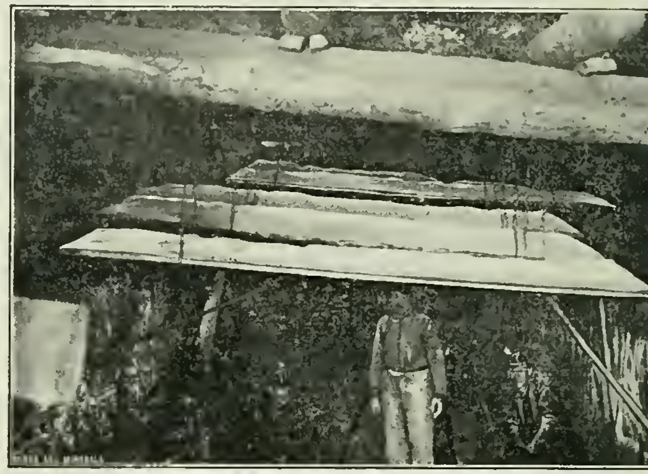

Fig. 3. Adobe Dust on Shelves Hanging From Roof

The origin or the cause of the explosion was gas, but any suggestion that gas alone was responsible for the propagation of the flame for a distance of over half a mile will not bear investigation and can be dismissed. Before the accident the quantity of air entering the back slope was 20,000 cubic feet per minute, and the amount of methane traveling with the return air up the main slope has never been found to be as much as 1 per cent. of the mixture; three-tenths and one-half of 1 per cent. has been found. The explosion occurred about 9:30 p. m. on June 18 last, and the following are barometrical readings taken on the dates, and at times stated:

Date	Time	Reading
June 14	7 a. m.	23.57
June 15	7 a. m.	23.50
June 16	7 a. m.	23.70
June 17	7 a. m.	23.87
June 18	7 a. m.	23.80
June 18	9 p. m.	23.88
June 19	7 a. m.	23.88

The Hastings mine is located in the eastern foot-hills of the Rocky Mountains at an altitude of 6,450 feet above sea level. The maximum and minimum barometer readings recorded are, respectively, 23.99 and 23.00. It will be observed that the explosion occurred when there was a high and rising barometer.

Where the rock tunnel connects with the upper, or *A* seam, the height from the rail to the roof is 20 feet, tapering down for a distance of 200 feet to where the roof joins the ordinary height from rail to top of *A* seam. Wide openings also branch off in three directions at the top of the tunnel. These openings have other branches leading into worked-out areas filled with air no doubt lacking in oxygen. The explosion appeared to have gained its greatest force coming through the tunnel, every timber being swept out, but on getting expansion in the high and wide places the pioneering cloud split up, the flame no longer had that concentrated supply of fuel necessary for propagation, the pressure was relieved, and the explosion ceased. Had the slope continued with a cross-sectional area similar to that of the tunnel the explosion would no doubt have traveled to the outside with terrific force.

An important change might have been revealed by comparing the results of microscopical, chemical, and distillation examinations of small coal and dust gathered from the path of the explosion, and of coal from the *B* seam which had not been in contact with flame, a change which might have convinced the most skeptical as to the cause of propagation.

At the Delagua, Colo., mines, adobe dust has been applied over 8,500 linear feet of entries. And in case of an ignition of firedamp, or in the event of an explosion starting in any other way, reliance would be placed upon the adobe dust on shelves and projections along the entries to prevent the spreading of the flame. It is not considered possible for an explosion to be propagated, by the aid of small coal or coal dust, through the entries which are adobe dusted. Figs. 2 and 3 show the different arrangements of shelves in the fourth and fifth north entries. These two entries, with the cross-entries turned off them, are treated in this manner. The first, second, and third north main entry districts are still sprinkled with water, so that at the present day there is a good opportunity to compare the two methods in use at Delagua.

Up to the present time adobe dust has not been applied at the face of working places. Firedamp is seldom found and then only in very small quantities. The coal is undermined and blasted with permissible explosives. Special shot firers are employed who condemn all shots drilled in the solid, or drilled deeper than the undermining. The charge limit is 1½ pounds of explosive tamped with adobe. It is seldom that more than 1 pound of explosive is used per shot, but over the charge limit is sometimes used in rock shots; and the roof, floor, and sides are thickly adobe dusted for 100 feet on each side before the shots are fired. Shot firers make daily report, as shown in Fig. 4, and strict compliance with the rules is enforced. Under these circumstances it has not so far been considered necessary to apply inert dust at the face.

Fig. 4

Efforts are made to keep the main roads clean, and free from accumulations of small coal, and coal dust, but success in this direction is not always attained on account of the quantity of coal which falls from the end-gate cars, and the difficulty in procuring regular labor to load out the piles of small coal at night. The two men who erect shelves and distribute adobe during the day time, scrape up the small coal which accumulates between the rails and leave it in piles along the side of the road. These piles are not considered dangerous, on account of containing a high percentage of adobe, and because of the heavy supplies of adobe dust on the shelves, but they are removed whenever men are available for the work. Occasionally water has been sprinkled between the rails where the roof and sides are covered with adobe dust. In the cross-entries reliance is placed upon the adobe on the shelves, and that which has been thrown on to the roof and sides by hand, also on the crude adobe which has been scattered over the floor and mostly reduced to dust by the traffic. Small coal and dirt in cross-entries is not removed except when it impedes the traffic.

About three times a month all surfaces of the fourth and fifth north haulage roads, and the slope are given a covering or coating of adobe dust which is applied by machine. This machine is composed of a small Roots blower belt-driven from a 3-horsepower direct-connected motor taking current through a trolley pole, the whole being carried on a truck. The quantity of dust which the machine will blow or distribute is 100 pounds in 12 minutes. The finer particles of dust propelled from the blower will travel a distance of over 2,000 feet suspended in the air where the air-current is traveling at a speed of 300 feet per minute. The mechanical dust distributing train consists of a locomotive, mine car containing dust in sacks, and the machine. Two men are employed, one on the locomotive and the other feeding the machine and handling the hose. The train seldom stops, but proceeds at a slow pace with the man at the hose spraying from side to side and on the roof. In this way over 2 miles of entries can be covered in a night. It is interesting to notice that after treatment of this kind entries driven through solid coal resemble rock tunnels.

In addition to dust placed on shelves, all ledges, holes, and natural projections along the entries are cleared of coal dust, and filled with adobe dust by hand, so that such places can never again become resting places for dangerous quantities of fine coal dust. The upper sides of all roof timbers are covered with adobe dust. All shelves which have been erected recently are practically fireproof, being covered on the upper side with thin sheet iron.

The thought has been expressed that large quantities of stone dust in mines may cause pulmonary troubles. Where adobe dust is used no trouble of this kind has developed, nor have the workmen in the mine suffered any discomfort. But undoubtedly

Table I. Altofts Shale Dust

Specific Gravity	Percentage of Magnetic Particles	Solubility in Distilled Water	Solubility in Dilute Hydrochloric Acid	Solubility in a Digestive Fluid

Adobe Dust				
2.77	.50	4.586	9.336	4.591

the adobe in the vicinity of Delagua is not of such a clayey nature as that found further south and in parts of New Mexico. It has been decided to install a mill for the purpose of reducing suitable shales to dust for use in the mines at a future date.

Through the kindness of Doctor Garforth the Delagua adobe has been microscopically examined by Mr. H. Crowther, who has made a comparison of the Delagua dust with the Altofts dust made from clay, or argillaceous shale, inasmuch as the latter has been favorably reported on by Dr. J. S. Haldane, the eminent physicist (see report of Mining Association of Great Britain, page 120): "The dust used at Altofts colliery for stopping coal-dust explosions is from soft shale, and is certainly not of such a nature as to give rise to any anxiety as to the effects produced by inhaling it, particularly as the amount inhaled would be

Fig. 5. Gathering Dust From Country Roads

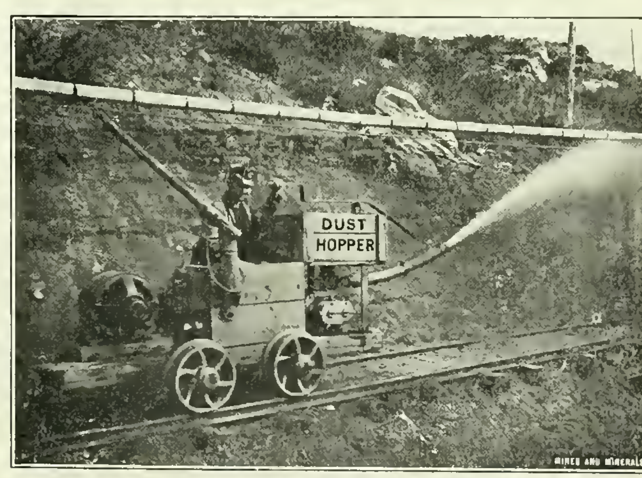

Fig. 6. Dust-Blowing Machine

small . . . . It would be well to point out, however, that dust from hard stone, fireclay, sand, or any material containing free silica ought not to be employed."

In Table 1 are given the specific gravities and the solubilities in several fluids of the two kinds of dust.

It will be seen that the adobe has a high ratio of solubility, and were this point alone considered the dust would be most suitable for dusting a mine. The microscope shows that the adobe contains two kinds of siliceous particles; one consists of flakes of clay, the other of rounded grains of quartz with few cutting edges. The flakes of clay are alumina silicate. It contains also traces of oxides of iron, mica, and limestone.

The free silica is in the form of chalcedony, an amorphous form of quartz. The chalcedonic particles are more or less rounded, and few in proportion are pointed or cutting. Formerly the material has been subjected to attrition under water, hence many of the particles are smooth. It is inert and contains no substance that would give off any injurious gases or fumes. The free silica in adobe is in less irritating form, except as regards insolubility, than in any of the siliceous materials hitherto examined. At a later date the writer will deal with the matter of inert dusts suitable for use in mines in an article illustrated with drawings magnified 85 diameters, and drawn under polarized light.

The wooden end-gate car is the chief cause of the presence of coal dust on all mine roads. The small coal which falls through the bottoms, sides, and ends of the cars is quickly reduced to dust by the traffic. The removal of all dust is impossible, but with the introduction of dust-proof cars and rotary dumps, the application of the stone-dust remedy is simplified, the amount of dangerous dust to be diluted or rendered harmless being trifling compared with the quantity always in evidence where the end-gate car is in use. Where new mines are about to be opened up it is important that the proposed type of car be given more consideration than has been customary in the past.

Old Wire Ropes for Return Circuit in Mines

Written for Mines and Minerals

At the Taylor mine, belonging to the D., L. & W. R. R. Co., at Taylor, Pa., for the past 2 years old wire ropes have been used to conduct the return currents from the electric motors. At this mine the coal is brought to the shaft by means of tail-rope haulage, the mine cars being gathered and delivered to the haulage by electric locomotives. Part of the live workings are about a mile from the shaft. At first it was attempted to conduct the return currents, as the usual custom is, through the rails, the track of the tail-rope being bonded throughout its length. But this road is crooked, as it follows the old gangways, and as there are several bad hills, the cars are more than ordinarily liable to get off the track, with the result that a good deal of work was needed to maintain the bonding. In the best laid track, bonds will work loose. For each time a joint is passed over by a car or motor there is more or less movement, even with well-blocked ties, and as solid wire bonds and channel pins were used, any movement destroyed the quality of the connection.

To overcome this difficulty, recourse was had to some old, rejected inch-and-a-quarter wire rope; this has been in use for a couple of years and no attention has to be given to that part of the return circuit. The rope is merely strung on the props along the tail-rope line, being placed at the bottom of the props on which the feed cable is strung. In making the connection between the pieces of the rope, the brightened ends are inserted into a short piece of lead pipe and then the pipe is filled with solder, so that the connection is intimate.

The use of old wire rope has been carried a step further by the Lehigh Coal and Navigation Co. In a paper read before the Panther Valley Mining Institute, Mr. Albert Loonars gave a description of the manner in which that company was using old wire ropes as auxiliary to the bonding along roadways where electric motors do the haulage.

A fact that is not always appreciated by the ordinary mine electrician or mine foreman accustomed to the use of steam, is that in the use of electricity, the return circuit must be kept in good condition if the motor is to do the work of which it is capable. In the use of steam, a leak in the exhaust pipe is of no account unless a condenser is used in connection with the engine. With electricity, not only must the feed line be maintained in good condition, but the return as well. A motor is built to do a certain amount of work at a certain voltage, using a certain current. If the voltage drops for any cause, the number of amperes, which is often indefinitely spoken of as the current, will be increased. The result of this is that the armature heats up. In fact one of the most frequent causes for the burning up of armatures is the poor condition of bonding along a track. For each bond in the best of condition will occasion a loss of voltage, though the amount is negligible. But when a gap occurs without any bond, the loss in voltage may amount to a large quantity, even sufficient to stop a motor.

From Mr. Loonars' paper and the subsequent discussion, the following information was gained:

The Lehigh Coal and Navigation Co. uses between 20,000 and 30,000 feet of rope in a year. In the past this rope has been merely thrown aside, but recently the idea was conceived of laying it in the ground along the motor haulage roads and connecting the track by means of bonds to this old wire rope. The track is bonded as usual and every 250 to 300 feet a cross-bond is made to the wire rope, the attachment to the rope being made by soldering a clamp on to the rope, so that the connection is good. The idea is that the wire rope shall serve as an auxiliary to the bonding of the rails, so that if a bond should be broken, the motor may still have a return connection. It is best to have both rails bonded and cross-bonded, for the return from the electric locomotives passes through the wheels, and the connection is better when it is possible to use the surface of four wheels rather than two.

Along the main haulage roads, the largest size of rope is laid, and along the lateral gangways, the smaller sizes, the inch and inch and a quarter. Where the road is only to be used for a short time, dependence is placed upon the bonds alone.

Iron is not so good a conductor as copper, having a value about one-sixth that of copper. But the steel from which hoisting ropes are made is of a good quality, low in carbon and manganese, so that its conductivity is good. An 1½-inch hoisting rope is equal to a 30-pound rail in its capacity to conduct an electric current.

The results from using this old discarded rope have been excellent. It has been found that the motors can haul larger trips with less effort and with a reduction in the amount of sand used and consequent wear on wheels. Moreover, the number of armatures which are burnt up has been decreased.

Mining Society Notes

Notice of society meetings should be sent to Mines and Minerals to arrive not later than the 15th of the month prior to the month in which the meeting is to be held.

A meeting of the old students of the Freiberg Bergakademie will be held on Friday evening, December 20, at 7:00 o'clock in the "Hofbrau Haus," Broadway and Thirtieth Street, New York City. Dinner will be served in one of the private rooms, price per plate, $1.50 or $1.75.

The West Virginia Mining Institute will hold its next annual meeting at Parkersburg, W. Va., December 11 and 12. E. B. Day, secretary, 108 Smithfield Street, Pittsburg, Pa.

The Coal Mining Institute of America will hold its annual meeting in Pittsburg, Pa., December 18 and 19. C. L. Fay, Wilkes-Barre, Pa., Secretary.

The New York Section of the American Institute of Mining Engineers held its annual meeting at the Engineering Societies Building, 29 West 39th Street, New York, on Friday, November 22, 1912, at which Nelson Horatio Darton, of Washington, D. C., presented a paper on "The

Structure of the Modern Anthracite Basin Relative to Forms of Folds." The principal feature was a map showing the structure of the basin by 100-foot contours on the lowest notable coal beds. The map comprised all available mine map data and results of studies of sections and outcrops. It was prepared mainly as a basis for the investigation of the occurrence of methane in the coal. There were also shown details of flexures revealed by mining, illustrating the unreliability of ideal sections of deformed strata constructed from scattered dip observations. L. D. Huntoon, secretary, 160 Broadway, New York City.

The Secretary of the Canadian Mining Institute, H. Mortimer Lamb, Montreal, Quebec, has issued notice that nominations for president of the Institute, two vice-presidents, and ten councillors are in order, and that these nominations should reach the Secretary not later than January 1, 1913. Those that propose contributing papers should have them in the hands of the Secretary not later than January 15.

Pennsylvania State College held Pennsylvania Day, Friday, November 22, 1912. The exercises consisted in the dedication of the new Mechanic Arts building, an address by Hon. John C. Bell, Attorney-General of Pennsylvania, who was introduced by Gov. John K. Tener; a review of the regiment of 1,200 college cadets by Major-Gen'l T. J. Stewart, of N. G. of P.; inspection of buildings; football game; dances at the various fraternity houses, etc., etc.

AMERICAN INSTITUTE OF MINING ENGINEERS

The one hundred and third meeting of the American Institute of Mining Engineers was held in Cleveland, Ohio, beginning Monday, October 28, and ending Thursday, October 31. Headquarters were at the new Hotel Statler.

The afternoon of Monday was devoted to registration. Monday evening at 8:15 there was an informal gathering at the headquarters, but most of the out-of-town members did not report until the following morning.

On Tuesday at 10:00 A. M., Mr. D. T. Croxton, chairman of the local committee of arrangements, introduced Mayor Baker, of Cleveland, who greeted the Institute, and in the course of his address queried what would become of mining engineers after all of the present deposits were exhausted. In his reply, President Kemp answered this query by pointing out that what was wall rock a few years ago, has become the ore of today. Thus in his characteristic manner he epitomized the changes that are taking place in the mining of ore, and the extraction of metals. A time limit of 20 minutes for the reading of papers and 5 minutes for discussion was announced. During the forenoon the following papers were read: "Recent Developments in the Inspection of Steel Rails," by Robert W. Hunt, Chicago, Ill.; "Notes on Titanium and the Cleansing Effect of Titanium on Cast Iron," by Bradley Stoughton, New York, N. Y.; "Cuyuna Iron Ore Range," by Walter A. Barrows, Jr., Duluth, Minn., and Carl Zapffe, Brainerd, Minn.; "The Action of Various Commercial Carbonizing Materials," by Robert R. Abbott, Cleveland, Ohio; "Measurements and Relations of Hardness and Depth of Carbonization in Case-Hardened Steel," by Mark A. Ammon, Cleveland, Ohio; "Notes on Ruff's Carbon-Iron Equilibrium Diagram," by Henry M. Howe, New York.

During the discussion, Professor Stoughton showed that 80 per cent. of the data on carbonization is at present unknown to the general profession, inasmuch as it is locked up in the archives of private corporations. A vote of appreciation was then extended to Messrs. R. R. Abbott and M. A. Ammon for the extended data that they had given in their papers noted above.

The afternoon session convened at 2 o'clock and the following papers were read during the afternoon: "Blowing In Blast Furnaces," by Ralph H. Sweetser, Columbus, Ohio; "Alloys of Cobalt with Chromium and Other Metals," by Elwood Haynes; "Manufacture of Coke," by W. H. Blauvelt, Syracuse, N. Y.; "Manufacture of Coke," by F. E. Lucas, Sydney, C. B.; Concentration of Iron Ores," by N. V. Hansell, New York, N. Y.; "Effect of Alumina in Blast-Furnace Slags," by J. E. Johnson, Jr., Ashland, Wis.

In connection with his paper on the "Alloys of Cobalt With Chromium and Other Metals," Mr. Haynes showed some very interesting articles that were made of these alloys. These included cutting tools, razor blade, drawing knife, and a turning made with one of the cobalt chromium tools, which was very remarkable. This alloy is not only hard but resists corrosion to a very marked degree.

The papers upon coking brought out a very interesting discussion by Mr. Blauvelt, representing the Semet-Solvay Co., and Doctor Schniewind, representing the Otto-Hoffman Co., in regard to the relative value of horizontal and vertical-flue ovens.

Tuesday evening was devoted to an informal smoker, at which some remarkable moving pictures were shown, illustrating the mining of iron ores in the Mesabi field, the transportation to the docks, the loading of vessels at the docks, passage of vessels through the Sault Ste. Marie canal, the unloading of the ore at lower lake points, and most remarkable of all, pictures illustrating the various processes of the Bessemer and open-hearth methods of making steel, and the rolling of the same into rails and other shapes. Professor Kemp also gave one of his characteristic illustrated talks upon mountain climbing.

The session of Wednesday morning was devoted to a discussion of the proposed changes in the constitution of the Institute. A preliminary statement was made by President Kemp, outlining the changes in organization that had been made necessary by the incorporation of the Institute in connection with the United Engineering building of New York City. A detailed explanation of the several propositions that had been presented to the members of the Institute by letter ballot was given by Mr. Rand, Mr. Kirchoff, Mr. Olcott and others. The proposition to introduce a new form of membership as fellows, as included in Article 4 in the proposed constitution submitted by the committee consisting of J. W. Richards, Charles Kirchoff, and C. F. Rand, was not favorably received by the meeting. The discussion throughout was spirited but carried on without friction.

Wednesday afternoon, at 1:30, a special train provided for the American Steel and Iron Co., left the B. &. O. station for Cuyahoga Valley, stops being made at the following plants: American Steel and Iron Co., Central plant, Cuyahoga plant, and the Newburg Steel plant. At 7:00 P. M. a subscription banquet was held for the members, ladies, and guests, in the banquet room of the Statler. The chairman of the local committee Mr. Croxton, was toastmaster, and called upon Captain Hunt, Mr. Moore, Mr. Mather, Mr. Kelly, Mr. Kirchoff, Mr. Gayley. Mr. Mather gave an interesting account of the methods being used by Cleveland-Cliffs Iron Mining Co., and other mining companies in connection with the sociology of mining, including better housing, playgrounds, institutes, etc.

The session of Thursday morning was held at the Case School of Applied Science. Of the papers that were read, the one which probably attracted the most attention, was that by Prof. Charles H. Fulton of the Case School, upon the "Constitution and Melting Points of a Series of Copper Slags." This point was debated to a considerable extent in connection with the blast furnace discussion of the previous day. Professor Fulton brought out many points, which had a direct bearing upon the previous discussion. The program also included a sightseeing tour of the C. & P. ore docks and the National Carbon Co.'s plant.

The Cleveland meeting was characterized by a new spirit of discussion and was voted by many of those present as one of the most interesting meetings that the Institute has held in years.

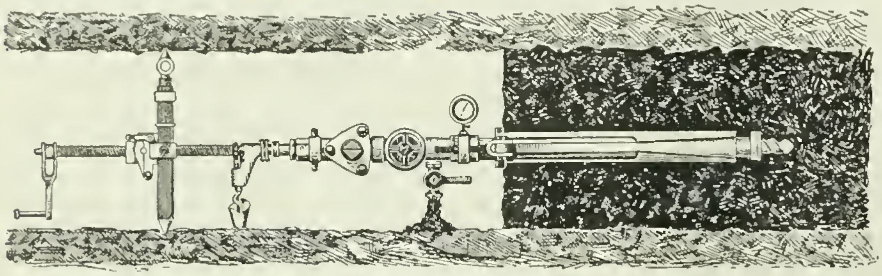
American Exports of Coal

According to the United States Consular Report, the exports of coal to Mediterranean countries during May and June, 1912, were as follows: Austria-Hungary, 5,400 tons valued at $14,850; France, 11,219 tons, valued at $33,657; Italy, 58,811 tons, valued at $159,902; French Africa, 23,734 tons, valued at $64,082; Egypt, 34,365 tons, valued at $92,786.

Horizontal Mine Boring Under Pressure

By Frank C. Perkins

The apparatus shown in the accompanying drawing and photograph is said to be the most expeditious yet invented for boring long horizontal holes to drain old mine workings in which dangerous gases



Machine for Tapping Water Under Pressure, in Place

and water have accumulated under pressure.

It has been used successfully in collieries in tapping heavy pressures of water and gas and holding them in full control until drained.

It is maintained that with the apparatus old mine workings can be tapped under any pressure with perfect safety; that is, a water pressure can be on the bore hole at the time of holing, and with the special valves and cocks, water or gas can be shut off under any circumstances.

The tube boring rods are made with flush joints, whereby the rods are worked and inserted through the packed stuffingbox, this being watertight during the time of boring and after the water or gas is tapped the full length of the rods and the drill point can be withdrawn outside the cock which is then shut, and the stuffingbox unscrewed so that the drill point can be withdrawn; this operation being perfectly safe and without the least escape of any water or gas.

The apparatus can be readily handled by an ordinary workman and when water or gas is found it is held under control and can be either run off from the apparatus or piped away to some convenient place.

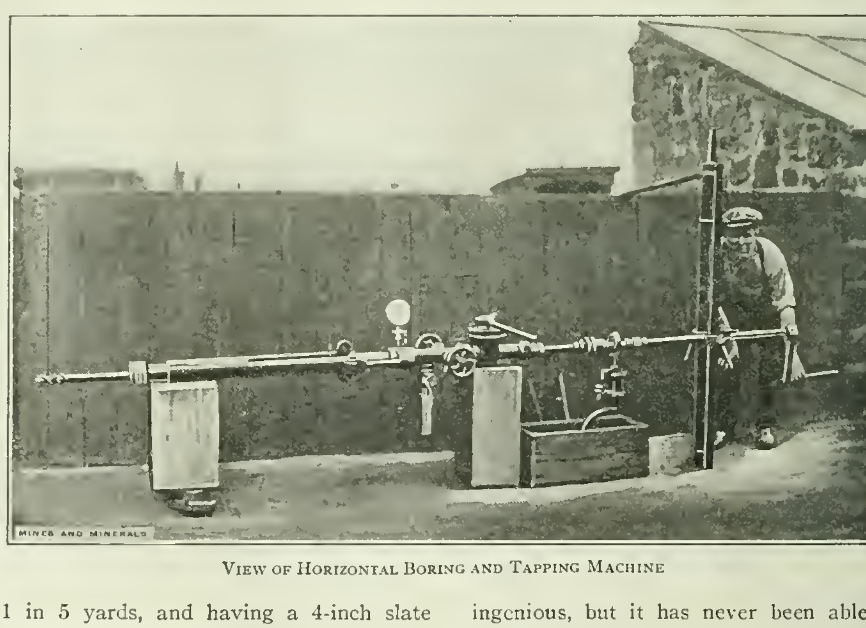
The boring rods are easily handled, and when boring to the rise several valve rods are used. The rods are kept full of water when being screwed together to avoid the inside of rods getting choked and to avoid any escape of water through the rods after the holing is made.

If it is desired, the apparatus can be firmly secured in a few minutes and tested up to 1,000 pounds pressure per square inch before commencing work; and after the water is run off, or the full length of bore hole is made, the apparatus can be withdrawn in 5 minutes and is then again ready for further use.

By means of special arrangements a small apparatus can be withdrawn under any pressure, and a larger one inserted for the purpose of enlarging the bore hole if desired. It is said that this apparatus can be used for boring up, down, horizontal, or at any angle. The record bore hole made with it is 702 feet and still in coal. The record pressure tapped was 257 pounds per square inch, although it is stated that five equipments have been constructed to tap water at 650 pounds pressure per square inch at the Dover colliery, in Kent, England.

The new record in horizontal boring, 702 feet, performed at Middleton colliery, near Leeds, is far beyond the record boring of 210 feet made at the Washington colliery, County Durham, some time ago, and the later record of 372 feet, made at Westerton colliery, County Durham, in both of which borings the old workings were successfully tapped under 62 and 82 pounds pressure per square inch, respectively.

The Middleton colliery hole was bored in a 4 foot 6 inch seam, dipping about



View of Horizontal Boring and Tapping Machine

1 in 5 yards, and having a 4-inch slate band 22 inches from the top.

It is said that the bore hole was started above the slate band and for the full distance the hole kept in the coal between the slate and the roof. This is considered remarkable, since horizontal holes bored with diamond drills are apt to be deflected in an upward direction. During the boring operation water to wash out the cuttings is pumped through the hollow drill rods that are attached from time to time as the hole is lengthened.

A water trough 1 ft. × 2 ft. × 9 in. deep is required for the pump water. At the beginning of a bore hole, drills are used with two holes in them, and in case the rods have to be withdrawn when the bore hole is some 10 yards in, then a drill rod is used with a spring valve, as the spring prevents the small holes in the bit from getting choked. This rod is fixed to the drill point, and when the rods are inserted a ball valve avoids the borings getting inside the rods and choking them up.

It is claimed that the most suitable place to start the bore hole, that is for working the pump and turning the plane handle, is about 16 inches from the bottom. The entire success of the boring depends on the pump, and it is therefore advisable to clean the valves at the beginning of each shift, also to use clean water.

Lubrication of Mine-Car Wheels

By L. A. Christian

[The following is an abstract from the paper entitled "Lubrication," which was read at the Charlestown, W. Va., meeting of the West Virginia Mining Institute.]

The lubrication of mine-car wheels is a subject which apparently has not been given sufficient consideration, either by mine-car wheel manufacturers or mine operators.

The cavity type of mine-car wheel is ingenious, but it has never been able to satisfactorily prove its value, owing to the numerous available and unsuitable lubricants which the market affords. As a matter of fact, oil is not the proper material for cavity mine-car wheel lubrication. While the wheel may have been designed originally for the use of oil, the idea has never worked satisfactorily in practice. There is too much lost motion between the axle and the wheel and on the end thrusts to warrant an economical use of oil. There is no exaggeration in the statement that at least 50 times more oil is wasted than is consumed in lubricating these wheels. Owing to the mechanical construction of the wheels a high grade oil will afford no better efficiency than a cheap oil, as its fluidity will cause it to waste freely, irrespective of its lubricating properties and price. Therefore, as much benefit and economy will be derived through the use of cheap black oil as from the use of high-grade oil in this kind of wheel.

A solidified grease is more inappropriate than thin oil in cavity mine-car wheels, because the grease is pushed to the outside wall of the cavity and clings there, refusing to flow by gravitation through the oil channels from the cavity to the axle. The hub may be three-fourths full of heavy lubricant and the axle run dry. The lubricant must be of a fluidity to feed through these openings when the car is at rest, but if the lubricant is too fluid it will work out rapidly when the wheel is in motion, leaving the axle and wheel dry.

A grease has been produced for mine-car wheels of the cavity type which can be used also in the roller-bearing wheels, as it possesses the proper viscosity to feed through the small opening from the reservoir to the axle when the wheel is at rest. This grease is not soluble in water. A metal surface coated with it is immune from outside chemical attack. It contains no alkaline or acid ingredient, consequently it will not injure a metal surface which has been coated with it; in fact, the lubricant is a natural preservative of mine-car wheels and axles, for no matter how corrosive the mine water may be it cannot attack a metal surface coated with this grease. When this car grease was first put on the market it was too viscous to flow freely through the hub to the axle; finally, however, a process was found which furnished a satisfactory lubricant.

When mine cars are lubricated with black oil and the car wheels submerged so that mine water gets into the cavity of the wheels, the oil is forced out and the wheels run without lubrication until they are again oiled. This grease contains such body that water cannot force it out of the wheels in case the cars stand in water over night. The grease is semifluid and will not change in consistency under extreme conditions of heat or cold.

Several tests were made in the extreme cold weather of January, 1912, and it never failed to develop the same lubricating efficiency in temperatures from 10 degrees to 20 degrees below zero as it developed with considerably more moderate weather. This was proved at Hazleton, Pennsylvania, where the temperature reaches 20 degrees below zero, and at Danville, Ill., where the temperature was frequently 15 degrees below zero.

Perfect lubrication contributes enormously to the reduction of wear and tear of mine cars, and a semifluid mine-car grease contributes also to a reduction in the labor of keeping the cars oiled.

One application of mine-car grease lasts from 3 to 6 months; the time being proportional to the size of the lubricating reservoir. Reservoirs of 1⅛ pounds capacity hold a sufficient supply of grease to run the wheels 3 months and longer.

Where wheels are not equipped with plugs to the cavities, the hubs should be tapped, and threaded for a screw plug before applying mine-car grease; otherwise it cannot be expected that the lubricant will stay inside and feed to the axle properly. Some consider that it is not worth while to plug these holes where oil is employed, as unscrewing and screwing in the plugs is done too often to derive any economy or benefit therefrom, owing to the frequent application of oil, but if wheels having these holes are plugged, even when oil is used, better lubrication is obtained; for when the cars are being pulled around the curves the ends of the axles push toward the outer end of the hub and force the oil out of the holes if they are not plugged. The time occupied in unscrewing and screwing in these plugs would decrease oil bills, but where grease is applied, and one application is sufficient to run a wheel from 3 to 6 months, the labor of putting in plugs cannot be considered an expensive operation.

There are wheels to be found about every mine that are apparently worn out, but which can be put into service when they are lubricated with mine-car grease instead of oil. This grease is applied to wheels by a grease gun.

The mine-car grease has been extensively tested in the laboratories of the William Cramp & Sons Ship and Engine Building Co., Philadelphia, Pa., to determine the lubricating qualities of the grease, under the direction of N. H. Schwenk, engineer of tests, and in the laboratories of the Cornell University under the direction of Prof. R. C. Carpenter, and in each instance has developed a lower frictional resistance than any lubricant tested in comparison.

Illinois Civil Service Examination

W. R. Robinson, Secretary and Chief Examiner of the State of Illinois State Civil Service Commission, sent Mines and Minerals the questions asked in the recent examinations for the position of manager of Mine Rescue Stations. The examination is divided into Training and Experience, eleven questions; First-Aid and Mine Rescue Appliances and Methods, sixteen questions; Organization and Administration of Mine Work and State Laws relating to same, thirteen questions; General Line Operation, eleven questions. The questions are practical and hard for those unacquainted with the rescue practice taught. Under Training and Experience, some of the questions are as follows:

(7) What experience have you had that would assist you in planning and instructing others to keep a record of the relative value of different kinds of rescue apparatus as regards their efficiency and economy? (8) (*a*) Have you a certificate of proficiency in first-aid training? (*b*) In mine rescue training? Give names of your instructors and the place where you were trained in each. (11) What experience have you had in entering an explosion and mine after an accident?

Under First-Aid and Mine Rescue Appliances and Methods, the following questions are asked: (6) How much oxygen per minute does a normal man require? How do you determine the amount of oxygen an apparatus is furnishing? (7) Suppose you were wearing a mine rescue apparatus while hurrying into a mine to save a man and you felt suddenly as though you could not get your breath. What is probably the cause and what would you do? (12) If you found a man overcome by gas and burned about the body, and with an arm broken, what would you do? (14) Describe fully a Pulmotor and its action. (18) Name and describe the location of the principal arteries in the human body.

Under Organization and Administration of Mine Rescue Work and State Laws relating to same, the following questions are found: (2) What appliances for fighting fires and for use in case of accident and for rendering first-aid, should be found in every mine according to the Illinois mine laws? (5) If, as Manager of Rescue Stations, you lived in Springfield, and at 7 A. M. one morning you received a telegram that there had been an explosion in Saline County, what would you do before and after you reached the mine? Give reasons for your procedure.

Under head of General Line Operations, the following questions are found: (6) Under what conditions may afterdamp become explosive? (9) If after an explosion you found yourself in an explosive entry of gas and air, what would you do? (10) In an abandoned part of a mine the atmosphere is practically all marsh gas and blackdamp; in another part there is only 10 per cent. marsh gas in the air. While wearing a rescue apparatus would you consider one part more dangerous than the other, to the exploring party carrying electric lamps and safety lamps?

Monobel and Carbonite

"Permissible Explosives"—Different Grades, and the Circumstances to Which Each Is Suited

During the past two or three years much has been written and said about "Permissible Explosives." Long articles concerning them have appeared in magazines and newspapers; and government representatives have lectured about them all through the coal regions. It should be remembered, however, that in this instruction but little explanation of "permissible explosives" has been made to the miner—the man who uses the explosives, for whose particular benefit they were produced, and who should be most interested in them.

With this thought in mind the Du Pont company prepared a booklet, for the benefit of the miner, who has not had information on "permissible explosives."

For many years the loss of life and damage to property, due to accidents in coal mines, has been a matter of great concern.

Investigation has shown that in bituminous coal mines the most serious accidents have been due to explosions of mine gas or coal dust, often caused by the explosives used in blasting the coal. Careful study and tests have proved that mine gas and coal dust can be ignited much more easily by some blasting explosives than by others. It was found that large charges of any explosive are more likely to ignite mine gas and coal dust than smaller charges.

Also, that it is exceedingly important that every bore hole be "tamped" with damp clay, or similar incombustible material, from the charge of explosives to the mouth of the bore hole, to obtain the full explosive force and especially if gas or dust explosions and fires are to be prevented.

Another matter, and one just as important, is that only very strong detonators (blasting caps or electric fuses) should be used with the explosives. This is because the weaker detonators, especially if they are a little damp, often ignite the explosives or set them afire instead of exploding them, and this invariably ignites mine gas, if any is present, and causes a more or less disastrous explosion or fire.

Realizing the need of explosives particularly adapted to gaseous or dusty soft-coal mines, arrangements were made about 10 years ago to test and investigate Carbonite and Monobel explosives in this country. The explosives were put on sale, about 4 years ago, with the guarantee of the Du Pont company, in all parts of the United States where coal mines are located.

Soon after this the United States Government, through a branch of the Department of the Interior, established a station at Pittsburg, Pa., for testing explosives and for investigation along other lines tending to make coal mining less dangerous. A testing gallery was built at this station, and manufacturers of explosives were requested to submit their explosives for test.

Some time before this the Du Pont company had sent representatives into many coal mines throughout the country to explain the advantages of the permissible explosives, and to show the miners how to use them, so that they would blast the coal without costing any more than the explosives used in the past.

Shortly after the completion of the Government testing station the Du Pont company installed in their eastern laboratory a gallery where explosives can be fired into gas and coal-dust mixtures exactly as is done in the Pittsburg gallery.

Almost everywhere the miners realized how much safer they were when they used these explosives. They also discovered that these "permissible explosives" gave off less smoke and fumes than anything they had used before. In most cases the miners soon learned to use these explosives, when the right kind was furnished them, so that they could mine coal at no greater, or even at less, cost than when the old explosives were used. A few men, however, who tried to use Carbonite where Monobel would have done best, or who did not have the proper grade of either Monobel or Carbonite for their work, had trouble at first. Some wanted to continue with blasting powder because they knew just how to use it. However, when they learned that blasting powder, no matter how little of it was used, always ignited the gas and coal dust in the testing galleries, and the Monobel and Carbonite, when properly loaded, never caused an explosion, even these men were glad to use Monobel or Carbonite.

Every miner knows that good judgment and experience are necessary to blast coal properly, because the coal in one mine may be harder or softer than in another mine, and may lie differently. The thickness of the seam must also be considered. All of this makes it necessary to space and point the bore holes differently in different places, and to use lighter or heavier charges of explosives.

Different kinds of permissible explosives exactly suited to almost every kind of blasting have been produced, each one intended for some particular kind of work; some of these are for soft coal, others for medium coal, and still others for hard coal. Some are better in wet work than others, and some are specially intended for cold weather.

None of the "permissible explosives" can be depended on to do good work if a detonator (blasting cap or electric fuse) weaker than the No. 6* is used with them. They will also fail to bring down the coal or rock properly, unless the bore hole is tamped to the mouth or collar. It takes more explosive to do the same work when only a little or no tamping is used. In hard-shooting coal or rock, each cartridge or stick, unless the work is very wet, should be slit lengthwise with a knife, and then be pressed firmly into the back of the bore hole with a wooden stick so as to leave no air space around the explosive.

"Permissible explosives" cannot be exploded with fuse alone or with a squib, but a blasting cap or electric fuse must be used and they cannot be depended on to explode with full force and minimum flame unless detonators as strong as No. 6 electric fuse or No. 6 blasting caps are used to explode them, and they are not passed by the Government as "permissible explosives" if weaker detonators are used.

Two kinds of "permissible explosives" must not be used in the same bore hole, and neither blasting powder nor dynamite must ever be used in the same bore hole with a "permissible explosive." The best way to explode "permissible explosives" in a coal mine where gas or dust exist is by electricity. To do this, electric fuses, and, unless the mine is wired for electric firing, a blasting machine and a coil of leading wire should be used. If several bore holes are fired at the same time, and they are too far apart for the electric fuse wires to join each other, connecting wire should be used between them.

Monobel is an explosive which can be used in gaseous or dusty coal mines and is classed as a nitroammonia explosive. It is made in six qualities.

No. 1 is quick acting and is intended for hard coal, hard-shooting soft coal, and soft coal which is to be coked. No. 6 is a low-freezing grade of No. I.

No. 2 is slower acting than No. I, and usually gives better results in blasting coal. It is as strong as the same weight of 60-per-cent. dynamite, but it is lighter than 60-per-cent. dynamite and has about one-third more cartridges to the case. On this account a cartridge of No. 2 would not do the same amount of work in rock as the same size cartrridge of 60-per-cent. dynamite, but it is equal in strength to the same size cartridge of 40-per-cent. dynamite, although it is much slower in action and does not shatter the coal so much.

*No. 6 cap contains 15.43 grains of mercuric fulminate.

Monobel No. 2 is much better than blasting powder or dynamite for blasting hard coal, because it does not make any smoke or fumes that will hurt the miner; and after a little practice the miner can learn how to get out the coal cheaper than he can with blasting powder or with dynamite.

In wet work the cartridges should not be slit or broken, and should not stand in the water any longer than just time enough to load, tamp, and fire the shot.

Monobel No. 4 is the same in strength, action, and lack of fumes as No. 2, but is a low-freezing explosive.

Monobel No. 3 is adapted to mining screened coal. It is just as strong as No. 2 but so much slower acting that miners who have learned how to use it, mine the softest coal without breakage and with no more expense than with black blasting powder. It is practically without smoke or fumes, but should not remain long in wet holes before firing.

Monobel No. 5 is the same as No. 3 except it is doped to prevent freezing.

All grades of Monobel are put up in cartridges, enclosed in pasteboard cartons containing 12½ pounds each. The cartons are packed in wooden boxes containing 25 pounds or 50 pounds. Table 1 gives the size and the number of cartridges in a box containing 50 pounds and, of course, a box containing 25 pounds has just one-half as many cartridges.

Table 1

Weight of Monobel in Case	Number of Cartons in Case	Size of Cartridges	Number of Cartridges in Case
50 lb.	4	1 in.×8 in.	About 205
50 lb.	4	1⅛ in.×8 in.	About 165
50 lb.	4	1¼ in.×8 in.	About 135
50 lb.	4	1½ in.×8 in.	About 100
50 lb.	4	1¾ in.×8 in.	About 74

Monobel No. 1, No. 2, and No. 3, may freeze at from 45° F. to 50° F. Monobel No. 4, No. 5, and No. 6 will not freeze unless they have been subjected for a considerable time to the coldest weather met with in this country and often not even then.

All grades of Monobel begin to lose efficiency after they have gotten wet, so in damp or wet blasting it is better not to cut or break the paper shell of the cartridge, but to load each hole quickly and to blast it as soon as possible.

When the coal is hard and the work dry, the best results will be obtained if the cartridge shells are slit and the entire charge is pressed firmly with the wooden tamping stick into the back of the bore hole and then tamped to the mouth of the bore hole with clay. If the No. 3 or No. 5 shatter or break the coal too much, do not break or slit the cartridge shell, so that there will be air spaces about the charge. This will decrease the force of the blast and bring down the coal in large size.

Carbonite, which has been used since before 1898 in England, contains some nitroglycerine, doped to meet the conditions demanded of permissible explosives; namely: a short flame, slow velocity of detonation, and comparatively low temperature and heat of detonation. It is made in six grades.

Carbonite No. 1 is intended for blasting hard coal, is not quite so strong, but makes a little more smoke and fumes than Monobel No. 2; however, it stands water better. Carbonite No. 2 is not quite so strong as No. 1; is also slower in action, and shatters the coal less. Carbonite No. 3 is slow in action, and is intended for soft coal. Carbonite No. 4 is the slowest acting of the carbonites, and if used in the right way will break down the coal with little, if any, more breakage than black powder or Monobel No. 3. Like the other carbonites it stands water very well and does not give off a great amount of smoke or fumes. Carbonite No. 5 is the same as No. 2, and Carbonite No. 6 is the same as No. 3, except they are adapted for low freezing. Table 2 gives the size and the number of cartridges in a case containing 50 pounds of four cartons weighing 12½ pounds.

Table 2

Kind of Carbonite	Size of Cartridges	Number of Cartridges to 50-Pound Case
Carbonite No. 1......	1¼ in.×8 in. 1½ in.×8 in. 1¾ in.×8 in.	About 100 About 75 About 50
Carbonite No. 2......	1¼ in.×8 in. 1½ in.×8 in. 1¾ in.×8 in.	About 130 About 100 About 75
Carbonite No. 3......	1¼ in.×8 in. 1½ in.×8 in 1¾ in.×8 in.	About 130 About 100 About 75
Carbonite No. 4......	1¼ in.×8 in. 1½ in.×8 in. 1¾ in.×8 in.	About 105 About 80 About 55
Carbonite No. 5......	1¼ in.×8 in. 1½ in.×8 in. 1¾ in.×8 in.	About 130 About 100 About 75
Carbonite No. 6......	1¼ in.×8 in. 1½ in.×8 in. 1¾ in.×8 in.	About 130 About 100 About 75

The carbonites will not explode properly when frozen. Carbonites Nos. 1, 2, 3, and 4 may freeze at from 45° F. to 50° F. Carbonites Nos. 5 and 6 will not freeze unless they have been exposed for a considerable time to the coldest weather met with in this country and often not even then.

All grades of Carbonite resist water well, but in very wet work the cartridges should not be slit. For best and cheapest work, all bore holes should be tamped from the charge to the mouth of the bore hole. It is to be understood that no explosive is an absolutely safe explosive, but that those termed permissible are less apt to do damage by exploding gas and dust than some others.

Prize Contest for Safety Lamp

Oil and benzine safety lamps have advantages, but they contain various faults, the greatest being that they are not perfectly firedamp proof. Electric mining lamps also are not safe enough and do not indicate firedamp or chokedamp.

The Association for the Mining Interests in the District of Dortmund, has resolved to offer a prize of 25,000 marks ($6,250) for a useful electric mining lamp provided with a trustworthy gas indicator. The lamp and gas indicator must comply with the following conditions: They must be firedamp proof, even after damage, and serviceable for at least 12 hours without interruption; they must be handy, durable, securely lockable, simply constructed, simple to attend, and economical in operation. The gas indicator must show at least—in the same degree as the benzine mining lamp—firedamp (CH_4) and chokedamp (CO_2).

After burning for 12 hours, the lamp must still show a light strength of at least one Hefner candle.*

A prize jury consisting of the following members will award the prizes: Geh. Oberbergrat Bornhardt, as representative of the Chamber of Commerce; Geh. Bergrat Kaltheuner, as representative of the Royal Mining Chamber at Dortmund; Bergrat Gerlach, as Mining Officer; Bergrat O. Mueller, as representative of the Miners' Association; Bergassessor a D. Winkhaus, as representative of the Miners 'Association, Section 2; Professor Heise, as representative of the Mining Bank of Westphalia; General Director Lüthgen, General Director Janssen, Bergrat Johow, Director Meyer, Director Pattberg, as representatives of the Association for the Mining Interests in the District of Dortmund.

The prize jury reserves the right to name additional members. Its decision will be final and it may divide the prize if several useful solutions are submitted. If none of the applications is in entire accordance with the given conditions, the next best solutions will receive part amounts of the prize.

The applications must comply with the following demands:

1. Three lamps must be sent to the Verein für die bergbaulichen Interessen im Ober Bergamtsbezirk Dortmund, in Essen-Ruhr, Germany.
2. Three copies of the descriptions, drawings, and particular instructions for operation must be submitted.
3. The documents must be written in the German language.
4. Applications must be received not later than October 1, 1913.

The results of the contest will be published in *Glückauf*, *Der Bergbau*, and *Der Kompass*, *Colliery Guardian* and Mines and Minerals.

* The British standard candlepower is obtained from a sperm candle weighing six to the pound and burning at the rate of 120 grains per hour. The Hefner candlepower is .92 of the standard British candlepower.

The Letter Box

Readers are invited to ask or answer any question pertaining to mining, or to express their views on mining subjects in this department. All communications must be accompanied by the name and address of the writer—not necessarily for publication. The editors are not responsible for views expressed by correspondents.

Gases

Editor Mines and Minerals:

SIR:—Will some reader of MINES AND MINERALS advise me as to the difference between methane, light carburetted hydrogen, marsh gas, and firedamp? Do these names mean the same gas or do they apply to different mixtures of other gases?

Nanaimo, B. C. COAL MINER

Centrifugal Pumps

Editor Mines and Minerals:

SIR:—I have read considerable during the past year on the use of "multiple-stage centrifugal pumps" in shaft mines. Will some reader familiar with their use advise me as to whether they possess any advantage in efficiency or economy over duplex direct-acting steam pumps? MANAGER

Springfield, Ill.

Handling Slacked Carbide

Editor Mines and Minerals:

SIR:—I would like to know for my own benefit if calcium carbide is injurious to the system and if so in what way and how a slacked carbide should be handled. The carbide light is the best the miner has ever had and I would like to see it stay if there are no injurious drawbacks. J. W. G.

Wilgus, Pa.

Gases From Acetylene Lamp

Editor Mines and Minerals:

SIR:—On page 189 of your issue for November, I see an inquiry signed "T. S. Almond," which interests me. As secretary of the International Acetylene Association, it has been necessary for me to go into the safety of acetylene in connection with mines as well as its other many fields of usefulness.

The first question, "What effect (if any) do the gases given off from the acetylene pit lamp have on the miner?" can be answered briefly: "No effect whatever." The gases given off are simply carbon dioxide and water vapor. Far less of these gases are given off by the acetylene lamp than any other. No other gases are given off.

Second, "What are the elements of the gas given off by carbide and what is carbide made of?" Only one substance is given off by carbide and that is acetylene. Acetylene is a combination of hydrogen and carbon in the relation of two atoms of hydrogen to two atoms of carbon. There are no poisonous or detrimental elements. An unlighted acetylene lamp would only give off one-third of a foot of acetylene if all of the carbide was exhausted, without ignition. This would take over 2 hours. There could be no possible accumulation of gas from miners' lamps under any circumstances. Calcium carbide is made from a combination of lime and coke melted together in the electric furnace. It will not burn, it cannot explode, it is unaffected by any substance except water. When it is brought in contact with water, it gives off acetylene. Acetylene miner's lamps are used throughout the world in numbers approximating a million and nothing but benefit has come to the miner from their use. No accidents have been reported.

A. CRESSY MORRISON

79 Wall St., New York

Calcium Carbide

Editor Mines and Minerals:

SIR:—Replying to T. S. Almond's questions regarding acetylene in the November issue:

Carbide, or more properly calcium carbide, C_2Ca, has been known since 1862 and was first made by heating a zinc-calcium alloy together with carbon. It is commercially prepared today by heating coal, or coke, mixed with limestone, in an electric furnace to a high temperature. When water is brought into contact with it the result is as follows:

$$\underset{\text{(Carbide of calcium)}}{C_2Ca} + \underset{\text{(2 atoms water)}}{\frac{HOH}{HOH}} = \underset{\text{(Calcium hydroxide, slaked lime)}}{Ca(OH)_2} + \underset{\text{(Acetylene gas)}}{C_2H_2}$$

Therefore, the "elements of the gases" given off from carbide are carbon and hydrogen.

The acetylene pit lamp is probably less injurious to the miner than the oil lamp, as the former does not form nearly the same amount of soot and smoke as the latter, which soot is irritating and harmful to the lungs. ODIN DORR

Cannelton, W. Va.

Calcium Carbide

Editor Mines and Minerals:

SIR:—I submit the following in answer to question of T. S. Almond relative to gases from calcium carbide:

Calcium carbide is prepared by heating lime (CaO) with carbon in the electric furnace. Under the influence of the high temperature the calcium is liberated to a certain extent by the action of the carbon on the lime, and unites with the excess of the carbon, part of the carbon going off as CO (carbon monoxide) and the excess of carbon united with the Ca forms CaC_2 (calcium carbide).

The reaction taking place when water is added is, viz., $= CaC_2 + 2H_2O = Ca(OH)_2 + C_2H_2$. The gas thus prepared sometimes contains small amounts of sulphuretted hydrogen (H_2S) which gives it its disagreeable odor, but it does not occur in sufficient quantities to have any deleterious effect on the user.

It will explode when combined with air, but the limits of explosion are much wider than for coal or any other gas, and I know of no case on record of its ever having caused any ill effects on the miner in any way.

F. S. JOHNSON, Chemist

Scientific Management

Editor Mines and Minerals:

SIR:—I have read a good deal about scientific management and efficiency, but it always seems to be applied to factories where the class of work is constant. I would like to know if it has ever been applied to mining, even in a modified form. And if it has been applied, I would like to know the manner of its application and whether it was successful.

Scientific management is given credit for the ability to reduce costs. Any one who can reduce costs has the right to talk and I would like to listen to him.

Pittsburg, Pa. SUPERINTENDENT

Action of Acids on Concrete

Concrete drains have suffered more or less damage, some of them in comparatively short periods from the time of their construction. In every case the destructive action was traced to the presence of acid in the water which reached the drains either internally or externally. In one case the swampy soil surrounding the drain contained iron pyrites, and the water became charged with sulphuric acid; in the other cases, the air in the drains was heavily laden with hydrogen sulphide, which slowly oxidized to sulphur and sulphuric acid. Other mineral and organic acids, such as hydrochloric, oleic, acetic acids, and carbon dioxide were found almost as noxious. It is concluded that the destructive action of acids is due to two causes: The formation of certain calcium and aluminum compounds, especially calcium sulphate, which is accompanied by a large increase in volumes; and the formation of soluble compounds, especially calcium bicarbonate, which dissolve and cause the concrete to collapse. The chief remedies proposed are: To provide adequate ventilation inside the drains; to use dense, non-porous clinker, poor in lime, as basis for the concrete; and to cover the exposed surfaces of the concrete with a coat of tar, or, best of all, to protect the foundations of the drains with tar felt or asphalt.

The Hamilton No. 8 Mine

Geology of the Region Around Arma, Kan.—Description of the Coal and Methods of Working

By L. L. Wittich

THE Hamilton Coal and Mercantile Co. has recently developed a new coal mine on land leased from ex-Congressman Edward Ridley, 1 mile north of Arma, Crawford County, Kansas.

Crawford County is the banner coal producer in Kansas, and has been for many years; but most of the coal has come from the vicinity of Pittsburg and not from as far north as Arma. In southeastern Kansas the producing mines work coal beds found in the Cherokee shales, which correspond to the lower coal measures of Pennsylvania,

FIG. 1. ENGINE AND HOISTER HOUSE, HAMILTON NO. 8 MINE

including the Pottsville conglomerate, as the shales rest on the Subcarboniferous limestone here known as "Mississippian limestone."

Above the Cherokee shales comes the Oswego limestone, and above that the Labette shales, Pawnee limestone, Altamont limestone and shales, all in the Marmaton formation, which with the Cherokee shales are included in the Lower Coal Measures of Kansas, as shown in Table 1.

As little mining has been done so far north as Arma, three drill holes were put down to test the lease, and the same general formation was found in each hole. Seven coal beds were passed through at depths ranging from 238 feet to 241 feet, six of which varied from 3 inches to 8 inches in thickness, while the seventh averages 3 feet 2 inches in thickness and is exceedingly uniform.

The workable coal bed is the lowest one in the Cherokee and it is proposed by Mr. James Hamilton, president of the company, to mine all the coal possible and allow the upper beds to be conserved.

In the anthracite fields of northeastern Pennsylvania the Pottsville conglomerate is the lowest measure of the Carboniferous series. In it is found the Lykens Valley coal bed, which as a fuel has no superior in that region. In West Virginia the millstone grit that corresponds to the Pottsville conglomerate contains the Pocahontas coal, which is an excellent semibituminous coal.

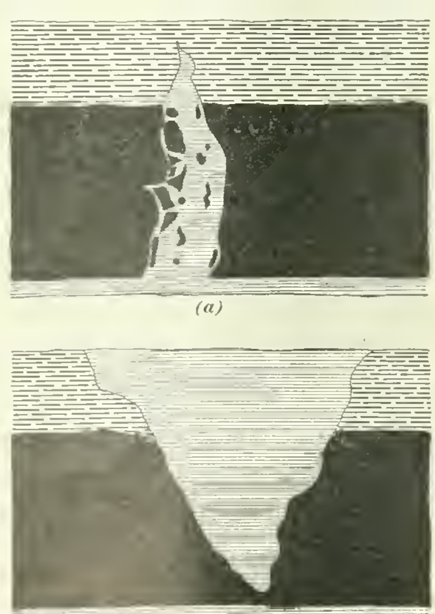
Further to the south, on the border of Tennessee and Kentucky, some of the best bituminous and cannel coal in these two states is found in the Lea conglomerate, which in physical structure approaches the Pottsville conglomerate, it having water-rounded quartz pebbles.

In Kansas the Cherokee shales correspond to the Pottsville conglomerate, millstone grit, and Lea conglomerate, being the lowest member of the Carboniferous formation. In the anthracite fields, Mauch Chunk red shales and Pocono sandstone represent the Subcarboniferous strata; west of the Alleghany Mountains what is known as mountain limestone forms the Subcarboniferous, and this in the Mississippi Valley is termed the Mississippian or Subcarboniferous limestone.

The quality of the coal in the bed worked is exceptionally good, and throughout the greater part of the area mined there is no trace of slate in the coal. It is clean coal between layers of slate, except where there is an occasional "horseback"; then it is poor in quality.

What are termed "horsebacks" in Kansas are clay-filled fissures formed after the coal was consolidated.

The fissures or "clay veins" usually are narrow, averaging perhaps less than 5 feet thick as they are found in the coal. They generally pass through the coal and into the shale above, often reaching almost to the surface, but sometimes thinning to a mere fissure with no apparent thickness only a few feet above the coal, as shown in Fig. 2 (*a*). At other times they do not pass through the coal from below and again they penetrate the coal from above as shown in Fig. 2 (*b*).



(*a*)

(*b*)

FIG. 2. "HORSEBACKS"

In other fields fissures in the coal that have been filled with clay seeping in from above are called "clay veins" while "horsebacks" are rolls in the floor of a coal bed evidently formed before the coal had hardened.

Owing to the thickness of the bed, it is necessary in order to make headroom for the mules to brush the roof in entries, but it has been found advisable to make the height barely sufficient for the mules; for by cutting

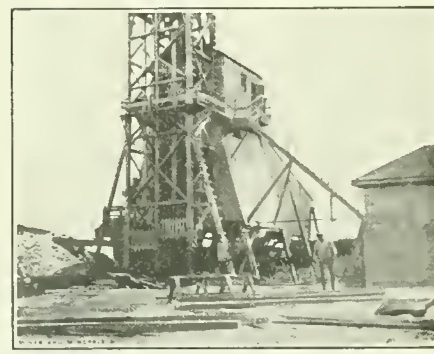


FIG. 3. DERRICK AND TIPPLE, HAMILTON NO. 8 MINE

too high, a shale is encountered which requires constant trimming. The first few feet above the coal is a strong slate which does not show a tendency to fall in slabs.

Nearer the eastern border of the Cherokee shales where the Mississippian limestone outcrops, coal is worked by stripping the dirt from above it, but at Arma the great depth of the coal from the surface is due to land at this place being on the backbone of a divide. The elevation of the coal bed is higher than to the south, also has thicker cover, and the dip is gradually to the southwest and west away from the Ozark dome. The main shaft of the No. 8 colliery of the Hamilton company is 8 ft.×14 ft. inside and is the upcast; the downcast, a short distance away, is 8 ft.×10 ft. A blowing fan 14 feet in diameter furnishes ventilation for the mine, this system being favored because the warm air from the mine passes up the hoisting shaft and there is no accumulation of ice in the winter; the men at the bottom of the shaft are also better able to work in cold weather than would be the case were the hoisting shaft a downcast. As the fan is reversible, the change to an upcast can be made quickly if necessity warrants. The downcast is equipped with a stairway, making it an escapement shaft, to be used in case of accident or stoppage of the cages in the main shaft.

While it is customary in some parts of this coal field to work the coal longwall, in Crawford County the double-entry room-and-pillar system is generally followed.

In the rooms no roof or floor is removed and only occasionally are timbers needed to support the roof. The capacity of the colliery is about 400 tons daily, but this will of course increase when the development is extended. The coal in mine cars is hoisted on cages and dumped into a hopper-bottomed bin of large capacity. From this bin it is passed gradually over shaker screens which size it before delivery to the railroad cars. Lump, nut, and slack are made, the mine run going over all the screens to cars on a third track. All coal that passes through a $\frac{3}{4}$-inch space in the screen is termed slack; all that passes through a $2\frac{1}{2}$-inch space in the screen is termed nut and all over $2\frac{1}{2}$ is lump.

The southern Kansas coal district and the coal districts of the adjoining states of Missouri, Oklahoma, and Arkansas are surrounded by a large and thickly populated area that produces no coal. There is always a good market for the fuel, as a result, and the recently noted tendency of the natural gas fields to fail in their supply has increased the demand.

Book Review

Methods of Air Analysis, by J. S. Haldane, M. D., LL. D., F. R. S. 128 pages, with index, 24 illustrations. J. B. Lippincott Co., Publishers, Philadelphia, Pa. This little book deals with a subject of importance so far as coal miners are concerned. It explains: The collection of samples for analysis; apparatus for general air analysis and gas analysis; calculation and statement of results of analysis; portable apparatus for determining small percentages of carbon dioxide, methane, or carbon monoxide at mines worked with naked lights; portable apparatus for routine firedamp estimations; gravimetric determination of moisture and carbon dioxide in air; recognition and determination of small proportions of carbon monoxide in air; determination of dust in air. The methods described are only such as are designed to meet every-day needs in connection with the analysis of air and comparatively simple gas mixtures. The price of the book is $1.75.

The Index of Mining Engineering Literature, comprising an index of mining, metallurgical, civil, mechanical and chemical engineering, by Walter R. Crane. This is the second volume by Professor Crane along this line. It is printed by John Wiley & Sons, New York. Price, $3.

Strength of Materials. This book by Mansfield Merriman has reached its 6th edition, and has been revised and reset. The number of articles has been increased from 72 to 91, the number of illustrations from 48 to 54, and the number of problems from 140 to 230. Answers to some of the problems are given, and in these strenuous times answers to all problems given a student should be given. It is discouraging to work out problems and then ascertain in the recitation room that a mistake has been made. The book contains 166 pages and is a much better book than the earlier editions, although they were good. The price of the book is $1. John Wiley & Sons, New York, publishers.

The Mining World Index of Current Literature, Vol. 1, First Half Year 1912, compiled by Carpel L. Breger, has made its appearance. It is an international bibliography on mining and the mining sciences and is published by the *Mining World*, of Chicago, Illinois. Price, $2. It is double indexed for authors and subject matter, and is divided into three parts, Geographic; Ores and Mineral Products; and Technology; all in 12 chapters arranged for convenience.

Washington Geological Survey. Bulletin No. 3. The Coal Fields of King County, by George Watkin Evans.

This bulletin has been written apparently with a full remembrance of the character of the readers for whom it is intended, for the people in general of the state of Washington. It is not written so as to appeal only to people engaged in mining, but so that it might be a guide to any one interested in the coals of King County. But while the appeal is general, attention has been paid to details so that the book contains that information which is valuable to a mining man. It contains maps and cross-sections of the seams of coal, with full descriptions of the various districts into which King County is divided. Moreover, the report is well and simply written.

Days of Gold. In a pamphlet prepared for the centenary celebration at Kamloops under the direction of the Hon. Richard McBride, Premier and Minister of Mines of British Columbia, is given an excellent account of the early gold days of the '60's in British Columbia. There it is stated, in speaking of the Cariboo region, that "it was the gold rush there in 1859 that raised it from the position of a fur country to the dignity of a colony and finally a Province." The pamphlet contains quotations from various sources giving a short and succinct account that pictures the distant days. The statements given as to the richness of certain of the claims then worked show the cause for the boom that the region of the Fraser River had. The Cunningham claim is here stated to have produced $9,050 in one day and to have averaged $2,000 a day for the whole season. Sir Richard McBride had this book prepared primarily for the old timers, many of whom gathered at the celebration.

Chemical Arithmetic and Furnace Charges. Stoichiometric calculations have formed part of the chemical exercises in colleges in the United States but have rarely been reduced to a systematic course. Regis Chauvenet, A. M., B. S., LL. D., has compiled a course in Chemical Arithmetic which he has put in book form under the above title. The book is an excellent one, and will be found extremely useful for the student, since answers are furnished to the examples given. The calculations of furnace charges is in Part II, and should also appeal to the engineer or student, since they are between two covers and not in several books. The book has 302 pages with index and is printed by J. B. Lippincott & Co., Philadelphia.

Coal Mining in Arkansas. By A. A. Steel, Professor of Mining, University of Arkansas. Arkansas Geological Survey. A. H. Purdue, State Geologist. 632 pages, illustrated. The first eight chapters constituting Part I give a comprehensive outline of the entire coal mining industry of Arkansas, including an outline of the Arkansas mine laws and suggested modifications chiefly with a view to adequate propping and mine inspection. In Chapter VII, Professor Steel furnishes a forcible argument for the repeal of the mine-run law which compels operators to pay the miners the same price for slack coal and slate as for clean coal. Part II is purely technical, and includes a discussion of the best methods of protecting the miners from disease and accidents and for reducing the waste of coal and producing better coal without ultimate increase in cost. The final chapter is an interesting discussion of various plans for reducing the high cost of mining by a better adaptation of the mining methods to Arkansas conditions.

Every coal mining man in Arkansas needs this book, which can be obtained by application to A. H. Purdue, State Geologist, Fayetteville, Ark , and the payment of 22 cents in postage to cover cost of transportation.

EXPLOSION-PROOF MOTORS, H. H. Clark, of the Bureau of Mines, has been making investigations on Explosion-Proof Motors. The results of his investigations are incorporated in Bulletin 46, Bureau of Mines. This can be obtained by writing to the Director Bureau Mines, Washington, D. C.

THE DESIGN OF STEEL MILL BUILDINGS, by Milo S. Ketchum, C. E., third edition, McGraw-Hill Book Co., publishers. Price, $4.

This book is so well known that no detailed review of the book is needed. To this, the third edition, the chapters on stresses in framed structures and in bridge trusses, as well as the specifications for steel-frame buildings, have been rewritten and enlarged. In addition, Appendix III on structural drawings, estimates, and designs, containing 78 pages, 30 tables, and 24 cuts, has been added.

Temporary Shaft Head

Written for Mines and Minerals

The illustration shows a temporary shaft head that is in use at one of the shafts of the Underwood mine, which is being opened by the Pennsylvania Coal Co., at Throop, Pa. This shaft has been sunk by contract and at present the openings in the coal seams are being driven. According to the customary practice in the region, as soon as the shaft had been sunk into solid rock, the concrete lining was put in. Solid rock is very close to the surface here. The concrete has been built above the surface level, so as to raise the level of the top of the shaft and allow filling around the cribbing. In this case, there is about 20 feet of concrete work, and upon this the temporary head-frame has been built.

This temporary head-frame is used, with slight alterations, for hoisting by means of a carriage while the gangways are being driven. The engine being used in hoisting has a plain cylindrical drum, which will accommodate two ropes. To balance the weight of the carriage, another pulley was placed on the head-frame between the back-stays as shown in Fig. 1. Over this pulley was hung a sinking bucket, which was filled with short pieces of old iron rails. As the temporary head-frame does not cover the whole shaft, there is plenty of room for the movement of the bucket in the space between the carriage way and the end of the shaft.

The fan, a small force fan, is placed directly over the shaft at one corner of the concrete lining, so that the air is forced directly downward, avoiding any turns.

The shaft is fenced about so as to avoid accidents. In front of the hoisting compartment there is a gate made out of a wooden rail pivoted by a hinge at one end so that the other end may be rotated when lifted vertically. The weight of the gate is partly balanced by means of a pulley and chain so that it can be handled easily.

FIG. 1 TEMPORARY SHAFT HEAD

Coke From Coal

The percentages of coke obtained from various kinds of coal are about as follows: Cannel coal containing 44.71 per cent. volatile matter gives 55.29 per cent. of coke in gas retorts, and bituminous coal containing 34.72 per cent. volatile gives 65.28 per cent.

In Semet-Solvay retort ovens Connellsville coal containing 32 per cent. volatile matter gives 72 per cent. coke; Morris Run coal containing 20 per cent. volatile gives 83 per cent., and Pocahontas coal containing 18 per cent. volatile gives 85 per cent.

In beehive ovens Pocahontas coal with 18 per cent. volatile matter gives 62 per cent. coke, Morris Run coal with 20 per cent. volatile gives 60 per cent., and Connellsville coal with 32 per cent. volatile gives 64 per cent.

Mine Accidents, 1911

The Annual Report of the Department of Mines of Pennsylvania for 1911, records 615 fatal accidents in the mines during the year The causes of these accidents were as follows: Falls of coal, slate, and roof, 253 or 41.14 per cent.; by cars, 92 or 14.96 per cent.; explosions of gas, 34 or 5.53 per cent.; explosions of powder and dynamite, 21 or 3.42 per cent.; electricity, 2 or .32 per cent.; blasts, 67 or 10.89 per cent.; falling into shafts, suffocation by gas, and miscellaneous causes, 146 or 23.74 per cent.

Of these fatalities, 337 or 54.8 per cent., were due to the carelessness of the victims themselves, 45, or 7.31 per cent., were due to the carelessness of others and 233, or 37.89 per cent., were classed as unavoidable.

It is a sad commentary on the recklessness of mine workers and on the discipline in the mines when 382, or 62.11 per cent., of the lives lost were sacrificed to carelessness. In the accidents classed as unavoidable it is evident that there were many from which, while they were not due to gross carelessness, the element of carelessness was not entirely absent.

Dust Explosions

Influence of Composition and Fineness of Dust, and the Presence of Gas on the Liability of Ignition

*By C. M. Young**

A CONSIDERAble portion of the following material will appear in Volume X of the report of the Kansas State Geological Survey and is now published with the permission of the Director.]

The explosion of coal dust is a combustion so rapid that the mine air and the gases formed are violently expanded by the heat. It is necessary that there be present fuel and oxygen in proper amounts and that they be ignited.

If we assume that no combustible gas is present all the fuel must be supplied by the dust. In most cases some gas is doubtless present, but it may be in quantities too small to be detected by the safety lamp. However, it has been demonstrated that even very small amounts of gas may aid an explosion.

Assuming, however, that all the fuel is to be supplied by the dust, it becomes important that we know as much as possible of the conditions under which the dust is explosive. Some students of the subject have expressed the opinion that any combustible dust may be explosive under favorable circumstances. It is my opinion that this is not the case. Anthracite dust is certainly combustible but it seems not to be explosive. This is to be expected if we remember the method of combustion of anthracite. An isolated piece surrounded by air will not burn because the heat generated by combustion is not sufficient to maintain the reaction. If we wish to burn it we must surround it by a medium which does not readily convey away the heat generated. In practice this is accomplished by having a large number of pieces of fuel lying together. In this way only so much air is in contact with each piece as is necessary to supply oxygen and the heat is not dispersed in heating an excess of air, and loss by radiation is also diminished.

Since the heat value of anthracite is high, it might seem that the burning of each particle of dust would furnish enough heat to raise the surrounding particles to the ignition temperature if they were not too far away. That this is not the case is doubtless due to the fact that, small as may be the particles of dust, they are very far from being molecular, and combustion can take place only on the outer surface. The heat is therefore developed slowly and is at the same time carried away, so that the temperature is lower than it would be if all or a large part of each dust particle burned nearly instantaneously. The combustion does not spread to the neighboring particles and there is no explosion. If it is assumed that the particles are so close together that there is little opportunity for the dispersal of heat, there will not be enough air for complete combustion, and the heat developed will be too little to permit the spread of the combustion.

The dusts of some bituminous coals and of many other substances are not only combustible, but in some cases they are explosive. The great distinction between bituminous and anthracite coals is the fact that the former contain combustible volatile matter. It seems to be this fact that renders them, in some cases, explosive. When the coal is heated, the volatile matter is distilled and is separated from the coal as gas or vapor. The combustible part may be ignited and burned. If it is mixed with air in proper proportion it may be exploded. The fixed carbon remains behind and may or may not be burned.

It is this possibility of the distillation of the volatile matter which makes bituminous coal easy of ignition. When heat is applied the gas is distilled, and it is this gas which burns first. If the coal is suspended in the air in the form of a fine dust the gas is set free in intimate mixture with air, and the mixture of gas and air will be explosive if the combustible matter and the oxygen exist in the proper proportion. The gas set free from the coal will have definite explosive limits, just as natural gas and other explosive gases have. There must be present in the air, then, neither too much nor too little of the gas. As will be shown more plainly later, the presence of too much gas is much more rare and improbable than the presence of too little.

Since a certain amount of gas must be present, it is evident that it can be supplied by a certain amount of coal of a given composition, and that the amount of coal necessarily decreases as the percentage of volatile combustibles increases. It will then be possible to get an explosive atmosphere by distilling the gases from a comparatively small amount of coal high in volatile combustible matter. No definite statement of the amount of volatile combustible matter necessary can be made. It evidently depends largely upon the nature of the coal and the amounts of the moisture and ash.

Recently a sample of coal was sent to me for examination from a mine in which an explosion had taken place. This was claimed by some to have been a dust explosion while others believed that it was caused by gas. The dust failed to explode without the addition of a combustible gas, methane being used. Analysis showed that the coal contained only 13.4 per cent. volatile combustible matter. It seems impossible that the dust from such a coal should be explosive under any ordinary circumstances.

In order that the distillation and combustion, when once initiated, may be self-sustaining, it is necessary that the dust be suspended in the air. It is apparent that the ease of suspension depends largely upon the fineness of the dust particles. Any solid substance, no matter how small, will fall through the air, but the rate of fall will depend upon the relation of weight to surface exposed. We may assume that the specific gravity of all coal particles is the same, though this is not strictly true. The rate of fall will then depend upon the surface exposed, being slower as the size of the particle is decreased. If the air is in motion with an upward velocity equal to the rate of fall of the particle in still air, the particle will remain suspended. Air in motion does not move in straight lines, but the friction against the walls of the passages causes eddies, so that there are always currents which are blowing in a more or less vertical direction and these tend to raise the dust into the air and keep it suspended. If these currents are strong enough the dust will not settle out but will remain in suspension. No practical ventilating current will be strong enough to keep the coarser sizes of dust in suspension, while no such current will be slow enough to allow the finer sizes to settle out. It is apparent then that the danger increases with the fineness of the dust, other things being equal. It has been found by experiment that only those dusts which will pass through a 200-mesh screen are kept permanently in suspension in an ordinary current.

The size of the dust also has a great influence on the ease with which the volatile matter is distilled. The dust is exposed to high temperature during only a very short time. If it is in comparatively large fragments the heat will not have time to penetrate to the interior and only the outside of the fragments will be coked; that is, not all of the combustible gases which are in the coal will be set free and mixed with the air. The probability of an explosion is therefore small because it is only in circumstances out of the ordinary that enough of this coarse dust will be suspended in the air to set free a sufficient amount of gas to make an explosive mixture with the air.

On the other hand, if the dust is fine, it will be heated through in the brief exposure to high temperature and all or nearly all of the gas will be driven out. Therefore, less fine dust than coarse is required to make an explosive mixture with air. An examination of some dusts under the micro-

* Associate Professor of Mining Engineering University of Kansas.

scope showed that, in some cases, a large part of the dust which had passed a 200-mesh screen was very much finer than the openings in the screen. The openings in such a screen are approximately .003 inch in diameter, while some of the dust particles were only .00006 inch in diameter. It was found by experiment that dusts containing these small particles in large quantities were much more explosive than those made up more entirely of larger fragments, the quality of the coal being otherwise nearly the same. It therefore appears that a chemical examination alone will not determine the explosiveness of a dust, but that a physical examination is also necessary.

Two coals may be subjected to the same grinding process and yield different amounts of the very fine particles. This difference is due to differences in physical structure. Only a microscopic examination shows the great differences between coals in this respect.

It was also found that different portions of the same sample of coal may show this peculiarity. In the case of one coal it was found that if the coal was ground in stages, the 200-mesh dust being occasionally sifted out during the process of grinding, the first dust produced had a comparatively high explosive limit, while that produced last had a much lower limit. This last dust, produced from the least friable portion of the coal, showed a much larger proportion of very fine particles than that produced by the first grinding. It is not known whether this is a general fact.

The explosiveness also depends upon the nature of the volatile combustible matter. In some cases this is so tarry that the dust is bound together and cannot be suspended in air, even though the individual particles are sufficiently fine. This condition also tends to prevent the production of the finest dust. It was found that a coal from the Kittanning seam showed this quality and its dust failed to explode. It was also found that this dust contained few very fine particles.

The fact that dusts from coals low in volatile combustible matter fail to explode suggests that the addition of a combustible gas or vapor may make them explosive. This is found to be the case, and it has been found that when methane, in quantity too small to be explosive alone, is added to a mixture of dust and air containing too little dust to be explosive, the resulting mixture may be explosive. It was found that some dusts which failed to explode alone were made explosive by the addition of as little as 1 per cent. of methane. This fact indicates that there may be great danger in the presence of a very small amount of gas in the mine air. Tests for gas, as ordinarily conducted, will not indicate the presence of less than 2 per cent. and probably most fire bosses will not detect less than 3 per cent. with certainty. Thus it is apparent that a mine, which is not considered dangerous because of the presence of gas, may be dangerous because an undetected amount of gas renders the dust explosive. Also a disturbance of the ventilating current, allowing a slight increase in the amount of gas in the air, may be a much more serious matter than it is supposed to be.

The gas which is to be feared is not alone that natural to the mine, but the gases from explosives may have the same effect. Black powder, when fired in the presence of coal, sometimes yields gases which are combustible;* some of the safety powders always yield such gases, some never do, and probably others do so under certain conditions. It is therefore possible that the gases from explosives may render the dust with which they are mingled explosive, even if they are present in quantities too small to be explosive alone. There can be no doubt that a large number of windy shots are due to these facts. I speak of these as facts because they have been demonstrated.

When the dust distilled from the heated coal burns, the particles of coal, now partly converted to coke, are heated to a temperature at which they reduce the carbon dioxide resulting from the combustion of carbon monoxide. Since this temperature endures for a very short time it is probable that the amount of carbon monoxide thus produced depends largely upon the surface of glowing carbon exposed to the gas. It is certain that enough is sometimes produced to render the afterdamp exceedingly poisonous, as is proved by the fact that short exposure to it is frequently fatal, even though life may not be extinct when efforts at resuscitation are commenced. In some cases there is enough to render the afterdamp explosive when it is mixed with a fresh supply of air. Thus there may sometimes be a second explosion following the first.

The necessary oxygen is, of course, supplied by the mine air, and mine air commonly contains a sufficient amount. An unusually large quantity of carbon dioxide will reduce the activity of the air, and this will be especially the case if, as is usual, this gas has been formed by the consumption of a portion of the oxygen of the air. It is not often however, that mine air is in this condition.

Probably the most important variable of the air is its moisture content. The presence of water vapor renders the air less fit to support combustion, not because of the presence of less oxygen but because heat is absorbed in raising the temperature of the water vapor, and the temperature produced by combustion is therefore lower. A certain amount of fuel can produce only a certain amount of heat and if a portion of this heat is consumed in raising the temperature of the water vapor, in addition to that used in raising the temperature of the air and dust surrounding the igniting body, the resulting temperature may be too low to coke the dust and ignite the gas produced. Therefore, the presence of water vapor may prevent the occurrence of an explosion. This fact is now quite generally understood and there are many advocates of the humidification of air in dusty mines. There are certain objections to this procedure and these have been well stated and need no discussion here.

The temperature of the air may have a considerable effect. It has been said before that a sufficiently high temperature must be reached to coke the dust and ignite the gas, and if the temperature of the air is already high the heat necessary to produce this required temperature will be less than if the air is cold. The ordinary range of temperature will have little effect, but it is conceivable that a considerable compression of the air might result in a temperature that would be important. It is even possible that a wave of compression may traverse the air which will produce a temperature sufficiently high to coke the dust and ignite the gas produced. In this way an explosion might be produced at a point which the flame of the original explosion had not reached, traversing passages free from dust and originating explosions at new points. Thus the compression of the air may have an important effect in the propagation of an explosion, though it is not necessary to the inception of the explosion or to its propagation.

In order that the dust may be ignited, it is only necessary that it be raised to a temperature sufficient to coke it and to ignite the gas given off. In order that the flame may be propagated, it is probably necessary that the source of ignition be of considerable size, otherwise combustion at any one time will be so little that it will probably be confined to the immediate neighborhood of the igniting body. It has been proved in the laboratory that a bunsen burner or an ordinary miner's lamp will easily ignite dust, but it is not often that the air of a mine will contain sufficient dust in suspension for such means to ignite it. It would seem that nothing else would be so apt to do so as the large flame of a blown-out shot. This has the necessary temperature and heats a large volume of the mine air at once. Unless the flame from the shot impinges directly upon a deposit of dust, it is doubtful whether a single shot could both stir up the dust and ignite it, because the hot gases would become cooled before they could be mingled with the dust, but if previous shots had first stirred up the dust the chance of ignition would be very favorable.

The ease of ignition will be greater if the preceding shots have furnished a combusti-

* Gaseous Decomposition—Products of Black Powder, with special reference to the Use of Black Powder in Coal Mines. C. M. Young. Transactions American Institute Mining Engineers, Vol. XLI, pages 454 to 479.

ble gas, either from the explosive itself or from the coal. Windy shots which seem to have this origin are very frequent in the mines of Kansas, where black powder is used in excessive quantities.

In recent times there has been a great increase in the production of coal. This has been accompanied by changes in the conditions of mining. Larger quantities of coal are hauled over the roads and larger quantities of dust are produced in the haulageways. The increase in the size of the workings and in the number of men employed has necessitated the use of more rapid ventilating currents. The result has been more thorough drying of the dust and the suspension of more of it in the air. The use of explosives has increased much more rapidly than the production of coal. This results in the production of more dust in the rooms and, in some cases, in the production of larger quantities of combustible gases. These changes and possibly others have been accompanied by an increase in the number of dust explosions.

The foregoing notes are offered as a small addition to our knowledge of dust explosions. We already know much of the phenomena of such explosions, but we do not know all. If we did, it would be possible to explain every explosion and to positively state the precautions necessary for the prevention of explosions in the future. We cannot do this. Indeed, it is not infrequently the mine which seems safest that offers an example of the deficiency of our knowledge. But this knowledge is constantly and rapidly increasing. The subject has many phases and there must be study of all of them before we can claim general knowledge of it. This article presents a few of the more important observations made in a study of mine explosions and is written with the purpose of adding something to our knowledge of the subject, which when collected, sometime in the future, may be found so complete as to enable us to state clearly the causes of explosions and their remedies.

The Value of Study to Mining Men

*By Samuel McMahon**

Our bodies at all times perform various functions with little thought on our part. How many of us ever stop to consider what a wonderful thing it is to breathe, see, hear, taste, smell, and move from place to place? Not many of us I fear are impressed with these wonderful acts because they are going on continually, and the regularity and ease with which they are accomplished make them cease to be a matter of much moment to us. Scarcity adds value to things, but common things may be so very wonderful that scientists and philosophers are unable to explain them, and yet from the fact of their frequent occurrence they do not arouse a sense of awe in us. Now this is the position of mining men. The fact that we go to work at a certain time, quit at a certain time, and that for this work we receive a certain salary, is clearly impressed upon our minds; but for this very reason the work to most of us is liable to become ordinary, and we lose sight of the fact that we are engaged in an interesting and educating work. We go each morning into the mine and send out coal which centuries ago an allwise Providence stored there for the use of mankind. When we enter the mines, our minds do not go back to the ages when this black mass covered the earth in vegetable form. We have all heard the theory of how coal was formed, but few of us think deeply on the subject and try to understand the conditions on which this theory is based. A doctor must be familiar with the human body, its composition and the effects of drugs; a lawyer must be on intimate terms with Blackstone, and have a knowledge of technical law points; a clergyman not only must study the Bible, but Bible history; the merchant must educate himself along lines which will make him successful; and so it is in every walk of life, the successful men are those who are full of their subject, and by being informed along the lines in which they are engaged are ready to take advantage of an opportunity. By means of study these men at the crucial moment are masters of the situation. I speak now of the successful men in all the chosen walks of life; and though we may not admit it, we all either now or at sometime past earnestly desire "success," which consists in nothing more than doing well, whatever there is to do. We are a body of successful men, mine foremen, superintendents, and inspectors, and we are all trained to manage a mine successfully. Why should we not be as well versed in our work in life as men in other callings?

I am well aware that all of us, speaking for the mine foremen, are physically tired after a day's work and the idea of study and mental effort at night is irksome, but a chapter from some book on mining would be as easily read and understood as the newspaper. Reading a good book in the evening is no more of a task, than reading a paper, an act which the majority of us perform religiously, but it must be done systematically. The trouble is, that we submit too much to the routine and monotony of life. We get into a rut—and this does not refer alone to mine foremen. We fail to see what surrounds us and to prepare ourselves to step through the door when opportunity opens it to us. We should get as much happiness from life as possible and make our lives as broad and full as it was intended they should be, but let us endeavor to educate ourselves until we excel. Men like Lincoln, Garfield, and others, whose advantages for education were not so good as ours, were crowned with success, simply because they endeavored to be ready when the opportunity arrived.

Mining men have as interesting subjects to study as there are. To be familiar with the scientific part of our work we must study geology; then we can appreciate the principles involved. The great Scotch geologist, Hugh Miller, early in life was left to the care of his mother, the widow of a sailor; later he became a stone mason; always laboring under difficulties, he succeeded in writing the books that made him famous. Miller said: "The best schools I have attended are schools open to all; the best teachers I have had are, though severe in their discipline, always easy of access; and the form in which I was, if I may say so, most successful as a pupil, was the form to which I was drawn by a strong inclination, but at which I had less assistance from my brother men or even from books than from any of the others; there are few of the natural sciences which do not lie quite as open to the working men of America and Great Britain as geology did to me." We cannot all be authors or all famous men, but some of us will, if we read, be better fitted to take up higher positions. Some of us may be managers or called on to fill the honorable position of mine inspector. I quote Miller because he had few advantages and received his education in the woods, under the earth, from trees and brooks, and his writings were on geology principally, a subject which touches our work so closely we should all be interested. Read, study, learn, satisfy the desire of the mind for knowledge if only to enjoy life more fully. My argument is that mine foremen need to study more than any other professional men. To bring intelligence into work through judicious reading makes us better workers, better citizens, and better family providers. In this age of machinery and improved methods of doing business, practical mine foremen are in demand. Try this plan of reading for self-improvement and I am sure the habit will grow until you will have to satisfy that God-given curiosity and supply the matter to the mind.

* Russelton, Pa. An abstract from a paper read at a local institute of mine foremen.

Fast Tunnel Driving

The driving of tunnels has presented much interest of late years, for projectors and contractors have striven to establish world speed records in advancing horizontal excavations. A notable instance of this sort of rock breaking occurred in the Henrylyn tunnel, at the end of West Clear Creek, in central Colorado. In 29½ working shifts of 8 hours each, this tunnel was pushed 293 feet through solid granite, or practically at the rate of 1¼ feet per working hour. The tunnel is 8 feet by 10 feet in section; is to be 15,550 feet long; and is intended to divert water from the Pacific watershed to the plains of Eastern Colorado for irrigation.

Answers to Examination Questions

Examinations for Second Grade Mine Foremen Held in the Bituminous Regions of Pennsylvania, 1912

(Continued from November)

QUES. 10.—(a) Would there be any advantage derived in the safety to life and in economy of operation of mines if a uniform system of timbering the working places was adopted and strictly carried out, such a system to be suitable to the existing conditions in each mine? (b) What distance would you set props apart under varied conditions of roof and bottom? (c) State the conditions of roof and floor where you are employed.

ANS.—(a) Yes, under any circumstances, and particularly if the spacing of the props is changed from time to time as conditions of roof and floor change, as these will in any mine. Roof falls are usually caused by lines of weakness due to invisible cracks extending through the roof slate to the sandstone or other rock constituting the true roof of the seam. Sooner or later the weathering caused by the warm, moist mine air will destroy what cementing material there may be, and the pieces will fall. As these cracks are invisible and unequally spaced, it is plain that if the posts are set at a uniform and not too great a distance apart, the chances that they will hold one of these blocks are greater than if set at random and by mere guesswork. Also, under ordinary conditions, if the cracks are not visible, no posts at all will be set, and, thus, a uniform system of timbering offsets the absolute disregard for his own safety that seems characteristic of many a miner. (b) The proper distance apart for props under all the various conditions possible is difficult to give. In some mines no posts at all are needed and the roof remains standing for months and years after the coal has been worked from under it. In others, the slate falls as the coal is shot, or within a few minutes, hours, days, or weeks, according to locality. No set rule can be given for spacing props and it must be determined by experience for each mine. When the proper spacing is once determined it should be adhered to until underground conditions change, when a new spacing should be experimentally decided upon.

Mr. S. L. Goodale, quoting from Austin King, Chief Mine Inspector of the H. C. Frick Coke Co.,* says: "The stronger the roof is, the stronger the prop required; because the roof, if broken, is in much larger pieces; conversely, where the roof is broken and tender, the props set must be more numerous, and if these require to be set close enough to interfere with the carrying on of the work or the ventilation, cross-bar sets with latticework lagging must be substituted. Where there is a strong roof and bottom, the props should be set so as to permit the roof to ease, or gradually settle down, or the bottom to heave, and thus prevent the breaking of the prop or prolong its usefulness as such. Under such conditions they should not be driven very tight, and in such cases caps of short timber should be used, otherwise the invariable result is at first a bent, and later on a broken and useless prop."

Under most methods of systematic timbering the props are set at the four corners of a series of squares, with one prop in the center at the intersection of the diagonals from the corner props, in such a way that the greatest distance between any two props is 5 feet, 6 feet, or any other distance determined by the character of the roof. (c) This should be answered by stating actual conditions, as, for example, "A strong fireclay floor and a draw-slate roof averaging 8 inches thick with overlying sandstone."

QUES. 11.—What in your opinion are the things most neglected in the operation of a mine, whereby the cost of coal is increased and the sanitary conditions of the mine impaired?

ANS.—Probably drainage and ventilation are more neglected than other features of mine work affecting both the cost of production and the sanitary, or healthful (as distinct from safe or dangerous conditions), of a mine. Poor drainage means increased cost of haulage through improperly graded and neglected roads, with consequent increased power requirements, loss of time through cars being off the track, and the like. It also affects the health of the men by compelling them to work with wet feet or in wet clothes. Poor ventilation may be due to too small a fan, too small airways, or to neglected return air-courses choked with fallen roof rock, to neglect in driving breakthroughs at proper intervals so that the air may be carried to the face, to leaky doors and brattices, and to failure to properly split the air. In any case the cost of production is increased by the physical impossibility of the men doing their best in an impure and even poisonous atmosphere. The effect of such an atmosphere upon the health of the men is apparent.

QUES. 12—The water gauge reads 2 inches; the velocity of the air-current is 500 feet per minute and the length of air-course is 4,000 feet; what would the water gauge read if the length of air-course was extended to 8,000 feet and the velocity of air-current was increased to 800 feet per minute?

ANS.—The formula for the water gauge in terms of the velocity and length of airway is $i=\frac{ksv^2}{5.2a}=\frac{klov^2}{5.2a}$, in which l is the length, o the perimeter, and a the area of the airway, and k and v are the coefficient of friction and the velocity of the air, respectively. Only v and l vary, and as k, o, a and 5.2 are the same for each set of conditions, they may be dropped, and the formula for comparing the water gauge, when the velocity of the current and the length of the airway vary, may be written $i=lv^2$; that is, the water gauge varies directly as the length of the airway multiplied by the square of the velocity of the current. As the airway is twice as long, we have $l=2$, and as the velocity is increased from 500 to 800 feet a minute, $v=800\div500=1.6$. These are the ratios and represent the relative increases in the length of the airway and the velocity of the current. Substituting, we have $i=lv^2=2\times1.6^2=2\times2.56=5.12$. That is, under the new conditions the water gauge is 5.12 times what it was under the old ones. As the gauge was 2 inches under the old conditions, it is $2\times5.12=10.24$ inches under the new.

QUES. 13.—(a) In case a workman is in contact with a live electric wire, how would you release him? (b) Should a workman be rendered unconscious from electric shock, or by inhaling noxious gases, what would be your method of procedure, in each case, to revive him?

ANS.—(a) Miner's Circular No. 5, of the United States Bureau of Mines, gives most excellent directions for handling those suffering from electric shock, and from it we quote as follows: "While removing the victim from the electric circuit, be careful not to get a shock yourself. If there is a switch right at hand, cut off the current at once; but if there will be any delay in cutting off the current, remove the body from the circuit by means of a piece of dry wood, used either to roll or push the body aside or to lift from the body whatever is carrying the current to it. Tools with dry wooden handles, such as picks or axes, may be safely used for this purpose. The body of the victim can be safely grasped if your hands are protected by several thicknesses of dry cloth, or if you stand upon a piece of dry wood.

"When you can do nothing else, you may be able to short-circuit the line with which the victim is in contact, and thus blow the circuit breaker or fuses which protect that part of the electric system.

"A short circuit may be made by placing an auger or drill or a piece of pipe so that it will connect the two sides of the electric circuit. For example, in case the victim is in contact with a trolley wire, the auger, drill, or pipe should be thrown across the trolley wire and track rail, so as to be in contact with both. In doing this, be sure that the auger, drill, or pipe leaves your hand before it touches the current-carrying part

*"Safety Through Systematic Timbering," by Stephen L. Goodale, Professor of Mining and Metallurgy, University of Pittsburg, MINES AND MINERALS, November, 1911.

of the circuit, as otherwise you will get a shock yourself."

(b) The method of restoring respiration after an electric shock is the same as after suffocation from inhaling bad air. In any case do not attempt to restore breathing in case of suffocation from impure air when the victim is in the same bad air that overcame him; first get him where the air is pure, and if possible, outside the mine, if there is the least question as to the quality of the mine air.

Quoting further from Bulletin No. 5, noted above: "When the victim has been removed from contact with the current, turn him on his back, loosen the clothing from around his neck, chest, and abdomen, and place a log, a rolled-up coat, or something of similar size and shape under his shoulders in such a way as to throw his head back and his chest up. The next thing to do is to draw out the victim's tongue, which can best be done by grasping it with a piece of dry cloth. This act clears the windpipe, and unless it is done, the victim cannot be made to breathe. If the rescuer is alone, he will have to keep the tongue in this position by tying it with a handkerchief or a bandage passed over the tongue and under the jaw. The tongue must be held in this position while giving artificial respiration.

"Kneel behind the head of the victim, grasp his forearms just below elbows and draw them slowly backward until they are extended as far as possible over his head and hold them there for about one second Then slowly push the elbows forward and downward until the elbows are at the side and the hands folded over the stomach of the patient.

"Do not perform the operations hurriedly but take about 4 seconds for one series of movements. Usually a victim of electric shock can be made to breathe within an hour, and the movements should be kept up at least that long, even if the patient does not show any signs of being 'brought to.' The patient should be kept warm, and after he begins to breathe his limbs should be rubbed briskly and toward the heart, the hands of the rescuers being kept under the covering while this is done. This will help to restore the circulation which has been suspended for some time."

If a pulmotor, or mechanical device for restoring breathing, is available, it should be used.

Ques. 14.—What are the legal requirements for the protection of workmen in the installation of electric wires, along traveling or haulageways, and should the rails be bonded?

Ans.—"In underground roads the trolley wires shall be installed as far to one side of the passageway as practicable, and securely supported upon hangers, efficiently insulated, and placed at such intervals that the sag between points of support shall not exceed 3 inches. The sag between points of support can exceed 3 inches if the height of the trolley wire above the rail is 5 feet or more and does not touch the roof when the trolley passes under."

"At all landings and partings where men are required to regularly work or pass under trolley or other bare power wires, which are placed less than 6½ feet above the top of the rail, a suitable protection shall be provided. This protection may consist of channeling the roof, placing boards along the wire, which shall extend below it, or the use of other improved devices that afford protection."

"It is recommended that, where air or water pipes parallel the grounded return of power circuits, the return be securely bonded to such pipes at frequent intervals, to eliminate the possibility of a difference of potential between rails and pipes and to prevent electrolysis of the pipes. The rail return shall be of sufficient capacity for the current used, independent of the capacity of the pipes. On main haulage roads both rails shall be bonded, and cross-bonds shall be placed at points not to exceed 200 feet apart."

Ques. 15.—If a workman had his leg broken, or had arteries severed, what would be your method of rendering first aid to him in both cases?

Ans.—In the case of a broken leg place the patient in a comfortable place upon his back with the injured leg upon a coat or two, or a sack filled with straw or anything soft. Cut the clothing in the seams and remove it from about the fractured part carefully. If no splints are available make one of a piece of thin wood, or even of a piece of a powder keg cut out with an axe. Pad the splint and place it, and if need be a second one opposite it, over the fracture so that it will extend above and below the break in such a way that the broken bones do not rub upon one another. Then bandage it in place. Lay the patient on one of the ordinary mine stretchers and carry him carefully to daylight, being careful to arrange the stretcher so that the broken leg is not again bent. In event of a compound fracture, before the splints are applied the bleeding must be stopped and the wound dressed, the method of treatment depending upon the nature of the hemorrhage. Splints must be applied but not bandaged too tightly.

A severed artery may be known as the blood comes out in jets. The object of the first-aid treatment is to stop the flow of blood at some convenient point between the heart and the wound. Cover the fingers with antiseptic gauze and press the wound to stop bleeding while the more permanent first aid is being administered. Artificial pressure should then be applied a short distance above the wound and at such a point as not to hurt the wound or the bones, if these be broken. For applying artificial pressure, two sticks may be placed on opposite sides of the severed artery and held together by two handkerchiefs, one about each pair of ends, or a tourniquet may be made by wrapping a handkerchief or lengths of gauze about the part to be compressed, making the outer end into a loop through which a stick is passed. Any desired degree of tension may be obtained by twisting the stick, but no more should be applied than is necessary to stop the bleeding. The part should then be bandaged, arranged so that the dressing will not slip, when the patient may be carried out on a stretcher, using the same precautions to prevent pain and discomfort as in the case of fractures.

Ques. 16.—(a) Give the advantages and disadvantages of the different kinds of explosives used in blasting coal and rock, and what precautions would you enforce for the handling of them? (b) What kind of a needle and tamping bar would you use and why?

Ans.—(a) The explosive commonly used in blasting rock is dynamite, consisting of nitroglycerine held in absorption by sawdust, infusorial earth, or some similar porous substance. It detonates with extreme rapidity, that is, it is "quick acting," shattering the rock into small pieces, which is an advantage in cleaning up with shovels after a blast. Further, being far more powerful than ordinary black powder, less of it is needed to produce a desired effect than the slower acting explosive, and consequently smaller holes, drilled at less cost, may be used in connection with it. It is also better adapted to shooting in wet ground than powder, as it is supplied in practically waterproof casings.

The original black powder, now being replaced by the so-called "permissible" or "safety" powders, consists of an intimate mixture of nitrate of potash, sulphur, and charcoal. It is, compared with dynamite, slow in action and is better adapted to blasting coal than the quicker acting explosives, as it shatters it less.

The permissible powders are generally quicker acting than black powder, but much slower than dynamite. They are well adapted to blasting coal, particularly in gassy or dusty mines, where, by reason of their detonating with an extremely short flame, they will not readily ignite either of these two dangerous elements.

Explosives should not be stored underground and no more than needed for one shift should be taken into the mine at one time, except that when shot firers are employed they may, naturally, take in enough for their use. When preparing holes for blasting, the shot firer should leave on the entry all but enough explosive to charge the holes in the room. Cans containing explosives should not be opened, nor should explosives be handled or made up into cartridges, within 5 feet of a lamp, which must be placed in such a position that sparks may not be blown from it into the powder. Nor must a miner smoke when handling explosives, nor carry them in the same case with, or store them near, detonators. No explosive should be forcibly pressed into a hole too small for it, and no explosive should be removed from a hole, nor should another hole be drilled and charged nearer than 12 inches to one that has missed fire. Clay, or some incombustible material, and not coal slack, must be used for tamping, and all holes must be tamped solid for their entire length. All powder must be carried into the mine in metal cans or in receptacles of equally safe material, which must not be allowed to come in contact with live electric wires. Powder must not be stored in a tipple or weighing office and naked lights must not be used while it is being weighed or given out.

(*b*) A copper needle and a tamping bar of wood, or of wood tipped with copper, must be used in charging and tamping holes. Copper does not strike a spark when coming in contact with the iron pyrites so common in coal seams, and the danger of prematurely igniting the charge is thus avoided.

(*To be continued*)

Coal Mining Notes

The Northwestern Improvement Co. is arranging a plan for hauling loaded and empty cars at the foot of their No. 4 shaft, at Roslyn, which greatly facilitates the work and also decreases the cost of operation at least $18 per day.

The plan of operation is as follows: A loaded trip is dropped in until one or more cars reaches the advancer, which is then started through the clutch and the whole trip advanced until the head car reaches the knuckle. While the head car is covering the distance between the head-sheave and the knuckle it will be uncoupled, and after passing the knuckle it runs by gravity over either one of two loaded tracks to a position in front of the cage landing. Two cars should always be in position awaiting the landing of the cage, and while these two are being placed upon the cage, and while the opposite cage is descending, two other loads are fed into position on the opposite loaded track. When the cage has landed the feeder is started and the front car is fed on to the cage, bumping off the empty. The cage is then raised, bringing the lower compartment into position; then the feeder is started and the second car is fed on to the cage. Both feeders are then stopped by throwing out the clutches, and at the same operation a stop is placed over the rail to prevent the incoming loads from entering the shaft sump. Shafts are run continually, the feeder chain being started and stopped when desired by positive jaw clutches. All the feeder mechanism except the feeder chain lies below the floor line, so that the cager may walk from one cage to the other without any interference. The empty cars after being bumped off the cage run by gravity over a kick-back and on to a car haul by which they are elevated to a level sufficient to permit of their running into a slight dip, when they will be coupled, oiled, and made ready for the return trip.

This plan only necessitates the employment of one cager and a boy to operate the advancer and uncouple the cars, one boy to couple the empties, and one boy as oiler.

Princeton, B. C., Coal Mines.—Mr. Frank Bailey, of Princeton, B. C., sends the following information. The Princeton Coal and Land Co. has its mine in good shape to handle recent orders of 500 tons per day from the coast and interior cities. This company has invested some $75,000 in an up-to-date plant, with a daily capacity of 500 tons, and the coal obtained from the large seams which underlie the Princeton coal basin is a first-class domestic coal. An office has recently been opened in Vancouver and when transportation facilities now under construction are completed to the coast, the demand will be greater.

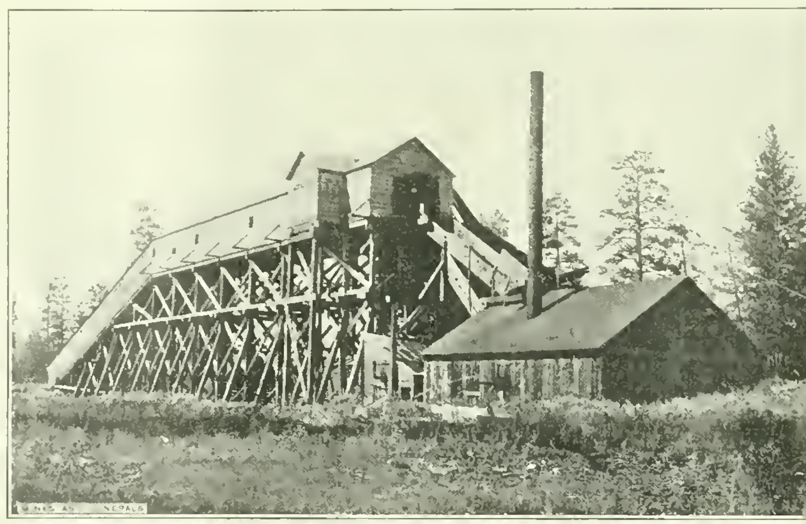

FIG. 1. COAL TIPPLE NEAR PRINCETON, B. C.

Fig. 1. shows a tipple near Princeton, B. C. The coal is reached by a slope, and the trestle slope is housed to make it possible to work economically during the winter months.

The Columbia Coal and Coke Co., of Coalmont, lately sold to the Canadian Pacific Railway Co. $1,000,000 worth of its bonds, and there is no doubt now that the Kettle Valley Railway (C. P. R.) will immediately build up the Tulameen Valley to tap the Tulameen coal basin at Coalmont.

The V. V. & E. Railway (Great Northern Railway) has been running trains up the Tulameen to Coalmont all summer from Princeton and Spokane, and the contracts are let to Messrs. Guthrie, McDougall & Co., for the immediate construction of 42 miles of grading from Coalmont to the summit of the Coquihalla Pass, and other contractors are working from the Fraser Valley to connect the Great Northern Railway at the summit.

Recreation Hall, Leisenring.—In addition to other rational sociological ideas adopted by the H. C. Frick Coke Co., a recreation hall for the use of the employes has been provided at Leisenring, No. 1 plant, in the Connellsville region. This hall was opened with appropriate ceremonies on Columbus Day. After other exercises, the orchestra discoursed dance music and an opportunity was given both old and young to indulge in this pleasure during the afternoon, and until 12 o'clock midnight. The opening exercises and pleasures subsequently provided were under the direction of Mr. Chas. B. Franks, superintendent of Leisenring No. 1 plant.

The Stanton Mine, in Livingston County, Ill., belonging to Rutledge & Taylor, has made a record by hoisting 4,260 tons of coal in 1 day from a two-compartment shaft. This is at the rate of 3.5 cars per minute, each car holding 2.5 tons.

Teaching English.—Among the features of the Young Men's Christian Association work in this country is teaching English by a method which combines English with life saving and practical instruction. This is accomplished by aid of the book "Mine Accidents and Their Prevention," published by the Coal Department of the Delaware, Lackawanna & Western Railroad Co., combined with Roberts system of teaching English which has been described in MINES AND MINERALS.

Care of Tools

The care of tools is quite as important as any other detail of track work. All tools should be kept clean, sharp, and in good order. All new tools should be marked with the company's brand by the storekeeper. When tools are worn out and need replacing, the worn-out tools should be returned to the supply house.

Each track-laying gang should be provided with a strongly made tool box of sufficient size to contain the complement of tools and it should be furnished with a substantial lock.

Prize Contest

With the idea of stimulating interest in practical mining questions, and at the same time drawing out ideas from our readers who constitute a large portion of America's most progressive mining men of all classes, we offer the following prizes:

For the best answer to each of the following questions, we will give any books on mining or the sciences related thereto, now in print, to the value of $3.

For the second best answer, similar books to the value of $2 will be given.

Both prizes for answers to the same questions will not be awarded to any one person.

CONDITIONS

1. Competitors must be subscribers to Mines and Minerals.

2. The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

3. Answers must be written in ink on one side of the paper only.

4. "Competition Contest" must be written on the envelope in which the answers are sent to us.

5. One person may compete in all the questions.

6. Our decision as to the merits of the answers shall be final.

7. Answers must be mailed to us not later than one month after publication of the question.

8. The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes, and to mention the numbers of the questions when so doing.

9. In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.

10. Employes of the International Textbook Company, or of Mines and Minerals, are not eligible to enter this contest.

Questions for Prizes

1. *Calculation of Size of Fan Required for a Given Circulation.*—What size and type of fan would you employ for the circulation of a volume of 160,000 cubic feet of air per minute against a water gauge of 2 inches? Show method of arriving at size.

2. *Diffusion of Mine Gases.*—(*a*) Why does marsh gas, CH_4, diffuse more rapidly into the air-current than carbonic acid gas, CO_2? (*b*) In a close place, where the ventilation is poor, is there any limit to the diffusion of marsh gas into the atmosphere?

3. *Distance Between Centers.*—(*a*) Given a gangway driven due north and chambers turned on a course N 75° W so that there will be 50 feet between centers, what is the distance on the gangway between center lines?

(*b*) If the course of the gangway is changed to N 20° W 20 feet inside of the center line of a chamber, what will be the distance on the course of the gangway between the center lines of the chambers?

4. *Size of Pumps.*—If a mine is making 4,000 gallons of water an hour and the shaft is 260 feet deep, what is the size of a plunger pump which will be necessary to take care of this water? What is the size of a centrifugal pump?

Some Air Analyses

In the Proceedings of the South Wales Institute of Engineers for September are published "Further Notes on the Analyses of Mine Air," by J. W. Hutchinson and E. C. Evans, an abstract of whose former paper was published in the September number of Mines and Minerals. These notes were made to "ascertain what effect a slowly rising or falling barometer had on the quantity of methane issuing from cavities or old workings, and also what effect the varying speed or stoppages of the fan had on the quantity of methane in the air-currents." The place chosen for the sampling of the air was at the outby end of an old main return airway, which was of considerable length with a large area of goaf and old workings on each side. The outby end of this return had been stowed up some years previously, as firedamp was always more or less present, and the quantity varied considerably. A pipe, 12 inches in diameter, passes through the stopping and rubbish in order to carry off the firedamp from the inside. It had been found necessary to have a current of at least 25,000 cubic feet of air per minute always circulating in order to keep the roadway leading to the upcast from the stopping in safe condition. Samples were taken hourly, 75 yards from the end of the pipes, the barometer being read simultaneously.

Upon analysis of the samples it was found that the quantity of firedamp in the air increased rapidly with a fall in the barometer; that a fall of half an inch in the barometer was accompanied by an increase from a trace to 3 per cent. of firedamp. But as the barometer began to rise, the quantity of firedamp given off fell rapidly; a rise of .16 inch in the barometer causing a fall of 2.48 per cent. in the quantity of firedamp.

The conclusion to be drawn from these analyses is that dangerous conditions may result from any slight fall in the barometer, where a body of gas exists in old workings.

In the tests on the stoppage of the fan, it was found that the percentage of firedamp increased steadily during the stoppage and then rose rapidly as soon as the fan was started again, the barometric pressure of the mine being lowered by the starting of the fan.

Prospectors report finding a large deposit of good anthracite coal in the foothills of the Rocky Mountains, 243 miles southwest of Edmonton, B. C. The Highwood range of mountains, which runs to Mist Mount, 10,300 feet above sea level, presents an unbroken formation for fifteen miles, in which there is a continuous ridge of coal. The seams cover an area of one and a half miles in width and extend 3,000 feet below the surface, the reported depth of the Kootenai series. The seams show dips of from 46 to 82 degrees with thin coverings of shale, slate, and sandstone. Tests show the coal is of a grade almost corresponding with Pocahontas.

ORE MINING & METALLURGY

Florida Phosphate Practice

Steam Shovels and Hydraulic Mining—Steam and Oil Engines—Electric Power Transmission

*By John Allen Barr**

FLORIDA phosphates, classed as hard rock, soft rock, land pebble, and river pebble, are found in Eocene, Miocene, and more recent geological horizons. The hard-rock phosphate occurs massive, laminated, and as boulders piled together, also in the form of pebbles where the other rocks have been broken by weathering and water movements. This kind of material possesses a variable structure from compact to fibrous, and while usually of a creamy color is frequently found stained with iron oxide.

Fig. 1. Hydraulic Phosphate Mining

The soft-rock phosphate occurs in deposits by itself and associated with hard-rock phosphate. It may be clayey or sandy and fill spaces between boulders of hard-rock phosphate. It is evidently a secondary deposit formed by the disintegration of other phosphates of lime.

It carries from 20 to 30 per cent. less phosphate of lime than hard-rock phosphate, which varies from 80 to 86 per cent.

Land-pebble phosphate is essentially a mass of whitish phosphate pebbles varying in size from grains to 1 inch in diameter, averaging possibly a little over one-quarter inch. They are hard and have usually a matrix of phosphatic clay and sand. The percentage of phosphate of lime which the pebbles contain is from 75 to 80, but the average material as mined would not reach this standard. This ore is mined open cut, by dredging, and by hydraulicking; it is then washed, dried, and shipped to fertilizer works, mostly abroad.

River-pebble phosphates are found as bars in the rivers of southern Florida, and with them are found the fossil remains of vertebrates. The river pebble is blue or black, varying from 1 inch downward in size, and frequently occurring as the hardened casts of small molluscs.

It is presumed that river-pebble phosphates are derived from land-pebble phosphates, and also from hard-rock phosphates. The percentage of phosphate of lime in the river pebbles is between 58 and 68; at present river dredging for phosphate pebbles is not as active as the mining operations for land pebbles.

Florida phosphate beds are covered with soil to varying depths, which is removed by means of steam shovels or hydraulic nozzles. If the deposit is below water level, traction dredgers working on the land, or floating dredges, are used.

The overburden of land deposits is stripped from the ore by steam shovels, a cut being taken the full swing of the shovel boom, and the shovel moved forward a short rail length when this is finished.

The capacity of the dipper or shovel varies from 1 to $2\frac{1}{2}$ cubic yards, and the boom and dipper arm is made to conform to the depth of the alluvions. For example, a 35-foot boom will raise material 18 to 20 feet above the shovel track and make a cut 35 feet wide. The cars to carry the overburden are standard gauge of 12 cubic yards capacity. They are usually dumped by hand, although some of the more recent cars have air dumping arrangements which are controlled from the engine cab. The cars are run out to the dump and handled in the usual manner, care being taken not to waste the material where it will cover future work. Steam shovel work is done by contract, the price being 20 cents per cubic yard.

Whenever conditions are favorable and space available for the disposal of material, the overburden is removed by the hydraulic method shown in Fig. 1, and pumped into an abandoned excavation from which the phosphate has been removed. The cost of stripping by the hydraulic method is from 5 to 8 cents per cubic yard. The overburden in Florida phosphate fields is favorable for this kind of work, being clean, fine sand, with some pebbles, the majority of the foreign substances being sods, stumps, and palmetto roots. Occasionally the sand is cemented and grades into a soft but tough sandstone which must be blasted before hydraulicking. Owing to the overburden

* Assistant Manager, Mt. Pleasant Phosphate Co., Tenn.

33—5—5

containing little clay, it can be stacked in large dumps that do not liquify and run into the streams.

In Florida where hydraulic stripping is practiced, hydraulic mining may be also, in which case the material is broken by playing one or more streams of water under a pressure of from 90 pounds to 140 pounds per square inch against the face of the deposit. This operation, which is shown in Fig. 2, causes the rock containing the phosphate to crumble and flow into a ditch cut in the underlying marl. The flow is aided at times by additional water from a $\frac{1}{4}$-inch-nozzle ditch hose, the object being to drive the material into a sump about 8 feet square also cut in the marl. From the sump the material is lifted by an 8-inch or 10-inch centrifugal pump and discharged into the washers. Since the rock material consists of firm sand and round phosphate pebbles, very little of it being over $1\frac{1}{4}$ inches in diameter, it is easily made to flow through the ditch into the sump, on a grade of 2 inches to the foot, by the use of about 10 times its weight in water.

Fig. 2. Breaking Down Rock With Hydraulic Nozzle

The hydraulic nozzles are connected to the main water supply pipe which is usually 10 inches in diameter. Where two nozzles are worked each has from 200 to 500 feet of 6-inch diameter, flanged, spiral-riveted, galvanized water pipe. Asphalt roofing paper or tar board is used for flange gaskets. At one or two convenient places, in this 6-inch line, a ball-and-socket joint is applied to facilitate the lateral movement of the nozzles. This ball-and-socket joint is shown in Fig. 3(*a*).

When two nozzles are used they are pointed so as to wash the material to a central point, which is the ditch leading to the sump. In case the ditch clogs, an auxiliary hose is coupled just back of the nozzles and the flow of water from this is used to move the material to the sump. After the face of the rock is mined so far away from the sump that the material does not flow properly through the ditch, a new sump is blasted 50 to 75 feet nearer the working face, and the pump is moved to it. The pressure required for hydraulic mining of this kind is not high, but the work demands a large volume of water in order to transfer the material through the ditch to the sump and not choke the pump by an excess of solids.

The outfit for transferring the ore to the washer consists of a centrifugal pump of the volute box type, with chilled cast-iron facing, directly connected to the slip-ring motor. The tail-piece of the pump, which must be made flexible, is raised from the sump by means of a set of triple blocks suspended from a tripod. This arrangement is necessary, because whenever the mouth of the suction pipe becomes clogged with grass, roots, etc., it must be raised out of the water for cleaning. In case the distance is more than from 800 to 900 feet between the mine pump and the washer, a relay pump is usually installed. In such cases the mine pump discharges into a sump from which the relay pump, Fig. 4, draws its material and forces it to the washer. The sump is used owing to the difficulties arising from back flow and water hammer when operating two centrifugal pumps in series. Where the centrifugal pump discharges without much head, the end of the pipe line is elevated for a pipe length at an angle of 45 degrees in order to furnish sufficient pressure head to work against and prevent vibrations in the pump.

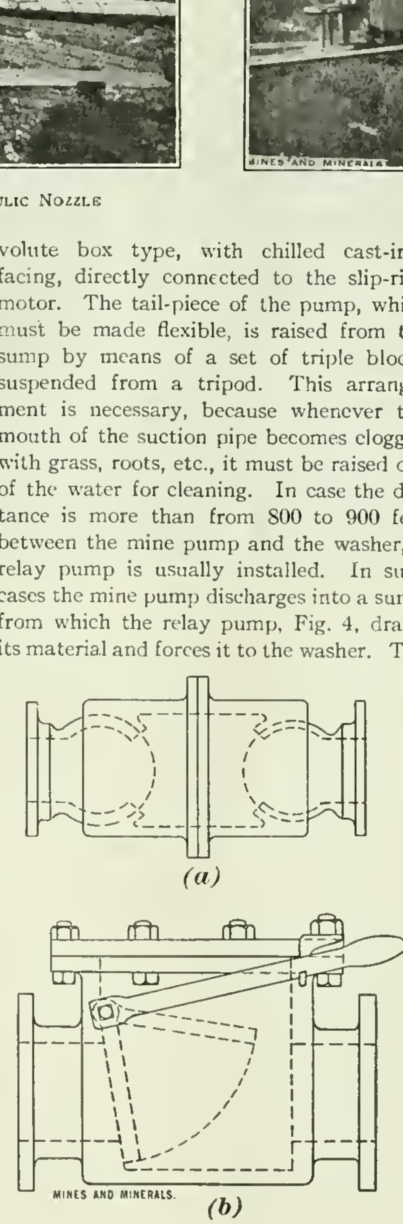

Fig. 3

Some difficulty has been experienced with the heavy rubber pump suction hose reinforced by spiral wire, owing to its high cost, \$125 to \$150, and the uncertainty of its lasting more than from 2 to 6 months. Mr. Langsford, master mechanic, has invented a device which has successfully supplanted the rubber suction, at his plant, the Prairie Pebble Co. It resembles an expansion joint and being of cast iron is practically indestructible. It is supplied with water packing to prevent the admission of air into the tail-pipe, but it permits motion in one direction only, which is sufficient in the cases under consideration. Between the Langsford joint and the pump, and as near the former as possible, a flap valve shown in Fig. 3 (*b*), is placed, to be used when priming the pump. It is a check-valve held open by a lever and a latch to prevent the valve from being closed whenever the pump loses its vacuum, and the water rushes back toward the sump. Should the valve be closed by this blow back it would create a water hammer, and burst the pump.

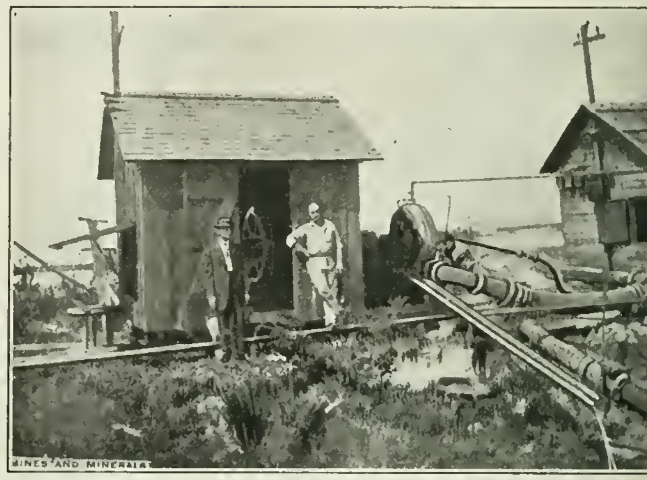

Fig. 4. Relay Pump

Mr. Blood, of the Florida Mining Co., has invented a simple flexible joint which replaces the expensive and short-lived flexible hose tail-pipe at much less cost. It is so constructed with an inner lining, as to prevent the sand and phosphate coming in contact with the rubber. It is a double diaphragm of heavy rubber sheeting with an iron thimble, flanged as shown in Fig. 6, to connect with the pipe line. An inner thimble is used to carry the material and prevent its coming in contact with the rubber.

The majority of the new phosphate plants are equipped both with steam and electricity for driving the machinery. The 8-inch and 10-inch centrifugal pumps are driven by General Electric motors of the slip-ring induction type, 60-cycle, 75-horsepower, 2,000 volts, and $21\frac{1}{2}$ amperes, with street-car controller having three resistances, a Thompson ammeter, and an oil circuit breaker. The pump, motor, and other parts are mounted on skids, so as to be readily moved, and the motor is covered with a light frame house as shown in Fig. 4.

Practically all the water pipes and pump pipes used in the Florida field are of steel

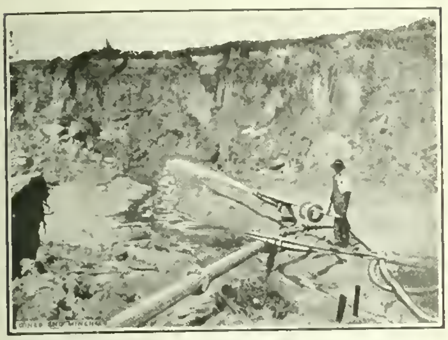

FIG. 5. HYDRAULIC NOZZLE

with peaned flanges and cardboard gaskets. The flanges, which come separated from the pipe, are generally put on by men who work on contract.

The preparation of phosphate pebble for market is comparatively simple and is practically the method described by Francis Wyatt in his book on "The Phosphates of America" which reached its fifth edition in 1894. The methods of mining and transporting the material have changed greatly, and the plants have been so enlarged that even though the preparation remains the same, the conditions are quite different and demand more engineering and executive skill.

After the material reaches the washer from the mines it is delivered to a relay pump as shown in Fig. 6 without going into a sump. This pump lifts the material to the top of the washer, where it is discharged into a launder that feeds a rotary screen, having $1\frac{1}{4}$-inch holes. The screen makes two products: an oversize consisting of mud balls and coarse rock which is sent directly to the tailing pond, and an undersize which is discharged on to an inclined stationary screen with $\frac{3}{64}$-inch slot openings, where some of the sand is removed, the operation being assisted by sprays of water. The oversize from this screen passes to a 16-foot double log washer which discharges the material into another 16-foot single log washer. These logs separate the particles of phosphate, sand, and pebble from the silica by reason of their grinding and mixing action. Wash water is also supplied to the logs, which assists the separation by moving the silica sand backwards and over the tail-gate of the log box. The last set of logs discharge on to a shaking screen which further eliminates all but from 6 per cent. to 8 per cent. of the remaining silica and the greater part of the water. The dewatered material from this screen goes directly into a hopper-bottomed storage bin over the railroad tracks.

The Prairie company's washer is driven by a motor back geared 5 to 1, the countershaft running at 103 revolutions per minute with sprocket drive. This is a 60-cycle machine of about 30 horsepower, 220 volts, 75 amperes.

The Florida Mining Co.'s washer probably represents the best practice in the field. Its special feature, aside from its superiority in heavy structural work, is the idea of passing the mud balls and the coarse phosphate pebbles to a roll crusher, where they are disintegrated and discharged to the log washers in such shape that they can be cleaned. The log washers are double 20-foot logs solidly constructed and well designed, the paddles being large and heavy.

The central spindle of the log is a heavy hollow shaft to which the paddles are bolted with locknuts, a feature superior to the four separate angle irons in some other logs. The angle-iron logs, however, have one advantage in their later design, in that there are no stuffingboxes at the tailing end, these being replaced by a chilled cast-iron gudgeon and bearing supplied with fresh water to keep out the grit.

At this particular plant they are mining phosphate material containing some yellow clay such as is found intimately associated with the Tennessee phosphate, and contrary to expectations it was not entirely removed by the hydraulic mining, nor by passing it through two pumps; but when it had passed through the logs it was removed in large quantities in the first screen in the form of mud balls; some of the yellow clay passed through the second set of logs where it was loosened and removed by a second screening. It was the intention to pass these mud balls through the crusher, or rather a disintegrator, so that the entrained phosphate might be liberated by the logs.

Flat screens are very economical in repairs but in some places they might have a tendency to clog up with the clay, and it is to be noted that the French company, who are washing clayey material, employ rotary screens entirely.

Boiler Plants.—At the Prairie Pebble Co. works there are twelve 135-horsepower water-tube boilers whose flue gases pass through four economizers. At the Florida Mining Co., Scotch marine boilers are used. The objection to the Scotch boiler is the poor circulation of water, owing to an underlying circulating ring, which gives trouble by filling with scale, thus forming a constant menace to the safe running of the boiler. The boiler rooms are fitted with feedwater weighers, Bristol recording gauges for steam pressure, and also temperature gauges for the feedwater. The recording instruments together with the feedwater temperature instruments are arranged conveniently on a large board within the boiler room. By this means a constant check is kept on the running of the plant and pounds of water per K. W. hour at the switchboard computed at the end of each day.

The boilers are fired by hand, the coal passers getting coal from a small car which runs back and forth on the track before the boilers. Ashes are removed from the basement by a similar system.

This is the only plant in Florida visited that uses superheated steam. It is a well-known fact that, with turbines especially, economy increases with the superheat and noticeably prolongs the life of the blades by reason of the absence of moisture. The reason that superheat has met with failures in this country is due to its not being adaptable to all cases and more especially to the old type of engine which is not constructed to withstand the higher temperatures.

The boiler is fed, as a rule, by outside-packed plunger pumps designed to operate at very slow speeds, that is, not over 15 strokes per minute.

The earlier and present universal practice is to use direct-acting compound or triple-expansion pumps for furnishing water to the hydraulic nozzles at the mines and to the washer. The Florida Mining Co. has a triple-expansion pump capable of furnishing 4,000 gallons of water per minute, which it delivers at a pressure of 150 pounds per square inch. The Prairie Pebble Co. uses a somewhat similar pump made by the Worthington company. Their pumping plant consists of three triple-expansion, duplex, direct acting pumps, size 12 in.×19 in. and 30 in.×17 in.×24 in. These pumps have a capacity of 2,800 gallons per minute, each.

The only centrifugal pumping plant that supplies water to the pipe nozzles is installed by the new French company. This company uses a three-stage turbine pump, direct connected to the 250-horsepower induction motor, and it delivers water to the nozzles at a pressure of 140 pounds per square inch. The experience with this

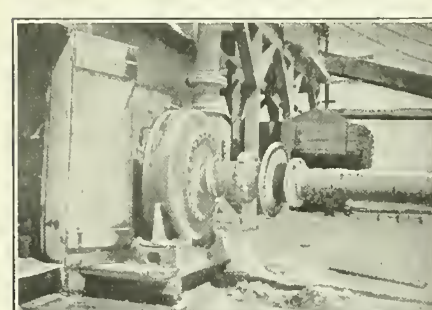

FIG. 6. FLEXIBLE JOINT

pump in the field has been that, when new it was very satisfactory, but when pumping gritty water, such as must be the case at most of the mines, the pump lining soon wears and the pump has a low efficiency.

The newest pumping stations being built

contain the Corliss flywheel condenser pump. The principal advantage of this pump for this kind of work over the direct-acting pump is principally its high duty, which often is at least one-third more. The duty of the direct-acting pump seldom goes over 90,000,000 gallons, while that of the Corliss flywheel pump approximates 120,000,000 gallons in 24 hours. The flywheel pump is less liable to become broken by failure of the governor to act, or by bursting of the pipe line.

Air compressors are installed at this plant to pump water from artesian wells, using the principle of the Pohle pump. The efficiency of this arrangement is from 30 to 40 per cent., and it would seem as if a centrifugal pump driven by a vertical shaft in a sump would increase this efficiency considerably, say, from 30 to 60 per cent.

The Prairie Pebble Co. has one Ingersoll-Rand cross-compound air compressor, with Corliss valve motion, automatic air valves, and a capacity of 2,027 cubic feet of air per minute. They also have one tandem-compound Sullivan air compressor with Corliss valve motion capable of furnishing 2,450 cubic feet of air per minute.

The Prairie Pebble engine room presents no special features, as it has been built up piece by piece and is not the main power plant. Exclusive of the pumps which have been described, there are two four-valve automatic engines direct-connected to 2,300-volt generators; there is an alternator engine of 325-horsepower capacity when running at 200 revolutions per minute, belted to a 240-kilowatt, 2,300-volt generator; one 300-horsepower Harrisburg piston-valve engine making 250 revolutions per minute and direct-connected to 240-kilowatt, 2,300-volt generator.

The Florida Mining Co. generates power with a 300-kilowatt turbine of the Parsons reaction type. This unit is direct-connected to a 300-K. V. A., 2,300-volt turbogenerator.

The Charleston Mining Co., at Fort Mead, has a 1,000 K. V. A. vertical Curtis turbine and are installing a 600-K. V. A. horizontal turbine of the same kind. For a smaller unit than 3,000 K. V. A. and less, the horizontal turbine is preferable by reason of the absence of the forced feedstep oiling system, such as is necessary in the vertical type. The chief advantage of the turbine over the reciprocating engine is its simplicity, low first cost, ease of upkeep, and the possibility of using a lower-priced operator. It is also much more compact than the reciprocating engine.

While turbines of 1,000-kilowatt capacity and larger are designed for as economical steam consumption as the ordinary reciprocating engine, still with high pressure and superheat, the poppet-valve engine holds the record for thermal efficiency, but at higher first cost, and cost of maintenance.

The Prairie Pebble Co.'s central power station is the largest in the field and consists of eight sets of tandem-connected, three-cylinder, Deisel oil engines, direct-connected to a revolving field alternator, of 2,300 volts, 75½ amperes, three-phase, 60 cycles, 164 revolutions per minute. The Deisel engine operates on the principle of the four-cycle gas engine, the difference being that the air is compressed in the cylinder to 750 pounds, giving, thereby, temperature above the flashing point of oil. Just before the highest pressure point of the stroke, oil is injected with air, causing the explosion and generating power by the expansion of the gases on the down stroke. Crude oil, or distillate, can be used in this engine, but the Prairie Pebble Co. uses a lighter distillate, as it was found that the crude oil was detrimental to the life of the engine on account of its carbonizing the cylinders.

The one and only advantage of the Deisel engine is the low fuel consumption, it being one-half that of the steam engine; that is, a thermal efficiency of about 30 per cent. It is very much like a gas engine except that it has more troubles. Its high cost of upkeep and repairs, and its periods of trouble would soon overcome its superior advantage of fuel consumption in a country adjacent to coal mines. It is essential for the continual operation of the plant that there be one or more reserve engines available, when, as is frequently the case, it becomes necessary to make repairs, especially after the plant has run for about 5 years.

It is important for the proper operation of the Deisel plant that the chief engineer thoroughly understand his business, and one who has that requisite can command a salary from $2,000 to $3,000 per year. But he is cheap in the end compared with the low-priced and inefficient engineer.

The Deisel plant of the Pierce Phosphate Co. has been in operation about as long as the Prairie Pebble Co.'s plant. This plant consists of six three-cylinder Deisel engines. This company has also a gas-producer plant operating a 1,200-horsepower tandem, two-cycle gas engine, direct-connected to the revolving field alternator that is run parallel with a Deisel plant, which has five 2,300-volt alternating-current generators, and one 500-volt direct-connected generator.

The gas producer has given considerable trouble but is now in such shape that it has a thermal efficiency of from 28 to 30 per cent., and uses any fuel from peat to sawdust.

It seems to be the practice in the Florida phosphate field to use 2,300-volt, three-phase, 60-cycle alternating current for all power purposes, and 500-volt direct current for trolley work. Where the transmission lines are carried from 2 to 3 miles or more, it is the practice to step up the current to 17,000 volts and step it down to 2,300 volts at the distribution station. Direct current is generated at the Prairie Pebble central station by three synchronous motor-generator sets. The advantage of this set over the rotary converter is that the field can be over excited to bring the power factor near unity. The synchronous motor is not satisfactory when improperly installed and operated. It is affected by line surges, change of voltage and load, requiring separate adjustment of the field for each change of load. This latter may be accomplished, however, automatically.

Frequent flooding of the pumps in the mine pits necessitates that the motors be dried. At the Florida Mining Co. this is done by connecting a General Electric transformer of 60-cycle pole type, 20,000-watt capacity, primary 2,300 voltage, which will give a normal current through the stator with the rotor stationary and all resistance cut out. The voltage to which the line current is stepped down must be sufficient only to send normal current through the winding. When drying a transformer of from 2,300 volts to 440 volts capacity the secondaries are short-circuited, and 110 volts are sent through the primary, with the result that normal current is obtained in both windings.

Heaviness of construction is noticeable in all new equipment in the Florida field. Much of the construction is reinforced concrete and steel so that almost perfect rigidity is obtained, a feature essential for the economical operation and successful working of shaft lines. In cases where supports are not entirely rigid, ball-and-socket pillow-blocks are used for the regular work. The heavy stationary rigid pillow-blocks are much used in large sizes, placed on end-adjustable base plates.

The lubrication is principally by grease cups, on account of the excessive dust which precludes the working of chain oil bearing; however, in any place where dust is not excessive the self-oiling pillow-block is not only more economical in oil but requires attention only once a month and uses a grade of oil which gives a lower coefficient of friction. On account of the excessive amount of dust and grit about drives, sprocket and chains are almost universally adopted for transmission of power. The heavy kinds of chain are used. It is noticeable with all of these drives that none exceed the proper speed for chain, viz., 500 feet per minute.

Manganese chains are being adopted with excellent results. Where the belts can be used, chains should not be given preference, for the well-designed belt drive will last for years. The only reason that belts give so much trouble and wear out so quickly is that they are over stretched, the designers not giving sufficient attention to their installations. The belt drive properly installed is from 6 to 8 per cent. more efficient than the chain drive. No rope drives are used in Florida on account of the universal employment of electric power. At the Prairie Pebble Co., the large 150-horsepower drier-shed motors are connected to the main line shaft by a Renold silent chain.

This excellent speed reducer is kept well lubricated with graphite grease free from grit.

The wet rock elevators of the Prairie Pebble mill are placed at 57-feet centers. These elevators have a pitch of $4\frac{3}{4}$ inches per foot. The elevator buckets, 8 in.×18 in., have round bottoms. The manganese chains work on an 18-inch traction tail-pulley and a 30-inch traction head-pulley traveling at the rate of 235 feet per minute.

The dry-rock elevators are constructed along the same lines but their length is divided into two vertical lifts, to reduce the weight on each chain. These elevators have given perfect satisfaction, the use of manganese chains insuring long life, freedom from breakdowns, repairs, and frequent renewals. They are all single strand elevators which obviates any trouble with unequal wear on chains. However, unequal wear may be reduced by leaving one of the tail-sprockets loose to compensate this difference and permit ascending buckets to come parallel.

The Phosphate Mining Co. and the new French company both have double-strand elevators with 22-inch cups. This arrangement permits of a positive discharge by running over a double set of head-sprockets and allows the speed of the elevator to be reduced on account of not needing centrifugal action for bucket discharge.

Practically all of the conveying is done by flight or drag conveyors. The best conveyor of this kind in the field is in the wet bins of the Prairie Pebble Co. It has a chain with 24-inch head-and-tail sprockets on $62\frac{1}{2}$-foot centers. Every third link in the chain has a flight 11 inches wide and 5 inches deep. Roller idlers 8 inches in diameter are placed every 12 feet, and the speed of the conveyer is from 60 to 100 feet per minute. The journal bearings are supplied with grease cups. The phosphate material is allowed to make its own bed in the concrete trough, thus eliminating the frequent renewal that would be necessary if the flight were allowed to drag upon iron plates as is the case in most conveyers. There is practically no trouble with this drag.

With the exception of the Prairie Pebble Co., the majority of the new dryers are of the rotary type, manufactured by the Georgia Iron Works. These are set level, the material being fed at the cold end and worked to the hot end by spiral flights on the inside of the shell. All of the dryers are fired by oil, which accounts for their large capacity and easy operation. The only objection to the use of rotary dryers is where the rock contains clay that clogs the spirals. Rotary dryers are about 50 feet long and require about 5 horsepower to run them. Their capacity is about 100 tons of well-drained sand in 10 hours or 120 tons of rock, and to dry this quantity of material requires from 5 to 6 tons of coal One man can fire two dryers with coal, provided the coal is in front of the furnace.

The most noteworthy part of the construction is the storage bins of all the plants. The Prairie Pebble Co. has a reinforced bin, 525 feet long by 75 feet wide by 30 feet deep, not including the clearance over the tracks. It is composed of three compartments with four tracks overhead for the car haul and three tracks underneath for the railroad.

At the Prairie Pebble mill car hauls are the source of much trouble and wear and Mr. Langford heartily agrees with the suggestion that two motor-driven distributing cars would perform this work much better and at less cost.

The storage shed being built by the Phosphate Mining Co., has as a special feature an overhanging side of cantilever effect that allows the bins to project over the railroad tracks on this side. This construction does not appear to be a very desirable feature. The mill building, or that part over the dryers, is of reinforced concrete columns with slab floors having reinforced beams.

For the considerable tonnage in the Florida field these large storage bins are very desirable. For instance, the Prairie Pebble Co. work 20,000,000 tons through their plant; the Wales plant, 3,000,000 tons. On the face of this it would not seem that the Wales plant would be justified in the erection of an expensive storage bin.

The storage bin of moderate capacity, say 20,000 tons, would cost about $80,000, representing a charge of $2\frac{2}{3}$ cents against 3,000,000 tons, and the ordinary storage shed with an electric crane would only represent a charge of .003 mill per ton. Judging from the above figures the ground level storage with an electric crane is cheaper for loading from the storage pile into cars. The structural work for storage house as well as for dryer shed could be of steel and last longer than the mine.

Wet storage sheds should be constructed with an electric crane on steel supports with a slope drainage floor and with no retaining walls on the side. It has been found by experience that to drain this kind of material side walls greatly interfere with the rate of drainage. The shed floor can be built of planks with cinder drain underneath and all underlain with drain tile

The "Billy White" Cut

*By William J. Crocker**

Much has been written relative to the wedge, the star, the sidehole, and other cuts for opening drifts and mining tunnels, but the "Billy White" cut, while good in any hard ground, is especially useful in tough rocks that have no slips, faces, or walls to which shots may break.

This cut derives its name from one William White, a miner who first used it in the tin mines of Cornwall. The round of holes for this cut is drilled as shown in Fig. 1.

* Negaunee, Mich.

Three holes, 1, 2, and 3, are drilled straight into the breast, exactly in a line with one another, at a distance of 5 inches, center to center, thus making the distance over all 12 inches, assuming the holes are each 2 inches in diameter. Another hole 4, is drilled 7 inches to the right of the first three holes and in a horizontal line with hole 2. Hole 5 is drilled 12 inches to the left of hole 2 and in the same line as hole 4. These five holes complete the drilling of the cut. All are put in horizontally or looking down just enough to hold water.

The success of this cut lies mainly in drilling the holes in planes with one another and in shooting them in the proper rotation.

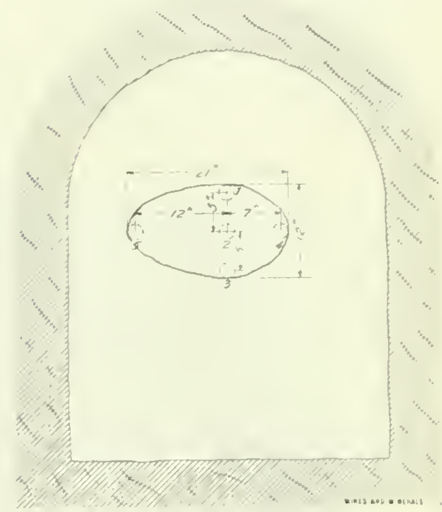

FIG. 1. THE "BILLY WHITE" CUT

Four of them are loaded in the usual manner, care being taken to cut the several fuses of slightly variable length so that the holes will go off in the following order; viz., 1, 3, 4, and 5. Hole 2 is drilled merely to provide space for hole 1 to break to, and is never loaded. Each shot creates more clear face for the following shot. After holes 1 and 3 have gone, the chamber is about 12 inches vertically by 5 inches horizontally and somewhat oval in section. After all the holes have shot, there is produced a chamber about 12 inches by 21 inches, as shown in the illustration.

A feature of this cut is that it breaks as big at the bottom as at the collar. I believe the scheme will break as deep as is ever desired. I have brought them 6 feet in the Hartford mine, Negaunee, Mich., and in the East Pool mine, Cornwall, England. I have also known this cut to be used in regular 6-foot holes in the Glen Deep and the Vogelstrius Deep mines, of South Africa. This success may be understood by noting that hole 1 has but 3 inches of rock to break and has 2 inches of relief in hole 2. The rest of the round is obvious. I find that this cut takes no more powder than do other cuts, but on the other hand, it often accomplishes its function with less powder. The full bore of the tunnel is obtained by the usual placing of holes that will break to this initial cut.

Practical Cyaniding—Part 5

Operation of Vacuum Filters—Precipitation—Zinc Shavings and Boxes—Use of Zinc Dust

*By John Randall**

THE operation of forming slime cake by means of a vacuum is the same in all cases, and as a general proposition the more vacuum the pump produces the sooner will the cake be formed with any given slime pulp. To form the slime cake, the filter leaves are submerged in the slime pulp and the vacuum pump is connected to them. To prevent the pulp solution from falling below the top of the filter leaves, a steady stream is permitted to run into the tank, while, to prevent the slime from settling, air agitation is practiced, or else the slime is pumped from the bottom and returned at the top of the tank. The time required to form the cake will depend on the slime treated and its dilution. With

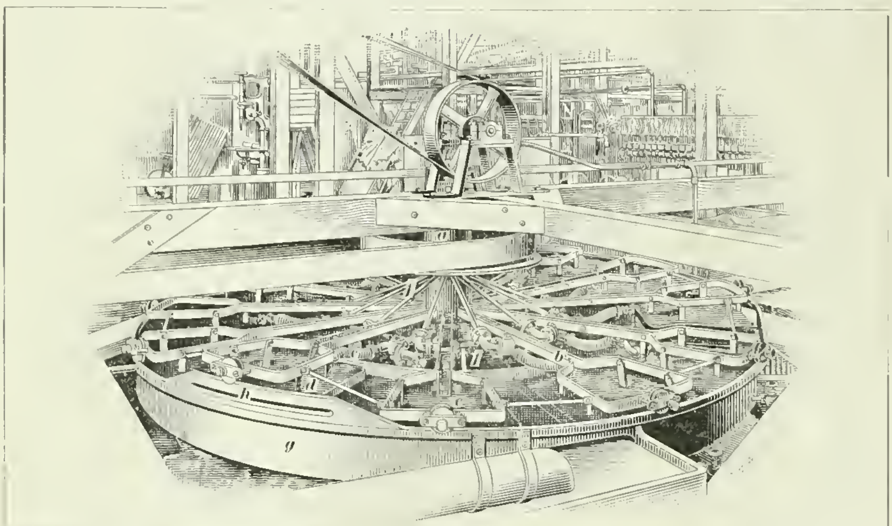

Fig. 1. Ogle-Ridgway Filter

uniform pulp solution of medium settling slime, it is about as follows:

Time of Formation Minutes	Thickness of Cake Inch
5	.250
10	.375
20	.500
30	.625
40	.750
50	.875
60	1.000

After the slime has caked to a sufficient thickness, which is determined by measurement, the vacuum is lowered in order not to dry out the cakes while they are having their solutions changed. A crack in a slime cake causes a channel through which the wash solution will flow instead of through the cake, and thus the main object of the wash solution, that is, the displacement of the gold solution, will be abortive. During the time that the filter leaves are being changed from tank to tank in the movable process, or during the time the slime pulp is being drawn and the tank refilled with wash solution in the stationary process, the vacuum is kept on the filter leaves, but the pressure is lowered until it is not more than 5 pounds per square inch. As soon as the tank is filled with wash solution, the vacuum is increased to 28 inches, or 13.72 pounds per square inch, or the normal working pressure, and continued until the gold solution has been displaced. The time required to displace the gold solution is more than the time required to form the cake. It will vary from 50 to 120 minutes, depending on the kind and thickness of the cake and the pressure employed in its formation.

The quantity of wash solution necessary to completely displace the gold solution will approximate between two and three times the quantity of gold solution remaining in the cake, that is, if 35 per cent. of moisture remains in the cake, 1 ton of the cake will require from .7 ton to 1.05 tons of wash solution for its displacement. The first half of the wash solution can be sent directly to the gold solution tank, and the second half to a tank where it may be brought up to the standard used for agitating the pulp. When the washing process has continued as long as previous experiments indicate that it should for the complete displacement of the gold solution, the vacuum is again reduced, and the wash solution remaining in the filter tank is returned to the wash-solution tank.

The operation of displacing the wash solution with water is sometimes omitted, but the economy of doing this should be carefully considered. In most cases a water wash will pay for the trouble. For example, suppose that 35 per cent., or 6.72 tons, of moisture remains in a cake and that the wash solution contains 25 per cent. of cyanide. Since .25 per cent. of 1 ton is 5 pounds, this cake will contain $5 \times 6.72 = 33.6$ pounds of cyanide. At 20 cents a pound, this will amount to $6.72. There is also a possibility that the solution in the cake will contain some gold as well. The time occupied in displacing the wash solution is reduced to one-fifth of that consumed in displacing the gold solution, and the liquor that passes through the filter is sent to the wash solution tank. The vacuum is now shut off entirely, and the wash water remaining in the tank is used to flush out the slime cake from the tank; or, if the water is scarce, part of the water is pumped to the wash-water tank and only part used for flushing purposes.

If the agitation of the slime and cyanide solution was thorough, the slime cake is now ready to be removed to the tailing heap. For this purpose, one of the following methods may be adopted:

1. Water may be admitted to the interior of the filter through the vacuum pipe at a pressure of about 8 to 10 pounds per square inch until the slime has left the filter leaves. The filter leaves not being constructed to withstand pressure from the inside, must be kept submerged while the cakes are being discharged in this way.

2. Water and air under pressure not to exceed 10 pounds per square inch are considered by some preferable to either air or water alone. Where the combination of air and water is adopted, the filter leaf is bounded on all four sides with iron pipes, and the air is admitted from the lower pipe while the water is admitted to the filter through the upper pipe. With air and water in combination, it is not necessary to keep the filter submerged, since either air or water will find a ready exit through those places in the filter cloth where the cake has been displaced.

3. Compressed air may be used to displace the cake, although it is not so effective as air and water or air and steam.

The filter leaves must be kept submerged when air alone is used. The cake drops into the hoppers of the filter tank and is sludged out if all the water is to be wasted, but if water is valuable, valves are placed in the sides of the tank just above the commencement of the hopper and the water saved to this level.

The water introduced into a filter must be free from sediment and organic matter, otherwise the pores of the cloth are liable to be closed, and in addition organic matter might precipitate the gold in solution. The water necessary for discharging filter cakes, per ton of cake will, vary from 1 to 2.5 tons for wet cake, the former being the quantity required when part of the water

* Metallurgist, Boulder, Colorado—Article commenced in August, 1912.

is saved and the latter when no water is saved. When dry cake is discharged by air and water or steam and water, only about one-half ton of water is required, and this is needed mostly for washing down filter leaves and sludging out the tank previous to the next operation.

An acid tank is a necessary adjunct to vacuum filters wherever lime is used, Frequently, lime is required to counteract acidity in the ore, or to settle slime. The calcium oxide becomes converted into calcium carbonate and precipitates on the filter leaves. Unless the calcium carbonate is removed, the filter in time becomes practically useless, owing to the meshes in the cloth becoming clogged. To raise the filter leaves and transfer them to the acid tank, a differential pulley is attached to an overhead crawl The filter leaves are removed in baskets and submerged for about 6 hours in a bath of 2-per-cent. hydrochloric acid, after which they are removed and rinsed in clean water to clean them of acid and stop the action between it and the lime. It may be necessary, where much lime is used, to adopt a stronger acid solution, say a 5-per-cent. solution, and draw it through the filter by a slight vacuum, the vacuum pipes being attached to the filter basket during the cleansing operation. The filter leaves are treated in regular sequence, a certain number each day, while the frequency of the treatment depends on the quantity of lime used in the process.

Thin cake vacuum filters are rapidly gaining favor on account of the greater tonnage capacity of a given filter area, also the rapid passage of the washes through the thin cakes minimizes diffusion losses. The Ogle-Ridgeway filter, Fig. 1, was introduced at the Great Boulder Proprietary mine in Kalgoorlie, West Australia, where it was required to treat as much slime as the filter presses there use. An exhaustive trial extending over 1 year showed that it was able to treat slime for 8 cents per ton, which was 25 cents less than the filter presses could do. The filter, which is practically automatic, is capable of treating the tailing from the decantation process in South Africa, where 6,000,000 tons of slime was treated annually by the decantation process, involving a loss of $1,000,000 per annum through incomplete extraction. The success of the Ridgeway filter depends on the use of a thick pulp that does not exceed 55 per cent. in moisture. Thickeners are now made that can be depended upon to furnish a pulp even thicker than is required for this filter.

The Oliver continuous filter shown in Fig. 2, differs from all others in washing the cake by means of a spray instead of immersing it in the wash. The automatic style of its operation is in line with the increasing tendency toward continuous methods in all stages of ore treatment. It seems to combine the good features of the Ogle-Ridgeway with greater simplicity of design. A feature of the Oliver that is particularly important in mills of moderate capacity is that no attendant is required, the attention that the solution man has time to bestow upon it being generally sufficient. These filters are running on pulp containing as high as 66 per cent. moisture. Operating costs per ton including renewals of the filter surface range from 2.9 to 4.6 cents per ton.

Conditions Affecting Slime Filtration. Practical experience has demonstrated that slime from different ores varies so much in its physical properties as to require different kinds of filters; or speaking more definitely, a filter giving good results on one class of slime may fail when called upon to treat another class. In plants where sand and slime are separately treated, the slime may be made more permeable by adjusting the classifier so that a greater amount of very fine sand is mixed with the slime. Coarse sand in a very clayey slime does not help filtration and may hinder it, as the nearly impervious slime fills the voids between the coarse grains which are themselves impermeable. Even throwing all the 200 mesh sand into the slime will not make the cake more permeable unless the quantity of fine sand is great enough so that the voids between the grains will not be entirely filled by the colloidal slime. The pressure allowable in slime filtration depends upon the nature of the slime. In some attempts to use pressure filters where vacuum filters gave low filtering rates, it has been found that greater pressure decreased the filtration rate or stopped filtration entirely. Each type of filter seems to have a different range of usefulness, some being of special value only in the treatment of a given kind of slime.

Experiments by George J. Young, Professor of Mining and Metallurgy, Mackay School of Mines, Nev., have standardized and put in definite form a considerable amount of information on the subject of slime filtration, as well as brought to light some original discoveries. He found that the portion of the cake next the canvas is most dense and that there is a progressive decrease of density toward the outside, and that a cake when taken from the water shrinks in the direction of its thickness but regains its original thickness when again immersed in the water. He draws a parallel between some slime cakes and a mass of rubber balls, the deformation of the balls under pressure tending to close the interstitial spaces having a relation to the amount of pressure used.

Fig. 3 gives the average filtering rate deduced from Professor Young's experiments. If we assume for convenience that the pulp in any case is thickened to 57.45 per cent. moisture before going to the filter plant, then the number of pounds of water per minute drawn through the filter will equal the dry weight of slime built up on the cake in the same time, provided the cake contains 35 per cent. moisture. It will be seen from the diagram that cake building proceeds with great rapidity at first but falls rapidly until at a cake thickness of one-third of an inch the rate of building has dropped to a comparatively low point. By measuring the diagram, disregarding fractions beyond the first decimal place, we find the time required for building each layer one-tenth inch in thickness to be as shown in Table 1.

These time computations are based on the usual assumption that a slime cake 1 inch thick weighs 8 pounds per square foot. At 35 per cent. moisture the dry weight of such cake would be 520 pounds per 100 square feet or 52 pounds for each tenth

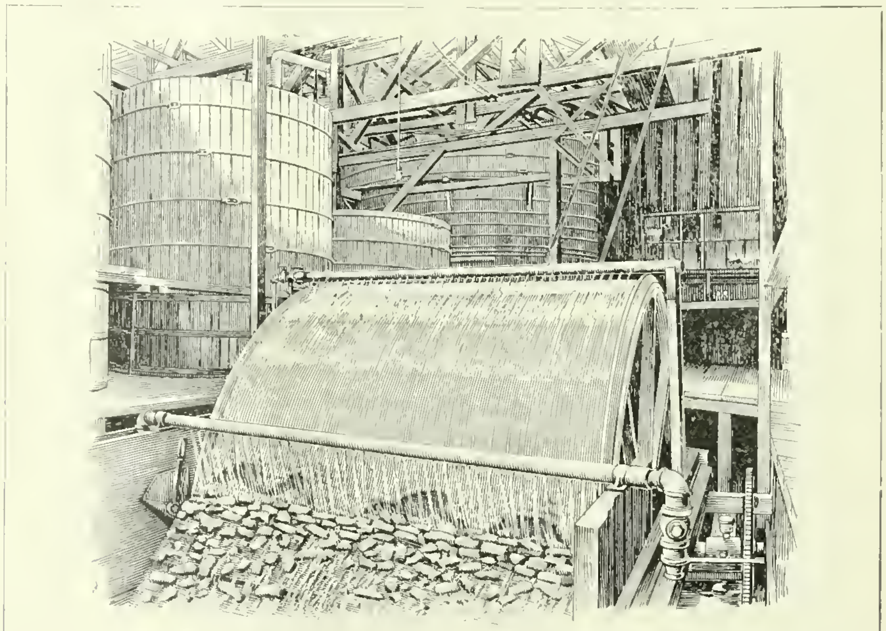

Fig. 2. Oliver Continuous Filter

of an inch in thickness. The time required is therefore computed as that required to deposit 52 pounds in each layer. It will be noticed that while slightly over 1 hour is required to build the 1-inch cake, the first three-tenths is built in less than 6 minutes. This serves to explain the comparatively large capacity of thin-cake filters. Another circumstance deserves notice. During washing the rate of travel of the wash solution or water through the cake 1 inch thick is only 6 pounds per minute. At 35 per cent. moisture there are 280 pounds of solution in the 100 square feet of cake. Assuming that every molecule of the water travels through the cake at the same rate of speed, 280÷6 or 46.7 minutes would therefore be required for the water to move 1 inch. The rate of travel per minute would be the reciprocal of this number, which is .0214. A filtration rate of two-hundredths of an inch per minute is sometimes, but not always, less than the diffusion rate of the dissolved gold from the cake out into the wash, and accounts for the enrichment of the wash solution often observed in the operation of thick-cake vacuum filters.

Professor Young summarizes the subject as follows:

1. The proportion of clayey material in ores which are to be subjected to all-sliming and filtration should be maintained at a minimum.

2. The slime pulp should be as free as possible from sands coarser than No. 150 screen, and as large a proportion of the pulp as possible should consist of material passing a No. 200 screen.

3. The slime pulp before filtration should be settled to as thick a consistency as is possible consistent with easy circulation in pumps and in pipes.

4. The temperature of the slime pulp should be maintained between 20° and 30° C. or higher.

5. The temperature of the wash water and the pulp should be the same.

6. Vacuum pressures should be varied until the proper intensity for the given slime is obtained.

7. Where very clayey slime is to be filtered, as much fine sand should be crowded into the pulp as it will carry without undue settling and clogging.

8. No. 10 canvas supported by slats gives the best all-round service for thick cake, and No. 12 canvas on wire netting answers the requirements for thin-cake filtering machines.

9. With slime containing a large proportion of colloidal material, presssures greater than those obtainable with vacuum apparatus are of questionable advantage.

10. With slime containing a large proportion of clayey material the vacuum filter should be used.

11. With slime containing a small proportion of clayey material and much fine sand, both vacuum filters and pressure filters could be used with perhaps equally good results.

12. With slime containing much coarse and fine sand, the chamber filters with air agitation and high pressures would perhaps give the best results.

TABLE 1

Layers One-Tenth Inch in Thickness	Filtration Rate in Pounds of Water Per 100 Square Feet Per Minute	Time in Minutes Required to Build One-Tenth Inch in 57.45 Per Cent. Pulp
1	90.0	.6
2	32.0	1.6
3	15.0	3.5
4	10.0	5.2
5	8.0	6.5
6	7.0	7.4
7	6.5	8.0
8	6.0	8.7

10	5.0	10.4
Total time		60.9

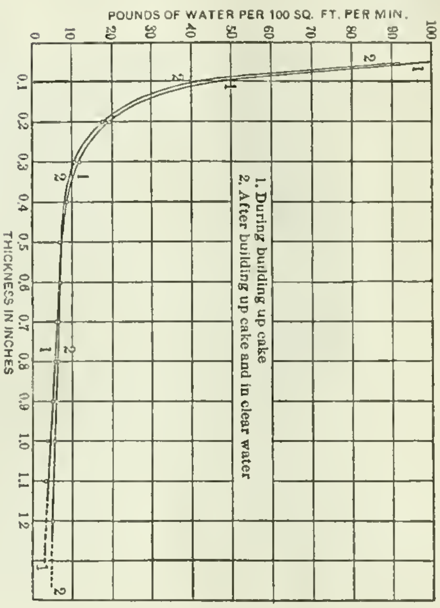

FIG. 3. AVERAGE FILTERING RATE FOR SLIME CAKES, NO. 10 CANVAS

13. Of the vacuum filters the thin-cake continuous filters are a decided improvement over the thick-cake filters.

It will be seen from this discussion that the successful treatment of ore slime means much more than mere mechanical routine and should receive the most earnest and painstaking attention from the mill superintendent.

White Precipitate.—Owing to the numerous impurities in ores many substances find their way into cyanide solutions or become associated with them. When the precipitation boxes are reached the various solutions are broken up by hydrolysis and the deposition of the gold, thus forming compounds that produce a loss of cyanide and are troublesome to handle. The conditions that govern the formation of grayish-white porous precipitate are not thoroughly understood, but as a rule when it forms on the zinc, gold is being imperfectly precipitated.

The double salt of potassium aurocyanide is precipitated from the solution by means of zinc filaments of such thickness that 1 pound exposes about 1,500 square feet of surface to the solution. The precipitation of gold takes place according to the reaction expressed by the equation

$$2KAu(CN)_2+Zn=K_2Zn(CN)_4+Au_2$$

The double salt formed in the precipitation is directly decomposed into hydrated zinc oxide, $Zn(OH)_2$, potassium cyanide, and free hydrocyanic acid, according to the equation

$$K_2Zn(CN)_4+2H_2O$$
$$=Zn(OH)_2+2KCN+2HCN$$

Both the potassium cyanide and hydrocyanic acid are free to form other compounds, which it is evident that they do, because ferrocyanide of zinc and potassium, $K_2Zn_3Fe_2(CN)_{12}$ and zinc cyanide, $Zn(CN)_2$, are found in the white precipitate. Zinc hydrate forms on the zinc shavings, particularly where weak cyanide solutions, from .01 per cent. to .03 per cent., have been used, thus impairing their usefulness. Strong cyanide solutions dissolve the zinc hydrate as formed, or it may be dissolved by the addition of fresh cyanide solution at the head of the precipitation boxes.

If lead salts are used in the dissolving solutions, the lead deposits on the zinc and falls off, thus keeping a surface of zinc clear for the precipitation of gold. Similarly, lead prevents copper from depositing as a layer on the zinc and interfering with the precipitation of gold. Common salt or ammonium salts in solution appear to assist precipitation owing to their slight solvent action on zinc hydrate.

If the sodium or potassium cyanide fed into the zinc box contains alkali carbonates and there is lime in the gold solution, the efficiency of the zinc is impaired, owing to its surface being partly insulated from the gold solution by a coating of calcium carbonate, which forms according to the reaction

$$Na_2CO_3+Ca(OH)_2=CaCO_3+2NaOH$$

Protective alkalinity. Potassium cyanide in dilute solutions dissolves zinc cyanide in accordance with the equation

$$2KCN+Zn(CN)_2=K_2Zn(CN)_4$$

The double salts of potassium cyanide with base metals are soluble in excess of caustic alkali, and will therefore not form to a great extent if there is sufficient free alkali present. Thus zinc hydrate will not form when the following reaction can occur:

$$K_2Zn(CN)_4+4KOH$$
$$=K_2ZnO_2+4KCN+2H_2O$$

These reactions point to the necessity of a protective alkalinity to prevent the loss of cyanide, and to obtain good precipitation of gold. When the precipitation of gold occurs in the zinc box there is a loss of alkalinity that is proportional to the percentage of plus or minus alkalinity in the solution. To insure good precipitation and reduce the consumption of zinc, there should be protective alkaline hydrate. So long as free caustic alkali is present, any carbon dioxide will be converted into carbonates, thus protecting the cyanide in the solution.

Composition of white precipitate. The residues, termed the white precipitate, in the zinc boxes at Ferreira Deep mine were found to have the bases given in Table 2. In addition to the ingredients given, the white precipitate will contain variable quantities of calcium and lead sulphates, oxides, or carbonates.

TABLE 2. COMPOSITION OF WHITE PRECIPITATE

Base	Per Cent.
Ferrocyanide of zinc and potassium, $K_2Zn_3[Fe(CN)_6]_2$	10.45
Zinc cyanide, $Zn(CN)_2$	22.73
Zinc hydrate, $Zn(OH)_2$	54.79
Copper oxide, CuO	.40
Ferric oxide, Fe_2O_3	1.00
Silicon oxide, SiO_2	1.03

By comparing the analysis of a solution entering and leaving the precipitation boxes it was found that 81 per cent. of the ferrocyanide remained in the box and went into the white precipitates. There was a reduction of nearly 50 per cent. in potassium cyanide, which accounts for the formation of ferrocyanide of zinc and potassium.

If there is a certain strength of potassium cyanide in the solution, ferrocyanide of zinc and potassium will not be precipitated, but if this strength is lowered precipitation will occur.

When copper is present in the gold solution, it covers the zinc with a bright metallic copper covering. This copper deposit is observed in the lower compartments first, from which it gradually works toward the highest. The precipitation of the gold is very slow when the zinc is coated with copper.

According to Virgoe there is a higher and and a lower copper potassic-cyanide salt formed. The higher salt has the formula $K_4Cu_2(CN)_6$ and is formed when a small quantity of copper is dissolved in a dilute cyanide solution containing an excess of potassium cyanide. This salt solution is said to be a fair solvent for gold and silver, but the lower copper salt, $K_2Cu_2(CN)_4$ which is formed when there is considerable copper present, has no solvent power. Copper goes readily into a soluton of .1 per cent. potassium cyanide, but is only slightly dissolved by solutions containing .05 per cent. of potassiun cyanide. It has been found that dissolved copper is precipitated faster from a weak cyanide solution than from a strong one. It is evident that the precipitation of copper occurs most readily from such solutions as contain the higher salt; in other words, from weak cyanide solutions.

The precipitation of copper from a weak solution may be effectively prevented if a strong cyanide solution is allowed to drop in the first compartment of the zinc box, particularly if the protective alkalinity is preserved during precipitation. To prevent deposits of copper in the precipitation boxes from strong solutions, the zinc shavings are sometimes coated with lead by being placed in a 10-per-cent. solution of lead acetate. This lead-coated zinc will precipitate gold from weak cyanide solutions and leave the copper in solution. It is difficult to work ores containing much copper on account of their large consumption of cyanide and the difficulty of precipitating the gold in the presence of copper.

Frothing.—The presence of organic compounds will sometimes cause excessive action on the zinc, generating hydrogen so vigorously that frothing is the result. Frothing is generally accompanied by a lack of oxygen in the solution. This should be remedied at once, but frothing due to the presence of organic matter cannot be prevented. In weak solutions it does not always accompany an excessive zinc consumption.

Precipitation Obtained.—When good precipitation takes place the solution leaving

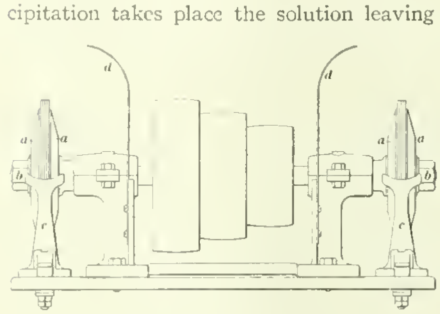

FIG. 4. ZINC SHAVING LATHE

the zinc boxes will not contain more than 8 to 12 cents gold per ton irrespective of its value on entering. Solutions poor in gold or silver do not usually admit of as clean precipitation as richer ones.

Zinc Shavings and Boxes.—In filiform, or thread-like turnings, zinc shavings are generally used for the precipitation of gold and silver from potassium cyanide solutions containing those metals. The shavings should be free from arsenic or antimony, but a little lead in their composition is an advantage, as it promotes rapid precipitation by forming a voltaic couple with the zinc. Zinc sheets and zinc amalgam have been tried, but zinc shavings are preferred, because of the ease with which cyanide solutions attack them. They also allow the free and rapid passage of the cyanide solution, and the screens through which the gold precipitate falls are not clogged by the zinc. The action of the zinc on the gold solution is a simple substitution of zinc for gold, according to the equation.

$$KAu(CN)_2+Zn=K_2Zn(CN)_4+2Au$$

According to theory, 1 pound of zinc should precipitate about 6 pounds of gold; but in practice it requires $\frac{1}{2}$ to 1 pound of zinc for every ounce of gold precipitated. The double salt of auro-potassic cyanide is one of the most stable of gold salts, but its decomposition by zinc is practically complete. The precipitated gold is not redissolved by potassium cyanide so long as there is zinc present. The potassium zinc cyanide remains in the solution that passes to the sump tanks.

Zinc shavings are usually cut from disks of No. 9 Brown & Sharpe gauge, 12 inches in diameter. They have a 1-inch hole in the center, weigh about $\frac{1}{2}$ pound each, and are .114 inch thick. The shavings are usually cut by a machine like that shown in Fig. 4, twenty disks being held in place between cast-iron washers *a* by means of nuts *b* at each end of the mandrel that is passed through the hole in the center of the disks. Then, as the mandrel is revolved, usually at the rate of 350 revolutions per minute, the shavings are cut from the disks by sharp steel tools steadied on iron rests *c*. Guards *d* prevent the shavings getting under the belt of the machine. Zinc shavings, as ordinarily packed in a zinc precipitating box, weigh about 6 pounds per cubic foot; they should be thin enough to burn when lighted by a match. Some machines have an automatic feed mechanism that can be arranged to cut three thicknesses of shavings automatically. The lathe will make 150 pounds of zinc shavings per day of 8 hours. The proper thickness of zinc shaving is $\frac{1}{500}$ (.002) of an inch. Shavings from $\frac{1}{400}$ to $\frac{1}{800}$ inch in thickness are used.

Zinc shavings should be uniformly distributed in all compartments of the zinc box except the last one, which is left empty to collect any particles of zinc and gold that they may be carried from the others. The corners of each compartment should be well packed to prevent the solution passing through in channels. The speed with which the solution should flow through the boxes can be determined by tests on the outflowing solution for the presence of gold. Where gold precipitation takes place under proper conditions, the metallic deposit on the zinc is brownish-black, and precipitation should take place in the first compartments. In imperfect precipitation, the deposit is frequently gray or of a dull metallic color. The dry precipitate seldom contains more than 40 or 50 per cent. of gold and silver, the remainder being finely divided zinc and its impurities. The precipitation in the zinc boxes is influenced by the amount of cyanide present in the solution.

Fresh zinc shavings should be added daily to the last compartment of the precipitating boxes. The partly consumed zinc should be brought up a step so that the first chamber contains zinc partly consumed and rich in bullion, while the last chamber contains fresh zinc. Zinc on which bullion is already deposited is more active than new zinc; it is, therefore, advisable to replace the dissolved zinc in the upper compartments with zinc from the lower compartments and add the fresh zinc to the last compartment. Zinc boxes should not be disturbed oftener than necessary to keep them from channeling; and then the work of rearranging the zinc should be carefully and gently done, as the gold precipitate when detached is liable to be carried past several compartments and lost in the sump.

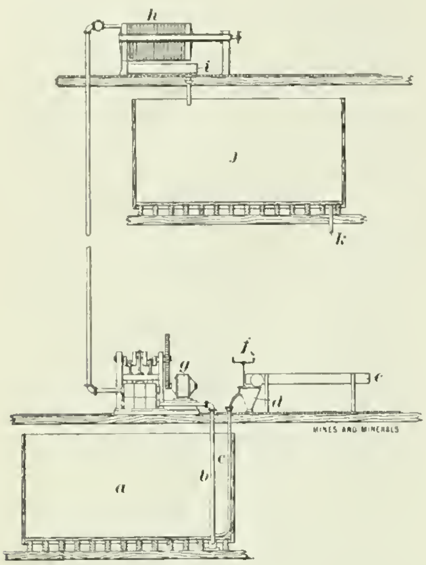

FIG. 5. MERRILL PRECIPITATION EQUIPMENT

The usual rate of flow for all zinc boxes is 1 ton of solution per day (24 hours) for each cubic foot of zinc. If the weak box does not give satisfactory results at this, it may be run more slowly. A weak zinc box should not be run unless there is a good reason for its use.

If a mill is equipped for two solutions and it is desired to use only one zinc box, proceed as follows: After a vat has been leaching for nearly half its allotted time it will be found that the effluent solution contains only about one-fourth as much gold as it did during the first day. This effluent should be turned to the weak sump which may now be called the mill sump. This solution containing some gold is standardized, all the additions of cyanide being hereafter made to this solution alone. This mill solution is used on the vats during the early portion of their leaching period, thus supplying the zinc box with a solution richer in gold than could otherwise be obtained. This rich solution after parting with its gold in the zinc box is called "barren" and goes to the barren sump to be used on the vats during the latter part of their treatment. The solutions alternately change places, the mill solution becoming barren after passing through the zinc box. The plan generally saves zinc and cyanide, as only one-half of the solution is required to pass through the zinc. The consumption of zinc is generally nearly proportional to the amount of solution passing through the box and has little relation to the amount of gold deposited.

Zinc Dust Precipitation.—The low price of zinc dust as compared with zinc shavings has led to many attempts to use it as a precipitant for gold on a milling scale. While some of these attempts have been fairly successful, the method had no advantage over the use of zinc shavings until the Merrill precipitation press was devised. These presses are particularly applicable to large mills where the trouble and expense of cleaning up so many zinc shavings would be very great. At the Homestake, where the press was first used, it is precipitating the gold from 4,000 tons of solution daily. The method is also particularly applicable in treating ores containing a large amount of silver, which makes a bulky clean-up. In using zinc dust the zinc consumption is much reduced, owing to the shorter time of contact of the zinc with the solution and the fact that the zinc dust is added to the solution only in proportion to the amount of metal to be precipitated. Another advantage in the use of zinc dust is that a complete clean-up of the mill can be made, while in the use of shavings it is necessary to carry over a large amount of bullion in the zinc boxes. Security from fire is also an advantage.

This method of precipitation can best be understood by reference to Fig. 5. The pump *g* is connected by pipe *b* to elevate the precious-metal bearing solution from the usual sump tank *a* through the filter press *h*, the barren filtered solution flowing by pipe *i* from the press to the storage tank *j* for reuse.

The precipitant of zinc dust is spread upon the belt of the automatic feeder *e*, which is arranged by means of a float and counterweight to travel at a speed proportionate to the volume of solution pumped. The dust drops into a small agitating, or mixing cone *d*, where it is pulped with air and solution from pipes *f*, and overflows into the suction of the pump. The mixed stream of solution and precipitant passes up the discharge column and into the filter press, where the precious metals and any excess of zinc remain, and the clear, barren solution flows to the storage tank.

The filter presses, Fig. 6, used for this work are of a special type. The frames or containers are triangular in section, and the feed-pipes are so arranged that the solution and zinc enter from the bottom or apex of the frame. Thus any excess of zinc remaining in the press from a previous pumping is kept in agitation by the incoming fresh solution and the maximum precipitating efficiency is obtained.

The operation of the press is as follows: Air is blown through the press until the product contains from 5 to 10 per cent. moisture. This takes from 1 to 2 hours at 6-pound to 10-pound air pressure. The contents of the precipitate containers or frames are then discharged into a box mounted on rollers, which is run on to scales and weighed. Core samples for moisture and assay are taken if desired. Fluxes are then added, and after mixing, the product is shoveled directly into the melting pots, all these operations taking place in the original clean-up box.

With silver ores no acid treatment of the product is necessary, the raw product from the presses being from 50 to 80 per cent. metal, depending on the richness of the solution precipitated.

In the case of gold ores the product is either briqueted with litharge and cupeled, or the usual acid treatment and pot melting may be employed.

Electrical Precipitation.—This method gained considerable prominence in South Africa during the early history of cyanidation, being introduced there by the Siemens & Halske Co., of Germany, one of the ablest engineering firms in Europe. Much valuable scientific data was collected by Doctor Siemens as to the possibilities and limitations of the method. The inventor found and demonstrated that in order to precipitate the gold from 100 tons of cyanide solution per day 10,000 square feet of cathode surface were required, and also the same amount of anode surface. The cathodes were made of sheet lead and the anodes of iron. The installation cost was high and the power required for generating the electric current was a considerable item of expense.

Many other futile attempts have since been made to bring the method into practice on a milling scale, generally by men not conversant with the principles involved. However, one important improvement has been made by Mr. Charles Butters that is giving good service. It consists in making the anode of peroxidized lead, thus obviating the destruction of both the anodes and of a considerable quantity of cyanide, which occurred in the Siemens-Halske method. Some cyanide is also saved over the zinc method as no zinc potassic cyanide is formed. This advantage is believed to be more apparent than real, as a large portion of the zinc finally separates from the solution as zinc hydrate.

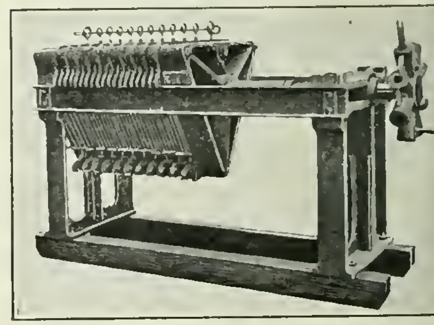

FIG. 6. ZINC DUST PRECIPITATION PRESS

Charcoal Precipitation.—The use of charcoal as a precipitant for gold has been the subject of numerous patents, and the method has been used in a few instances, but has never attained commercial importance.

The Magdalena Mining District, N. Mex.

A Zinc-Lead-Silver District the Development of Which Shows Interesting Geological Features

By Edgar G. Tuttle, E. M.

THE Magdalena mining district, in Socorro County, N. Mex., is distant about 27 miles west of the town of Socorro from which a branch line of the Atchison, Topeka & Santa Fe Railroad runs northwesterly about 27 miles to Magdalena. The district includes a portion of the north end of the Magdalena range, also the towns of Magdalena and Kelly.

The principal mining operations are near Kelly, about 3 miles southeast of Magdalena, on the west slope of the range. A good wagon road, with a slight upgrade, connects the two towns.

The Magdalena Mountains rise to an elevation of about 9,000 feet; the summit being about a mile east of Kelly. The range is about 25 miles long, north and south, the east slope continuing to the valley of the Rio Grande, but broken with intervening ranges and spurs, the most important of which are Socorro Peak and the Lemitar Mountains. The highest point in the Magdalena range is "Old Baldy," with an elevation of 10,800 feet. To the west of the town and these mountains are broad elevated plains, with widely separated mountain ranges.

The elevation of Socorro is 4,571 feet; the elevated plains around Magdalena, about 5,500 to 6,000 feet; the mining operations around Kelly about 7,500 to 8,000 feet.

The Magdalena mining district has been described in Professional Paper No. 68, of the United States Geological Survey, from which some of the following data are taken.

The first claim staked out in 1866 was the Juanita, whose outcropping vein shown in Fig. 2 stands prominently in view about one-quarter mile southeast of Kelly.

In the upper part of the vein oxidized lead ore carrying silver, and in places a little copper, occurs.

The early workings of the Graphic mine, which was located less than a month later, yielded sandy carbonates which were smelted on the ground in an adobe furnace and the bullion hauled to Kansas City in ox carts.

Gustav Billings who obtained control of the Kelly mine in 1881, built a smelter about 2½ miles west of Socorro. The furnace was favorably located, at the time, for treating ores from southwest New Mexico and Old Mexico, and later fuel was obtained from the coal fields of northern New Mexico. The smelter treated lead-silver ores from Magdalena and some silver ores from mines near Socorro until about 1890 when the Windom bill went into effect increasing the duties on certain grades of lead-silver ores coming into the United States from Mexico. Then followed the establishment of larger smelting plants in Mexico and at El Paso, which were nearer the main supply of ores than the Rio Grande Valley smelter at Socorro. Due to this cause and the high freight rates, the Billings smelter closed down about 1893.

The plant employed 500 to 1,000 men and when the smelter closed down Socorro became nearly deserted.

FIG. 1. MAGDALENA RANGE, FROM MAGDALENA, N. MEX.

In 1896 the Graphic smelter was built, near Magdalena, and treated the red-lead surface ores. This supply diminished and the furnace closed down in 1902.

From 1894 to 1902 the Kelly and Graphic mines were only slightly worked. Then the Sherman-Williams Paint Co. bought the Graphic mine.

In 1904 Mrs. Billings sold the Kelly mine to the Tri-Bullion Mining and Smelting Co.

The surface ores were mostly lead carbonates with copper carbonates in small quantity. A little deeper, zinc carbonates came in. As greater depth was attained, zinc and lead sulphides with iron sulphides and occasionally some chalcopyrite were encountered.

FIG. 2. JUANITA VEIN

This has been the chief zinc producing camp of New Mexico. A large part of the ore has been used for the manufacture of zinc-lead paint.

Up to 1907 the ore was shipped crude. Then attention was given to concentration with more or less satisfactory results.

About 1908 the Mistletoe and Magdalena Tunnel Co. had completed a pneumatic concentrator which operated for a while.

In 1909 the Tribullion Smelting and Development Co. began operating a wet concentration plant with roasters and magnetic separators for the treatment of the zinc-lead-iron sulphide ores which they were mining from the deeper workings of a continuation of the same ore horizon as worked near the surface at the original Kelly workings. The Tribullion owns this property but leases it, allowing the lessee to mine the oxidized ores.

About this time the Ozark Smelting and Mining Co., operating the Graphic mine, after various tests, erected a concentrating plant to treat the Graphic ores. The plant contains ore sizers, dry concentrating tables, a roasting furnace, and magnetic separators. The mine and mill are closed down for the present and some experiments are being made with the flotation process.

The basal rocks are pre-Cambrian, consisting of greenstone schists and granite. On these rest formations of the Carboniferous system, designated in ascending order: First, the Kelly limestone group (Mississippian series) lying immediately above the basal rocks. Second, the Sandia formation resting on the Kelly limestone. Third, the Madera formation on top of the Sandia. The Sandia and Madera formations belong to the Magdalena group of the Pennsylvanian series of the Carboniferous.

Ryolite, andesite, and porphyry rocks are also exposed over parts of the field.

The stratified formations of the Carboniferous are approximately conformable and have a general strike of about N 30° W and dip westerly at an inclination of 30 to 40 degrees. On the east side of the Magdalena range the formations are reversed and dip easterly. The principal developments on the east side of the mountain are at Water Cañon. Although the indications here are very promising nothing of importance has as yet been developed.

The Kelly limestone formation varies from about 70 to 150 feet in thickness and is the principal ore-bearing horizon of the region. Except at its contact with the basal rocks and the overlying Sandia formation, it consists of 60 to 150 feet of fine-grain subcrystalline limestone, near the middle of which is a hard compact layer of limestone, 4 to 8 feet thick, known as "silverpipe" limestone, or the "east," or "lower silverpipe."

The silverpipe varies in color in different parts of the field, from white to light blue, buff, and red, and it is of a fine close texture by which it is readily recognized. In development work, when the silverpipe is encountered it can generally be accurately determined how far it is necessary to drive, and in what direction, to reach the ore. It thus serves as an indicator.

Near the top of the Kelly limestone there occurs at some localities another layer of silverpipe, known as the west or upper silver-

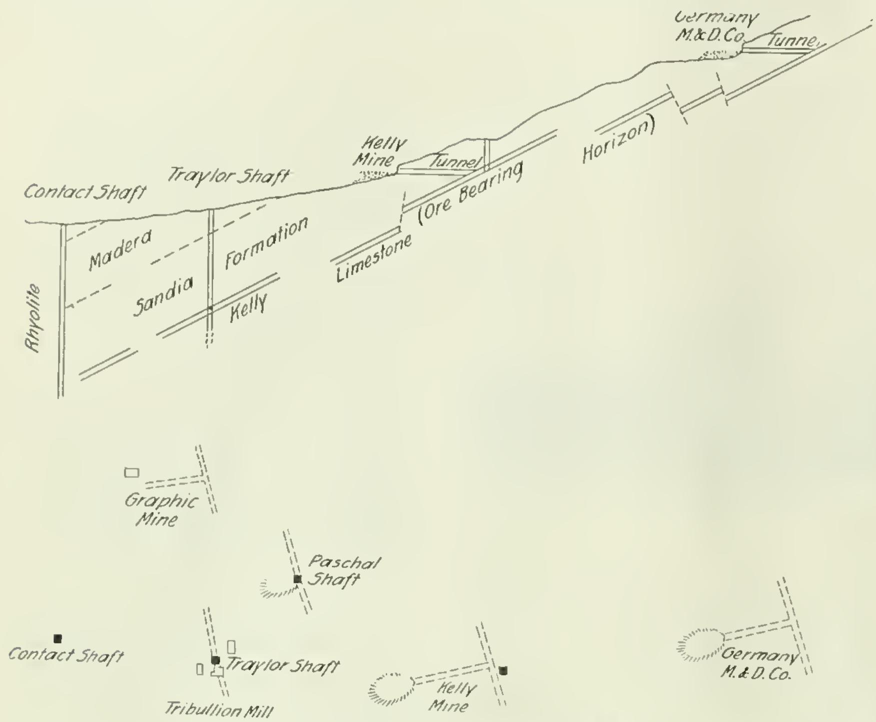

Fig. 3. Section and Plan of Workings on Kelly Limestone, Magdalena District, N. Mex.

pipe. This in some places attains a thickness of 3 feet, but is frequently entirely absent.

The Sandia formation is probably more than 400 feet thick and less than 700 feet. It consists of shale, quartzite, limestone, and conglomerate. One body of shale in the lower part of this section rests immediately on the Kelly limestone formation.

The Madera formation is the uppermost of the series and consists of 400 feet, more or less, of mainly blue compact limestone with some shale. The ore deposits are fairly regular and conformable with the stratification of the sedimentary rocks. The ore is fairly continuous, except where interrupted by faults or other disturbances. It varies considerably in thickness, being 20 feet and more in the upper workings on the carbonate ores and the outcrop workings in the region of faults or dikes, where it is somewhat of an irregular ore body. In the deeper workings on the dip to the west, the ore varies from 6 to 16 feet in thickness, although in some places it pinches out.

Table 1. Assays of Ores From Magdalena Mining District

Name of Mine	Assay: Lead Per Cent.	Zinc Per Cent.	Copper Per Cent.	Iron Per Cent.	Silica Per Cent.	Gold Ounces Per Ton	Silver Ounces Per Ton	Description

1907				37,523	39,905	77,428
1908	72	244	344	675	156,296	157,631
						$2,942,767

In the deeper workings the ore is a zinc-lead sulphide in combination with iron pyrites and a little gangue.

In the upper workings the ores are zinc and lead carbonates sometimes associated with copper in small quantity, also occasionally with a little gold and silver. Beautiful specimens of white and green smithsonite, sphalerite, and azurite have been found.

The ore may be regarded as a limestone replacement, the deposits making in the bedding planes of the limestone.

There are five or six ore horizons, but the two in the Kelly limestone are the only important ones so far as known.

The first ore horizon is at the contact of the Kelly limestone with the underlying basement greenstone. Some ore is occasionally found here.

The second ore horizon is in the Kelly limestone below the 4 to 8 feet of lower or east silverpipe limestone. This is the bed worked by the Kelly mine and at depth by the Tribullion.

The third horizon is in the Kelly limestone above this silverpipe. This is the bed worked by the Graphic mine.

These beds or horizons are the most important.

A fourth ore horizon is in the 2 to 10 feet of silicious fine grain crystalline limestone

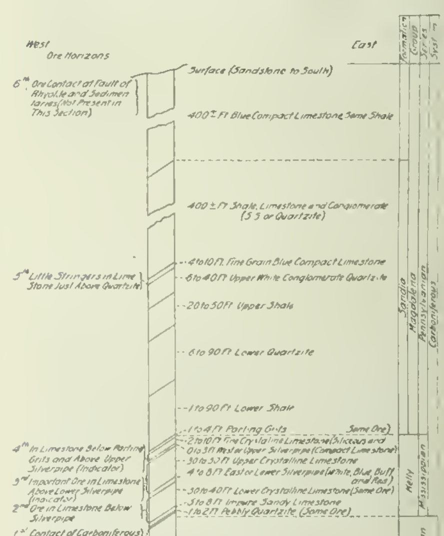

Fig. 4. Geological Section, Magdalena Mining District

above the upper or west silverpipe. A little ore is occasionally found here.

A fifth horizon consists of little stringers of ore in the 4 to 10 feet of limestone above the upper white conglomerate quartzite in the Sandia formation.

A sixth occurrence of ore is as a contact of the sedimentaries with the rhyolite. This is shown in the eastern part of the field.

Favorable conditions for the making of ore have been created through the disturbances caused by rock intrusions, also a system of fracture and fault zones and accompanying mineralizing agencies.

The fault lines extend N W and S E generally. The most important of these disturbances is the Kelly-Graphic fault, extending on through the Juanita property, northwesterly, near the Kelly and Tribullion mines to the Graphic mine. Near this fault the ore body was very large at the Juanita mine, and the ore beds are very thick at the Kelly mine.

The sedimentaries and their ore-bearing horizons are probably cut off where they come in contact with the intrusive rocks about one-fourth mile west of Kelly.

The assays in Table 1 are interesting in that they show the wide variation that occurs in ores in the same district:

Up to 1904 the production of the Kelly and Graphic mines was $5,800,000, and for the whole district $6,600,000 to $8,800,000. From 1904 to 1908 the production, as far as reported, was about $3,000,000 of various grades of ore. The metal values are given in Table 2.

Since 1908 the production of the district has been about $800,000 to $1,500,000 annually. Exact figures are not at hand, but the average is about $1,000,000 yearly. The total output of the camp from the beginning to date is approximately $15,000,000.

Men *vs.* Machines

[Under the above title, Josiah Bond, mining engineer, Patagonia, Arizona, publishes an article in the Mexican *Mining Journal*. The following is an abstract. —Editor.]

It frequently has been put forward as an argument that as soon as a mine is somewhat developed, machines can advantageously replace hand labor. Miners generally believe, for instance, that machine drilling will undercut hand drilling so much as to leave no choice in the matter. It seems certain, however, that no general assertion to this effect can be sustained, if consideration is confined to the single item of costs.

It is also assumed by many that more rapid progress can be made with proper machinery and proper men to run it, than by hand labor. Often it may be legitimate to incur the expense of such a plant to insure greater speed; as, for example, in the case of a property that, for reasons of administrative policy, must be developed and brought to a productive stage as quickly as possible. Such rapid progress will perhaps make an attractive showing to the ordinary class of stockholders, but the value of such a procedure from this purely sentimental point of view is discouraged, since the overhead charges will necessarily be increased. An acquaintance of the writer, wishing to sink a 200-foot shaft, submitted the proposition to a contractor, who offered to do the work for $2,000, providing he were permitted to do the work by hand, and to use a whim for hoisting. He also agreed to finish the contract in 3 months, if a large amount of water did not develop during the progress of sinking. The nearest railroad was 2 miles distant, was at a lower elevation, and there was no wagon road built. However, this owner deemed the proposal too slow, so he built 2 miles of wagon road, and bought and installed a plant consisting of a boiler, steam hoist, air compressor, machine drills, and all accessories. The plant worked well, no water was found and at the end of *six* months, the shaft was down 170 feet, the owner had spent $22,000, and the project was bankrupted.

A most ridiculous sight is to see a fine hoisting plant standing idle over a shallow shaft, say a shaft less than 200 feet deep It is a conspicuous monument to the ignorance or the vanity of its owners. Once in a while it happens that the shaft is sunk to greater depth later; but it more often is the case that the plant is sold to others who may perhaps do just as foolishly with it. The writer knows of one such plant that has been placed over six different shafts, every one of which was less than 175 feet deep.

It is astonishing how some stockholders, who are generally successful business men in their own lines, will require the management of their mines to uselessly spend money in an effort to get quick action, when the patient carrying out of a slower program would more likely insure the success of their enterprises. Sometimes the result of such a policy has been that the management, being unable to stem the tide, has deliberately "let things slide" and has gone in for any graft that could be devised while the available capital lasted.

If a shaft is to be sunk through known, very wet, ground, that will require power-driven pumps, it is economy to erect the power plant so that all of the work may be done by machinery. In such a case, the investment in plant will be but slightly augmented, and the cost of operating it will be chiefly in the increased consumption of fuel. If it should happen that drainage can be effected by occasionally pumping a few hours, the operations of sinking may be so arranged as to secure the greatest benefits from the power plant, that can be kept running close to its highest efficiency. If the flow of water is so small that its removal will not require power pumping for an interval corresponding to the space between other operations of shaft sinking, then it will be cheaper to sink the shaft by hand.

The writer sunk two shafts on the same lode, about 1,500 feet apart. One of these he sunk by hand to a depth of 275 feet. The other he sunk by drilling with compressed air, also using the same form of power for pumping. The cost of the shallower shaft averaged $6 per foot, including everything; while the cost of the deeper shaft was $17 per foot including everything except the interest on the plant and its depreciation. The conditions in these shafts were practically identical. The water, in each case, could have been easily handled by a bucket.

In tunnel work, hand labor shows up to decided advantage. A certain company drove a 5'×7' adit 2,000 feet, using compressed air for drilling. The progress was a trifle less than 3 feet per shift, and the cost per foot was $14.87, exclusive of salary for management. A portion of this work was done by contract at an excessively high figure, but making due allowance for this, the actual cost per foot was more than $12. Just afterward, in the same rock, a 4'×6½' tunnel was driven 1,200 feet by hand labor. The progress was a trifle over 2 feet per shift, and the cost $4.60 per foot.

One of the main reasons for the difference in favor of hand work lies in the fact that there is practically no loss through "overhead charges" when, for any one of many reasons, the regular progress is not being made. There may be a significant loss if a shift, using machines, gets behind with its duties.

The arguments in favor of hand work apply principally to mines operating upon small scales. The larger the scale of operation and the greater the cost of administration and management, the more economical will mechanical work be found. If a company has 100,000 tons of blocked ore, and can add to the reserve at the rate of 5,000 tons per month by hand labor, the cost per ton of ore thus produced, chargeable against management at $1,000 per month, would be 20 cents. Were the work done by machinery, more than four times as much ore might be produced, so that the item of management cost would be reduced to 5 cents per ton. All other fixed charges that are independent of tonnage would be correspondingly reduced by about 75 per cent. This saving would soon pay for the mechanical installation.

In a general way, machinery will pay best when it can be used steadily during its natural life to its capacity. If the work is intermittent and limited, it will be cheaper to do it by hand.

There are many cases in which hand work is entirely impracticable as in deep mining. The hoisting of ore and the lifting of water from deep workings call for machinery. The outlook is that most of the mining of the future will call for machinery. Deep mining will be the order of business; and labor is becoming so scarce that machinery must be resorted to, to perform most of the work.

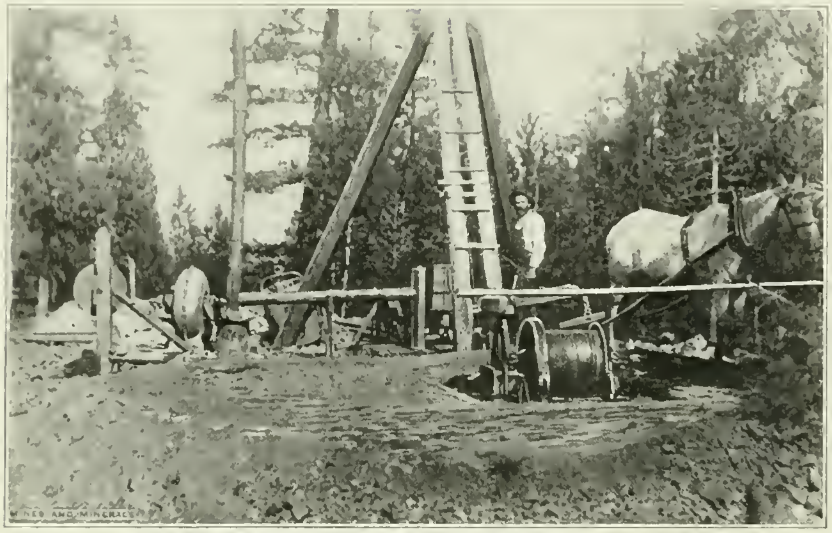

Fig. 1. Ada B Shaft, Princeton, B. C.

Princeton, B. C., Mining Notes

*By Frank Bailey, M. E.**

Considerable development work throughout the Similkameen and Southern British Columbia has been carried on steadily for the last 9 months and is still improving and showing valuable commercial tonnage at depth.

The Hedley Gold Mining Co., of New York, that owns and operates a large group of mines in Camp Hedley (in the Similkameen Valley, 35 miles below Princeton) continues to distribute its usual quarterly 25 per cent dividend to the stockholders The property today has more ore blocked out in the Nickel Plate mine than ever before, and its diamond drills have proved also the existence of payable ores on the surrounding properties. Production of the Hedley Gold Mining Co.'s mines up to June 30, 1912, is approximately $4,157,310.

Besides the development of the above company, the Kingston mine and adjoining properties have been worked, but are not as yet in the producing stage; they also are controlled by American capital.

C. H. Brooks is employing about 20 men developing the Golden Zone group of claims which was opened some years ago. A. Creelman, the superintendent, is sinking a 300-foot shaft, and running drifts both ways on the 150-foot and 250-foot levels, blocking out considerable commercial ore. Development work is also being carried on on the Apex group by M. K. Rogers, L. W. Shatford, M. P. P., and associates.

The British Columbia Copper Co., of Greenwood, B. C., and New York, has been developing its large holdings on Copper Mountain, which is about 12 miles south of Princeton. Late last year it took a bond on the Voight group of 62 mineral claims, on which it has several diamond drills at work on different parts of Copper Mountain, with Mr. Mitchell in charge. This summer it took another bond on the Silver Dollar and Ada B mineral claims, which have shown large deposits of high-grade cupriferous ores in their working shafts. It has been reported that the British Columbia Copper Co. will install a large smelter near Princeton in the near future, to treat its ores on Copper Mountain. It has declared a second dividend of 15 cents a share, payable October 15, aggregating $88,726.35. A similar amount having been disbursed in August, this makes the total dividends to date $526,-643.35.

[Mr. Bailey sends two photographs on shaft sinking, on which he makes no comment. Fig. 1 is the "Ada B" prospect shaft, which is down so deep it has headings that require a tripod head-frame, horse-power hoister, and blower ventilating fan, in fact has passed the "strong-arm" hoister stage. Fig. 2 is the Silver Dollar prospecting shaft which has passed the horsepower hoister stage and uses the steam winch, shown on the ground to the left of the three men. This prospect uses buckets, and in addition an ore car on the surface. The underground working is ventilated by what seems to be a "steam siphon," the air pipe being held in position by poles to the rear of the shaft. In prospecting work of this kind where fuel is scarce the horsepower hoister can lift 100 tons of rock in a day, from a depth of 150 feet, and were it not for the other uses to which steam is applied there would be no portable boilers hauled around for sinking prospect shafts.—Editor.]

Whipsaw Camp has received considerable attention this summer and the owners of the different properties are well pleased with the general outlook, and expect to have several shipping mines next year. The ore is a high-grade silver-lead carrying both gold and silver besides a little copper; work was carried on all last winter by Messrs. Knight & Day, in driving a long tunnel on the vein. Whipsaw Creek is situated at the foot of Kennedy Mountain, and empties into the Similkameen River opposite Copper Mountain; the camp is situated on Whipsaw Creek, about 10 miles south of Princeton.

The new silver-lead camp situated at the summit of the Hope Mountains, near the head waters of the Tulameen River, has changed its name from Summit Camp to that of "Leadville" where three different Spokane companies have lately bonded several groups of silver-lead properties, and will continue development work all winter. The Provincial Government has lately surveyed a wagon road from Tulameen City up the river to Leadville and this will be built before spring.

* Princeton, British Columbia.

Standard Silver Mine

A Description of the Development, the Ore, and the Method by Which It Is Treated in the Mill

*By William Fleet Robertson**

THE Standard mine in 1911 was one of the most successful developments with depth of any property in the Slocan, B. C., mining district, and now has more ore developed—practically ore in sight—than at any time in its history. The Standard vein cuts through three properties, the Alpha, Standard, and Emily Edith, each of which has already made a record as a large shipper of silver-lead ore. These properties are located on the slope of the mountain on the east side of Slocum Lake, and on the north side of Four-mile Creek, which flows into the lake at the town of Silverton.

The vein fissure cuts through the Slocan slates in a general east-and-west direction, and has been developed by various adit tunnels from the upper workings of the Alpha, the highest of the three properties, at an elevation of 2,834 feet above Slocan Lake, down to the lowest workings of the Emily Edith, which are at an elevation of about 720 feet above the lake.

The general slope of the hillside along the line of the fissure is from 20 to 30 degrees, and, as the ore shoots dip into the hill, the adit tunnels become quite long before they reach the ore shoots, when any depth is attempted.

The vein in the upper workings of the Alpha is somewhat irregular and broken, but as it goes down the hill it becomes more uniform. In this fissure there are shoots of ore between which the fissure is almost barren.

On the Alpha the ore shoot was discovered practically on the surface, dipping into the hill; and before the property was shut down in 1894, owing to litigation, some 1,200 tons of high-grade silver-lead ore were shipped, chiefly from a large body of galena and from lead carbonates found near the surface. This property has lain idle since 1894; it was held for some years by the late N. F. McNaught, and is now owned by his estate.

The development consists of five adit tunnels driven in on the vein; the upper tunnels contained good ore, but Nos. 4 and 5, the two lowest tunnels, did not reach the ore shoots, although the vein there is clearly defined.

It would seem that these two tunnels had not been driven far enough in to expect to strike the ore shoot seen in the upper levels, and that allowance had not been made for the dip of the ore shoot into the hill and the low slope of the hillside.

A scheme was in progress last fall not only to extend these lower levels, but also to prospect the ground at a greater depth by using one of the Standard tunnels, permission to do so having been granted by that company.

The Standard mine, owned by George H. Aylard, of New Denver, and John A. Finch, of Spokane, consists of three Crown-granted claims, the Shunieaw, Standard, and Surprise, and the same partners have also acquired the adjoining property of the Emily Edith company.

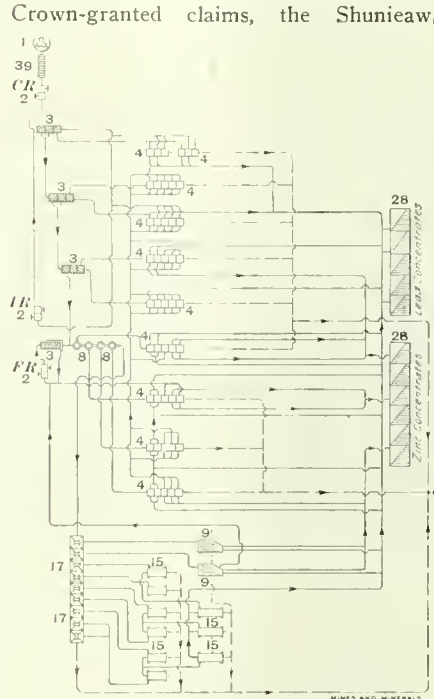

Fig. 1. Flow Sheet, Standard Mill
1, Crusher; *CR2*, Crushing Mills; *IR2*, Intermediate Rolls; *FR2*, Fine Rolls; 3, Trommel; 4, Jigs; 8, Classifiers; 9, Concentrating Tables; 15, Frue Vanners; 17, Spitzkasten; 28, Ore Bins

The Standard mine has been opened up by a series of adit tunnels, the highest at an elevation of 1,987 feet above the lake, or 300 feet lower than the lowest tunnel of the Alpha, while No. 6 tunnel is at an elevation of 1,414 feet above the lake, thus developing between these levels a vertical depth of 573 feet, while it is considerably more on the slope of the vein.

No. 1 tunnel appears to have been above the ore shoot, and was driven in some 85 feet without striking anything very encouraging.

No. 2 tunnel, some 77 feet vertically lower down, was driven in about 250 feet, and passed through a shoot of ore about 150 feet long, which extended upwards to the No. 1 tunnel.

No. 3 tunnel is 81 feet lower than No. 2, and has been driven in 415 feet, passing through the same ore body as seen in No. 2.

No. 4 tunnel, 100 feet lower, has been driven 900 feet, and has also passed through the same ore body, which here extended for 300 feet along the level.

No. 5 tunnel is 125 feet lower than No. 4, and after having been driven 1,300 feet struck the ore body, which continued for about 300 feet, having a maximum width of over 40 feet, of which 20 feet was clean galena and 20 feet ore, which would concentrate approximately three into one.

No. 6 tunnel had, in September last, been driven in about 1,800 feet, the face showing strong mineralization, with blende and a little galena, but not enough to constitute ore.

About 200 feet back from the face, a small fissure, carrying a little galena, had been followed off to the left by a drift; this drift in following the ore had assumed the shape of a letter S, and contained a very nice stringer of ore, galena, and blende—quite sufficient, in September, to be workable.

Later advices from the mine indicate that this drift, as it was extended, opened up a very considerable body of galena ore, and that the drift had become parallel to the main tunnel, but some feet to the left.

Whether this particular ore body is the downward continuation of the ore body developed on No. 5 is not yet determined; it appears to be rather too far out, and then, again, it may be the top of an ore shoot from below which did not extend up to the No. 5 level; work being done will, however, soon solve the question.

The showing of ore on No. 5 level is one of the largest exposures of high-grade galena ever seen in British Columbia, and is practically intact up to No. 4 level, constituting a block of "ore in sight" above No. 5 level, which on a rough calculation figures out to a net value in the neighborhood of $1,000,000.

The ore shoot is at its strongest on the No. 5, and so, undoubtedly, continues for some distance below; whether the ore found in the No. 6, some 200 feet lower, is the same ore body has not been proved, but it probably is, in which case over $2,000,000 more of ore will be available.

The ore shipped in former years gave smelter returns which averaged about 60 per cent. of lead and 80 ounces of silver to the ton, and there is no doubt this continuation of the ore body will run about the same.

Concentrator.—The owners of the property were, last fall, completing the erection of a concentrating mill, which has since been finished and is now running. This mill is situated on the town-

* Provincial Mineralogist. In the 1911 Report of the Bureau of Mines, British Columbia.

site of Silverton, adjacent to the lake shore, and is connected with the No. 6 tunnel of the mine by a self-acting aerial tramway, 7,900 feet long. The flow sheet of the mill is shown in Fig. 1.

At both the upper and lower terminals this tramway is provided with separate bins for clean and concentrating ores, so that each can be sent down separately, permitting of the clean ore being shipped from the mill without further treatment, while the concentrating ore will go through the mill process.

The advisability of this procedure is evident, as the higher values in silver are usually contained in gray copper, "freibergite," or some high sulphide which, from its nature, crushes to a fine powder, causing great losses in slime, so that a large proportion of the values would be lost in water concentration. By shipping the cleaner ores direct, this loss is obviated, although at the expense of a somewhat increased freight and treatment charge.

The water for power and washing purposes is taken out of Four-mile Creek (sometimes called Silverton Creek), about 2 miles up from the lake; the intake is formed by a short tunnel driven through a projecting shoulder of rock in a cañon forming a natural dam, which cannot be swept away by the freshets to which the creek is liable every spring.

From the tunnel intake the water is conveyed by ditch and flume for about half a mile, passing on the way, by tunnels, through two gravel and clay sliding banks, in which the water is confined in tight flumes.

At a point just below the wagon road to the Emily Edith mine, the water from the ditch enters a 20-inch iron pipe, and is conveyed down to the creek level, where, beside the wagon road, an air-compressor plant has been installed. This plant consists of a 10-drill air compressor of the Canadian Rand type, driven by a 5-foot Pelton waterwheel, working under a head of 160 feet, the whole being housed in a well-constructed, permanent building.

The waste water from the Pelton wheel is caught up by a second ditch line, this time on the north bank of the creek, and is conveyed by flume along the hillside to a point directly above the concentrating mill, down to which the water is conveyed by a 16- to 12-inch iron penstock, about 1,200 feet in length.

At the compressor plant a by-pass is arranged so that, if for any reason the Pelton wheel is not in operation, the water can be passed, by opening a valve, from the compressor penstock directly into the concentrating mill flume.

The Emily Edith mine is an extension, down the hill, of the Standard, and, although formerly owned and operated by another company, has of recent years been acquired by the Standard company. The Emily Edith has not been worked since about 1904, and, as the shale country rock weathers easily, the old workings today reveal nothing and cannot be examined.

The mine was originally opened up by some seven or eight adit tunnels, mostly driven in on the vein from the outcrop, although some were primarily cross-cuts to the vein. The highest of these tunnels is at an elevation of 1,128 feet above the lake, approximately 286 feet vertically lower than the present lowest (No. 6) tunnel on the Standard. The lowest tunnel on the Emily Edith is at an elevation of 720 feet above the lake; therefore the vein has been explored in this property for a vertical height of 408 feet.

As far as can be gathered from the old mine plans, the tunnels have been driven, respectively, starting with the highest, 140 feet, 250 feet, 300 feet, 370 feet, 410 feet (partly cross-cut), 350 feet, and 220 feet. It would, therefore, seem as if such development as had been done was exceedingly superficial when it is considered that the two lower tunnels in the adjoining Standard had to be driven 1,200 feet and 1,800 feet before reaching the ore shoot which has made its success, and that there remains a considerable section of the vein absolutely virgin and unprospected.

The mine formerly produced a considerable tonnage of galena ore running well into silver, but associated with a high percentage of blende.

It is expected that the Standard company will commence the development of the Emily Edith as soon as the Standard No. 6 tunnel is producing.

The property is thoroughly equipped with good office, laboratory, bunk, and cook houses, from which a wagon road leads down to the main wagon road up Four-mile Creek.

The accompanying flow sheet of the Standard concentrating mill has been made from a sketch kindly furnished by the management after the mill was completed.

The mill, which was started in the spring, treats about 100 tons of milling ore daily with results that are satisfactory to the management. Later advices from Angus McInnes, mining recorder, state that the galena in No. 6 tunnel gave place to 8 feet of zinc ore.

Cost of Milling in South Africa

The following data, taken from the *South African Mining Journal*, are published with a view to allowing the hydrometallurgists in Canada, Mexico, and the United States to compare their cost sheets with the South Africans. There are some matters which increase the cost over that in the western hemisphere; on the other hand there are matters which decrease the cost. Among the first may be mentioned supplies; and among the latter, large tonnage treated, which materially decreases in fixed charges. No particular choice of mines has been made, and the results have been obtained from the yearly reports of the companies. The assay value is reported in pennyweights, one of which is equivalent to $1.0335. The report was in shillings and pence, which has been converted by considering one shilling 25 cents, and 1 penny 2 cents United States money. So far as costs of reduction are concerned the Wolhuter, with its 120 stamps, is run at less cost per ton milled than the Crown Mines, with its 620 stamps.

Low Costs at Wasp No. 2 Mine

Successful Methods Employed in Stripping, Mining, and Milling Ore of Very Low Grade

*By Leroy A. Palmer**

THE Wasp No. 2 mine has made a record for low cost of mining and treating gold ores that has probably not been approached by any other company operating on the same tonnage, the annual report for 1911 showing a total cost for mining, milling, and treating bullion, including all general expenses, of $1.25 per ton.

The property is located in South Dakota, about 7 miles from Deadwood, on the Chicago, Burlington & Quincy Railroad, connection with which is had by an inclined tramway. The company's property extends about 2,500 feet north and south and 1,000 feet east and west, in the so-called "flat formation" that contains several of the well-known mines of the region, including the Golden Reward which, next to the Homestake, is the largest producer in the Black Hills.

The ore-bearing formation at the Wasp No. 2 is a massive Cambrian quartzite with noticeable iron stain. This quartzite has an average thickness of 19 feet and overlies the Algonkian schists of the region. Above the quartzite is a layer of friable sandstone, also Cambrian, and soil to a total thickness of 10 feet on the average. All of the strata are conformable and flat. The quartzite is traversed by a large irregular dike of porphyry which strikes across it in a direction slightly east and south and is evidently the source of mineralization. This dike faulted the Cambrian beds with a throw about 20 feet and, toward the south end, split into two dikes, one of which curved over so that the intervening ground was almost enclosed by the porphyry. Between these two dikes, in the earlier days of the mine, an ore body 60 ft. × 40 ft., yielded $65,000.

For some time, mining was carried on, where the overburden is thickest, by underground methods to recover the gold found in some shoots in the sandstone, but as this work demonstrated the presence of gold in the quartzite, systematic tests of this formation were made and showed that it carried an average of $2.40 in gold per ton. This is slightly above the average ore being treated at present, which is $2.20 in gold and .2 ounce in silver recovered per ton. The schist under the quartzite shows an occasional shoot of high-grade ore, one 40-ton shipment of wolframite ore from one of these shoots recently yielding $10,000 in gold.

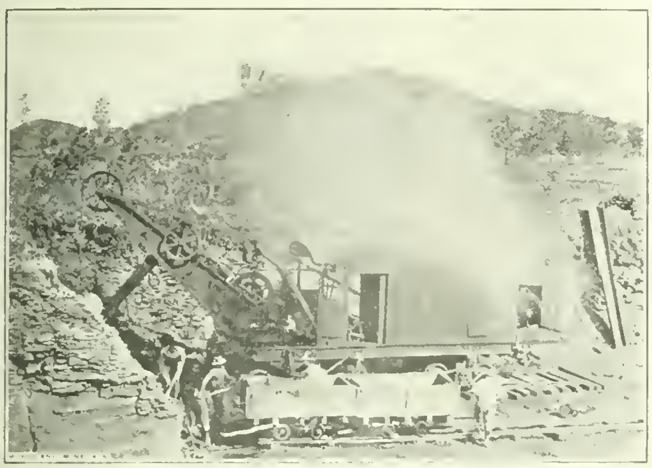

FIG. 1. STEAM SHOVEL STRIPPING, WASP NO. 2

FIG. 2. LOADING BY HAND, WASP NO. 2

Stripping is carried on by two methods. The overburden on the north side of the pit is removed by a 35-ton steam shovel, while that on the south side is stripped by hand after the soil has been removed by a slip scraper. The sandstone is drilled with 3¼-inch Ingersoll-Rand piston machines, each hole being given a burden of 12 to 14 feet. The object of this excessive burden is to prevent the rock being thrown from the free face into the pit where it would mingle with the ore or would have to be hauled out, and to cause the shot to "kick back" and thus loosen the rock on all sides of the hole. The hole is chambered with about 15 sticks of 20-per-cent. Ætna dynamite and is then loaded with three or four kegs of black powder which is fired by a fuse. One such shot will loosen about 50 yards (solid) of capping. Two-yard cars, hauled by mules, are used for handling the capping which is dumped into the worked-out portion of the pit. On the south side, the quartzite is drilled by machines, the average depth of the holes being 19 feet. Ten feet of this depth is drilled with a cross bit and the remainder with an ordinary chisel bit. The holes are given a burden of 8 feet more than their depth, are chambered with 200 sticks of 40-per-cent. dynamite, and are fired with 30 kegs of black powder. Such a shot will break 3,000 tons of rock, a six-day, smill run, and, as shown in the illustration, the ore is broken in large blocks and dumped directly in front of the face.

The broken ore is loaded by hand, the pieces too large for handling being drilled with a 2½-inch Ingersoll-Rand plugger. On the north side of the pit, the ore is shoveled direct to the mill skip, but on the south side, it is transferred by 20-cubic-foot cars which are trammed over a platform and side-dumped into the skip. Two 500-ton bins are in process of construction to provide some storage and to do away with the inconvenience of handling the ore under the present system.

The mine force consists of 70 men, all told, and the daily output is 500 tons, a little more than 7 tons per man.

The ore is loaded into two 5-ton mine skips running on a double, 4-foot gauge track laid with 40-pound steel rails. A double hoist geared to a 52-horsepower General Electric induction motor hauls a skip at a speed of 500 feet per minute up the plane to a 200-ton slope-bottom bin at the mill, where the usual wide-tread arrangement causes it to dump automatically. The haulageway is 1,500 feet long on the slope, with a grade of 10 per cent. up to the last 200 feet where it is 18 per cent. On its way, it passes through a 40-foot cut which is snow-shedded to obviate drifting full in winter. Adjacent to the hoist room at the mill, is the compressor room containing an Ingersoll-Rand, straight-line, three-drill compressor working to 80 pounds pressure.

From the bin, the ore is fed by eccentric feeders to two No. 6 Gates gyratory crushers which crush to pass a 3-inch ring. Each crusher discharges to an 18-inch elevator, with pans 18 in. × 8 in. × 8 in., running at a speed of 210 feet per minute. These elevators dump over 1½-inch grizzlies, each to a No. 4 Gates gyratory crusher, crushing to 1½ inches and discharging to a 300-ton bin.

*Denver, Colo.

33—5—6

Each crusher is driven by a 50-horsepower motor and each elevator by a 1-horsepower motor.

Below this bin, are four sets of 16"×36" rolls, two sets used for roughing and two for finishing. All have a speed of 100 revolutions per minute and are driven by 48-inch, wooden pulleys, the usual type of "bull wheel" used on a gravity stamp battery. The roughing rolls are set to ¼ inch and are fed from the bin by swinging feeders actuated by cams. The product from each pair of rolls is delivered to an elevator, similar to the one described, but running at a speed of 340 feet per minute. This dumps onto a stationary screen having ½-inch mesh and set at an angle of 45 degrees. The undersize of this screen goes to the finished-ore bin while the oversize returns by gravity to the finishing rolls. Each pair of rolls is driven by a 50-horsepower motor. A 30-horsepower motor drives the feeders and elevators.

At each end of the finished ore bin, is a solution storage tank of 25,000 gallons capacity. The main tank room is 72 feet by 108 feet and contains six sand tanks, each with a capacity of 420 tons, fitted with the usual duck and cocoa matting bottoms and four 18-inch, bottom-discharge valves. The ore is fed through rack-and-pinion gates to an 18-inch rubber belt conveyer. The conveyer frame is mounted on wheels so that it is movable back and forth on a track, and its motion is reversible so that it may dump to any one of the six cross-conveyers delivering to the different tanks, thus doing away with the usual arrangement of trippers. A 1-horsepower motor drives the main conveyer and a 40-horsepower motor drives the feeders and cross-conveyers.

Quicklime, sufficient to give a protective alkalinity of 2½ to 3 per cent., is spread over the surface of the ore. The strong solution, consisting of 5 pounds KCN per ton of water, is then turned in. Instead of the usual arrangement of pipes running into the bottom of the tank, the pipes are led up the side to the top where they discharge into a wooden compartment that conducts the solution beneath the filter bottom. This has the advantage of making all of the stopcocks readily accessible from the tank floor and, with the coarse crushing practiced, gives sufficient pressure to cause the solutions to permeate the sands.

After 12 hours treatment, the strong solution is run to a 10,000-gallon tank and thence to the strong zinc box. A weak solution—3.2 pounds to the ton—is next run on for 12 hours, after which it is run to a 10,000-gallon tank and thence to one of the two weak zinc boxes. Next the sands are washed, the wash water running to the weak solution sump. The tank is emptied by shoveling through the valves to 1½-ton cars which are trammed to the dump. Six men empty one of the 420-ton tanks in an 8-hour shift.

Precipitation is on zinc shavings contained in three metal zinc boxes, each 16 ft.× 4½ ft.×2 ft., with two rows of six compartments. The first compartment of each box is filled with excelsior to act as a filter and the remaining compartments with zinc shavings.

Strong and weak barren solutions each flow to a 25,000-gallon sump tank, from which they are pumped by a 5¼"×6" triplex pump, having a capacity of 60 gallons per minute, to the storage tanks where they are brought up to standard strengths. The pump is driven by a 45-horsepower motor that can be belted through a countershaft to either one of two pumps, only one of which is used at a time.

The precipitate is transferred to a 900-gallon tank and given the usual acid treatment for 3 hours, after which it is transferred to a vacuum tank and is dried by a Gould vacuum pump. At the refinery, it is slagged with borax glass and soda and is run down, in clay crucibles, in an oil-fired Donaldson tilting furnace.

Power, Labor, Etc.—Electric power is purchased from the Redwater plant of the Consolidated Light and Power Co. It is received at 1,500 volts and stepped down to 440 volts at which voltage it is distributed. The following motors, all General Electric, three phase induction, are in use:

Use	Number	Horse-power	Total Horse-power
Two coarse crushers	2	50	100
Two elevators from coarse crushers	2	1	2
Two fine crushers	2	50	100
Four rolls	2	50	100
Two elevators to fine bin and four roll feeders	1	30	30
One conveyer	1	1	1
Three conveyer feeders and cross-conveyer	1	40	40
One solution pump	1	10	10
Total			383

Power per ton of ore treated, .766 horsepower.

In one corner of the mill is a machine shop in which is equipment sufficient to handle all ordinary repairs for the mine or the mill.

The regular day shift at the mill consists of 2 crushermen, 1 rollman, 1 solution man, 7 tankmen, 3 helpers, 1 millwright, 2 roustabouts.

The night shift employs only four men, one each to crushers, rolls, solutions, and tanks. A general foreman has charge on the day shift and the solution man has charge on the night shift. All shifts are of 8 hours, and the minimum wage at both mine and mill is $3 a day.

Supplies are delivered by the Burlington railroad to a spur at the foot of the hill. From this point they are hauled by a 52-horsepower electric hoist up an incline 1,300 feet on the slope with an average grade of 20 per cent. Coal is hauled in side-dump cars that pass over the storage bin, while all other supplies are delivered to one of three convenient landing places.

Costs.—During the year 1911, 160,860 tons of ore were treated at an average cost per ton of $1.25, as follows: Mining, .5348; milling, .6682; general expense of all kinds, .0435; total, $1.2465.

The average of the heads in gold was $2.196, and the average of the tailing was $.53, thus giving an indicated extraction of 75.8 per cent. The actual extraction as shown by the bullion returns was 76.31 per cent. In addition, 31,654.27 ounces of silver were produced, equivalent to a recovery of .1967 ounce per ton.

The mining expense given above was divided as follows: Stripping, $12,692.00, 30 per cent., $.1604 per ton. Mining, $31,078.18, 70 per cent., $.3744 per ton.

Consumption of chemicals for June, 1912, was as follows: Cyanide, .36 pound per ton of ore treated, cost $.0778; zinc, .39 pound per ton of ore treated, cost $.0377; lime, 2.30 pounds per ton of ore treated, cost $.0109; total cost for chemicals, $.1264.

The Wasp No. 2 has been paying dividends, made possible by the very low cost attendant on the operations, at the rate of about $60,000 per year. These low costs are largely due to the natural favorable conditions for mining and milling; the advantage of open-cut work as against underground methods; and the coarse crushing and straight leaching, as against fine crushing and agitation. At first thought, it might appear that the extraction could be bettered, as no doubt it could be. However, when it is considered that the higher extraction would call for the fine crushing of a hard quartzite and that there would be required additional equipment and labor for the slime treatment that would secure a further recovery of 30 to 40 cents per ton in value, it appears that the present method shows the greater economy.

So far, the Wasp No. 2 has been largely an experiment. Consequently, the management did not make heavy investments in the matter of equipment until the feasibility of treating so low a grade of ore was conclusively proved. The steam shovel was installed this spring, but it has been successful, and the stripping costs for the current year should be lower than the figures given. By next year, it is the intention to have another shovel for loading the ore, and saddle-tank locomotives for handling the cars. These should materially reduce the force at the mine with a consequent lowering of mining costs.

The writer wishes to acknowledge the courtesy of the officials of the Wasp No. 2 Mining Co., and especially that of Mr. S. L. Williams, mine superintendent.

It has been estimated that five-eighths of the world's supply of sapphires comes from the alluvial workings of southeastern Siam.

Lithium

The Forms in Which It Occurs, Its Uses, Methods of Determination, and Processes of Extraction

*By Anil A. Anderson**

Spectroscopic traces of lithium are found in nearly all igneous rocks and in many springs. When lithium minerals occur to any great extent they are associated with granites and adjacent rocks which have been altered by hot gaseous emanations—a process known as pneumatolytic action. The places of occurrence of lithium are practically those of tin, but the large deposits of tin seldom contain workable deposits of lithium minerals. The lithium minerals are found ordinarily associated with beryl, columbite, wolframite, tourmaline, uranium-radium minerals, and the various minerals carrying phosphorus.

The lithium minerals of economic importance are amblygonite, a fluophosphate of aluminum and lithium, $Li\ (AlF)PO_4$, containing theoretically between 7.6 per cent. and 9.5 per cent. Li; spodumene, a silicate of lithium and aluminum, $LiAl\ (SiO_3)_2$, containing theoretically between 4.5 per cent. and 7 per cent. Li; lepidolite, a lithia mica, $R_3Al(SiO_3)_3$, R_3 being generally Fe, Mg, and Li in varying proportions; and lithophilite, a phosphate of Fe, Mg, and Li containing between 8 per cent. and 9 per cent. Li.

Most of these minerals occur in workable quantities in California, Maine, Massachusetts, New Hampshire, North Carolina, and Black Hills, South Dakota.

Since 1909 the Black Hills have afforded the entire production of lithium minerals used in the United States, and before 1909 they produced most of it. The minerals mined in the Black Hills are spodumene, amblygonite, and of less importance, lithophilite and lepidolite, all of which are found in connection with tin ores and mica minerals in pegmatite dikes. Probably the most noted lithium mine is the Etta mine, about 1½ miles south of Keystone in the southern part of the Black Hills, in Pennington County, South Dakota. At this mine the crystals of spodumene lie at all angles in extremely coarse pegmatites carrying tin, which led to the original opening of the mine. The crystals found are the largest of their kind in the world; one crystal was 42 feet in length with a cross-section of 3 ft. x 6 ft. Thirty-seven tons of the mineral were obtained from this one crystal. These crystals of spodumene, termed "logs" by the miners, weather readily when exposed to the action of the atmosphere and water. A feature of interest is that amblygonite is almost wholly absent from this deposit, while in the Peerless mine, one-half mile away, it occurs in large masses associated with spodumene. The spodumene, however, is of no importance.

At the Peerless mine, near Keystone, Mr. Herman Reinhold, of Omaha, Nebraska, mined a large deposit of amblygonite in 1907 and 1908. The mass, about 20 feet wide, was pearly white, and had one good cleavage plane. It has been worked to a slight depth but has produced several hundred tons of the ore.

There are several other mines in the vicinity of Keystone and a few in the vicinity of Hill City and Custer that have been worked for their lithium minerals. Among these are the Bond mine, about 5 miles south of Custer, and the Ingersoll mine, 1½ miles west of Keystone. The mineral mined at these places is amblygonite with a small amount of lepidolite and spodumene.

The compounds of lithium used in the arts are lithium carbonate (Li_2CO_3), lithium hydroxide ($LiOH$), lithium bromide ($LiBr$), and lithium chloride ($LiCl$). The metal itself has no practical use. It oxidizes quite readily, is soft and of low specific gravity. It has, however, been proposed for the generation of hydrogen in aeronautics. One pound of lithium will generate over 25.5 cubic feet of hydrogen at normal temperature and pressure, when treated with sufficient acid.

The carbonate is used in the manufacture of artificial lithia waters and for medicine. Eminent physicians have claimed that it has a neutralizing effect upon uric acid, which in the blood gives rise to certain diseases. Equally eminent physicians, however, have recently claimed that it does not possess such power. Small amounts of the carbonate are used in the manufacture of fireworks. The hydroxide is used mainly in storage batteries of the Edison type, in connection with alkaline electrodes, in which the depolarizing electrode makes use of an oxygen compound of nickel, whereby the capacity of the battery will be increased and the time during which the capacity is a maximum will be prolonged. The chloride and bromide of lithium are used in photography and in medicines. Spodumene when occurring fresh and glassy with an emerald green color sells for high prices as a gem.

Before amblygonite was mined at the Peerless mine the price of lithium carbonate was $2.50 per pound, but upon opening up this vast amount the supply became greater than the demand and a drop in prices ensued. Lithium carbonate now brings 40 cents per pound.

Lithium belongs in the alkali group with sodium, potassium, rubidium, and cæsium. It is a soft, silver colored metal, has a specific gravity equal to .5936, atomic weight equal to 7. Its valence is one. It melts at 180° C. and vaporizes at about 1,000° C. It very closely resembles sodium, potassium, rubidium, and cæsium in its reactions. In the wet way it may be distinguished from potassium and ammonium salts in that it forms no precipitate with chloroplatinic acid (H_2PtCl_6), while on the other hand it forms an insoluble (Li_2CO_3) upon the addition of a carbonate, while potassium and ammonium salts do not.

Lithium salts give to the non-luminous flame a carmine red color, which is visible as violet through a blue glass, but is obscured by a green glass, giving a distinction from potassium. $LiCl$ is soluble in absolute or amyl alcohol while sodium and potassium chlorides are almost insoluble.

The best and quickest method for the qualitative determination of lithium is the spectroscopic determination, or if a spectroscope is not available the ordinary flame test as described above may be used. The lithium spectrum is characteristic.

The standard quantitative determination is the J. Lawrence Smith method and is as follows: One-half gram of the rock powder is ground fine in a large agate mortar, mixed with its own weight of sublimed ammonium chloride, and the two thoroughly ground together, then four grams of calcium carbonate are added and the grinding continued until a thorough mixing has resulted. The contents of the mortar are transferred to a 20-30 centimeter crucible, which is capped and placed through a hole in a piece of strong asbestos board and heated for 10 minutes by a low flame placed at considerable distance beneath. As soon as the odor of ammonia is no longer perceptible the nearly full flame of two Bunsen burners is substituted for 40 to 50 minutes. The sintered cake detaches readily from the crucible as a rule; if not, it is softened in a few minutes by hot water and digested in a dish until thoroughly disintegrated. It is first washed by decantation, and any lumps are broken up by a pestle, then thrown on a filter and well washed with hot water. The residue should dissolve completely in hydrochloric acid without showing the least trace of unattacked mineral, not even of quartz, though sometimes a few black particles of iron ores will dissolve slowly.

The next step in the determination is the separation of calcium and sulphuric acid, which will be present in practically every lithium ore. All but a trifling amount of the calcium is separated at a boiling heat in a large porcelain or

* In the *Pahasapa Quarterly.*

platinum dish by double precipitation by ammonia and ammonium carbonate. The combined filtrates are evaporated to dryness and the ammonium salts are carefully driven off. From the aqueous solution of the residue—but a few cubic centimeters in bulk—the rest of the calcium is thrown out by ammonia and ammonium oxalate, the last thing being more effective than the carbonate. The filtrate is evaporated to dryness and gently ignited; the residue is moistened with hydrochloric acid to decompose any alkali carbonate that may have been formed, again evaporated, ignited and weighed. On solution in water a few tenths of a milligram of fixed residue is invariably left, which should be collected, ignited, and weighed in the same crucible or dish in order to arrive at the weight of the chlorides.

If the rock contains sulphur this will be in part found with the chlorides as sulphate. Therefore, if the sulphur is at all considerable in amount it must be removed by a drop of $BaCl_2$ before the final precipitation of the calcium. The excess of barium is removed by ammonium carbonate and the last of the calcium by ammonium oxalate as before.

From this solution the lithium is determined by Gooch's method, as follows: To the concentrated solution of the chlorides, amyl alcohol is added and heat is applied, gently at first, to avoid danger of bumping, until the water disappearing from the solution and the point of ebullition rising and becoming constant for some time at a temperature which is approximately that at which the alcohol boils itself, the chlorides of sodium and potassium are deposited and lithium chloride is dehydrated and taken into solution. The liquid is now cooled and a few drops of strong hydrochloric acid added to recover traces of lithium hydrate in the deposit, and the boiling continued until the alcohol is again free from water. If the lithium chloride is small, it will now be found in solution and the chlorides of sodium and potassium will be in the residue. If, however, 10 or 20 milligrams of the lithium chloride is present, it is advisable at this point, though not absolutely essential to the attainment of fairly correct results, to decant the solution from the residue, wash the latter a little with anhydrous amyl alcohol, dissolve the residue in a few drops of water, and repeat the separation by boiling again in amyl alcohol.

To the solution add H_2SO_4, evaporate to dryness, take up in water, filter to remove carbon that has been deposited from the alcohol, place in porcelain or platinum dish, evaporate to dryness, ignite at a low red heat, and weigh as Li_2SO_4. From this weight the Li may readily be calculated.

This method is accurate under proper manipulation and is used in the determinations of lithium in waters and minerals.

But little information in regard to the extraction of lithium from its ores is available. Numerous electrolytic methods are known. A process has also been proposed by Hugo Muller and is outlined in Roscoe and Schorlemmer's "Treatise of Chemistry." It consists of dissolving the mineral acid with a ferric salt. The solution is evaporated and the chloride of lithium removed by dissolving in water. Manganese can be removed from the solution by treatment with barium sulphide and the excess of barium removed with sulphuric acid. The lithium is finally evaporated with oxalic acid and ignited to convert to the carbonate.

Another method employed in a Paris, France, refinery is by using H_2SO_4 contained in acid sodium sulphate, pulverizing the acid sulphate and the ore, then mixing them in exactly determined proportions, gradually heating this mixture to redness, lixiviating the roasted mass to obtain a solution of lithium sulphate, and after purification, precipitating the lithium as the carbonate Li_2CO_3 by the addition of sodium carbonate.

Calumet & Hecla

The annual report of the Calumet & Hecla Mining Co. for the year ending December 31, 1911, shows that 74,130,977 pounds of copper were made by the company during the year at an average cost of 8.52 cents per pound, which is exclusive of the $90,355 paid for interest on the notes in excess of dividends received from subsidiary companies.

At the end of the year the company had a surplus of $11,720,106.

The cost per pound in 1910 amounted to 8.96 cents and in 1909 it was 8.28 cents.

Calumet & Hecla stamped 2,909,972 tons of rock in 1911, and the mining cost per ton of rock, not including construction work, amounted to $1.84, as compared with $1.92 in 1910; $1.93 in 1909, and $2.15 in 1908. The copper per ton of rock averaged 35.47, while in 1910 it was 25.77. The average price received for the product for the year was 12.85 cents.

Total dividends paid to the close of 1911 totaled $115,850,000, and dividends received from subsidiary concerns amounted to $1,048,882. The statement of the assets and liabilities does not include the present timber holdings of the company, which are conservatively estimated at 492,000,000 feet.

President Shaw says: "Development work in ground adjacent to the Red Jacket shaft is very nearly completed. Openings in the five forties continue to show ground of about average quality. At the Hecla and South Hecla branches ground opened is quite up to the average of last year. Openings on the Osceola lode have shown ground of average quality and even greater amounts of good ground have been opened and mined on the foot-wall side of the lode."

The holdings of Calumet & Hecla in its subsidiary companies are as follows:

Companies	Shares Issued	Shares Owned December 31 1911
Ahmeek	50,000	24,800
Allouez	100,000	43,000
Centennial	90,000	43,500
Cliff	60,000	19,400
Dana	40,000	36,500
Frontenac	20,000	20,000
Gratiot	100,000	50,000
Isle Royale	150,000	27,500
La Salle	302,977	152,977
Laurium	40,000	33,500

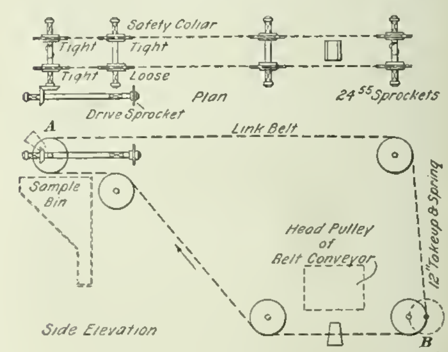
White Pine, preferred	3,792	3,792
White Pine, common	85,320	43,202

Mill Feed Sampler

By L. M. Banks*

The apparatus shown in the accompanying sketch is used in sampling the mill feed in the No. 6 concentrator of the Arizona Copper Co., at Morenci, Ariz.

It comprises a moving sample bucket supported between two chains about 18



Sampler

inches apart, so arranged as to run through the discharge from a belt conveyer.

The bucket is made of sheet steel, is bolted to special links on the chain, and is easily renewable. The chains are of the commercial type known as link belt and run on 24-inch sprockets. Each of the five shafts contains two sprockets—one tight, the other loose. Shaft B is provided with a take-up and spring. The device is driven from a line shaft by means of bevel gearing on shaft A.

The sample is taken, as above stated, when the bucket passes through the ore stream from the belt conveyer. The bucket then moves up at an angle of nearly 45 degrees and dumps while passing around sprocket A, the sample discharging into one of three wooden bins. One bin is reserved for the sample from each shift. The samples caught in the bins are subsequently cut down to laboratory size by coning and quartering.

*Mining Engineer, Morenci, Ariz.

Mineral Pigments in Pennsylvania

The Different Minerals Used, and Their Analyses—Methods of Mining and Preparing

In report No. 4 of the Topographic and Geologic Survey of Pennsylvania, will be found the economic geology of ochers, metallic paint ores, black, yellow, and red shales, iron ores, and minor products. The "Mineral Pigments of Pennsylvania" is by Benjamin L. Miller, and, while a report, is virtually a textbook on the geology, mining, and manufacture of mineral paints. The following abstract it is believed will prove interesting reading.

Materials containing over 30 per cent. iron are classed with iron ores, below this per cent. of iron, as ochers, provided their chemical composition agrees in other respects. Thus ocher is a variety of clay. When pure, clay is white; but more usually it is colored red or yellow by iron oxides, forming red and yellow ocher. Unless otherwise specified, ocher means clay permeated with anhydrated ferric oxide. It has a decidedly golden yellow color, a specific gravity of 3.5, and contains 20 per cent. or over of hydrated ferric oxide. Ocher is found in nature and cannot be produced artificially, and if burned so that the hydrate is converted into anhydrate iron oxide it will form red ocher. Red ocher is also found in nature.

Metallic paint is a commercial term applied to material containing more than 30 per cent. ferric oxide. The term does not represent any definite composition, and the iron oxide varies from 33 to 64 per cent.

Sienna is a deep-yellow, high-grade ocher, which if burned produces a dark red substance. Umber, or brown ocher, is a variety of yellow ocher consisting of iron and aluminum silicates, containing varying proportions of manganic oxide, its degree of color varying according to the percentage of the latter. The raw variety is drab in color, which on burning changes to reddish brown, and is called burnt umber.

In eastern Pennsylvania, ocher is mined by "open cut" and by shafts. The pockety nature of the deposits does not justify elaborate equipment, and the mines soon cave after operations cease. Little timber is used in some mines except in the shafts and main drifts, but if much water is present the squeezing action of the clay requires much timber, even in the small stopes. In most of the mines the ocher is a band, and drifts run from the shaft in either direction. When a pocket of ore is found that extends upwards, overhead stoping is practiced. In drifting it is usual to follow on the ore in whatever direction it extends; and where it pinches out the drifting is carried on in almost any direction, but mainly parallel to the principal band where there seems to be such an arrangement of the ore. After mining, the ore is wheeled in barrows to the shaft, loaded into buckets and hoisted to the surface, where it is washed and prepared for shipment.

As the ore comes to the surface, it is mixed with clay, limonite nodules and fragments, and pieces of chert. The clay is not removed by washing, but the hard particles are. Log washers are used effectively; the ocher and clay flow out the lower end, while the hard particles are worked by the blades to the upper end and discharged. The good iron ore is picked from the hard material at the upper end and when sufficient has accumulated it is sold to some nearby furnace. The ocher and clay are carried by the wash water to nearby settling troughs that are slightly inclined so that the water flows slowly through them. The current is also retarded by baffle boards behind which the coarser particles settle. At one mine the water carrying the suspended particles passes through 28 troughs, 14 to 16 feet long and 13 inches wide. The coarsest sand settles in the first two or three, and sediment diminishes in size in each trough until the last one is reached, where the little sand present is extremely fine. From the troughs, the water and suspended material flows through a launder to a series of settling ponds, roughly rectangular in shape. An average settling pond is made by digging a few feet in the surface and throwing the excavated material so as to form an embankment. It will be possibly 40 ft. × 25 ft. and from 3 to 4 feet deep. Settling ponds are frequently in series, so that the coarsest material will settle in the first pond and the finest in the last. The overflow from the last pond flows away through a pipe.

It is possible to grade the material by diverting the wash water from the best grade of ocher brought to the surface into a certain pond, while that in which there is much clay goes into another pond. When a pond is filled the surplus water is allowed to evaporate until the material is in a condition where it can be dug and carted to the drying sheds. It may be several weeks or months before a condition is reached where the material can be removed to the drying sheds. At some places steam is used for drying in the winter, but usually the material is air dried. From the drying shed it is ground in French buhr mills and then shipped in bags or barrels.

An analysis of material coming from near eastern Pennsylvania before and after burning is given herewith. Neither analysis is complete and it is probable that the undetermined material was the cause of the loss of the silica in slagging.

Analysis

	Before	Aft r
Silica	39.70	39.00
Ferric oxide	37 40	42.35
Alumina	12.36	13.33
Magnesia	1.37	Traces
Moisture	7.83	2.50

There are but three known deposits of "umber" in Pennsylvania, one about 2½ miles north of Bethlehem; one about 5 miles east of Doylestown, and one about 1 mile west of Bethel. The first two have been operated at intervals, while the last is a prospect.

The term sienna is properly applied only to those pulverulent substances whose composition is that of a high-grade limonite ore. With an increase in silica and alumina, sienna passes into ocher. The sienna from Neversink Mountain near Reading, Pennsylvania, has the following analysis according to C. K. Williams & Co., of Easton:

FeO_3, 69 per cent.; SiO_2, 24 per cent.; Al_2O_3, 3 per cent.; combined water and undetermined properties, 14 per cent.

The ore is taken from the mine in wheelbarrows, partly dried, and shipped. This deposit is worked to the amount of between 125 and 200 tons yearly and the material is worth about $20 f. o. b. at Reading.

Carbonate of iron has been mined in Carbon County for pigment since 1856. The ore resembles an impure limestone, and were it not for its specific gravity, 3.25 to 4, might be taken as such. The dark blue color oxidizes to red on exposure, and, where weathered, is termed "sunburned ore." Mr. A. S. McCreath stated that the elements in the raw ore existed for the most part as carbonates, and furnished the following percentage in an analysis of roasted ore:

Fe, 34.6; Mn, 9.29; Al_2O_3, 2.492; CaO, 3.510; MgO, 1.081; S, .674; P, .018; SiO_2, 16.21; loss in roasting, moisture, and CO_2, 24.35. Sometimes the fossils constitute as much of the ore as the cementing material that binds it; and this is to be expected, as the ore belongs to the Devonian period and is located between the Oriskany sandstone and the Marcellus shale. As the ore bed dips from 60 degrees to 70 degrees, it is worked along the strike by drifts and stopes. The drifts are 7 feet high and 5½ feet wide, the ore being 2 feet thick, and are timbered by stulls hitched to the cement rock hanging wall every 3 feet, and resting on a timber leg 9 inches in diameter, at the other end. This two-stick timbering is closely lagged above and on one side. In case of shaft mining, a pillar of ore is left each side for protection, and beyond this stoping commences. The drift is advanced 30 to 40 feet at a time, after which a section of this length is stoped to the surface.

This work of underhand stoping requires that at the top of the stope a drift be kept in advance and the remainder on an inclination, so that gravity will assist in moving material to the level. The stopes are 4 to 6 feet wide, 2 feet being ore, the remainder clay and cement rock.

The ore is carefully assorted and rolled down the stope, the clay and cement rock being used as filling on the stulls. At intervals risers are driven from the top of the stope to the surface for fresh air, which is conducted to the face through timbered airways. The ore is drilled by hand and blasted with dynamite. After being taken from the mine the ore is stored in sheds until needed at the mill, where it is first calcined and then ground. As the ore comes from the sheds it is in lumps which are broken by sledge hammers so that they are not larger than 6 inches in diameter.

The kilns are situated so that the charging doors can be reached from a trestle without hoisting the ore. Kilns are constructed of brick, 25 feet high and 10 feet in diameter. Fireboxes are built on either side of the kiln, and these increase the width at the base to 18 feet. The fuel used is wood, and the ore is heated to a cherry red, and remains in the kiln about 24 hours, 10 tons being withdrawn every 12 hours and an equal quantity of raw ore charged at the top. The object of calcination is the elimination of the sulphur of the pyrite, the carbon dioxide, and the moisture, thus obtaining a dark reddish-brown colored oxide. After withdrawal from the kiln the material is crushed to about the size of buckwheat, then conveyed to bins on the top floor, from which it is fed to 36-inch buhr mills and vertical mills, and ground to impalpable powder.

Metallic paint is this powdered material mixed with oil. The finished product of the Prince Metallic Paint Co.'s mill gave the following percentage analysis: Fe_2O_3, 43.70; SiO_2, 38.65; Al_2O_3, 5.79; MnO_2, 1.85; CaO, 1.80; MgO, 2.04; moisture, .30; undetermined, 3.33.

Black shales, ground and sold under the name of mineral black, are extensively used in paint, but there is a tendency for the shale to settle out of the oil.

Yellow shales are utilized in the manufacture of paint and when ground fine and mixed with oil are said to be serviceable. Their principal use is for making oil cloth and linoleum. They are lighter than ocher in color and seldom contain more than 5 per cent. hydrous iron oxide.

Red shales, Clinton iron ore, graphite, soapstone, talc, barite, chromite, pyrite, and clay are also used as pigments.

The Use of the Pantagraph

By H. G. Henderson

The pantagraph, although a well-known and useful instrument for the enlargement and reduction of plans, is hardly regarded with favor by mine surveyors in cases where extreme accuracy in the work to be done is necessary. The main reasons for this are two in number. In the first place the graduations on the arms of the pantagraph cannot give sufficient detail to suit all cases. For example, the reduction of an ordinance town map which is $\frac{1}{500}$ scale, to be drawn to 50 feet to the inch or $\frac{1}{600}$ scale can only be managed with difficulty, as the setting of the instrument to effect such work can

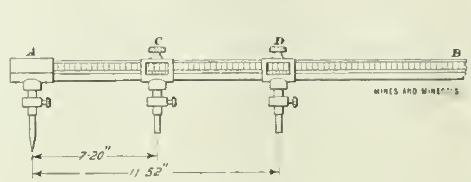


Fig. 1

only be accomplished by the tedious system of "trial and error." The second consideration is that of temperature variation. The instrument may possibly have been graduated in the height of summer, whereas it may be required for use in the depth of winter, or vice versa, and under such conditions the expansion and contraction of the metal arms makes reliability not to be expected.

The writer some years ago discovered the fact that the radii of the pantagraph after being set are always in proportion to the numerators of the representative fractions of the two scales of the plan under construction. He accordingly had a pantagraph "setter" made as shown in Fig. 1. The portion AB represents a piece of hard wood, say 50 inches long, accurately divided into inches and decimals. At A there is attached a fixed socket, while at C and D there are two traveling sockets with verniers reading to $\frac{1}{100}$ inch. These sockets hold, as shown, two blunt-ended metal styles or spills and one longer pointed spill, all three being interchangeable. In order to show the application of this setter it may be supposed that it is desired to enlarge the plan from 50 feet to the inch to a scale of 30 feet to the inch. The representative fractions of these scales are respectively $\frac{1}{600}$ and $\frac{1}{360}$, the denominators of course being 600 and 360. Now the ratio of 600 and 360 is equal to that of 6 and 3.6 but since these distances are rather small for the purpose they may be each multiplied by 2, giving ratio numbers of 12 and 7.20. The setter is then taken and the spill C is clamped to read 7.20" while the spill at D is clamped to read 12". The pointer spill is then inserted in the socket at A and is dropped into the fulcrum funnel of the pantagraph. The other two traveling funnels are then worked with the hand simultaneously until the blunt-ended spills C and D drop easily into them. The traveling funnels are then clamped, the setter rod is carefully withdrawn and the instrument will then be found to be accurately set. It will generally be found that the pantagraph can be worked more easily if the fulcrum spill be placed between the other two. This can very easily be arranged by making the distance A to C 7.20" as before while instead of making the distance A to D 12" this distance A to D should be made 19.2" or the sum of the two numbers. In other words the distance CD becomes 12". It is obvious that with a setting rod no graduations on the arms of the pantagraph are necessary and there need be no fear whatever as to error through unequal contractions and expansions of the arms. Moreover, at the present time pantagraphs are made of flat brass rods, but in the new method above described tubular rods might supersede these with great advantage both with regard to lightness and rigidity.

Colorado Mineral Production, 1911

The value of the output of gold, silver, copper, lead, and zinc recovered from placers, gold-silver bullion, and from ore sold or treated in 1911, from Colorado mines, according to Charles W. Henderson, of the United States Geological Survey, was \$32,418,218, as compared with \$33,673,879 in 1910, a decrease in value for 1911 of \$1,255,661. These figures are compiled and tabulated strictly as a mine report and with reference to the locality of each individual mine, and not with reference to the locality of the shipping point of the product.

Cripple Creek supplied 56 per cent. of the total gold yield of the state, with an output of \$10,562,653, as compared with \$11,002,253 in 1910. Conditions in the Cripple Creek district were much the same in 1911 as in 1910, for the subsidence of water through the Roosevelt tunnel was so slow that it was not possible to increase operations. At the close of the year, after the tunnel had been driven farther, the water drained more rapidly. The gold yield from the San Juan region fell off considerably, San Juan and Ouray counties contributing chiefly to the decrease. Counties showing an increased output of gold were Boulder, Costilla, Gilpin, and Mineral. The placer output of gold was \$319,759, a decrease of \$75,706 from the output for 1910.

The number of deep mines producing metals in 1911 was 861, against 856 in 1910. The average total recoverable value per ton of ore produced decreased from \$13.67 in 1910 to \$13.50 in 1911.

Russian Platinum Industry

Written for Mines and Minerals

The long-threatened monopolization of the platinum industry by the Russian government may be said to have entered on its first legal phase by the acceptance of the proposition in legal form by the Duma. The opinion is held in Russia that Imperial sanction will be duly acquired; and that the Russian platinum industry will be a Russian industry in all its stages from the collection of the platiniferous sand to the production of refined platinum sheets, wire, etc.

The Russian platinum industry does not correspond to that importance which the platinum sands in the Urals warrant. In the course of the long series of years these sands have constituted practically the only source for supplying the world's market with platinum. The Urals provide about 95 per cent. of the world's production, and of all the remaining deposits of platinum known in the world the only ones worthy of mention are the sands of Colombia; which, however, because of their small production—about 360.7 pounds per annum—represent rather an historic interest as a place where platinum was first discovered, and where it has been produced for something like 2 centuries.

Since Russia has a practical monopoly of the production of platinum it might be expected that this would result in a large profit; as a matter of fact it is quite otherwise. Of the total platinum produced, only 2 per cent. is refined in the country, and 98 per cent. is exported unrefined. The metal is bought by a large foreign firm which controls the business and fixes the price according to its discretion. That is why platinum producers are entirely dependent on it, whilst on the other hand it would be much more natural that the price of platinum should be regulated by its producers, according to the demand and the cost of its production.

Turning to the question of refined platinum, it should be observed that refining, in Russia, is in an unfortunate condition, since under the prevailing industrial conditions the manufacturers might be able to sell abroad the refined metal at a higher price than in the crude form.

Besides this, the various associates of platinum such as iridium, rhodium, ruthenium, osmium, and palladium, which constitute by weight from 2 to 10 and even to 15 per cent., if held in Russia, might be sold at high prices. At present these metals, with the exception of iridium, are included in the number of insoluble metals, and are not paid for by the foreign refiners. The platinum refining laboratories, both existing in Russia and abroad, not only separate platinum from its associated metals, but they manufacture from platinum, sheets, wire, chemical vessels, and they also save the associated metals of the platinum group and manufacture preparations therefrom. The concentration of these laboratories in Russia would constitute a direct link between the national platinum industry and the foreign consumers of refined platinum, both in ingots and simple manufactures, since these constitute materials used in the jewelry industry, in the preparation of artificial teeth, and in other spheres.

In close connection with the monopoly of refined platinum in Russia will be prohibition of the export of crude platinum. While platinum refining laboratories exist in Russia, their operations are very insignificant, since in them no more than 360.7 pounds of platinum per annum are treated; but this is explained by the monopolistic position which is occupied by the foreign refiners. There is no doubt but they will be able to retain such a position if, without hindrance, they receive crude metal from Russia, since according to the conditions of the sale of refined metal the foreign refineries are in a better position than the Russian, and with a free export of the crude platinum it would be difficult to struggle with any stolen or secretly conveyed metals; whilst the appearance of such metal on the market would depress the price.

In view of this it will be necessary to prevent ingots carrying less than 99 per cent. pure metal from being exported. Following the example for the encouragement of the development of the gold production in Russia, loans should be granted to platinum producers, especially as running expenses necessary for working the mines. These questions according to the statutes of the Imperial Bank are being now brought under the consideration of a council of the bank.

Respecting the circulation of the crude platinum and trading with it in the empire, the existing freedom of circulation of this metal has, in the opinion of the Council at the Mining Department, led to the condition that the platinum produced by poachers and secret workmen and by servants, has been sold without hindrance; in consequence of which, not only has poaching and concealing of metal developed largely, but along with this the constant supply of platinum has increased as offered through merchants to foreign refiners at prices which do not accord with the actual expenditure in producing the metal at the mines. This encourages the foreign refiners' position, and brings sharp declines in the market value of the metal.

In order to successfully compete with the foreign refineries it is desirable to take measures which shall prevent the circulation or poaching of secret metal. According to the judgment of the Interdepartmental Council such measures are: (1) The exact registration of the platinum produced at the mines; (2) the issue by the mines of special certificates guaranteeing or indicating the place where the metal was produced; (3) an obligation on the part of every holder of metal to possess these certificates; (4) the registration by holders of platinum of the business done in it; (5) the institution of sufficient penalties for the non-observance of the rules issued with the object of giving force to the said measures.

Platinum Near Princeton, B. C.

*By Frank Bailey**

For the last year there has been a revival in the placer-mining industry on the Tulameen River, which is the richest alluvial platinum deposit on the North American continent. The British Columbia Platinum Co., Ltd., is one of the oldest companies operating in the Tulameen platinum belt. This company was organized as a development syndicate some years ago with a capitalization of $200,000.

In December last Mr. Bair, the president sent to the Department of Mines at Ottawa for examination a sample of 4 ounces of black sand, concentrated from 1½ to 2 cubic yards of river sand and gravel. On assay, this material was found to contain platinum at the rate of 521.57 ounces per ton of 2,000 pounds of concentrates; osmiridium, at the rate of 58.82 ounces; gold, at the rate of 75.82 ounces; silver, very small quantity, undetermined. The Platinum Gold Fields, Ltd., of Vancouver, B. C., was organized to explore the large gravel benches and bars of the Similkameen and Tulameen rivers, where they have lately taken 10 miles of dredging leases.

Last winter the company successfully prospected its ground with two Keystone drilling machines on the ice, proving the average value to be $19,362 per acre.

The Tulameen Gold and Platinum Co., Ltd., is the third company operating in the Tulameen platinum belt; its holdings are on the Tulameen River, between Eagle and Bear creeks, and on the Similkameen River below the holdings of the Platinum Gold Fields, Ltd.

A sample of black sand taken from one of the old placer tailings dumps, from which the gold had been taken out in early days, was assayed by N. W. Pirrie, Provincial Assayer of Vancouver, which gave the following results: Platinum, 3.83 ounces; gold .62 ounce; osmiridium, .04 ounce; silver, .24 ounce.

The old-time placer miners who came into the country during the Granite Creek excitement, discarded the platinum as it was at that time considered useless, and they called it "white gold" and dumped it out of their sluice boxes; later on a lot of it was bought for 50 cents per ounce and shipped to New York and London. Today it is worth about $45 per ounce.

Late this summer Messrs. Johnson, Matthey & Co., of Hatton Garden, London, (the big platinum buyers), sent out their

* Princeton, B. C.

expert, A. B. Coussmaker, M. E., from Siberia, to investigate the platinum possibilities of the Tulameen. Accompanied by Mr. Colby, of Baker & Co., New Jersey, they examined the field, with the result that Mr. Coussmaker has established a working camp and is at the present surveying the extensive bars and benches of the Tulameen River and its tributaries

Raising Shaft at Rolling Mill Mine

*By Edwin N. Cory**

The new shaft of the Rolling Mill mine of the Jones & Laughlin Steel Co., was raised from the 621-foot level to the surface by the following method:

The work was started from the level and carried through to surface with one continuous raise. A force of nine miners divided into three shifts of three men to each shift, working 8 hours per day, was employed. These men also trammed the material from the raise to No. 1 shaft, a distance of 750 feet, and put in the timber. The difficulties of raising so great a distance were successfully overcome and no accidents or delays occurred.

The raise was 8 ft.×8 ft. in size and was divided into three compartments as shown in Fig. 1. One compartment, 4 ft.×4 ft. including the timber, was used for hoisting tools and timber and a station was cut at the bottom of the compartment on the main level, in which was placed a small hoist. Another compartment, 4 ft.×4 ft. was used for ladders and an 8-inch air pipe from the fan, also one 1¼-inch pipe for speaking tube and one 1½-inch air pipe for the power drills. The other half of the raise 4 ft.×8 ft. was used for the rock broken in the raise, and was not timbered but kept filled with rock up to the height of the timber in the other compartments. A chute was constructed in the bottom of this compartment through which the rock was loaded into tram cars, as shown in Fig. 2. A fan was placed at No. 1 shaft which forced the air through the 8-inch pipe up to the top of the raise, the current going down through one of the compartments, thus securing perfect ventilation.

An Ingersoll-Rand, 2-inch cylinder butterfly-valve hammer drill was used, three machines being operated at one time to drill 18 holes in three rows, six holes in each row. The cut holes were drilled so as to break, when blasted, a space the entire length of the raise directly over the rock compartment as shown in Fig. 2, so that the other holes would throw the rock toward this opening and it would fall into the rock compartment. Before blasting, the ladder and bucket compartments were covered with 10-inch round timber, flattened on two sides to prevent rolling, and placed at an angle to deflect the falling rock into the rock compartment, necessitating only a minimum amount of shoveling. The space directly over the ladder compartment, was covered with 3-inch plank to permit the men to get away quickly when blasting, also to give them perfect protection in going up and down the raise. The blasting was all done with fuse cut in various lengths to give the desired results. After blasting, and while the smoke was clearing out of the raise, the miners would tram enough rock out of the chute so that timbering could be commenced at the top of the raise. A gin pole was erected about 8 feet from the last set of timber on which was hung a 10 inch sheave wheel as shown in Fig. 3, for the rope used in hoisting the timber from the level below. After the timber had been put in it was also used for hoisting drills and machines. The drilling machines were thoroughly overhauled after each round of holes while the miners were blasting and timbering, and no delay was occasioned during the work.

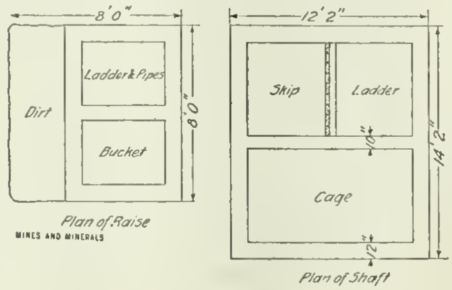

Fig. 1

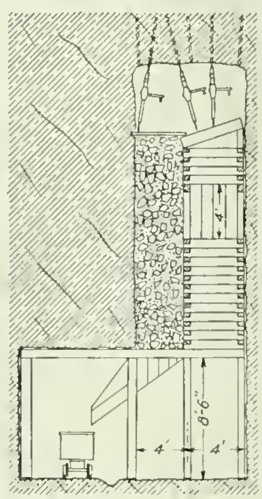

Fig. 2

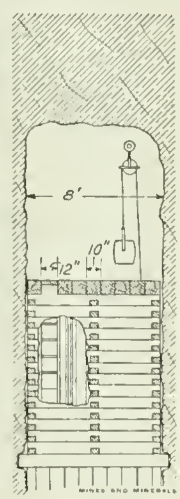

Fig. 3

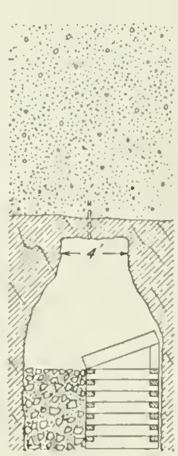

Fig. 4

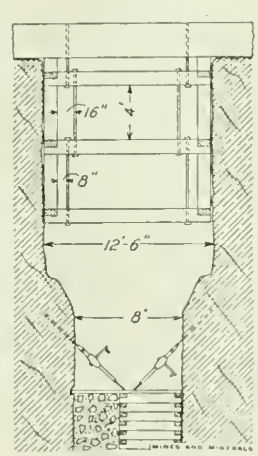

Fig. 5

When the raise had been carried to a height of about 200 feet, hitches were cut in the rock and a set of bearing pieces put in about 4 feet above the last set of timber, and planked up with 3-inch plank. This was done to take the weight of the timber for the next 200 feet instead of letting it rest upon the timbers below. Stations about 15 feet long were cut in the side of the raise every 200 feet, to shelter the men when blasting and save the exertion of going down the ladders the whole distance to the level below.

In this manner the raise was carried to the height of 570 feet, which was 51 feet from the surface, when a smaller raise was carried up, as shown in Fig. 4, a test hole being drilled in advance of the top of the raise to ascertain the depth of the sand. When within 18 feet from the surface, sand was reached by the test hole, and the raise continued, by carefully working through the sand, to within 10 feet of the surface. A hole was then drilled from the surface, blasting the sand through the opening below.

The work of enlarging the shaft was then begun. The surface at the opening made by the blast was leveled and two stringers, 2 feet 6 inches in diameter and 25 feet long, were placed in position for timbering through the sand. The dimensions of the shaft are 10 feet 2 inches by 12 feet 2 inches inside; 12"×12" fir timber was used and the plan of timbering is shown in Fig. 5. The principal feature of this work was the method used in enlarging the opening made by the raise to the dimensions required by the permanent shaft. The drills used in raising were also used for this work. The rock was drawn off through the chute at the 621-foot level the same as when raising, until it was lowered about 15 feet. The timber from the raise was then pulled out for a distance of 15 feet and the two smaller compartments covered over as before. The holes were drilled upwards at an angle of 45 degrees, and were started 10 feet below the permanent shaft timber and so located as to strip 5 feet of the shaft at one blast, thus making room for one set of the shaft timber.

Ordinarily this work is done by drilling holes downward, but, as the above method proved very successful, it was continued for the entire shaft. The use of the hammer drill seems to be a great improvement over the reciprocating drill with the shaft bars on tripods.

The progress of the work was as follows: Raising 621 feet; Number of days, 125; average progress per day, 5 feet; Cutting down 621 feet; Number of days, 114; average per day, 5.44 feet.

The work which was started September 5, 1911; was completed by July 15, 1912.

* Paper read before Lake Superior Mining Institute, August, 1912

NEW MINING MACHINERY

Manganese Steel for Economy

As evidence of the remarkable endurance of "Stag" Brand manganese steel, The Edgar Allen American Manganese Steel Co., of Chicago, Ill., and New Castle, Del., have a photograph of a pinion, together with others of the same make, that was used for driving conveying machinery, and was in continual operation for over 25½ months, while the average service given by cut-steel pinions under exactly the same conditions, was only 3 weeks. That the metal is wonderfully tough is unmistakable, for even though worn down very thin the teeth did not break. While it is not good practice to wear out a pinion to such extent, this is an example of the economy which results from using good manganese steel. The makers of "Stag" Brand manganese steel are turning out and selling many hundred tons of castings per month in the form of gears, pinions, and other heavy service equipment, which fact demonstrates the extensive adoption of this metal.

Motor for Stamp-Mill Drive

It has been the practice in the past to belt a large motor to a long line shaft and from this line shaft to connect each battery of 10 stamps with a belt. This method caused a loss of power in the transmission owing to the continual jar of the stamps throwing the line-shaft bearings out of alinement, and involving considerable loss in the belt friction when different groups of stamps are out of service. Following machine-shop practice a motor is now designed to belt directly to a battery of 10 stamps. It is of 25-horsepower capacity at 580 revolutions per minute and is constructed as shown in Fig. 1 with a back-gear cradle that carries a countershaft, and on which is mounted a gear and pulley for especially slow belt speed. The gear ratio is 27 to 99, giving a countershaft speed of approximately 650 feet per minute. The gear case is oil-proof. The cradle and gear-case are standard, but a smaller motor can be used where the drops are fewer per minute, or the stamps lighter. This combination of motor drive for each battery of stamps has the advantage of dispensing with the long line of countershafting and its consequent losses, and drive, the belt and cam-shaft of the battery when out of service. With line shaft drive the belt and cam-shaft of the battery continues to run when the battery is idle. The motor, gear, and pinion can be replaced or taken away for repairs without disturbing the line-up of the pulleys and the handling of the extremely heavy belt. An especially long sliding base is furnished to take up the stretch of belts. The cradle to which the motor is belted is securely held to the sliding base by means of four machine bolts which can be loosened when it is necessary to change the tension of the belt.

This individual motor equipment for stamp-mill drive, compared with the older

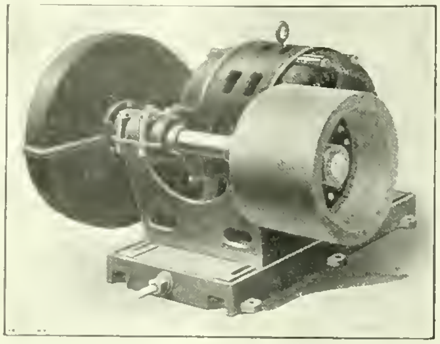

FIG. 1. MOTOR FOR STAMP MILLS

methods, and more particularly in preference to the long line-shaft drive with a single motor belted to the line shaft, seems to have a number of advantages and should serve to popularize the use of electric motors in stamp mills. The motor here described is made by the Westinghouse Electric & Mfg. Co. of Pittsburgh, Pa.

Ready-Made Houses

Modern steel building construction methods have been adapted in a unique way to the construction of dwellings, bungalows, and other types of frame structures. The application has been in the manner of construction rather than the materials used. Results obtained are striking and in some ways almost revolutionary.

As is well known all the material for the steel framework of modern office buildings is manufactured, sized, cut to exact lengths, shaped and numbered at the steel mills, ready for assembling, erecting, and bolting in place on the job. No further cutting or fitting is necessary after leaving the mills. Naturally this greatly facilitates the rapid and accurate progress for which this type of construction is noted.

Exactly this same system is now applied to the construction of a ten-room frame dwelling. Every piece of lumber in the house is first figured out in shape, size, length, breadth, and thickness by expert designers and draftsmen. These figures are turned over to skilled carpenters, operating fast machinery in the factory. The time-honored ways of the hand saw are eliminated and every cut, miter, and bevel is accomplished by machinery. Every piece of lumber is numbered and marked by a surprisingly simple system and the house, for it is a house now, is loaded into the car and shipped to destination. Everything for the complete house is included in the shipment at a stated price, except the masonry; all sills, joists, studding, rafters, siding, sheathing, flooring, porch work, stairways, windows, doors, frames, moldings, locks, hinges, nails, paint, oil and varnish, putty, shingles, lath, and plaster, in fact everything is included at a plainly stated price.

The ready-cut system of construction was first brought to public attention 7 years ago, since which time it has made wonderful progress. It practically eliminates the necessity for skilled laborers in erecting dwellings and cuts the usual time of erection in half—and at a proportionate saving in cost.

There are several firms selling material for houses by mail, but only one manufactures houses complete by the ready-cut system—The North American Construction Co., of Bay City, Mich., who are exclusive manufacturers of Aladdin houses.

Trade Notices

Change of Name.—The S. Jarvis Adams Co. announces the change of its name to the Pittsburg Iron and Steel Foundries Co.; the general offices are at the works at Midland, Beaver County, Pa.

Nokomis Mine Plant.—J. E. Rutledge of the Rutledge & Taylor Coal Co., St. Louis, Mo., also president of the Nokomis Coal Co., has awarded a contract to the Roberts & Schaefer Co., Engineers and Contractors, McCormick Building, Chicago, for the designing and building of a complete fireproof coal-mining plant of large capacity, to be built at Nokomis, Ill., contract price approximately $125,000. This plant will, in many respects, be similar to the large plant which the above company erected for the United Coal Mining Co., at their Mine No. 2, Christopher, Ill.

Loud-Speaking Telephone.—The Western Electric Co., installed ten of their loud-speaking telephones in the Boston Electric show. This telephone combines the articulating qualities of the telephone receiver, and has the intensifying qualities of the megaphone. The installation was made to demonstrate their use as announcers of interesting events about to take place at the exposition. They were also used to transmit music and were so loud in their doing it, that the leader of the band protested that "it interfered with the music he was playing."

Order for Boiler Compound.—The United States Government order for 85,000 pounds of boiler compound has again been awarded to the Geo. W. Lord Co. The boiler compound business is undoubtedly on a much better basis than formerly. Today the goods must have merit back of them to be able to stay in the field; for the engineer has learned more about the chemicals to be used for certain water troubles, and this has been brought about by the educational advertising campaigns carried on by the successful boiler compound houses in the field today. Of course, none of them tell what ingredients are used in their special formulas, but practically all the mystery as to what they are trying to accomplish has been removed, as the successful houses furnish a complete analysis of the water to show the engineer what he is up against. The credit for this is claimed by the Geo. W. Lord Co., who started furnishing certificates of analysis many years ago, when the boiler-compound business was in its infancy.

New Instrument Co.—Under date of October 8, 1912, the formation of the Davis Instrument Mfg., Co., Inc., 110 W. Fayette Street, Baltimore, Md., is announced. The company will manufacture and handle mining and scientific instruments, etc., of the highest grade; and accurate anemometers and their repair, test, and adjustment will be a specialty. Scientific instrument repairs are solicited. The officers are, Herbert Davis, president; A. U. Davis, vice-president; F. H. Holthaus, secretary treasurer.

The Joseph Dixon Crucible Co.—At the regular monthly meeting of the Board of Directors of the Joseph Dixon Crucible Co., on October 21, the following changes in the officers and Board of Directors were made on account of the death of Vice-President William H. Corbin. George E. Long, former treasurer, was elected vice-president to succeed Mr. Corbin; J. E. Schermerhorn, was elected to membership in the Board of Directors and treasurer of the company. Mr. Albert Norris was elected to the office of assistant secretary and assistant treasurer.

Catalogs Wanted.—O. M. Jones, 30 Church Street, New York City, who is a jobber and manufacturers' agent, selling materials used for steam, water, air, gas, and oil supplies, and specialties covering complete power plants, is desirous of obtaining from manufacturers of such equipment and materials complete catalogs, and price lists and best jobbers' discounts.

Lunkenheimer "Puddled" Semisteel Valves.—The increasing use of high pressures and superheated steam has created a demand for something better than the ordinary cast-iron, brass-mounted valves. To meet this demand, the Lunkenheimer company offer their line of "Puddled" Semisteel valves. "Puddled" Semisteel is an extremely high-grade iron and steel alloy, of close grain and great strength, not to be confounded with the mixtures made in cupolas where the admixture of steel with the iron is beyond control, and the resulting metals lacking in uniformity. The Lunkenheimer method is to melt the iron and steel together in a specially modified puddling furnace, thoroughly mixing them during the process, and by pouring off at the proper time and temperature, they secure an invariably uniform alloy. The best grade of Lake Superior charcoal iron is used and the percentage of deleterious chemical elements is kept very low, a result impossible to obtain in any cupola.

By this process, the tensile strength is controlled to any point between 30,000 and 40,000 pounds per square inch. Ordinarily, the strength maintained is 35,000 pounds, which is over 100 per cent. stronger than the cast iron used in the majority of valves, and about 50 per cent. stronger than that used in Lunkenheimer valves. The "Puddled" Semisteel valves have been extensively used in high-pressure plants carrying superheated steam, and have given satisfaction. These valves are made in two combinations as regards the material used for the trimmings; Combination C is guaranteed for 600° temperature and Combination D for 550°. Both combinations are suitable for 250 pounds pressure per square inch. For extreme conditions of pressure, superheat, and strain, the company manufactures the above line made of cast steel, the tensile strength of which is about 80,000 pounds per square inch. For lower pressures and temperatures, the line is made of a high-grade cast iron. A full description of these valves, together with that of the complete line of high grade engineering specialties made by the Lukenheimer company, can be obtained by referring to their 654-page catalog, 1912 edition, a copy of which will be sent upon request.

SUBSCRIPTION RATES

Single Copies.......25 cents
Yearly Subscription, including postage:
To United States, Mexico, Cuba, Porto Rico, Hawaii, and Philippines...$2.00
To Canada.......2.50
To all other countries.......3.00

The date after your name on the wrapper is that of the month to which your subscription has been paid. If you do not want to continue your subscription after that time, kindly notify us.

Notice to discontinue or change of address should be sent to the Scranton office.

When notifying us of a change of address always give your FORMER as well as your present address.

TABLE OF CONTENTS

OUR cover picture for this month shows a scene familiar to most of our readers. The cage, showing evidence of hard wear, is just about to be lowered down the shaft carrying with it the fire boss and miners to their day's work.

IN our Letter-Box department, a reader asks for information regarding the service rendered by "booster" fans. This is a matter of considerable importance to mine officials and we hope those of our readers who have had experience with them, or who have studied and investigated the subject will freely use the Letter-Box department to discuss it.

THE economic importance of a good light in mines has not long been recognized, and from ancient times the sputtering candle and smoky torch have held their place as illuminators without dispute. Recently, however, improved oil safety lamps and acetylene and electric hand lamps have been shown to result in increased output as well as greater comfort, safety, and economy, and it seems that the older lights must soon be superseded.

THE United States, while producing considerable silver in connection with copper and lead, has had very few strictly silver mines. According to the United States Geological Survey the silver production in 1911 amounted to 57,796,117 ounces, valued at $31,787,866. During the year ending October, 1911, Cobalt, Can., produced 32,000,000 ounces, valued at $16,500,000.

As the cheapness of gold is increasing, it naturally follows that the price of silver will rise, and this will set the prospectors to looking for more "Mollie Gibsons."

Rocky Mountain Coal Mining Institute

THE organization of the Rocky Mountain Coal Mining Institute by men who are in real earnest in their endeavors to make their own work and that of their subordinates more efficient, both in the matter of economical mining and in the safety of the mine workers, cannot be too highly indorsed. The Institute begins life vigorously and will undoubtedly prove beneficial in the influence it will exert on mining methods. The only criticism, MINES AND MINERALS can make, and it is made in all kindness, is that the annual dues of $2 per year are too low.

The membership of the Rocky Mountain Coal Mining Institute is scattered over a very large territory with, in many cases, rather inconvenient and expensive transportation facilities. As a result it will be impossible for many members to regularly attend the meetings, and unless the papers presented at the meetings and the often important discussions are printed and promptly distributed among the members, the absentees will miss one of the principal benefits of the organization. The editing of the papers, the stenographic reports of the discussions, and the illustrating, printing and distributing of the transactions, require considerable money, more probably than the gross amount received as dues. This, of course, is a matter that can be easily remedied by the Institute, and we merely call attention to it, so that if action on the matter is required, those of our readers who are members, may realize that a reasonable increase in dues may be necessary, and if such is the case, they ought to favor the movement.

Electricity in Mines

WHILE the Special Rules for the Installation of Electricity embodied in the Pennsylvania Bituminous Mine Law of 1911 practically saddle factory rules on the coal-mine operator and add to the cost of production, there has been little if any complaint against them. The object of these rules is of course to decrease the number of accidents in mines due to the use of electricity, and their incorporation in the new law was timely, for 39 persons, or .26 per 1,000 employed in the bituminous coal mines of Pennsylvania in 1911, were killed by electricity. In England at no time have the fatal accidents from electricity in 1 year exceeded 1.54 per cent. of the total, while in the bituminous mines of Pennsylvania in 1911, practically 8 per cent. (39 out of 490) of the fatal accidents were due to this power. The use of electricity in mines is a problem by itself, for conditions are quite different from those prevailing in electrical generating stations, where most of the employes have considerable technical knowledge, and where maintenance and supervision are observed necessarily. Underground, the numerous opportunities for the disarrangement of cables, conductors, and machines offer dangers of shock and mechanical injury that do not appear in surface work. While electrical accidents on the surface are confined to one or two individuals, in the mine the danger of setting fire to gas or causing a mine fire which may endanger the lives of hundreds calls for rigid laws governing the use of this power.

Under these conditions it must be admitted that if electricity is carelessly installed or supervised so as to produce sparking, serious accidents may occur, and this more than justifies the enactment of special rules for the use of electricity in mines, rather than in other places. Quite a number of the rules seems almost too simple for insertion in a state code because in the course of the construction of an electric plant they must be observed; however, the installation must be carefully maintained to avoid accident. The standard of underground electrical installations must be high and kept high by suitable supervision, but when it comes to deciding what rules should be made to prevent accidents, the entire list will become inoperative unless the miner is instructed in regard to the dangers liable to happen to him, and possibly others, provided he neglects to do his part.

The special rules relative to the use of electricity were proposed by the American Mining Congress for use in coal mines generally, and were adopted by the Commission whose duty it was to draft the new bituminous mine code prior to its enactment.

While the majority of coal operators take a proper view of their responsibilities, and the number of places where the installation of electricity is inherently dangerous is relatively few in this state, owing to the nearness of the coal to the surface, it is believed that the Inspectors should have the right to object to the use of electricity in certain places.

The experience and qualification of these men is such that it is unlikely any of them would recommend a matter which would entail expense merely to show authority, particularly when, if in the wrong, they would lose their case on appeal to the Director of the Bureau of Mines of Pennsylvania.

Mischievous Statements

THE following item clipped from the Philadelphia *Public Ledger*, of November 26, would be amusing if it was not untruthful and mischievous:

"The Rev. C. P. Futcher, who is conducting the Anthracite Social Service Mission of the Philadelphia Conference, with headquarters at Tamaqua, addressed the Methodist Preachers' Meeting in Wesley Hall yesterday upon his work among the immigrants.

"He said that agents of big companies induced them to leave their poor but neat homes in Europe by glowing promises of the prosperity that awaited them in America. In their ignorance some land in New York expecting to pick up gold in the streets. In the coal fields they find life the severest kind of drudgery, while they are compelled to live in miserable shanties.

"Speaking of the hard drinking of some of the foreign miners, Mr. Futcher quoted a mine superintendent, who declared that it was necessary, owing to the miners' diet. This consists of only one hot meal (a bowl of soup) daily. The rest of the day's menu consists of bread, without butter, a turnip and an onion."

Anthracite miners as a rule do not live under wretched conditions. Such a statement is an insult to thousands of anthracite mine workers. Those who live in hovels and squalor do so because it is the way they have lived for generations, and it is the cheapest way to live, from their standpoint, as it enables them either to save more money or have more to expend for "polinkey."

The implied statement that agents of big mining companies induced them to leave their "poor but neat homes in Europe by glowing promises of the prosperity that awaited them in America," is an absolute falsehood. The only agents who induce immigration to the United States are steamship agents. The mining companies are not in that business even in the most indirect way. There isn't a mine official in the country who would employ these non-English speaking men if he could get English speaking mine workers. The time and money the large mining companies are expending in teaching these men English through mining institutes, night schools, etc., is in itself a refutation of the statements of the Rev. Mr. Futcher.

The daily diet of the miners as given by that gentleman is also a misstatement. The anthracite mine workers are among the most prosperous wage earners in the country, and as a rule they purchase more and probably better food stuff than does the reverend gentleman who, for the sake of notoriety, or possibly an appropriation from the Methodist Conference, makes false statements regarding them.

It is such deliberate misstatements made by some few ministers that cause many men to wrongly judge those who tell the truth and paint conditions in true colors.

Substantial Sympathy

FOR many years it has been a custom at coal mines to suspend operations on the day of the funeral of a man killed by accident in the mine. Naturally, in the case of large mines especially, but comparatively few of the employes who were personal friends of the deceased attended the funeral. The result was considerable loss to the operating company and the mine workers, and no benefit, except an intangible sentimental benefit, accrued to the family of the deceased.

A commendable innovation was recently made by the employes of the Philadelphia & Reading Coal and Iron Co., at the Locust Gap colliery, at Locust Gap, Pa.

Instead of suspending work on the day of the funeral, entailing a loss of about $5,400 in wages for the employes, numbering about 1,800, they decided to remain at work, and to contribute 25 cents each to a fund for the benefit of the widow, thus giving her the substantial sum of $450 and saving themselves an aggregate of over $5,000. In this movement every employe including the officials joined, and the sympathy expressed in this substantial way was infinitely more practical than the old kind.

It is true that this plan has been in force at a few industrial establishments, and possibly at some mines, but it has been far from general. It is a plan that should be adopted at every colliery, and the amount each individual contributes should be such a sum as will be of material advantage to the widows and orphans. Regardless of any other remuneration which the widows and orphans of mine workers may receive, either through benefits, insurance, or other sources, when their wage earner is killed, a few hundred dollars contributed by the victim's fellow workmen is always acceptable and of real help.

The Fire Boss and Mine Accidents

ACCIDENTS will occur in coal mines as long as the human element, is involved in the industry. There are some accidents which cannot be prevented by any precautionary measure, but they are few. The greater number of the accidents are due to the carelessness of some one or a violation of mine rules.

The mine foreman is the official generally supposed to see that mine rules are enforced. His duties, however, are such that in an extensive mine he can only give general and occasional or cursory attention to matters other than the production of coal. He must, in a large measure, depend on the fire boss in the regulation of the actions of the individual employes. The very nature of the fire boss' duties stamps his office as the one that has most to do with the safety of the employes.

In most cases the fire bosses are capable men, but as the most capable fire bosses are from time to time promoted to foremanships there is frequently trouble to get men to take their places. In almost every field the fire boss must pass an examination to prove his qualification for the position. In some instances he must pass the same examination as do the assistant foremen. Miners capable of passing the required examination, and possessing the executive ability to enforce discipline, are usually men who can earn more as miners than as fire bosses, and besides they do not have to work the unseasonable and often long shifts required of fire bosses. Therefore they do not look on a position as fire boss with much favor. Its only advantage is that it is a stepping stone to possible promotion to an assistant foremanship or a foremanship.

In a recent conversation a State Mine Inspector said: "Many accidents in mines can be prevented by the fire bosses. They naturally visit each working place daily and are supposed to notice all other elements of danger to the men as well as the presence of gas. Under the mine foreman, the fire boss should have authority to require miners to promptly set necessary props, to use more caution in regard to the stability of the top coal, and to strictly enforce the mine rules under penalty of discharge for the violator. Naturally, a fire boss to do this must not only be a careful man himself, but he must possess technical knowledge and the executive ability and force necessary to secure prompt and full compliance to his orders. Such men, as fire bosses, are scarce. They are growing scarcer every year. There is but one remedy as I see it. The position of fire boss must be made more remunerative. The incumbent of the position must be paid a salary larger than the amount he can earn as a miner in shorter hours and with no responsibility other than his own safety. The position must be made more attractive to first-class men. Such men can do a great deal to lessen the number of accidents, and in my opinion no greater movement toward decreasing the number of mine accidents can be made than the employment of the best possible men as fire bosses at salaries that will warrant their accepting the positions."

Book Review

Coal. By E. E. Somermeier, Professor of Metallurgy, Ohio State University. McGraw-Hill Book Co. Price, $2 net.

In this book Professor Somermeier has given a concise yet comprehensive statement of the various aspects of coal. He has not only concerned himself with the chemical composition of coal and its determination by analysis; but has included chapters upon the improvement of coal by washing, and the purchase of coal under specifications. The material in this book is all new, having been gathered by the author. The contents are divided into 12 chapters as follows: Composition and Heating Value; Chemical Analysis of Coal; Sampling; Methods of Analysis; Determining the Calorific Value; Summary of Chemical Determinations; Improvements of Coal by Washing; Purchase of Coal Under Specifications; Flue Gas Analysis; Analytical Tables. There are 175, 6×9 pages in the book, including index, and no padding. In the preparation and arrangement of the book, Mr. Somermeier has kept in mind the mechanical and power-plant engineer; the chemical engineer, and chemist; and the non-technically trained business man and operator, who has to do with the buying and selling of coal. He advises the reader to pass over any discussion that is too technical or elementary for his needs and select whatever may be of interest and use. Unfortunately the business man who purchases and the man who sells coal are bound to be mystified, if they are unable to understand the text, which on this subject depends largely on theory and technical formulas.

The Metallurgy of Iron and Steel, by Bradley Stoughton, Ph.B., B. S. McGraw-Hill Book Co., publishers. Price, $3 net. This is a second edition of Professor Stoughton's authoritative book upon the metallurgy of iron. The subject matter of the first edition has been so thoroughly revised and added to, that this edition is practically a new book. Professor Stoughton is an authority upon iron metallurgy and has brought his book up to date, the first edition being published 3 years ago. The advances have been so great in this time that a new volume was needed.

Smoley's Parallel Tables of Logarithms and Squares, seventh edition, has just been published by the McGraw-Hill Book Co. Besides the tables of the previous editions which made the book so well known, this edition has two new features that will further enhance its value. The first is a diagram that enables the designer to obtain at a glance any side of a right triangle when the other two sides are given. Results may be obtained directly to eighths, and estimated with close accuracy to sixteenths. In cases where greater exactness is required, the second added feature of the book may be used. This is an additional table, giving in parallel columns logarithms and squares of linear dimensions up to 16 inches, by intervals of a sixty-fourth of an inch. These two additions will increase still more the reputation of the book as a time saver. In these days of rush and hurry, tables like these are a real asset to an engineer in calculating dimensions in feet and inches and for many similar purposes.

An Extension of the Dewey Decimal System of Classification Applied to the Engineering Industries, by L. P. Breckenridge and G. A. Goodenough, was originally issued as Bulletin No. 9 of the Engineering Experiment Station of the University of Illinois, in 1906. The filing and classification of engineering data has become a matter of much importance, and this bulletin was prepared for use as a guide in carrying out such work. The original edition of Bulletin No. 9 was subject to the usual gratuitous distribution, and the subsequent demands were such that a second edition was printed and ultimately distributed. Altogether 20,000 copies were sent out. The demand having continued, it was finally decided again to revise and to print a limited edition. This has now been accomplished and the revised bulletin, much extended as compared with the original edition, is ready for distribution. It presents subdivisions of subjects in such detail as to constitute a complete classification for most engineering industries, even though they are highly specialized. The revision has been made in accordance with the 1911 edition of "Decimal Classification" by Melvil Dewey.

The revised edition of Bulletin No. 9 will not be subject to gratuitous distribution. A copy will be sent postpaid upon the receipt of 50 cents. Address: W. F. M. Goss, University of Illinois, Urbana, Ill.

Electrical Trades Directory and Handbook, published by "The Electrician," Salisbury Court, Fleet Street, London, E. C., England. The new annual edition will be ready in January, 1913. This is a very complete directory of engineers, supply firms, manufacturers, etc., connected with electrical business throughout the world. Price, prepaid, in the in the United States, 18s. 6d.

Personals

George Porter, of Uniontown, Pa., has been appointed bridge constructing engineer for Fayette County, Pa., and Messrs. Chaney and Armstrong have been appointed bridge constructing engineers for Washington County, Pa.

George Watkin Evans, Mining Engineer and Geologist, of Seattle, Wash., was appointed by the Governor to represent the Commonwealth of Washington at the meeting of the American Mining Congress. He also represented Mines and Minerals.

George S. Barton, civil and mining engineer of Pittsburg, Pa., is engineer for the George M. Jones Co., of Toledo, Ohio, who are to develop large tracts of coal land near Bellaire, Belmont County, Ohio.

George M. Colvocoresses has opened an office at 43 Exchange Place, New York City, for the practice of consulting mining and metallurgical engineering. He is also prepared to advise on the development, management, and operation of mines and to value and report on mining properties.

William D. Waltman, civil engineer, for 5 years on the Panama Canal construction as general superintendent, and for the past 2 years with the Costilla Estates Development Co., at San Acacio, Colo., as chief engineer, has resigned the latter position and is now general manager of the Franco-Wyoming Oil Co., at Casper, Wyo.

W. E. Hamilton, 17 Deshler Building, Columbus, Ohio, is now an Ohio Correspondent for Mines and Minerals. He will write on important new developments, descriptions of new methods of production and handling output at mines. He would be pleased to receive any news concerning coal mines. Bell phone 7735 Main.

Robert L. Streeter, of the Department of Mechanical Engineering, Rensselaer Polytechnic Institute, Troy, N. Y., is writing a series of articles for the *Engineering Magazine*.

W. B. Powell has been appointed in charge of the Canadian government mine rescue station at Lethbridge, Canada.

William Brown Dickson was elected President of the International Steam Pump Co., on November 19, 1912. He succeeded the late Benjamin Guggenheim, who went down on the "Titanic."

COAL MINING & PREPARATION

Washery at Soddy Mine, Tennessee

A Plant for Cleaning Coal from Different Mines Each Containing Impurities Peculiar to Itself

*By Frank E. Mueller**

THE Durham Coal and Iron Co., of Chattanooga, Tenn., was organized to purchase several coal companies in Tennessee and Georgia, the largest acreage of which is along Walden's Ridge, from 20 to 35 miles from Chattanooga, north, being produced from the slack and some nut. The lump and egg are marketed as domestic coal.

The coal from the Soddy mine and it was due to market conditions and the need for a lower ash coke that the new company decided to build a modern tipple for preparing more sizes of steam and domestic coal and to install a more efficient washer to better the quality of the coke.

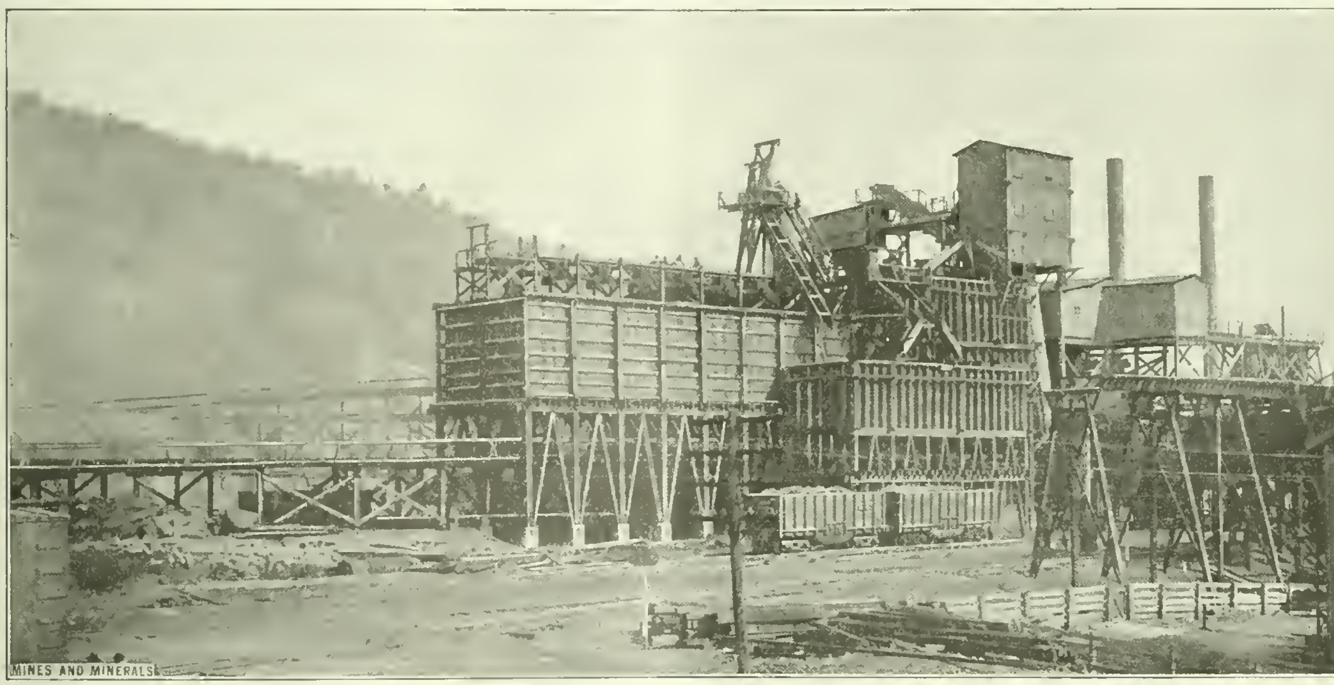

FIG. 1. COAL WASHING PLANT, SODDY MINE, RATHBURN, TENN.

along the line of the Cincinnati, New Orleans & Texas Pacific Railway.

The Soddy mine, at the town of Rathburn, is one of the oldest coal mines in the state, and is well known from the "Soddy coal" which bears its name. Here the No. 7, or Soddy seam, is opened about $1\frac{1}{4}$ miles from the railroad and at an elevation of 1,270 feet above sea level. This coal averages 27 inches in thickness and runs fairly uniform. It is hard and is shot from the solid, and the impurities which give trouble in making coke come from the top and bottom and are composed of fireclay, slate, and a bony rash. Such impurities, however, are found chiefly in the nut and slack coal produced and are easily separated in washing, coke prior to the time of the building of the new plant, was prepared over an old and inefficient tipple and washer;

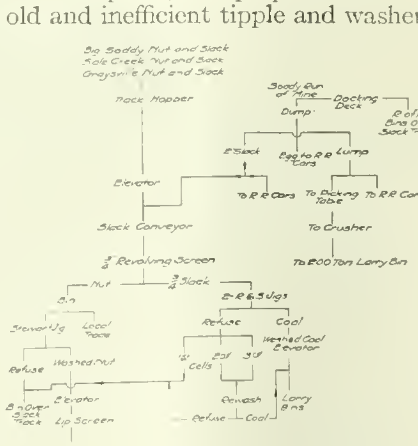

FIG. 2. FLOW SHEET, SODDY WASHER

The Soddy tipple receives Soddy coal only, but the washing plant treats not only the nut and slack from Soddy mine, but the nut and slack from other mines of the company.

At Chamberlain Siding, near Rathburn, the No. 7 seam is also worked at Big Soddy mine, the opening being 1 mile from the railroad and at an elevation of 1,240 feet above sea level. It averages 32 inches in thickness and is irregular, this coal being hand mined and shot from the solid. The impurities are chiefly a draw slate 8 inches thick that comes down with the coal and gives difficulty in separation.

The No. 2, or Nelson seam, is mined at Sale Creek, Tenn., about $1\frac{1}{2}$ miles from the main line, the

*Contract Manager, Roberts & Schaefer Co.

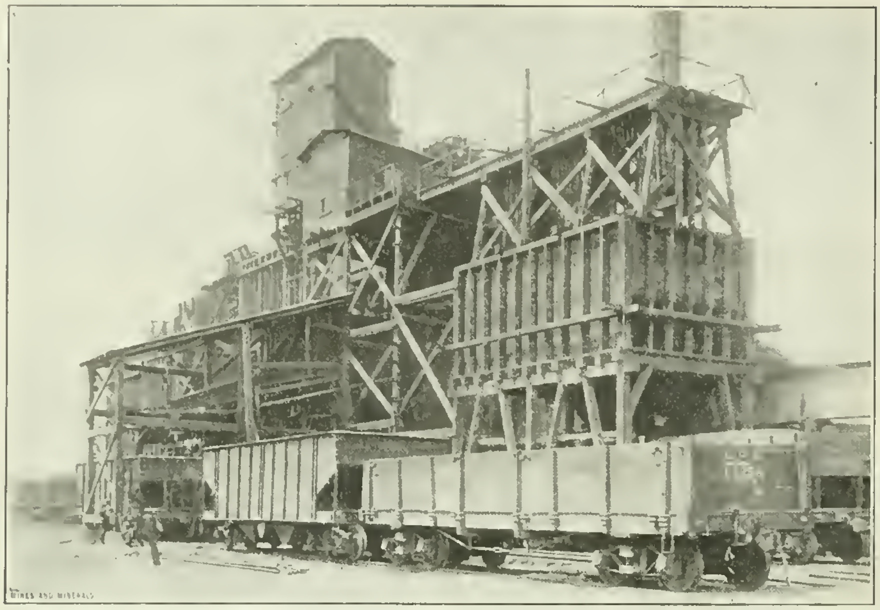

Fig. 3. Screens and Loading Chutes, Soddy Mine

elevation above sea level being 790 feet. This coal averages 42 inches in thickness and runs fairly uniform. The seam carries two bands of bone, each being about $1\frac{3}{4}$ inches thick, and difficult to separate from the coal, as the specific gravities are about the same. These bands occur in regular formation at about 12 inches and 30 inches from the top. The coal is undercut and also shot from the solid. The bone is the principal impurity in the seam, but slate and fireclay appear in smaller proportions.

At Graysville, Tenn., the No. 5, or Richland, seam is mined. The opening is about 3 miles from the main line of the railroad and at an elevation of 1,250 feet. The coal averages 30 inches in thickness and is irregular. It is friable and is hand mined. The principal impurity is a black rash that has never shown any regularity in formation, and a shot in a clean face of coal may bring out a pocket of this rash. It is sometimes found on the bottom and again at the top of the coal; yet, again, it will show running diagonally through the face of the coal. Its specific gravity is close to that of the coal, and hence gives difficulty in separation. Top slate is also to be found, but not in sufficient quantities to give any trouble in washing.

As all of the nut and slack coal from the mines mentioned was to be transported to the Soddy washer for coke making, great care was exercised in designing a washing plant to meet the varying conditions imposed, as Soddy nut and slack coal might be coming into the plant from the tipple at all times during the working day, and at the same time nut and slack coal from either Big Soddy, Sale Creek, or Graysville would be unloading and sent through the washer. As this condition could not be met in the old tipple and washer, the company decided to build an entirely new plant to meet the varying conditions of washing, and to improve the Soddy tipple as well. This task was intrusted to the Roberts & Schaefer Co., of Chicago.

A careful investigation of the old methods of washing in use by the Durham Coal and Iron Co. was made, together with analyses of the nut and slack coals from the Soddy and Sale Creek mines, which would constitute the bulk of coal going through the plant. It was found that the No. 7, or Soddy, seam would give no trouble, but in order to make a good separation of the Nelson and Richland coals from the impurities, the jigs should be so designed as to retain the coal in suspension a sufficient time to permit, with the proper pulsation, the separation of the coal and rash. To this end a new jig was designed. It was also found advisable to wash the nut and slack coals separately, not only on account of market conditions and the simplifying of the plant, but for effectiveness in washing.

Description of Plant.—The coal from Soddy mine is let down to the tipple in trips of 20 cars on to the loaded track, where they are uncoupled and run by gravity to the foot of a car haul which delivers them to the dump room. If a car looks as if it had been loaded with dirty coal, it is switched off to a track at the left, which leads to run-of-mine storage bins and over the bins. This car is then carefully examined, the amount of rock ascertained, and the miner docked accordingly, after which the coal drops below into the bin, from which it can be shipped as run of mine or it can be delivered into the boiler house through proper chutes. From the head of the car haul the cars pass over a cross-over dump, the empties returning by gravity to be made into trips preparatory to returning to the mine.

The coal is discharged from mine cars into a weigh basket, which in turn discharges the coal on to a pair of roller shaker screens, the plates of which are perforated and rolled corrugated to facilitate the screening of the coal. The chutes shown in Fig. 1 are arranged to screen and load lump, egg, and coal screenings on three tracks. Or, the screenings—that is coal passing through 2-inch

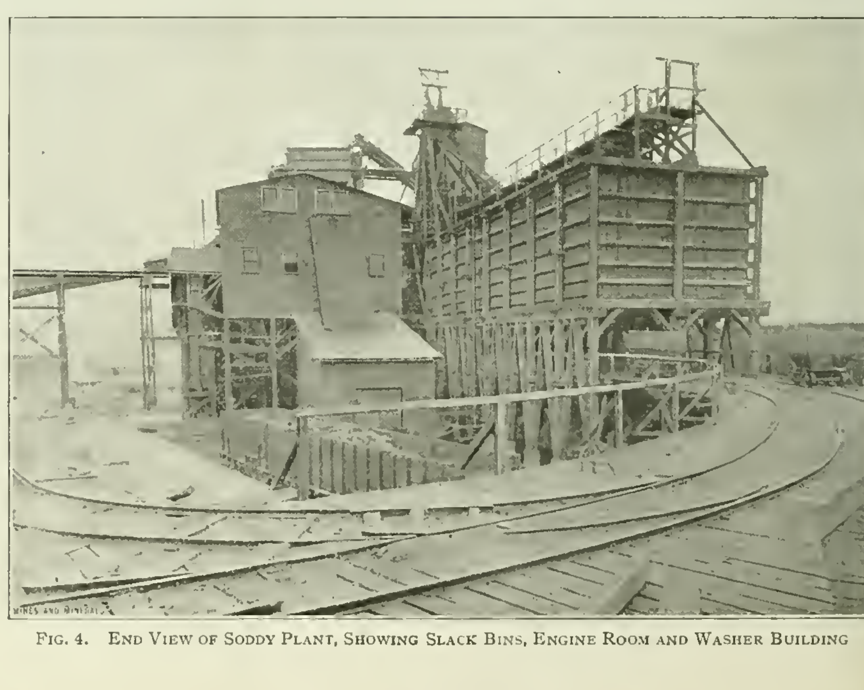

Fig. 4. End View of Soddy Plant, Showing Slack Bins, Engine Room and Washer Building

diameter holes—can be delivered direct to the elevator of the washer. The screens are also arranged so that a portion of the lump and egg coal can be diverted to a picking table from which the small amount of impurities can be removed by hand and the clean coal delivered to a Williams crusher. In the latter case, the coal is raised by a separate elevator to a 200-ton larry bin for making a special grade of low-ash coke. This coal without washing will analyze as low as 5 per cent. ash.

The nut and slack coal from the other mines is delivered to the washery in hopper-bottom railroad cars. and a receiving hopper has been provided under the slack track of the tipple. From this hopper the coal is fed into the same elevator that raises the nut and slack from the tipple screens to a flight conveyer, which delivers it to a revolving screen fitted with ¾-inch perforations. This screen separates the slack from the nut in order that each may be washed separately.

The nut coal is delivered from the discharge of the revolving screen by means of the chutes and telegraphs into a bin of about 25 tons capacity, which also serves as a local-trade bin. From this bin the nut coal to be cleaned is fed automatically into a Stewart jig, having a capacity of 25 tons per hour. The washed coal from the jig is sluiced to the nut-coal elevator tank, and raised from the water to lip screens located over the nut-coal bins shown in Figs. 1 and 4, and which serve the purpose of removing breakage caused by washing and handling. From the lip screens the nut coal is lowered into a storage bin of 100 tons capacity by telegraphs.

The refuse from the Stewart jig is sluiced to the final refuse tank from which it is elevated in a perforated bucket elevator to a 10-ton bin.

The coal which passes through the ¾-inch perforations of the revolving screen is discharged into storage bins, from which it is fed regularly to two Roberts & Schaefer Co. jigs, consisting of three compartments each with a total jigging surface of 126 square feet and having a capacity of 25 tons per hour. The coal fed into the first compartment is given a preliminary wash, after which it is sluiced to a second compartment wherein it is again washed, after which it is sluiced to the third compartment of the jig, where the final separation of rock and coal is completed.

Each jig compartment is independent of the other in order to facilitate repairs, and should any one of the three be out of commission, the other two can temporarily handle the product. All three plungers are arranged to impart different lengthed strokes at different speeds from one another, and all shafting is overhead, so that the operator has an unobstructed passageway to view the jig parts. Each jig compartment is provided with adjustable refuse valves, so graduated that the first cell takes out the bulk of the refuse, which, with the hutch product from jig screens, is sluiced to the final refuse elevator. The refuse from the second and third compartments, together with hutch products, can be delivered to an independent set of rewashing jigs or can be rehandled on the same jigs, this depending upon the percentage of ash desired in the coke.

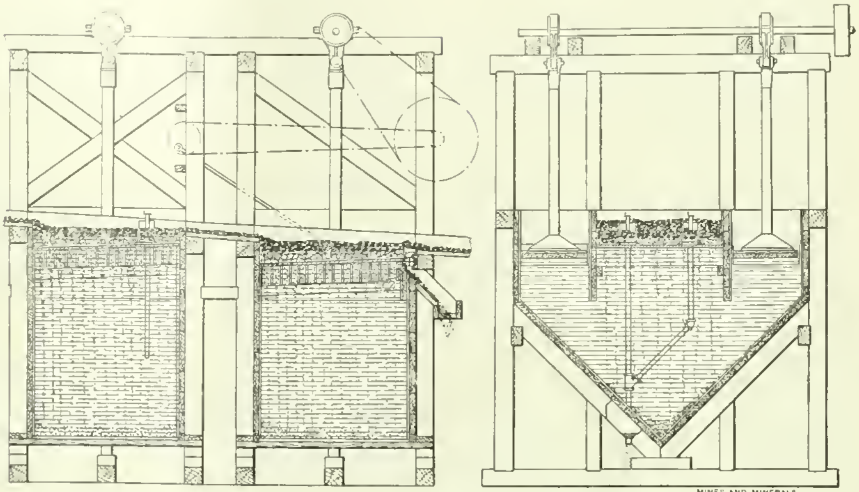

FIG. 5. SECTIONS SHOWING TWO COMPARTMENTS OF ROBERTS & SCHAEFER CO.'S JIGS

The washed product from the Roberts & Schaefer jigs is sluiced to the washed-coal tank from which it is elevated to a distributing conveyer located over the 800-ton slack bins, Fig. 4, or to a 100-ton bin located over the slack track, for shipment.

Provision is made to mix the washed nut coal with the washed slack whenever desired. Settling tanks for the recovery of the fine sludge and refuse have been provided, this sludge and refuse being returned to the jigs and the washed product mixed with washed slack coal; or with the minor additions to plant it can be used with the product from the rewashing jigs as boiler fuel.

It is worthy of note that the change from the old tipple and washer to the new plant was made without a single day's delay to the Soddy mine. The washer usually starts at 5 or 6 o'clock A. M. and continues throughout the day until 6 or 7 P. M., all depending on the amount of foreign coal on hand. An examination of the following analyses will show the results accomplished by this successful washing.

Average analysis of the Sale Creek, Graysville, and Soddy coals mixed, for month of October, 1912, was:

Unwashed mixed ¾-inch slack coals, 20.25 per cent. ash; washed coal (final), 10.62 per cent. ash; refuse final, including nut refuse, 55.10 per cent. ash; unwashed nut coal, 19.35 per cent. ash; washed nut coal, 9.45 per cent. ash; refuse nut coal, 63.08 per cent. ash; coke, 15.12 per cent. ash.

Percentage of rejections approximately 23 per cent. Refuse has averaged during month 3.96 per cent. float on a 1.45 specific-gravity solution, having given an ash analysis of 10.48.

As a comparison it may be of interest to give some analyses made, upon which selection of the types of jigs were based:

SODDY NUT ABOVE ½ INCH

	Per Cent.	Ash
Float 1.45 specific gravity	77	6.80
Sink 1.45 specific gravity	23	67.20
	100	

SODDY SLACK BELOW ½ INCH

	Per Cent.	Ash
Float 1.45 specific gravity	82	7.68
Sink 1.45 specific gravity	12	62.85
	100	

SALE CREEK NUT ABOVE ½ INCH

	Per Cent.	Ash
Float 1.45 specific gravity	61	9.11
Sink 1.45 specific gravity	39	57.00
	100	

SLACK BELOW ½ INCH

	Per Cent.	Ash
Float 1.45 specific gravity	75	9.80
Sink 1.45 specific gravity	25	57.50
	100	

Allowing for errors in sampling, variation in size of coal, and changes in mining conditions, the above results are exceptionally good and are indicative of the thorough manner in which the management of the Durham Coal and Iron Co. investigate and care for all their plants.

Coal Mining Institutes

Rocky Mountain Coal Mining Institute—Meetings of the West Virginia and Kentucky Institutes

By Special Correspondents

THE Rocky Mountain Coal Mining Institute, with a charter membership of 250 representative men engaged in coal mining in Colorado, Wyoming, Utah, and New Mexico, was organized in the hall of the House of Representatives in the Colorado State Capitol, Denver, November 13.

The membership comprises men engaged in coal mining in all capacities from miners to mine owners and managers. The meeting occupied the whole day, and at its adjournment the Institute was on a firm basis with a definite policy established and with particularly able, and greatly interested men as officers. E. H. Weitzel, manager of the Fuel Department of the Colorado Fuel and Iron Co., was unanimously chosen as the Institute's first president. Under the rules adopted, four vice-presidents, one from each of the four states, were elected. They are: for Colorado, W. J. Murray, Vice-President and General Manager of the Victor American Fuel Co., Denver; for Utah, W. B. Williams, General Manager of the Utah Fuel Co., Salt Lake City; for New Mexico, T. H. O'Brien, General Manager of the Stag Cañon Fuel Co., Dawson; for Wyoming, Frank A. Manley, General Manager of the Union Pacific Coal Co., Omaha.

An executive committee of thirteen members consisting of the president, four vice-presidents, and two members from each state, was provided for in the rules. The members named, other than the officers were: For Colorado, John P. Thomas, of Glenwood, and C. W. Babcock, of Denver; for Utah, F. N. Cameron, of Salt Lake City, and J. E. Pettit, of Coalville; for New Mexico, D. H. Summerville, of Gibson, and Alan French, of Raton; for Wyoming, P. J. Quealy, of Kemerer, and H. C. Campbell, of Rock Springs. F. W. Whiteside, of Denver, was chosen as Secretary-Treasurer. The annual dues for members were fixed at $2 per year.

Meetings will be held in June and November of each year, the places of meeting being points in each of the four states in rotation. The next meeting, in June, 1913, will be held in Salt Lake City; the November, 1913, meeting will be in Albuquerque, N. Mex., and the June, 1914, meeting will be in Cheyenne, and the next meeting in Denver.

The purpose of the institute is for the exchange of ideas and discussion of methods that will tend to safety and economy in coal mining operations.

That the institute will in time be productive of excellent results is assured by the class of men directing its work and the general character of its membership. It begins life under most encouraging circumstances, has the active support of the leading men in the coal industry in the territory it covers, and has a fertile field in which to carry on its work. In its membership are many men of more than ordinary mining ability, and their cooperation in the work of gathering and disseminating details of best methods of meeting the mining conditions of the Rocky Mountain coal fields will be productive, not only of greater economy in operation, but of increased safety of the mine workers. That the necessity for such an institute is a real one, is evidenced by the fact that each of the four states represented in the organization has had higher death rates from accidents in mines than almost any other coal producing state. In fact, but two other states show as high death rates as any one of the four Rocky Mountain states.

WEST VIRGINIA MINING INSTITUTE

From the point of numbers and enthusiasm the 12th annual meeting of the West Virginia Mining Institute was the most successful so far held. The meeting was held at Parkersburg, W. Va., December 10 and 11, 1912. Frank S. Smith, President of the Parkersburg Board of Commerce, delivered a felicitious address in which he welcomed the visiting delegates to the city. Neil Robinson, E. M., of Charleston, and J. C. McKinley, of Wheeling, accepted the hospitality of Parkersburg on behalf of the visiting members. President Frank Haas then delivered his address, and the election of officers for the ensuing year followed. They were as follows:

Mr. Neil Robinson, of Charleston, president; Prof. E. W. Zern, of Morgantown, secretary-treasurer. Vice-Presidents were moved up one notch: George T. Watson, first vice-president; John Laing, Charleston, second vice-president; R. S. Ord, Elkhorn, third vice-president; J. F. Healy, Elkins, fourth vice-president; J. C. McKinley, Wheeling, fifth vice-president. Executive Committee, Lee Ott, of Thomas; Prof. C. R. Jones, Morgantown; J. J. Lincoln, Elkhorn; Daniel Howard, Clarkesburg.

Frank Haas, consulting engineer, of the Consolidation Coal Co., Fairmont, W. Va., next delivered an address on "Conservation in West Virginia," in which he made some remarks not complimentary to the United States Bureau of Mines.

In the evening session Mr. J. C. Gaskill presented a paper on "Common Sense Mine Ventilation for Saving Horse Power in Operation of Mine Fans." A number of practical points were brought out and discussed.

J. E. Beebe, M. D., delivered an address on the "Value of Organization," and as a psychological demonstration said: "I have something in my pocket I have never seen, you have never seen, and none of us will ever see again." He then produced a peanut, broke the shell and ate the nut. Having got the audience's attention he gave a short talk with verbal illustrations on what organization had accomplished in the coal business and what organizations such as the West Virginia Institute were accomplishing for the technical end of coal mining. He was followed by W. W. Slocum who explained the Westinghouse plant in East Pittsburg by lantern slides. Interior views of the shops gave an insight to the immense electrical factories, and a general idea of the sociological end of the business was shown by interior views of the Casino and first-aid hospital.

The next paper taken up on the following morning was that of Prof. C. R. Jones on "The Progress Made by the Department of Mining Engineering at University of West Virginia." The paper developed a side issue which was debated pro and con to such an extent that the outcome was referred to a committe who should draft a resolution to be presented to the present legislature requesting an appropriation in behalf of the State Mining School.

Illinois has a large appropriation, West Virginia has almost nothing, while the latter state produces more coal, and in fact the entire state depends upon the mining industry. The suggestion that the operators pay a tonnage tax to support the University mining department, as they would be the ones benefited, is so small and narrow-minded that the writer could hardly realize the point was raised in good faith.

Mr. Josiah Kealey, of Fairmont, presented a paper on "The New Loader." G. A. Burril, Bureau of Mines, presented a paper, "Notes on Some Mine Gas Problems." Mr. H. A. Williamson of the engineering department of the Consolidation Coal Co., Fairmont, W. Va., read a paper on the "Relation of Forestry to Coal Mining." The last paper was by Sim Reynolds, inspector for the Hartford Insurance Co., defending the Bureau of Mines from Hogan's attacks.

On Tuesday evening after the meeting a large number of the members were entertained at the Elks Club by Lew Fields' Minstrel Troupe.

On Wednesday evening the Parkersburg Board of Commerce entertained the members at a banquet and smoker. This meeting will long be remembered although a number of familiar faces were absent.

KENTUCKY MINING INSTITUTE

The Kentucky Mining Institute held its winter meeting at Lexington, Ky., December 9, 1912, at which the following papers were read:

"The Relative Hazard of All Vocations in Relation to Mining," by Hywel Davies, Louisville, Ky. Mr. Davies' paper will attract attention, and possibly precipitate some discussion. It will appear in the February Mines and Minerals, and the columns of the journal will be open for its discussion.

A paper on "First-Aid Work," was read by W. L. Moss, general manager Continental Coal Co., Pineville, Ky.

At this meeting a plan was inaugurated to hold a State First-Aid Contest in May. A number of teams were pledged to enter the contest, and the Goodman Mfg. Co., of Chicago, has offered a handsome silver cup as first prize.

J. D. Rodgers, Superintendent of Mines, Miller's Creek Division of the Consolidation Coal Co., read a paper on "Preparation of Domestic Coal." Dr. J. D. Pryor, Professor of Anatomy and Physiology, read a paper on "Hookworm Disease," which is a classic and will appear in February Mines and Minerals. H. La Viers, Manager North East Coal Co., Paintsville, Ky., read a snappy paper on "The Successful Mine Foreman From Four View Points."

The following is a list of those who registered at the College of Mines and Metallurgy, State University: Hon. Henry S. Barker, President State University, Lexington, Ky.; T. J. Barr, Assistant Inspector of Mines, Lexington, Ky.; S. L. Bastin, Manager Star Coal Co., East Bernstadt, Ky.; Wm. S. Canning, Resident Engineer, Leet-Maupin Engineering Co., Jackson, Ky.; P. V. Cole, Assistant Inspector of Mines, Barbourville, Ky.; C. R. Conner, Engineer, Cunningham & Conner, Consulting Engineers, Huntington, W. Va.-Ashland, Ky.; H. G. Boumer, Westinghouse Electric and Mfg. Co., Louisville, Ky.; W. H. Cunningham, Cunningham & Conner, Consulting Engineers, Ashland, Ky.; Hywel Davies, President Mine Owners' Association of Kentucky, Louisville, Ky.; C. F. Fraset, Manager of Mines, Taylor & Williams Coal Co., Beaver Dam, Ky.; Thomas Gower, 152 Ohio Ave., Latonia Station, Covington, Ky.; J. Henry Hall, Manager Bastin Coal Co., Idamay, Ky.; Walter F. Hanley, 232 W. 3d St., Maysville, Ky.; B. M. Horndon, Georgetown, Ky.; W. E. Hobson, Frankfort, Ky.; George M. Humble, Engineer, Stearns Coal and Lumber Co., Stearns, Ky.; B. R. Hutchcraft, Mining Engineer, Hernando Bldg., Lexington, Ky.; H. La Viers, Manager North East Coal Co., Paintsville, Ky.; A. R. Long, Manager Ohio Valley Coal and Mining Co., De Koven, Ky.; Wilbert A. Miller, District Manager, Goodman Mfg. Co., Chicago; W. L. Moss, Vice-President and General Manager, Continental Coal Corporation, Pineville, Ky.; M. O. McKenny, General Electric Co., Madisonville, Ky.; Henry L. Noel, 252 Foote Ave., Bellview, Newport, Ky.; C. J. Norwood, Chief Inspector of Mines, Lexington, Ky.; Dr. A. M. Peter, Kentucky Experiment Station, Lexington, Ky.; J. W. Pryor, M. D., Professor Anatomy and Physiology, State University, Lexington, Ky.; R. D. Quickel, Fuel Agent, Q. & C. Route, Lexington, Ky.; Frank D. Rash, Vice-President and General Manager, St. Bernard Mining Co., Earlington, Ky.; J. D. Rogers, Superintendent of Mines, Millers Creek Division, Continental Coal Corporation, Van Lear, Ky.; A. D. Schoenseigel, 420 Fairfield Ave., Bellview, Ky.; Oliver S. Smith, 26 W. Robbins St., Covington, Ky.; C. W. Taylor, Vice-President and General Manager, W. G. Duncan Coal Co., Greenville, Ky.; H. E. Taylor, Mining Engineer, Williamsburg, Ky.; W. C. Tucker, General Superintendent, Wisconsin Steel Co., Benham, Ky.; David Victor, Chief Mine Inspector, Consolidation Coal Co., West Virginia and Kentucky, Van Lear, Ky.; H. M. Wilson, United States Bureau of Mines, Pittsburg, Pa.; R. M. Woodson, Kuttawa, Ky.

Hogan on B. T. U.

Say, Hogan, I've been radin' about British thermal units in coal. Wid all my work in the mines I've niver seen wan of thim to know it. D'ye know phwat they are?

Hogan

Well, Reilly, I'm not surprised that ye're not acquainted wid thim. 'Tis wan thing to mine coal an' another thing to know phat's in id. 'Tis only racintly that I knew there were such things as British thermal units in coal, 'an whin I heard iv thim I thried to find out phat they were from a book. Begorra, whin I read phat they were, deschribed be some high brow, I didn't know anny more than befoor. I have the book here in the house an' I'd lave ye rade it, if it wud do anny good, but I know you won't understhand it anny betther than I did mesel. But you know, Reilly, there are manny things in books we can't understhand, an' that's not sayin' the books are wrong an' iv no use. Some min can tell ye about phwat's in coal in a way ye can't understhand an' another will tell ye the same in a way ye can understhand. Whin I found that phwat the book said about thermal units wuz too dape for the little larnin' I had, I wint to see Father McGovern an' axed him could he tell me phwat they were. Says he, Hogan, 'tis a raisonable question ye're askin' me, an' wid a bit iv a twinkle in his eyes he said, though offhand I can tell ye more about the hate that some will feel if they don't mind their ways, mebbe iv I saw the book, tellin' phwat British thermal units are, I can exsphlain thim to ye. I had the book wid me, an' I showed him the place. Whin he read it, he said 'twas no wonder I didn't understhand it. He thought a little while an' thin tould me that coal, like iverything else, wuz med up iv iliments, which be the same token, Reilly, are the only things that are not thimselves med up iv other things. To find out phwat ilimints are in coal an' how much of aich ilimint is in id is the wurrk iv a chimist. "All coal is not the same, as you well know, Hogan," sez he. "There's hard coal, an' soft coal, an' coal bechune the two, an' coal that is naither wan nor the other, like the lignite they have in some parts of the counthry. Aich kind iv coal has some ilimints in it that projuce hate, an' some ilimints in it that are no good at all, at all, for making hate. They make the ash. All hard coal is not alike, naither is all soft coal or all lignite. Some has more hate projucin' ilimints an' less ash makin' ilimints than others, an' some has ilimints in it that makes clinkers and some has not. Now, sez he, the ilimints that projuce hate detarmine the number of British thermal units in the coal. The more hate projucin' ilimints in the coal the more thermal units."

Now, Reilly, it's plain to ye, isn't it? The hatin' quality iv coal is missured by the thermal units in it, and the name British Thermal Units wuz give thim bekase 'twas Englishmin that diskivered thim, an' that's a pity. I'd be betther satisfied if they were called Irish Thermal Units, or aven American Thermal Units, an' I don't see fwhy they're called out iv their name when they're in American coal.

But Reilly, aven whin we admit that hate units in coal are nicissary, I don't take anny sthock in this new fangled idea iv buyin' an' sellin' coal be the thermal units only, aven if the governmint does it and thereby sets a bad example fer others. Av coorse whin you buy a ton iv coal, or whin I buy it, we don't buy it be the thermal units. We buy coal an' lave it go at that, if there's not too much shlate or bone in it. If there is, we raise a hullabaloo, an' that's all the good it does us.

But it's the min that buy manny tons iv coal ivery year for sthame purposes that are buyin' it be thermal units, an' I don't think much iv the plan. If they'd buy it be the thermal units they cud get out iv it, there'd be more sinse in it. It's wan thing to find hate units in the chimist's laboratory an' it's another thing to make the same hate units do their work. The lads in the laboratory, that wear eyeglasses, smoke cigarettes, an' use the sink for a quare purpose, can find hate units in coal aisier than the lads in overalls fernist the bilers can get them out. Begorra, I think the brain units in a fireman are as nicissary as hate units in coal to make sthame an' kape the prissure showin' right in the gauge.

There's some coal that has a lot iv hate units in it, but it's the Divil's own sthuff to fire wid. Besides the hate units, it has other things in it that make clinkers the size iv the firebox. Av coorse all coals high in hate units are not that way, but some av thim are. Thin there's some coal that don't clinker that hasn't as manny hate units as wan that does, and bechune the two if I was payin' for id, I'd take the coal that doesn't clinker.

I'm tould that 'tis no hard matther for the chimists to larn has the coal the clinker-makin' sthuff in it, as well as the hate units. If that's so, fwhy don't the governmint highbrows advise the buyin' iv the coal be the hate units in id, wid a dhrawback fer the clinker units? Phwat is it that makes the clinkers? Well, Reilly, id's a common enough thing, fer it's iron mixed wid another ilimint that helps it melt an' glue the ashes together, an' be that means choke the dhraft and cause a lot iv throuble.

I'm thinkin' that if the ould way iv buyin' coal isn't satisfactory, an' they want a scientific way, the best plan would be to considher three things, an' they are: the price, the hate units, an' the characther iv the ash.

Yer right, Reilly, scientific ways are great ways if common sinse is mixed wid 'em.

Mine Surveying Wrinkles

*By W. J. Crocker**

In mine surveying accuracy must always be the first consideration, next in order comes the question of speed; the following "wrinkles" have been found beneficial in preventing mistakes in surveying, thus saving time, and incidentally lowering the cost while raising the standard of the work done.

Double Reading of Angles.—After the transit has been set up, leveled and centered, set the verniers at zero zero; that is, have the zero line of the upper plate coincide with the zero line of the lower plate; clamp both plates together, focus the telescope on the backsight, tighten the lower plate, the reading of the vernier still being zero zero; loosen the upper plate and focus on the foresight; when properly focused, tighten the upper plate and read the vernier. Suppose the reading to be 213° 46′, now loosen the lower plate and focus on the backsight again, this will not change the reading of 213° 46′; when focused, clamp the lower plate, loosen the upper plate and again focus on the foresight; if the previous reading of 213° 46′ was correct the vernier now should read 67° 32′. In doubling angles the transit is always turned to the right, making a complete turn around the circle, thus dropping 360 degrees; remembering this, the second reading of 67° 32′ plus the 360° dropped $= 427° 32'$; or, worked the other way, $213° 46' \times 2 = 427° 32'$; then $427° 32' - 360° = 67° 32'$. This method of doubling angles discovers errors in vernier reading, mistakes oftener being made in reading degrees than minutes, because the surveyor's attention is taken up in counting the lines representing minutes until he comes to the coinciding line, while a glance is all that is usually given to the reading of the degrees. By doubling the angle reading, it is possible to get a more nearly correct reading in drafty tunnels and drifts where it is hard to keep the plumb-bob from swinging. The greatest benefit is that any mistake made in reading the vernier is caught at the time of reading, and is not entered in the field-book notes, carried on in a line of survey, reduced in the office notes, and only discovered when a plat cannot be properly made, or the survey properly closed, thus necessitating a resurvey until the mistake has been located. It takes a little more time to double angles, but if only one mistake a year is saved by doubling, the precaution pays for its use.

Doubling the Tape Reading.—In most mine surveys a standard steel tape, graduated to feet, tenths, and hundredths of a foot, is used. In measuring between stations, usually from 60 to 100 feet apart, the rodman holds the end of the tape reading from zero up; he places the zero mark on the station at his end, the surveyor holding at the station where he measures from, reads, say, 87.14 feet, jots it down on a slip of paper, but does not tell the rodman what the reading is; then the surveyor holds the tape at the 100-foot mark, the rodman reading the tape at his end; if the rodman calls 12.86 feet, the surveyor puts it on his slip of paper, and adding 87.14 feet to 12.86 feet he gets 100 feet even, the length of the tape, and knows that the first reading of 87.14 feet is the correct distance between the stations, enters it in his field book and proceeds with his survey. This method will catch a mistake in tape reading at the time it is made and before it is carried into the field notes.

*Negaunee, Mich.

An aid in measuring between stations where the plumb-bob is suspended from the roof, is a small slip knot on the plumb-bob string; the transit telescope being leveled and sighted through, the rodman slides the little knot up or down the plumb-bob string until it is intersected by the cross-hairs of the telescope; it is then level with the axis of the telescope, and by measuring from the axis of the telescope to the knot, measurement is made on a level plane, and of course the shortest distance taken between the two points.

Aid to Focusing Underground.—If a sheet of white paper is held between the rodman's light and the plumb-bob string, the string will show up plainer, thus giving a quicker focus, and will also make the plumb-bob string stand out more distinctly against the cross-wires of the telescope when sighting.

Locating Old Stations.—In returning to carry a survey farther, it is wise to set up under the second station back, backsight on third station back, foresight on first station, and to read the vernier, thus checking the angle, and also to measure the distance between the set up and foresight. This precaution should be taken because it sometimes happens that the miners blast out the station last put in, it being nearest the working face, and they may replace it as near as possible to where it was; or if the timbers have been blown down the miners sometimes change the caps end for end; the distance between the last two stations would be the same, or so near it as to identify the station, but the angle would never check if the station had been disturbed in any way, consequently, by getting both angle and distance any change cannot fail to be detected.

Obituary

WILLIAM G. SIMPSON

William G. Simpson, the builder of the first anthracite coal breaker in Northeastern Pennsylvania, died at his residence in West Pittston, Pa., on December 7, aged 88 years. From 1861 till 1895 he had charge of construction work for the old Pennsylvania Coal Co., with his headquarters at Pittston, Pa.

Drains should be so made and graded that the water will be kept below the bottom of the ties, preventing decay to them and corroded rails and metal fastenings.

Mining Steep Dipping Coal

A Method Suggested to Meet Certain Conditions in Thin Seams in Arkansas

*By A. A. Steel, B. S. in C. E., and E. M.**

In Arkansas there is a good deal of coal of such steep dip that it is expensive and dangerous to run the cars down the rooms, even when wooden sanded rails are used. In some mines, the rooms are driven diagonally across the dip. This is not very effective and greatly increases yardage costs because the entries must be closer together for the same room length. In such cases, some saving can be made by also giving the entries an up-grade so they are more nearly at right angles to the rooms, which of course increases the cost of haulage.

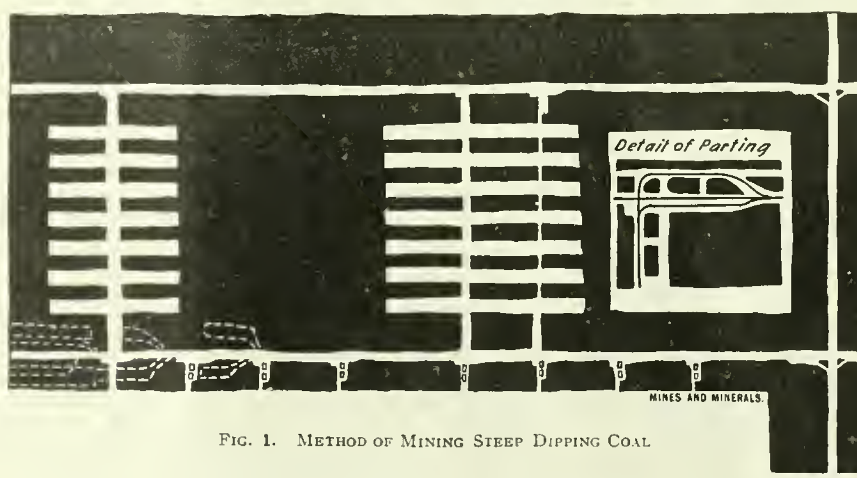

Fig. 1. Method of Mining Steep Dipping Coal

Instead of using these methods, it is far better to run the rooms nearly level and gather the cars by small engine planes off of a few main-level entries along which the cars are taken to the slope by electric motors. This plan is shown in Fig. 1. The method is very convenient and has been much used in the West, but failed in Oklahoma because the pillars in the soft coal were left so narrow that they rolled over. Under the existing breakthrough law, at least every second pillar must be kept narrow, but the width of the rooms can be held down to 24 feet or less and every second pillar should be 40 feet wide.

The track will be near the lower side of the room with space below it for all the waste. This material can be used to level up the track in high coal. In low coal, bottom brushing can be done to level the track. In all cases, the room men should be required to lay the track at such a grade that the cars must be pushed both ways and can be easily handled by one man. In order to keep the small hoist busy, it is best to complete the place before any rooms are started. The breakthroughs can be spaced to serve as necks for the rooms and the pillar workings on the air-course side. All rooms may be started full width because the room pillars must be adequate to prevent squeezes, and no real room necks will be needed.

Both the main entry and its air-course will carry a current of fresh air, and a separate split can be sent up through each small plane. The amount can be adjusted by a regulator at the top, and this air can be sent through the rooms by maintaining a curtain opposite each little pillar.

As soon as the rooms are finished, the pillars can be mined by taking a good-sized skip off the bottom and pulling back all the rest except a narrow strip to hold up for a time the gob above. The main entries may be protected above and below by omitting one or more rooms, and if necessary the pillars can be reenforced by shooting the roof and floor of the nearest room. The greatest strain will come on the entry above the robbed pillars, but this entry need be maintained only a short time after the rooms below are finished. At considerable depth the workings may in general retreat, and the pillars of the entry above can be promptly mined. In this case, the room above the pillar of the lower entry can be reenforced

*"Coal Mining in Arkansas."

readily by rock shot from the roof. These entry pillars can be mined by horizontal rooms connected with the main entry by inclined roads. The room farthest from the entry may be finished first, and the pillar beyond pulled before the next room is started.

In most cases, at the less depth, it will be possible to pull the pillars immediately. It is then advisable to drive the original planes a long distance apart and rob back the first

FIG. 2. STATION FOR DOUBLE-DECK SLOPE CARRIAGE

room pillars only on the side away from the main slope. The hoist can then be moved over to the line of breakthroughs in the large pillars, and the other room pillars robbed toward this new plane at the same time the rooms are being advanced on the other side, until the plane is moved again. In this way, the capacity of the small plane will be nearly maintained. The saving in yardage will be great, but twice as many partings on the entry will be necessary and a little more money must be invested in preliminary work.

To keep the motor busy, all the engine planes of the entry should be developed before the room mining is started. If the continuous-cutting electric machines are used in the rooms, as can be done readily in all the dips known in the state, the development work can be rushed by the use of the electric-air post puncher. There will be sufficient places rather near together to keep one machine busy on each entry. In a machine mine, the rooms will advance at an equal rate and the punchers will be concentrated occasionally on a single line of breakthroughs. This can be driven part way down from the room above for ventilation and to save moving the machines.

At most of the mines in high coal, it will be possible for a mule to drag the empty car up the engine plane, but the loaded cars had best be let down by fastening an old wire rope to a strong prop at the top of the plane and fastening the car to this rope by a screw clamp. The screw can be loosened just enough to let the clamp slide over the rope to lower the car. In low coal, the cars are best brought up by a light hoisting rope passing over pulleys and pulled by a mule walking in the entry.

In most places, the dip is not sufficient to interfere greatly with switches along the plane. Under these conditions, the cars can be handled in trains. The hoisting rope must, however, be so light that it can be readily pulled down the plane by the rope rider and it will rarely be possible to handle more than three cars in a trip. Even this introduces delays in shifting cars, and in general it would seem better to handle but one car at a time. The miners, according to their agreement with the operators, will handle the cars in level rooms both ways for 150 feet, but must not have to wait for a car. Under these conditions, there should be attached to the hoisting rope, two chains, one about 10 feet long and the other 25 feet. The empty car can be attached to the long chain and stopped when the other hook is opposite the loaded car waiting at the switch. The load is then attached to the short chain and pulled out on to the entry while the rope rider holds the long chain down in the cut in the curved rail while the wheels pass over it. The empty is then let down on the empty track and detached. The rope rider can signal the miners to run out their cars as needed. In longer rooms, the miners will push the cars one way, but it seems more economical under these conditions to handle the cars both ways for the miners and let them wait for the empty car until it can be brought up from the entry, and to handle the cars on the plane in trains.

The partings at the foot of the plane are most conveniently arranged as shown in detail on Fig. 1. The empty cars may be dropped off the end of a motor trip and run over the sidetrack. Any empty car standing here may be pushed to the end of the entry until a trip is gathered for the last plane. The old dip switch may be used for the loaded track and no yardage is needed. The rope will be pulled down the plane and attached to the empty trip; the operator of the little hoist will be able to see and avoid collisions with the entry motor, and the loaded cars will be placed so as to be attached to the end of the outgoing trip.

If the dip is steep, it is better to handle the cars on a slope carriage. For this purpose, it is recommended that a long carriage be used with two platforms. The empty car will be put on the upper deck and pulled up past the room so that the load can be put on the lower deck. The carriage is then lowered until the empty car can be taken off. The miner or loader is always ready to help the rope rider and there will be the least amount of delay in changing cars or waiting for cars. A gravity plane on which an iron counterpoise is run on an inside track depressed at the passing place might prove serviceable and economical, provided the slope weight is heavy enough to pull the slope carriage and the empty car and light enough to be raised by the slope carriage and loaded car. No electric power plant would then be needed. A single-deck slope carriage will work just as well, provided the cars come equally from rooms on both sides of the plane and the miners lay off in pairs, and will wait for their cars. The last feature would be unlikely and there will be a large expense for car pushers. All the slope carriages should have a device for holding them opposite the level track on the slope.

A sketch of the station at the bottom of the plane is given in Fig. 2. A similar arrangement with tracks on the same level can be used with switches, provided the cars are turned end for end at the slope. This can be done by dropping them from the motor on the parting on the far side of the slope, but there are no apparent advantages in this kind of parting, over the one shown in Fig. 1.

Each jig slope should be so arranged that the engine plane will be kept nearly busy. It is advisable to give the latter surplus capacity in order to provide good trips and to keep the pushers busy. If the arrangement of rooms, the speed of the travel, and the delays in switching, are known, this length is easily computed. The delay will be determined by the arrangement and the number of men. Two minutes per car may be assumed. It may also be assumed that the speed will be 600 feet per minute, that there are on each side of the plane four rooms in each 110 feet, and that each room yields four cars per day. Then in addition to the 60- or 75-foot pillar next the entry, 1,000 feet of slope will be required if three cars are handled at a trip. If only one car is handled at a time, as will generally be advisable, and if there is no reduction in the delay, the distance is 700 feet. A smaller hoist handling one car at 400 feet per minute will need 600 feet of plane. The daily output from each plane will then be about 320 tons, 224 tons, and 192 tons, respectively. If coal cutting machines are used with a pair of miners in each pair of rooms, the output will be increased slightly and it will be possible to make the planes shorter.

These figures show at once that only a few planes will be needed and the output can all be handled by one or two motors on a single pair of entries. Unless the planes be put in breakthroughs, it will be necessary to have at least two sets of planes in process of development while the first set is producing room coal.

As compared with driving rooms up the dip, the method here outlined has the disadvantage of requiring a little more capital for the initial development. It requires more machinery and, therefore, a different type of mine foreman is necessary. It is a slight departure from present methods.

The advantages of the method are a good extraction at a low interest charge, because the pillars can soon be mined; the entry yardage is greatly reduced; there are no wrecks and overworked mules; the haulage cost is less; and finally, it is the only satisfactory way of using mining machines in the moderately steep coal. It is in a way the system of twin haulage entries applied to steep coal.

The steep coal soon reaches a depth at which even 40-foot pillars will fail, and for thick coal it is then advisable to use a system of longwall retreating from the property line to the main slope. Entries driven double for ventilation, will divide the face into panels some 250 to 300 feet along the dip. Between these entries, conveyers discharging at the lower end may be placed along the retreating face. Some special piece of machinery can be attached to the lower part of these conveyers, for carrying the coal to the cars passing on a parting in the wide entry at right angles to the face conveyers. This is necessary to insure a heavy output without incurring the expense of maintaining a double-track entry beyond the end of the face conveyer.

It will be some time before such coal is opened and before the problem of labor for conveyers is adjusted. Until then no more discussion of this problem seems necessary. The thin seams of steeply dipping coal are best mined by the aid of conveyers and by the adoption of the longwall advancing method of mining.

Rational Mine Sociology

Written for Mines and Minerals

In Mines and Minerals for December, 1911, were illustrated and described the swimming pool and bath houses constructed at the Leisenring No. 1 plant, of the H. C. Frick Coke Co., near Connellsville, Pa. To this convenience and pleasure feature has since been added a recreation hall and a children's playground.

For a number of years past there was a large well-constructed frame Lodge building near the Leisenring No. 1 plant, which was erected by an organization on ground under free lease, with the stipulation that if the building ceased to be used for the purposes for which it was built it should revert to the land owners. For several years the building has not been used for the purpose for which it was constructed and it reverted to the H. C. Frick Coke Co. as owners of the land.

Charles Franks, superintendent of the Leisenring No. 1 plant, who takes great interest in the welfare of the miners and coke workers under his charge and who was largely responsible for the construction of the swimming pool, conceived the idea that if the building was moved to a more convenient location and put in first-class condition it would be a source of pleasure and benefit to the employes. He secured the consent of his superior officers to his plan, and the building, which had a remarkably good frame, was taken down and reerected near the swimming pool as shown in the illustration.

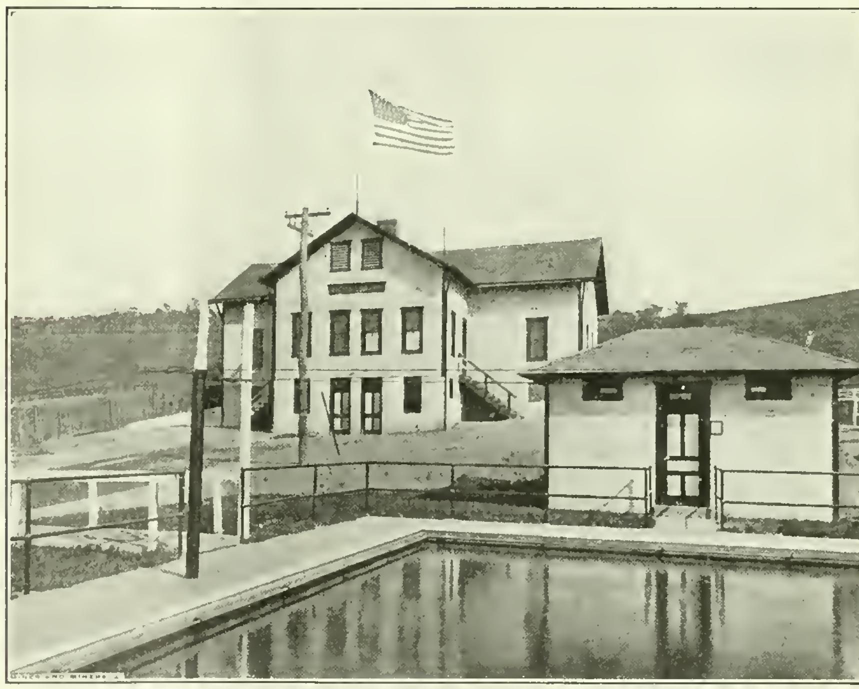

Fig. 1 Amusement Hall and Swimming Pool at Leisenring No. 1

The main portion of the building, two stories in height, is 30 ft. × 60 ft. The first floor is arranged as a gymnasium equipped with bowling alley, pool tables, and the usual gymnasium appliances. The second floor is a large hall equipped with a small stage. It has a smooth, polished floor and can be used for dancing or other entertainments, for serving dinners, or for basket ball.

On the stage there is an upright piano and a music cabinet. The two-story extension shown in the foreground contains a well-equipped kitchen and a boiler room on the first floor, the former being entered through the door on the left. On each side of the extension the steps shown lead to doors opening into a hall connecting with the main room on the second floor and also with lavatories and toilet rooms. The entrance on the right is for the women, and on the left for the men. This extension also has on the second floor a room fitted up for a barber shop. This is occupied by a competent barber who receives free rent in return for caring for the building and keeping it clean. As before this arrangement was carried out there was no barber nearer than Connellsville, the barber shop is a much appreciated institution. The entire building is heated by steam and lighted by electricity. The work of taking down the building and rebuilding it on its present site, of finishing the interior, painting both exterior and interior, the installation of water, light, and heat was all done by the mechanics regularly employed at Leisenring No. 1.

The piano, kitchen furnishings, and the entire equipment of the gymnasium were furnished by the employes at the plant, who have organized an athletic association with very moderate monthly dues. This recreation hall is naturally very popular with the employes and their families, who make free use of it, to their great enjoyment and benefit. The small building on the edge of the pool is the women's and girls' dressing room and shower baths; an exactly similar building to the right, not shown in the picture, contains a dressing room and shower baths for the men and boys. Back of these dressing rooms and to the right of the recreation hall is a children's playground, equipped with a swing, horizontal bar, trapeze, a teter or see-saw, a merry-go-round, a slide, and a large revolving cylinder. This feature of the recreation plant is naturally greatly appreciated by both the children and their parents.

It is a fact that should be significant to sociologists, that while the H. C. Frick Coke Co. has encouraged and aided this movement, not only in this case but others, a large part of the work is in the hands of the employes themselves, thus insuring their personal interest.

Concrete Coal Pockets

Written for Mines and Minerals

The Pennsylvania Coal Co., has commenced the erection of a new breaker at Throop, Pa., which is to be known as the Underwood breaker. In the construction of this breaker both reinforced concrete and steel are to be used; reinforced concrete for the coal and rock pockets, and part of the washery, and steel for the main part of the building, which will contain the washery.

The capacity of the coal pockets is to be 3,500 tons. The coal cars are to be loaded directly beneath the pockets, while box cars are to pass on the outside of the building and are to be loaded from a chute leading from the center of the bottom slab of the pocket. The slope on the bottom of the coal pockets is 9 in 12 and on the rock pockets 6 in 12. The width of these pockets varies from 10 feet 8 inches to 16 feet. Where the pocket is not over 12 feet wide, the floor slab is designed so as to carry the load without any beam for support. But for the pockets 16 feet wide a beam is placed beneath the floor slab. The walls of the pockets are designed as usual to carry that part of the load which comes from arching of the coal in the pocket and also to withstand the pressure against them when one pocket is full and the next empty. The posts beneath the points of the pockets are placed so as to be beneath the dividing walls, but beneath the outside walls the posts are spaced equidistant in a hit or miss manner in respect to the dividing walls. All beams and walls are thoroughly reinforced and tied to one another.

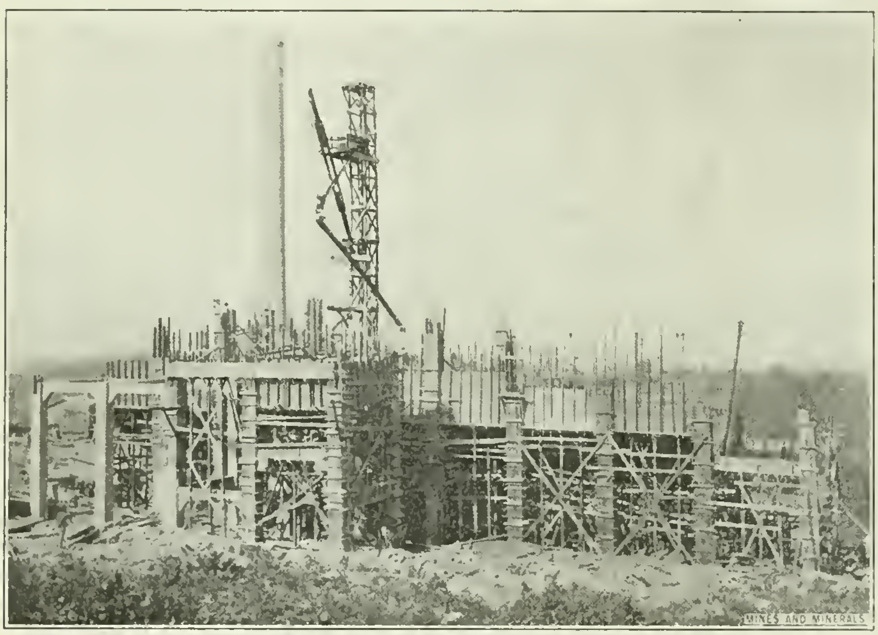

Fig. 1. Underwood Breaker, Showing Chutes for Pouring Concrete

In the construction of the concrete part of the breaker, the contractors have used the chute system of pouring the concrete and have thereby reduced the usual cost of pouring when using hand work and wheelbarrows, by two-thirds, being able to pour at a cost of 35 to 40 cents a cubic yard. With eight men working, from 10 to 12 cubic yards can be poured in one hour.

These chutes are made of sheet iron curved a little more than a semicircle and stiffened along the edge with a small size angle iron, which is cross-braced at regular intervals with a flat bar. At one end of the chute is a hopper and some of the chutes are trussed so as to stiffen them. In the construction of these pockets three chutes have been used; the first 50 feet long, the second 40 feet and the third 20 feet; making a total of 110 feet. The middle chute, 40 feet in length, is the only one which is trussed. The reason for this is that it is only supported at each end. By making the chute in three parts, the parts can be so manipulated, as they are hung from a boom, that the pouring can be done at any point of the work.

In the use of these chutes, the usual tower for hoisting is built out of 4"×6" timber, cross-braced, and having guy ropes to steady it. Instead of a carriage on which to hoist the mixed concrete, a bucket is used which automatically dumps into a hopper feeding the first chute. This chute is hung from a boom which is pivoted at the tower. The rope controlling the elevation of the boom is attached to the drum on the hoisting engine. The rope passes from the engine to the top of the tower, through a double pulley block to a single pulley block at the end of the boom, then back to the double pulley block on the tower and then through another single pulley block on the boom, and is then fastened to the tower. The boom is 50 feet long and is made of two pieces of 8"×10" timber, and two pieces of 4"×8" timber. The 8"×10" timbers are about 15 feet long and are placed at the ends, the 4"×8" timbers lap on the sides of these timbers so that a space the width of the timber is left between them, through which the first chute extends. The boom is trussed by two iron rods so as to stiffen it.

The first chute is hung from the hopper on the tower, at one end, and from a block and tackle at the end of the boom and is also supported near the middle by ropes attached to the boom. The second chute hangs from the first chute and is supported at its other end by means of block and tackle hung from the guy ropes of the tower. The third chute is short and hangs from the second at one end, while the other end is moved according to the part of the form it is desired to fill.

We are indebted to Mr. Richardson, of Williams & Richardson, contractors, Scranton, Pa., for the information concerning these pockets.

Carbon Dioxide Blower in a German Colliery

*By Bergrath Laske**

In the eastern district of Waldenburg are several collieries in which outbursts of carbon dioxide are not infrequent. One of these, which took place on September 17, 1911, in the Cons. Rubengrube, at Neurode, resulted in the death of a miner. The colliery is situated on the southeastern extension of the lower Silesian coal basin, from which it is separated by a 13-mile belt of barren coal measures. Here seven seams are distinguished, six of which are worked. The outburst took place in the uppermost or Josef seam (20 to 36 inches thick), which is immediately overlain by a thin band of plastic very tough clay, this again by thin beds of sandy shales, and these by some 330 feet of sandstones and conglomerates. Doubtless the tough plastic clay effectually seals up the carbon dioxide evolved by processes of oxidation.

The evolution of carbon dioxide in the workings has been noted for many years past. In the Josef seam it was first observed at the third, or lowest, level. At higher levels, considerable quantities of firedamp exuded from this seam; the other seams at the lowest level showed but little exudation, either of methane or carbon dioxide. It is reckoned that the daily evolution of carbon dioxide from the entire colliery amounts to 701,481 cubic feet. Outbursts were unknown at the colliery before 1911, and so far they have all taken place in the Josef seam at this level: it seems plain that forewinning operations have reached a zone subject to these outbursts. Between April 28, 1911, and the following September, twelve of these occurrences were recorded.

Special regulations were drawn up in May and perfected in July for guarding against sudden outbursts of gas, and for assuring the escape or rescue of the work people.

In the course of the night shift of September 16-17, 1911, at 12:45 A. M., a "double shot" was fired in the Josef seam, by means of an electric fuse. Exactly an hour later, the outburst of carbon dioxide took place, although the working face, apart from the fallen coal, which had been loaded and carried off, had remained untouched since the shot firing. Strenuous but unavailing efforts were made to save a miner who had been busied in setting the timbering in order; he had been knocked backwards by the blower against the packing, and was practically buried in small coal and rock debris. His lifeless body was recovered an hour later.

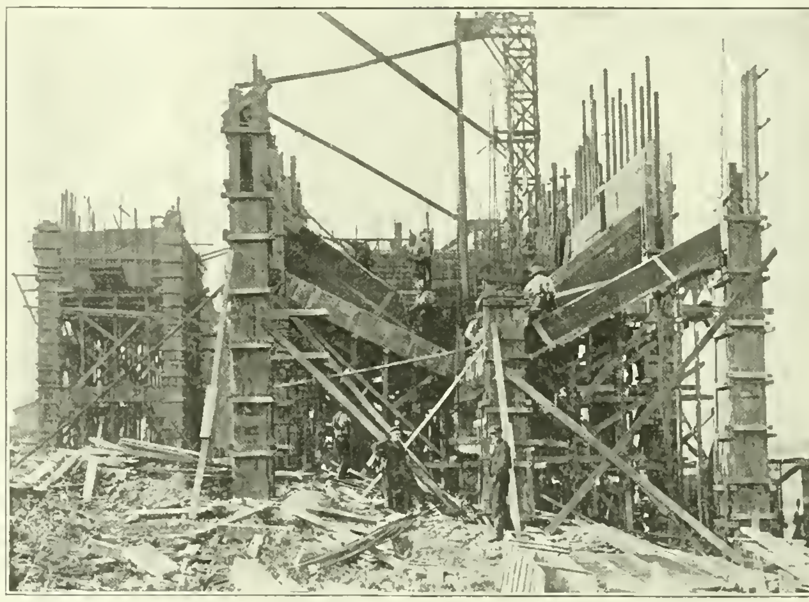

Fig. 2. Coal Pockets, Underwood Breaker

Why Leave Shaft Pillars?

Why leave shaft pillars is a question which W. H. Pickering and Basil H. Pickering raise in a paper read before a meeting of the Institution of Mining Engineers and published in the transactions.

The authors call attention to the fact that even when large shaft pillars have been left, crush has not been avoided and consequent damage to the shaft, necessitating in some cases that the shaft pillar be withdrawn to avoid repetition of the troubles. Different engineers have recommended various sizes of shaft pillars, but no rule can be laid down. In longwall works the breaks due to the settlement of the strata are parallel to the face, when it is reasonably straight and incline toward the solid coal, reaching the surface in advance of the working face. On starting longwall mining these breaks reach back toward the shaft and may affect it, all depending upon the physical condition of the strata.

Four methods of mining out the shaft pillar are suggested, using the common case where two shafts 150 feet apart are sunk. The first method suggested is that the mining be started at a point between the shafts; the second method, that headings be driven a certain distance and then the coal be mined back toward the shafts; third, that the mining be started at each shaft and continued in a widening circle. All of these methods Messrs. Pickering consider to be liable to damage the shafts. The fourth method, which they recommend, is to drive a heading between the shafts and beyond the shafts and with this as an axis to mine on both sides of the heading, removing all the coal and taking great care with the packing.

The advantages claimed in favor of not leaving a shaft pillar, are that the output is quickly reached after reaching the coal, that there is no waste of coal, and the danger of gob fires along the edge of the pillars is avoided. The material which had been broken in sinking the shafts and in making the roadways, would be used to make the tight packing around the shafts.

This proposal would not be advisable in case there were a fault, or the seams were inclined, for then the break would be uneven and the shaft would be damaged.

Prize Contest

With the idea of stimulating interest in practical mining questions, and at the same time drawing out ideas from our readers who constitute a large portion of America's most progressive mining men of all classes, we offer the following prizes:

For the best answer to each of the following questions, we will give any books on mining or the sciences related thereto, now in print, to the value of $3.

For the second best answer, similar books to the value of $2 will be given.

Both prizes for answers to the same questions will not be awarded to any one person.

CONDITIONS

1. Competitors must be subscribers to Mines and Minerals.

2. The name and address in full of the contestant must be signed to each answer, and each answer must be on a separate paper.

3. Answers must be written in ink on one side of the paper only.

4. "Competition Contest" must be written on the envelope in which the answers are sent to us.

5. One person may compete in all the questions.

6. Our decision as to the merits of the answers shall be final.

7. Answers must be mailed to us not later than one month after publication of the question.

8. The publication of the answers and names of persons to whom the prizes are awarded shall be considered sufficient notification. Successful competitors are requested to notify us as soon as possible as to what disposal they wish to make of their prizes, and to mention the numbers of the questions when so doing.

9. In awarding prizes, other things being equal, a carefully written and arranged answer will be given the preference.

10. Employes of the International Textbook Company, or of Mines and Minerals, are not eligible to enter this contest.

Questions for Prizes

5. *Booster Fan.*—An exhaust fan at a mine is capable of supplying 150,000 cubic feet of air per minute, and 40,000 cubic feet per minute more are required. The amount of unmined coal is insufficient to warrant sinking additional air-shafts, and leakage along the airways has been reduced to a minimum. Will a "booster fan" located in the mine meet the requirement? Give reasons for the answer, and state at what point such booster fan should be located, if in your opinion it will do the work.

6. *To Stop a Squeeze.*—A flat coal seam 8 feet thick lies from 350 to 450 feet below the surface, and has a strong bed of micaceous sandstone 40 feet thick next above the top slate which is 13 inches thick; a squeeze has started in an area of 20 acres which was originally worked on the pillar-and-stall system, and the pillars left are well distributed and constitute about one-third of the original coal. How would you proceed to stop the squeeze so as to eventually recover a maximum amount of coal in the pillars?

7. *Raising Water.*—In a certain region it is desired to concentrate into one sump the drainage of several mines, amounting as a maximum to 800,000 gallons per day of 24 hours, and raise it out through a shaft 550 feet deep. Which system will be most economical and efficient—piston pumps, centrifugal pumps, or hoisting in tanks, the water being slightly acidulated? Give reasons in detail.

8. *System of Mining.*—In the case of two seams of coal separated by 36 feet of comparatively soft strata and lying at a dip of 10 degrees, the upper seam is 6 feet thick and the lower seam is 8 feet thick, and it is desired to mine them simultaneously through one shaft 560 feet deep to the lower seam, and to have the daily production approximate 1,000 tons. The top over the upper seam is strong, that over the lower seam comparatively weak, and both seams give off considerable gas. What system of mining would be best as regards safety and economy?

Educational Notices

On Pennsylvania Day, November 22, 1912, at Pennsylvania State College, the first unit of the Mechanic Arts Engineering Buildings was dedicated. This building is intended to be the first of a series of interconnected units of similar size and design. It is the result of a special study made by the school of engineering to work out a structure which in form, size, and lighting would readily lend itself to laboratory, class-room and drafting-room purposes by simply shifting the internal arrangement. The materials are largely steel and red brick with brown sandstone trimmings. The new building is 110 feet long by 60 feet wide and harmonizes architecturally with the main engineering building.

The Oregon Agricultural College issued a Book on Camp Cookery, notice of which was printed in Mines and Minerals at the time. The demand for this book was so great that the supply was soon exhausted. Excerpts, however, will be published from time to time and will appear in Mines and Minerals.

Prof. E. N. Zern, of the Mining Department of the West Virginia University, is sending out posters announcing special courses in the School of Mines. This work is being promulgated in direct response to a demand from the mining interests of the state. Much benefit to the coal industry is bound to result from the higher efficiency and reliability of the men who, in addition to their practical knowledge of mining, will be well fortified in the theory of all pertaining to the art after having made good use of the facilities offered by the courses.

Robbing Coal Dust of Its Dangers

Experience in Applying Steam to the Air Current and Its Effect Upon the Dust in the Mine

*By Sim Reynolds**

Ever since we, in common with other mining men, became thoroughly convinced that coal dust was an element not to be safely ignored, it has been a vital question with us as to the best method of handling it. By "best" is meant that condition emanating from local circumstances: the most economical and at the same time the most effectual. Like other mining men, we have been more or less confused by the large number of methods suggested by the Federal Bureau and others interested in guiding us to a safe haven in this premise. We failed to take into account the fact that the general suggestions sent broadcast by the government men are intended to cover any case and any mine, between the arid operations of the Rocky Mountains and the more moisture-laden pits of the East; from the three-car-a-day drift, with an antiquated furnace, to the modern shaft or series of shafts ventilated by a fan with blades as wide in diameter as the walls of an ordinary house room, and 35 feet deep.

In the end we reached the conclusion that we must adapt the system to the local conditions regardless of any desire of our own, rather than try to fit the conditions to any given method. The natural conditions affecting mines cannot be changed. But men who are interested have experimented sufficiently to show a way out of the difficulty, no matter what kind of installation is run, and no matter what conditions have been imposed on the operation by Nature. For that reason, what we have to offer in this article will be of use only where steam is used or can be procured at an expense commensurate with the mine's output. Fortunately, perhaps, by far the greater number of mines have at hand steam in some form, or can procure it at a price within the limits set for upkeep.

In the first place let us explain that in the mine where these ideas are being carried out successfully, we have to contend with natural and artificial conditions about as adverse as are generally met in the United States. We have an overlying stratum which is "quickened" by moisture at any degree of temperature above freezing point—the uncertain stratum lying immediately above the Pittsburg No. 8 seam. So fearful were our predecessors in management concerning the possibilities of constant and costly roof falls that, despite the fact of their being wholly conversant with the air moistening method, even to the extent of giving it a slight but insufficient trial, a far different system was in vogue when we determined to change from the costly and inefficient water wagon and spray to the saturation of the air-current. Some sprinkling had been done at irregular intervals; and through the winter months persistently. At points where water lines were available a hose was used, at other places the water wagon and the bucket. That expense did not stand in the way of safety in this matter was evidenced by the fact that several men were detailed to do the wetting, for the mine is a large one. Poorly performed and unsatisfactory as the method then employed was, it kept several names on the pay roll, where now there is but one. These men were still drawing their salary for this work when on certain days we went through the various sections on a "coal-dust tour," only to find hundreds of places where no drop of moisture had apparently ever found its way. Almost anywhere, if one blew a breath on top of a timber or on a stone in a gob, a tiny cloud of dust would rise and partly float away on the current. In such an extensive mine the water wagon and spray method cannot produce any other result, at least not with a normal effort. To have wetted sufficiently for safety every square yard of even the live workings, let alone the innumerable places which were not as easily reached, would have taken a force of men and an amount of money impossible for any firm to stand.

These facts, and the knowledge that all the efforts then being made to make that particular mine safe were nullified, urged the immediate consideration of some other system. In face of the locked safety lamps, in face of the permissible explosives and shot firers to use them, even despite an occasional jail term for some law-breaking employe, in our opinion the mine was dangerous, because dry and explosive dust lay over acres upon acres of the floor, upon innumerable ledges and timbers of that vast mine, and in scores of air-courses and places where no tracks were available for the wagon nor any lines for the spray, only a place here and there being wetted as it ought to be. Our opinion being the one to warrant a change, we set about it in the following way.

The fan was steam driven. It was working on the exhaust principle. The first move was to reverse it and change it to a blower, making the main return air-courses the intakes, so as not to befog the atmosphere along the haulways. The pump-room is situated a short distance from the bottom of the downcast air-shaft, and the steam is conveyed from the power plant on the surface through a bore hole. We had two certain supplies of "dead" steam at hand, one from the fan and one from the pumps, neither serving any useful purpose. As would be the case in nearly any mine changing from water wagon and spray to the saturation system, we found a number of things to do, connections to make, etc. Most of this we were able to do with old pipe, and all of it at a nominal cost compared to the results which we anticipated, and which we did eventually get, although not quite so soon as we expected. On the surface a still greater volume of steam was wasted, and we made formal requisition for all of this steam after its use. We did not get it right away, although we had the promise of it. We did not let that stop us. Like many other mining men in direct control of a large operation we found that one can sometimes get things in an indirect way which one cannot get direct. Personally we believed in the idea and were willing to go to a little trouble to carry it into execution. We turned in all the available "dead" steam, and more or less anxiously awaited results. Not much materialized.

The mine, as we have said, was a large one, and the air-courses seemed to absorb all the moisture being sent into the mine, leaving none to float on the air-current into the live workings. Investigation after a week's trial showed that the active rooms and entries were still dry and dusty, no appreciable difference being noticed. Doubtless some changes had been wrought, but they

* This article will be followed at an early date by another by Mr. Reynolds entitled "Robbing Mine Air of Its Danger."

were so microscopic that they were far from satisfying. So down the shaft we laid a pipe line, and connected it with the fan exhaust, using in our first effort the only available steam nearby which was the pumps exhaust and was at our call without a great deal of trouble. It was a bit difficult, but we went after it, reluctant to see the steam going out into the air above where it was doing no good, while we needed it so very badly down below. This made some difference, but still not quite enough to suit us, so, not being able to get the use of the steam from the shops on the surface, we grinned slyly. We had casually remarked that the power plant on top emptied itself more or less frequently by blowing off, so perhaps it wouldn't notice a little extra to the pumps. This gave us quite a tidy volume of live and dead steam, and augmented our fears in another direction.

In common with many others we had read—but never seen tried in practice—of the theory that moistening the mine atmosphere—unlike moistening the mine walls and floor—would certainly prove detrimental to the health and working abilities of the employes. In this, as in the fears of others concerning the roof, our surmisings proved groundless in fact. In any event the trial has now become a permanent institution at the mine mentioned, and we have yet to hear the first complaint. Rather have heard many, who did not know "what had happened," express their agreeable surprise at the change which had come over the workings, wondering what had taken the irritating, dust-laden, dryness out of the air, and substituted a coolness and freedom from dust atoms unusual in that mine.

The hygrometer registering the amount of moisture contained in the air, was set up near the outlet of the mine and it gave us an exact knowledge of the amount of work our by-product aids were doing to lower the percentage of danger from coal dust. We watched it closely, also the inner parts of the mine. In a day or two after the application of the full power available we remarked the canvas checks becoming damp, and on close examination we could discern tiny drops of moisture on the smooth faces of the coal. The dust about the floor spaces, on ledges, timbers, and other innumerable places, which before had been easily dislodged by a man's breath and sent floating off in the air-current, was absorbing moisture to such an extent that we could pack it like moistened flour between the fingers, each atom so freighted with water that, through its power of adhesion consequent on its being wet, and its additional weight, it refused to be removed from its resting place by any force blown against it.

Our little battle with nature was won. The scientific questions relative to the principles involved did not interest us. For us and the several hundred men in that big underground plant, it was immaterial, in view of the facts previously stated, whether that little pinch of stolen live steam, and the larger volume of dead vapor from pumps and fan, wetted the mine air or merely (as the scientists tell us) served simply to prevent the quick absorption by the dry air of the natural moisture inherent to the mine itself. We were interested in results, not theoretical deductions, and got them as any man will who has half a chance and goes after them hard and persistently. With Mr. Frank Haas, we can assert from practical experience that many of the arguments adduced against the method herein detailed "emanate rather from opinions than from facts." And so far as the roof is concerned, we can faithfully assert that practical tests have proven most of the horrors prophesied to be largely imaginary. In the case mentioned here, where the roof strata are reckoned to be of a nature decidedly susceptible to atmospheric humidity, it has not required the constant service of even one man to clean up all the falls resulting in this very large mine from this cause alone during the winter months just ended. Such falls as did occur were mostly near the intake and along the air-courses, the effect of the change in the live workings not being sufficiently in evidence to be noticed. But even were this the case, it is, in the opinion of the present writer, far better for men and masters to have the security a little trouble will give sometimes, than run any risks from a dust explosion. It would not take the least of several disasters, caused almost if not entirely by dust, which we have with others helped to disburden of their cruelly broken and burnt dead, to pay morally and financially for more falls than are likely to occur from this source in any normal mine even unto the day the last car is mined. Such as do really happen, can be augmented or diminished in extent, by care or lack of it in timbering.

The worst faults thus far adduced against mine-air saturation are off set by the following things in its favor:

1. Ease of installation; it being possible in many mines to throw the entire plan into operation in a few hours' time.

2. Economy. The original expense is nominal, varying with the conditions at each mine and the amount of vapor needed. Unlike most other plans for this purpose, the system is mainly self-perpetuating, even in large mines the services of one man being generally ample to keep such falls as may occur cleaned up, watch the lines and the hygrometer, and increase or decrease the amount sent into the current accordingly, as he is instructed and the needs indicate.

3. Efficiency. Wherever air goes this method of "laying" the dust does effectual work. Places which could not possibly be reached by any other means will on investigation be found to be thoroughly dampened, quite as much so indeed as those more readily accessible. It is automatic, working as readily through the hours of the night as through the day, and causes no trouble with the union. The only thing which can put it completely out of commission is for the boilers on top to blow up, which is a far less possibility than many others underground.

Other results which are interesting as coming to our notice through actual test, and which have been proven conclusively to our satisfaction at least, are:

1. The workmen at the face suffer no inconvenience from the improvised humidity of the mine atmosphere when the hygrometer registers 95 degrees or less. With sufficient steam this degree of moisture can be attained even in cold, frosty weather, when for instance the Pennsylvania thermometers are registering anywhere from freezing point to 20° below zero, and the atmosphere outside contains about 55° of moisture. If no spare steam is available during the regular working hours of the day, an extra supply can be arranged for during the rest of the 24 hours. This gives the maximum effect throughout two-thirds of each working day, idle days, all of Saturday night, Sunday and Sunday night, without lessening the steam power for the regular work and without any appreciable addition to expense. We have had this done as occasion required and brought the humidity up to 100, which is too high for comfort when the mine is full of men.

2. We have proved that when the mine atmosphere was kept at this point for 10 or 15 hours it has

kept the entire mine in a very moist condition for several days thereafter, during which time the normal (90° to 95°) can be sustained, and the whole mine kept relatively safe from the dangers of coal dust.

In closing this article we feel impelled to add a few words regarding the subject as a whole, particularly as concerns the attitude still held by too many mining men, that coal dust is in itself not an explosive. We regret that there should even yet be those identified with bituminous operations who refuse to accept as serious the admonition sent forth concerning the possibility of an explosion of coal dust unaccompanied by methane to act as a detonator. To such it is perhaps useless to suggest that they read Miners' Circular No. 3, issued by the Bureau of Mines, with special reference to page 9, second and third paragraphs. Evidently they and their employes must participate in an underground holocaust, such as has caught so many in late years, before they can be converted, and then, as a rule, the victims of this ruthless conversion are not in a physical nor mental condition to profit by the experience. Such criminal indifference to positively proven facts should not longer be tolerated anywhere among any class of men identified with the bituminous mining industry. Years ago there was cause for doubt, and up to a certain point, we are decidedly partial to one's right to disbelieve. We would not have the proper freedom of thought of any man abridged. But there are cases when it would seem to be necessary, namely, when the persistent clinging to an antiquated idea long proven wrong, imperils human life and valuable property.
